Evidence sentence retrieval component in almost all previous works retrieves all the evidences through a single iteration (Yoneda et al., 2018; Hanselowski et al., 2018b; Nie et al., 2019; Chen et al., 2017; Soleimani et al., 2020; Liu et al., 2020). Stammbach and Neumann (2019) uses a multi-hop retrieval strategy through two iterations to retrieve evidence sentences that are conditioned on the retrieval of other evidence sentences. Then, they choose all the top-most relevant evidence sentences with the highest relevance scores and combine them. Our work follows a similar strategy, but differs from the prior work by combining only evidence sentences that belong to the same evidence set, and then processing each evidence set separately.

In claim verification component, Nie et al. (2019); Yoneda et al. (2018); Hanselowski et al. (2018b) use a modified ESIM model (Chen et al., 2017) for verification. Recent works (Soleimani et al., 2020; Zhou et al., 2019; Stammbach and Neumann, 2019) use BERT model (Devlin et al., 2019) for claim verification. Few other works (Zhou et al., 2019; Liu et al., 2020) use graph based models for fine-grained semantic reasoning. Different from the previous works, our model operates with claim-evidence set pairs instead of claim-evidence sentence pairs. Our model benefits from encoding, attending and evaluating at different levels of hierarchy, as well as from both contextual and non-contextual aggregations of the evidence sets.

3 Problem Definition

Given a set of ***m*** textual documents and a claim c_i, the problem is to find a set of evidence sentences $\hat{E}_i = \{s_1, s_2, ..., s_{|\hat{E}_i|}\}$ and classify the claim c_i as $\hat{y}_i \in \{S, R, NEI\}$ (i.e., SUPPORTED, REFUTED or NOT ENOUGH INFO). For a successful verification of the claim c_i, there are two conditions: (1) $\hat{E}_i$ should match at least one evidence set in the ground truth evidence sets E_i and (2) $\hat{y}_i$ should match the ground truth entailment label y_i.

4 Hierarchical Evidence Set Modeling

Our Hierarchical Evidence Set Modeling (HESM) framework consists of three components namely Document Retriever, Multi-hop Evidence Retriever and Claim Verification. Figure 2 shows an overview of our framework. The document retriever component retrieves the top K_1 documents that are relevant to the claim. The multi-hop retriever component retrieves the relevant top K_2 evidence sets from the K_1 retrieved documents via an iterative fashion. The claim verification component classifies the claim as SUPPORTS, REFUTES or NOT ENOUGH INFO based on the retrieved evidence sets. Following prior works, in our framework, we reuse the document retriever component from Nie et al. (2019), which works well in terms of relevant document retrieval. We mainly focus on and propose novel multi-hop evidence retriever and claim verification components.

4.1 Document Retriever

Document retrieval is the task of selecting documents related to a given claim. First, documents are selected by an exact match between their titles and a span of text of the claim. In particular, the CoreNLP toolkit (Manning et al., 2014) is used for retrieving text spans from the claim. To obtain more relevant documents, the same procedure is applied again after eliminating articles such as 'a', 'an' or 'the' from the claim, and once again after singularizing each word in the claim. For documents, whose titles are ambiguous (e.g., *"Savages (band)"* and *Savages (2012 film)*), a semantic understanding strategy based on *Neural Semantic Matching Network* (NSMN) (Nie et al., 2019) is performed to calculate the relevance of each of the documents by comparing the first line of each document with the claim. Finally, only the top K_1 ranked documents are selected.

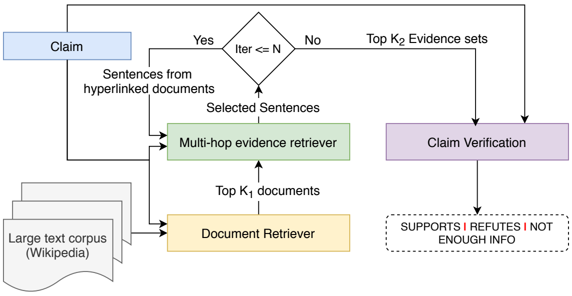

Figure 2: Our HESM framework.

4.2 Multi-hop Evidence Retriever

According to statistics of the FEVER dataset (Thorne et al., 2018a), 16.82% claims require multiple evidence sentences to verify their truthfulness, and 12.5% claims' evidence sentences are located across multiple documents. Based on this, we propose a multi-hop evidence retriever, which is an iterative retrieval mechanism with N number of iterations or hops. From analyzing the FEVER dataset, almost all the evidence sentences are at most two hops away from a claim, and thus can be retrieved in two iterations. Hence, for this work, we set N as 2. We retrieve a maximum of K_2 evidence sets for each claim. Each evidence set contains a maximum of M_s evidence sentences. With the recent success of Transformer (Vaswani et al., 2017) based pre-trained models in NLP, we incorporate the ALBERT model (Lan et al., 2020) as a part of our multi-hop evidence retriever. ALBERT is a lightweight BERT based model that is pre-trained on large-scale English language corpus for learning language representation.

In the first iteration, given a claim c_i, each sentence j in the selected documents from the document retriever is concatenated with the claim c_i as $[[CLS];c_i;[SEP];j]$ and passed through the ALBERT model. $[CLS]$ and $[SEP]$ are classification and separator tokens required by the ALBERT model. From the ALBERT model representation of each input token, the representation of the $[CLS]$ token is pooled and fed to a linear layer classifier to produce the two scores m^+ and m^- for selecting and discarding the sentence, respectively. In Transformer-based models, $[CLS]$ token is considered as a representation of the whole input. Then, a selection probability $p(x = 1|c_i, j)$ is calculated as a softmax normalization between the two scores. Only the top K_2 sentences with the highest m^+ scores and probability score greater than a threshold th_{evi1} are selected.

In the second iteration, each of the K_2 evidence sentences from the first iteration is considered as an evidence set. In the FEVER dataset, for claims requiring multiple sentences for verification, most of the sentences missed in the first iteration of retrieval are found in hyperlinked documents of the sentences retrieved in the first iteration. Therefore, in second iteration, the claim c_i, each of the K_2 evidence sentences j, and each sentence k from the hyperlinked documents in sentence j are concatenated as $[[CLS]; c_i; [SEP]; j; k]$ and fed as input to the ALBERT model. Similar to the first iteration, two scores m^+ and m^-, and a selection probability $p(x = 1|c_i, j, k)$ are obtained. Finally, for each evidence sentence j, a maximum of $(M_s - 1)$ sentences with the highest m^+ scores and probability score greater than a threshold th_{evi2} are selected and added to the corresponding evidence set.

4.3 Claim Verification

Claim verification is a three-way classification task to label the claim as SUPPORTED, REFUTED, or NOT ENOUGH INFO, based on the extracted evidence. Inspired by Hierarchical Attention Network (Yang et al., 2016), we propose a neural network that combines evidence sets hierarchically. While Yang et al. (2016) uses word-level and sentence-level attention to hierarchically combine words into sentences and sentences into a document, in this task, we use word-level and evidence set-level attention to hierarchically combine words and sentences into evidence sets, and evidence sets into an aggregated evidence. Different from Yang et al. (2016), we propose two ways of aggregating evidence sets. Also, we train each evidence set to be able to verify the claim individually. The model consists of two parts: (1) Evidence Set Modeling Block that contains a word-level encoder and attention layers to model each evidence set based on its words and sentences; and (2) Hierarchical Aggregator that contains evidence set-level encoder and attention layers to combine multiple evidence sets.

4.3.1 Evidence Set Modeling Block

The Evidence Set Modeling Block in Figure 3 takes a claim c_i and each evidence set e_j as input and returns: (1) a sequence output $u_1, u_2, ..., u_T$, that is the representation of each token in the sequence; (2) a pooled output p_j, that can be considered as a joint representation of the claim and the evidence set (3) a summarized vector s_j, that is also a joint representation of the claim and the evidence set obtained using word-level attention; and (4) the logits l_j from classification of the claim as SUPPORTS, REFUTES or NOT ENOUGH INFO, based on the evidence set e_j.

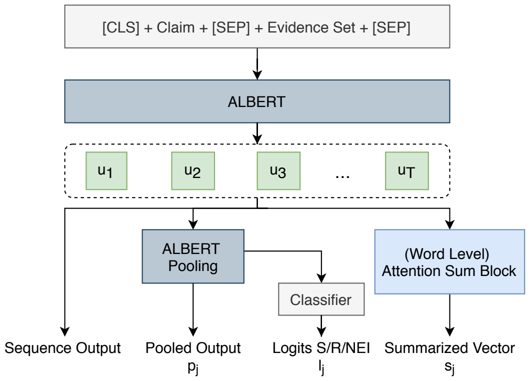

Figure 3: Evidence Set Modeling Block.

Word Encoder. We use the ALBERT model for word level encoder. Let J be the number of evidence sets retrieved for the claim c_i. First, all the sentences in an evidence set j are concatenated to form the evidence set sequence e_j, where $j \in [1, J]$. Then, the claim c_i and the evidence set sequence e_j are concatenated as $[[CLS]; c_i; [SEP]; e_j; [SEP]]$ to form the input sequence x_j. The word embeddings, $X_j \in \mathbb{R}^{T \times d}$, of the input sequence x_j is obtained from the ALBERT embedding layer, where T denotes the number of tokens in the input sequence x_j and d is the size of the word embedding. Then, the ALBERT model processes the input X_j and produces a sequence output $u_1, u_2, ..., u_T$ denoted by $U_j \in \mathbb{R}^{T \times d}$, which consists of the representation of each token t in x_j. The ALBERT model also consists of a pooling layer that returns the vector representation p_j of the $[CLS]$ token which is considered to be representation of the whole sequence in Transformer-based models.

$$U_j = \text{ALBERT}(X_j) \in \mathbb{R}^{T \times d} \quad (1)$$

$$p_j = \text{ALBERT\_POOLER}(U_j) \in \mathbb{R}^{d} \quad (2)$$

Attention Sum Block. Before describing word-level attention, we first describe the Attention Sum block which is used in the word-level attention. The Attention Sum block in Figure 4 returns a weighted

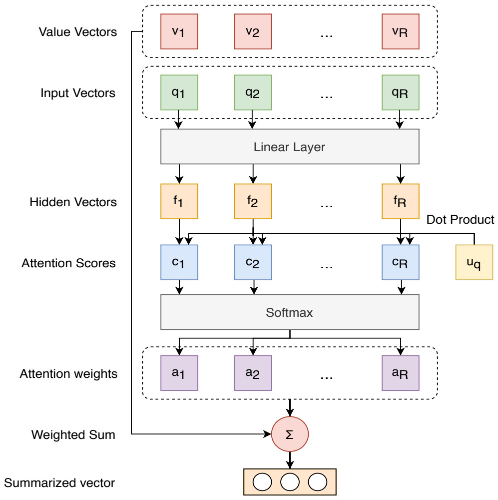

Figure 4: Attention Sum Block.

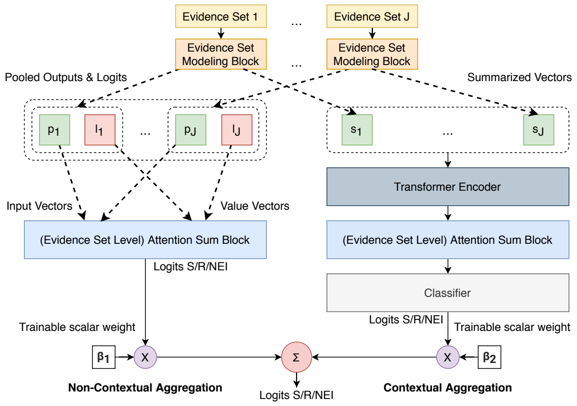

Figure 5: Hierarchical Aggregation.

sum of all the value token vectors v_1 to v_R, where the weights are calculated using attention between input token vectors q_1 to q_R and a trainable weight vector u_q that is randomly initialized. Each vector q_r is passed through a linear layer to get hidden representation f_r for each token $r \in [1, R]$. The hidden representation f_r is then subjected to a dot product with the vector u_q to form a scalar c_t which is the attention score for each q_r. Then, softmax is computed over all the attention scores c_1 to c_R to get an attention weight a_r for each token r. Finally, the value token vectors v_r are subjected to a weighted sum with attention probabilities from the softmax operation as weights and returns the summarized vector s. The attention weights denote the importance of each token in the value vectors sequence. The Attention Sum block is used in the following *Word Attention* and *Hierarchical Aggregation* components.

$$
\begin{aligned}
f_r &= W_q q_r + b_q, r \in [1, R] &(3)\\
c_r &= f_r^T u_q &(4)\\
a_r &= softmax(c_r) &(5)\\
s &= \sum_r v_r a_r &(6)
\end{aligned}
$$

Word Attention. In the word-level attention component, the sequence output u_t, where $t \in [1, T]$, of the evidence set j obtained from *Word Encoder* is passed (as both the input q_r and value v_r vectors) through the *Attention Sum block* to obtain a summarized vector representation s_j (denoted as s in Attention Sum block), based on the importance of each word. s_j is used in the *Hierarchical Aggregation* component in Section 4.3.2.

$$s_j = \text{ATTN\_SUM}(u_1, u_2, ..., u_T) \in \mathbb{R}^d \quad (7)$$

Classifier. The pooled output vector p_j containing representation of $[CLS]$ token from the Word Encoder is passed through a linear layer to obtain a three way classification score l_j (SUPPORTS, REFUTES and NOT ENOUGH INFO classes) of the claim c_i based on the evidence set e_j. This classifier verifies the claim based on the evidence set.

$$l_j = W_w p_j + b_w \quad (8)$$

4.3.2 Hierarchical Aggregation Modeling

The hierarchical aggregation component in Figure 5 takes the output of the Evidence Set Modeling block of all J evidence sets as input and produces the three-way classification score for the claim based on all the evidence sets. It consists of two types of aggregations namely contextual and non-contextual aggregations. Both components compute an evidence set level attention to combine all the evidence sets, forming a hierarchy.

Non-contextual Evidence Set Aggregation. Non-contextual aggregation combines the logits $l_1, ..., l_J$ of all the evidence sets to produce the aggregated verification logits l_{nc}. The motivation behind using non-contextual aggregation is that the majority of the claims need only a single evidence sentence/evidence set for verification. Therefore, we aggregate the logits instead of doing a contextual combination of evidence sets. This helps in avoiding the combination of context from multiple evidence sets without being distracted by sentences containing unnecessary information. The pooled output $p_1, ..., p_J$, and the classification logits $l_1, ..., l_J$ of all the evidence sets, from the Evidence set modeling block, are passed through the Attention Sum block to compute the aggregated representation of all the evidence sets. Here, the sequence of vectors $p_1, p_2, ...p_J$ forms the input vectors of Attention Sum block and the logits $l_1, l_2, ..., l_J$ forms the value vectors of the Attention Sum block. Thus, it aggregates the logits of all evidence sets based on the importance of each evidence set.

$$l_{nc} = \text{ATTN\_SUM}(p_1, ..., p_J; l_1, ..., l_J) \tag{9}$$

Contextual Evidence Set Aggregation. Contextual aggregation combines the representation s_j of each evidence set j with one another to produce the claim verification logits l_c. The motivation behind using contextual aggregation is that, even though we combine evidence sentences into evidence sets through the multi-hop retriever, our extracted evidence sets might not be completely accurate for some claims (i.e., some evidence sentences that belong to the same ground truth evidence set might be distributed across our extracted multiple evidence sets). Therefore, we combine the evidence sets contextually to overcome the limitation. Let $S \in \mathbb{R}^{J \times d}$ denote the summarized representations $s_1, s_2, ..., s_J$ of all the evidence sets $[1, J]$. S is passed through a Transformer encoder, in order to obtain contextual representations $m_1, m_2, ..., m_J$ denoted by $M \in \mathbb{R}^{J \times d}$. Here, the Transformer encoder layer ensures that the context from one evidence set is combined with other evidence sets. Then, the evidence set representations m_j, where $j \in [1, J]$, from the encoder are passed (as both the input q_r and value v_r vectors) through the Attention Sum block to obtain an aggregated vector representation k of all the evidence sets. Finally, the vector representation k is fed into a linear layer classifier to obtain the three way classification logits l_c of the claim.

$$M = \text{Transformer\_Encoder}(S) \in \mathbb{R}^{J \times d} \tag{10}$$

$$k = \text{ATTN\_SUM}(m_1, m_2, ..., m_J) \tag{11}$$

$$l_c = W_s k + b_s \tag{12}$$

Aggregated Logits. The aggregated logits are computed based on a weighted combination of the scores from contextual and non-contextual aggregations. The weights β_1 and β_2 are trainable weights that denote importance of each aggregation.

$$l = \beta_1 l_c + \beta_2 l_{nc} \tag{13}$$

4.3.3 Training Loss and Inference

The three-way classification logits l_j from the Evidence set modeling block for each evidence set j are subjected to a cross-entropy loss. All the losses from each evidence set j are averaged to get an aggregated loss L_{esm}. The aggregated classification logits l from the Hierarchical Aggregation Modeling block are subjected to a cross-entropy loss L_{ham}. The final loss is the sum of L_{esm} and L_{ham}.

During the inference, the aggregated logits l from the Hierarchical Aggregation Modeling is used as the final three-way classification score of the claim verification. The label with the maximum score is selected as the final classification label.

5 Experiments

5.1 Experiment Setting

In this section, we describe the dataset, evaluation metrics, baselines, and implementation details in our experiments.

Dataset. We evaluate our framework HESM in the FEVER dataset, a large scale fact verification dataset (Thorne et al., 2018a). The dataset consists of $185,445$ claims with human-annotated evidence sentences from $5,416,537$ documents. Each claim is labeled as SUPPORTS, REFUTES, or NOT ENOUGH INFO. The dataset consists of training, development, and test sets, as shown in Table 1. The training and development sets, along with their ground truth evidence and labels are available publicly. But, the ground truth evidence and labels of the test set are not publicly available. Instead, once extracted evidence sets/sentences and predicted labels of the test set by a model are submitted to the online evaluation system[1], its performance is measured and displayed at the system. In this work, we train and tune our hyper-parameters on training and development sets, respectively.

Baselines. We compare our model against 7 state-of-the-art baselines, including the top performed models from FEVER Shared task 1.0 (Nie et al., 2019; Hanselowski et al., 2018a; Yoneda et al., 2018), BERT based models (Soleimani et al., 2020; Stammbach and Neumann, 2019; Zhou et al.,

2019) and graph based model (Liu et al., 2020). Although we compare ours against all of them, the BERT based models are our major baselines since we use ALBERT, which is a lightweight BERT based model. The detailed description of the baselines is presented in the Appendix.

Evaluation Metrics. The official evaluation metrics of the FEVER dataset are Label Accuracy (LA) and FEVER score. Label Accuracy is the three-way classification accuracy for the labels SUPPORTS, REFUTES, and NOT ENOUGH INFO, regardless of the retrieved evidence. FEVER score considers a claim to be correctly classified only if the retrieved evidence set matches at least one of the ground truth evidence sets along with the correct label. Between the two metrics, the FEVER score is considered as the most important evaluation metric because it considers both correct evidence retrieval and correct label prediction.

For evidence retrieval performance evaluation, recall and OFEVER are reported since these two scores matter for the claim verification process. Note that OFEVER is the oracle fever score calculated, assuming that the claim verification component has 100% accuracy. As formulated by Thorne et al. (2018a), a maximum of 5 evidence sentences are extracted to calculate evidence retrieval performance. For our model's evaluation purpose, we assign the score of evidence sentences retrieved in first iteration to their corresponding evidence sets. Then, we sort the evidence sets based on their assigned scores and select at most 5 sentences from the evidence sets in the same sorted order.

Implementation, Training, and Hyperparameter Tuning. We set number of retrieved documents $K_1 = 10$, the number of iterations $N = 2$, maximum number of sentences retrieved in the first iteration per claim $K_2 = 3$, a threshold probability $th_{evi1} = 0.5$, the maximum number of sentences in each Evidence set $M_s = 3$, another threshold probability $th_{evi2} = 0.8$. Other detailed information is described in the Appendix.

5.2 Experimental Results and Analysis

Experiments are conducted to evaluate the performance of evidence retrieval, claim verification, and aggregation approaches. In addition, we conduct an ablation study. Only the claim verification experiment is conducted in the test set since each baseline's officially evaluated results are reported in the FEVER leaderboard. In the other experiments and analysis, we use the development set since the test set does not contain the ground truth of evidence sets/sentences and claim class labels.

5.2.1 Multi-hop evidence retrieval

As shown in Table 2, we compare the performance of our model with two baselines, UNC NLP (Nie et al., 2019) and BERT based model (Stammbach and Neumann, 2019). UNC NLP uses ESIM (Chen et al., 2017) based model, and Stammbach and Neumann (2019) uses a BERT based model. Since most other previous works either use ESIM based model or BERT based model for evidence retrieval, we compare with these two representative baselines (i.e., the results of the other 5 baselines in evidence retrieval would be similar to one of them). Our HESM with ALBERT Base outperforms the baselines, achieving 0.905 recall and 93.70% OFEVER score. We can also notice that multiple-hop evidence retrieval approaches (ours and Stammbach and Neumann (2019)) performed better than UNC NLP, which conducts a single iteration.

5.2.2 Claim verification

Table 3 shows claim verification results of our HESM model and baselines. Our model with ALBERT Large outperforms all the baselines,

Aggregation	LA(%)	FEVER(%)
Logical	68.92	66.32
Top-1	69.92	67.77
MLP	74.25	72.03
Concat	74.87	72.13
Attention-based	74.96	72.74
HESM	**75.77**	**73.44**

Table 4: Claim verification with different aggregation methods in development set.

Model	LA(%)	FEVER(%)
HESM	75.77	73.44
- w/o Evidence set level Loss	75.35	72.74
- w/o Non-Contextual Aggregation	75.33	72.74
- w/o Contextual Aggregation	73.70	71.96
- w/o Multi-hop evidence retrieval	73.53	71.92

Table 5: Ablation analysis in development set.

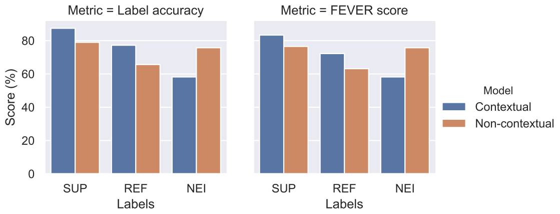

Figure 6: Performance of contextual and non-contextual aggregations given different claim labels.

achieving 74.64% label accuracy (LA) and 71.48% FEVER score. In particular, our model performed much better than the top performed models from FEVER Shared task 1.0 (i.e., UKP Athene, UCL MRG, and UNC NLP). Compared with baselines using BERT Base, our HESM with ALBERT Base performed better than them. Likewise, compared with baselines using large language models, our model with ALBERT large still performed better than them. This experimental result confirms that our model with ALBERT large improved 1.1% FEVER score compared with the best baseline, KGAT with RoBERTa Large, indicating our model's capability of producing more correct label prediction and evidence extraction. The reason why we chose to use ALBERT over BERT in our models is ALBERT consumes much less memory and is expected to have comparable performance to its BERT counterpart. Since the other models/baselines use BERT instead of ALBERT, for a fair comparison, we include a result of our HESM model with BERT Base. The performance is similar to the HESM with ALBERT Base model. This result confirms that our framework is more important than a specific language model used.

5.2.3 Aggregation Analysis

We compare our hierarchical aggregation with different baseline aggregation methods. Table 4 shows the results of aggregation analysis in the development set. Top-1 aggregation is using just the top-1 relevant evidence set to verify the claim. Logical aggregation involves classifying the claim as SUPPORTS or REFUTES if at least one of the evidence sets has the label SUPPORTS or REFUTES, respectively. In case both labels appear in the evidence sets, then the label from the top-scoring evidence set is used to break the tie. If both labels do not appear in any of the evidence sets, we predict the claim as NOT ENOUGH INFO. MLP aggregation is to use an MLP layer to aggregate the class label probability of all the evidence sets to get a final verification label. Concat aggregation concatenates all the sentences in all evidence sets into a string to verify the claim. Attention-based aggregation is similar to the aggregation technique used in Hanselowski et al. (2018b) using attention between claim and each evidence set to get the importance of each evidence set and then combine them using Max and Mean pooling. Finally, our HESM model aggregates evidence sets using hierarchical aggregation. From the results, we can see that our HESM model outperforms all other aggregation methods.

5.2.4 Ablation Study

Table 5 shows the label accuracy and FEVER score of our model after removing different components, including evidence set level loss L_{esm}, and contextual and non-contextual aggregations. All of the proposed components positively contributed to boosting the performance of our framework.

5.2.5 Contextual and Non-contextual Aggregations

In this section, we study the performance of contextual and non-contextual aggregations in different aspects in the development set.

Label-wise performance. Figure 6 shows performance of contextual and non-contextual aggregations with respect to the class labels. We use the logits l_c and l_{nc} to calculate performance of contextual and non-contextual aggregations. In both label accuracy and FEVER score, contextual aggregation performs better for correctly verifying a claim when the relevant evidence either supports or refutes the claim, whereas non-contextual ag-

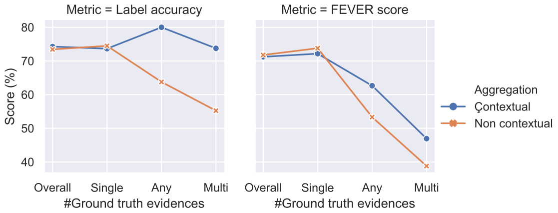

Figure 7: Performance of contextual and non-contextual aggregations given claims requiring different number of evidence sentences.

Aggregation	Weights	Attention accuracy
Contextual	0.48	90.93
Non-contextual	0.52	92.41

Table 6: Attention analysis for contextual and non-contextual aggregation

gregation performs better in identifying evidence that does not have enough information to support or refute the claim (i.e., claims with the label NOT ENOUGH INFO). Thus, each aggregation complements the other in claim verification.

Performance on claims requiring a different number of evidence sentences. Figure 7 shows the performance of contextual and non-contextual aggregations with respect to claims requiring a different number of evidence sentences for verification. *Overall* refers to all the claims, *Single* refers to claims requiring only a single evidence sentence for verification, *Any* refers to claims for which more than one ground truth evidence set exists, where some sets contain a single evidence sentence and some sets contain multiple evidence sentences, and *Multi* refers to claims that can be verified only with multiple sentences. Non-contextual aggregation performs better than contextual aggregation in claims requiring only *Single* evidence sentence, whereas contextual aggregation performs better than non-contextual aggregation in claims requiring *Any* and *Multi* evidence sentences. The results make sense because contextual aggregation combines the context of multiple evidence sets, while non-contextual aggregation usually selects one of the evidence sets based on the attention mechanism.

Attention analysis. In Table 6 we show the weights β_1 and β_2 of the final model and also the evidence-set level attention accuracy. The attention weights can be seen as the importance of each aggregation. The attention weights show that both the aggregations are equally important (0.48 vs. 0.52).

The attention accuracy denotes the accuracy of the evidence set-level attention from the attention sum block in both eq. (9) and eq. (12) of non-contextual and contextual aggregations, respectively. It evaluates whether the retrieved evidence set from multi-hop retriever, which matches one of the ground truth evidence sets, has the highest attention weight of all the retrieved evidence sets. In cases where the evidence sentences from the ground truth evidence set are distributed across multiple evidence sets retrieved from multi-hop retriever, the attention is considered accurate if all the matching evidence sets have higher attention weight than the non-matching evidence sets. Here, we consider only the claims for which the retrieved evidence sentences match at least one ground truth evidence set. In other words, we omit the claims with NOT ENOUGH INFO label and also the 6.3% claims for which the multi-hop retriever cannot retrieve evidence sentences that match at least one ground truth evidence set as shown in Table 2. The high attention accuracy for both contextual and non-contextual aggregation shows that our evidence-set level attention is highly capable of attending to the correct evidence sets.

6 Conclusion

In this paper, we have proposed HESM framework for automated fact extraction and verification. HESM operates at evidence set level initially and combines information from all the evidence sets using hierarchical aggregation to verify the claim. Our experiments confirm that our hierarchical evidence set modeling outperforms 7 state-of-the-art baselines, producing more accurate claim verification. Our aggregation and ablation study show that our hierarchical aggregation works better than many baseline aggregation methods. Our analysis of contextual and non-contextual aggregations illustrates that the aggregations perform different roles and positively contribute to different aspects of fact-verification.

A Appendix

Baselines. We compare our model with 7 state-of-the-art baselines, including the top performed models from FEVER Shared task 1.0 (Thorne et al., 2018b), BERT based models, and a graph-based model.

The top performed models from FEVER shared task 1.0 include UNC NLP (Nie et al., 2019), UKP Athene (Hanselowski et al., 2018a) and UCL MRG (Yoneda et al., 2018). All three models use a modified version of Enhanced Sequential Inference Model (Chen et al., 2017) for claim verification. UNC NLP model concatenates all retrieved evidence sentences together to verify the claim, whereas UCL MRG and UKP Athene models process each evidence sentence separately and aggregate them at a later stage. UCL MRG reports the best results with linear layer aggregation. UKP Athene uses an attention-based aggregation.

The BERT based models include Soleimani et al. (2020); Stammbach and Neumann (2019); Zhou et al. (2019). Soleimani et al. (2020) uses BERT-base and BERT-large for evidence retrieval and claim verification, respectively. They also experiment with both pairwise and point-wise ranking for evidence retrieval. Stammbach and Neumann (2019) uses two iterations of evidence retrieval similar to our work, but different from our work, they concatenate all the sentences retrieved. Zhou et al. (2019) reports performance for both BERT-concat that concatenates all the sentences and BERT-pair model that processes each claim-evidence sentence pair separately. GEAR (Zhou et al., 2019) uses BERT Base as backbone and aggregates claim-evidence sentence pair using a fully-connected graph-based evidence reasoning network. A graph-based model KGAT (Liu et al., 2020) uses a modified version of Graph Attention Network (Veličković et al., 2018) to model a graph constructed from claim and evidence. KGAT experiments with both BERT Base and BERT Large models as its backbone.

Detailed Implementation, Training and Hyperparameter Tuning. For training the document retriever, Adam optimizer (Kingma and Ba, 2015) is used with a batch size of 128, and cross-entropy loss is used. The maximum number of retrieved documents K_1 is set to 10. In the Multi-hop evidence retrieval stage, the number of iterations N is set to 2. For both iterations, the ALBERT-Base model for sequence classification is used and is trained using a batch size of 64 along with AdamW optimizer (Loshchilov and Hutter, 2019) and a learning rate of 5e-5. In the first iteration, we set the threshold probability th_{evi1} as 0.5, and the maximum number of sentences per claim K_2 to 3. We also use the annealed sampling strategy followed by Nie et al. (2019) to decrease the number of negative examples after each epoch so that model learns to be more tolerant about selecting sentences while being discriminative enough to filter out apparent negative sentences.

In the second iteration, we use the ALBERT-Base model to retrieve relevant sentences in hyperlinked documents of evidence sentences retrieved in the first iteration. Similar to the first iteration, we use annealed sampling here as well. We set the maximum number of sentences in an Evidence set, M_s to be 3. Finally, we choose either K_2 evidence sets or lesser, if a lesser number of evidence sets leads up to 5 evidence sentences since only 5 evidence sentences are considered for calculating FEVER score. We set the threshold probability th_{evi2} to 0.8 since we find that the model is able to retrieve correct evidence sentences with a high probability. Cross entropy loss is used in both iterations. Both the iterations are trained for 4 epochs.

Finally, in the claim verification stage, we use the hierarchical evidence set aggregator, which uses the ALBERT model as its backbone. We use AdamW optimizer with a batch size of 32 and a learning rate of 2e-5 and 4 epochs to train our final model. It also uses a 2 layer transformer encoder for evidence-set level encoding.

We use the PyTorch framework to optimize both Multi-hop evidence retriever and claim verification components. We use grid-search on development set to search over a batch size from $\{32, 64\}$, a learning rate from $\{2e\text{-}5, 5e\text{-}5\}$, and number of epochs from $\{2, 4, 6\}$. The maximum number of evidence sets K_2 is selected from $\{2, 3, 4\}$ and maximum number of sentences per evidence set M_s is selected from $\{2, 3, 4\}$. In claim verification, the number of transformer encoder layers in contextual aggregation is selected from $\{1, 2, 3\}$.

Program Enhanced Fact Verification with Verbalization and Graph Attention Network

Abstract

Performing fact verification based on structured data is important for many real-life applications and is a challenging research problem, particularly when it involves both symbolic operations and informal inference based on language understanding. In this paper, we present a **Prog**ram-enhanced **V**erbalization and **G**raph **AT**tention Network (**ProgVGAT**) to integrate *programs* and *execution* into textual inference models. Specifically, a *verbalization with program execution* model is proposed to accumulate evidences that are embedded in operations over the tables. Built on that, we construct the *graph attention verification networks*, which are designed to fuse different sources of evidences from verbalized program execution, program structures, and the original statements and tables, to make the final verification decision. To support the above framework, we propose a *program selection* module optimized with a new training strategy based on margin loss, to produce more accurate programs, which is shown to be effective in enhancing the final verification results. Experimental results show that the proposed framework achieves the new state-of-the-art performance, a 74.4% accuracy, on the benchmark dataset TABFACT. Our code is available at https://github.com/arielsho/Program-Enhanced-Table-Fact-Checking.

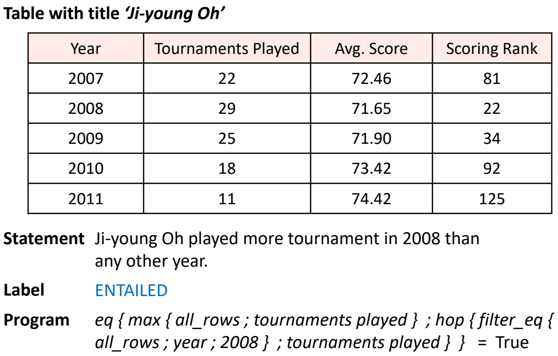

Table with title *'Ji-young Oh'*

Year	Tournaments Played	Avg. Score	Scoring Rank
2007	22	72.46	81
2008	29	71.65	22
2009	25	71.90	34
2010	18	73.42	92
2011	11	74.42	125

Statement Ji-young Oh played more tournament in 2008 than any other year.

Label ENTAILED

Program *eq { max { all_rows ; tournaments played } ; hop { filter_eq { all_rows ; year ; 2008 } ; tournaments played } }* = True

Figure 1: An example of fact verification over tables.

1 Introduction

With the overwhelming information available on the Internet, fact verification has become crucial for many applications such as detecting fake news, rumors, and political deception (Rashkin et al., 2017; Thorne et al., 2018; Goodrich et al., 2019; Vaibhav et al., 2019; Kryściński et al., 2019), among others. Existing research has mainly focused on collecting and processing evidences from unstructured text data (Liu et al., 2020; Nie et al., 2019; Hanselowski et al., 2018; Yoneda et al., 2018), which is only one type of data where important facts exist. Structured and semi-structured data, e.g., tables in relational databases or in the HTML format is also ubiquitous. Performing fact validation based on structured data is important yet challenging and further study is highly desirable. Fig. 1 depicts a simplified example in which systems are expected to decide whether the facts in the table support the natural language statement.

In addition to its importance in applications, the task presents research challenges of fundamental interests—the problem inherently involves both informal inference based on language understanding (Dagan et al., 2005; MacCartney and Manning, 2009, 2008; Bowman et al., 2015, 2016) and symbolic operations such as mathematical operations (e.g., *count* and *max*). Recently, pre-trained language models such as BERT (Devlin et al., 2019) have shown superior performances in natural language inference by leveraging knowledge from large text datasets and can capture complicated semantic and syntactic information among premises and hypotheses (Radford, 2018; Radford et al., 2019; Liu et al., 2019; Dong et al., 2019b).

[*] Equal contribution to this work. The work was done during the second author's visiting to Queen's University.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7810–7825,
November 16–20, 2020.

However, such methods tend to fail when verification requires the joint modelling of both symbolic operations and language inference (Gupta et al., 2020) such as the case depicted in Fig. 1.

To effectively enable symbolic operations and integrate them into language-based inference models, we propose a framework centered around programs, i.e., logical forms that can be executed to find evidences from structured data. Our model starts with a *program selection* module, for which we propose a new training strategy based on margin loss to find programs that can accurately extract supporting facts from tables. To bridge the semantic gap between structured programs and tables as well as to leverage the structures of programs, we propose a novel model based on *verbalization with program execution*. The verbalization algorithm interweaves with program execution in order to accumulate evidences inherently embedded in operations, and the algorithm recursively converts executed operations in programs into natural language sentences. Built on that, we propose *graph-based verification network* to fuse different sources of evidences from verbalized program execution, together with the original statements and tables, to support the final verification decision.

We conduct experiments on the recently proposed large scale benchmark dataset TABFACT (Chen et al., 2020). Experimental results show that our proposed framework achieves new state-of-the-art performance, an accuracy of 74.4%, substantially improving the previously reported best performance with the accuracy of 71.7%. Our detailed analysis shows the effectiveness of verbalization and graph-based verification network in utilizing programs to achieve the improvement. The analysis also demonstrates that the program selection optimized with the proposed training strategy based on margin loss effectively improves the final verification results.

2 Related Work

Fact Verification. Existing work on fact verification is mainly based on collecting and using evidences from unstructured text data (Liu et al., 2020; Nie et al., 2019; Hanselowski et al., 2018; Yoneda et al., 2018). FEVER (Thorne et al., 2018) is one of the most influential benchmark datasets built to evaluate systems in checking claims by retrieving Wikipedia articles and extracting evidence sentences. Recent proposed FEVER 2.0 (Thorne et al., 2019) has a more challenging dataset to verify factoid claims and an adversarial attack task. Some previous models are developed on the official baseline (Thorne et al., 2018) with three step pipeline (Chen et al., 2017a) for fact verification (Hanselowski et al., 2018; Yoneda et al., 2018; Yin and Roth, 2018; Nie et al., 2019). Others formulates fact verification as graph reasoning (Zhou et al., 2019; Liu et al., 2020). Natural language inference (NLI) task is also a verification problem which is fully based on unstructured text data (Dagan et al., 2005, 2010; Bowman et al., 2015; Parikh et al., 2016; Chen et al., 2017c; Ghaeini et al., 2018; Peters et al., 2018). Neural models proposed for NLI have been shown to be effective (Parikh et al., 2016; Chen et al., 2017d,e; Ghaeini et al., 2018; Peters et al., 2018), including models incorporating external knowledge (Chen et al., 2017b; Yang et al., 2019). Our work focuses on fact verification based on structured tables (Chen et al., 2020).

For verification performed on structured data, Chen et al. (2020) propose a typical baseline (Table-BERT), which is a semantic matching model taking a linearized table T and statement S as input and employs BERT for verification. The other model (LPA) proposed in (Chen et al., 2020) uses Transformer blocks to compute semantic similarity between a statement and program. A contemporaneous work (Zhong et al., 2020) proposes LogicalFactChecker aiming to leverage programs for fact verification. LogicalFactChecker utilizes inherent structures of programs to prune irrelevant information in evidence tables and modularize symbolic operations with module networks. Different from theirs, our proposed framework verbalizes the accumulated evidences from program execution to support the final verification decision with graph attention networks.

Semantic Parsing. A line of work uses program synthesis or logic forms to address different natural language processing problems, such as question answering (Berant et al., 2013; Berant and Liang, 2014), code generation (Yin and Neubig, 2017), SQL synthesis (Zhong et al., 2017; Yu et al., 2018) and mathematical problem solving (Kushman et al., 2014; Shi et al., 2015). Traditional semantic parsing methods greatly rely on rules and lexicons to parse texts into structured representations (Zettlemoyer and Collins, 2005; Berant et al., 2013; Artzi and Zettlemoyer, 2013). Recent semantic parsing methods strives to leverage the power of neural

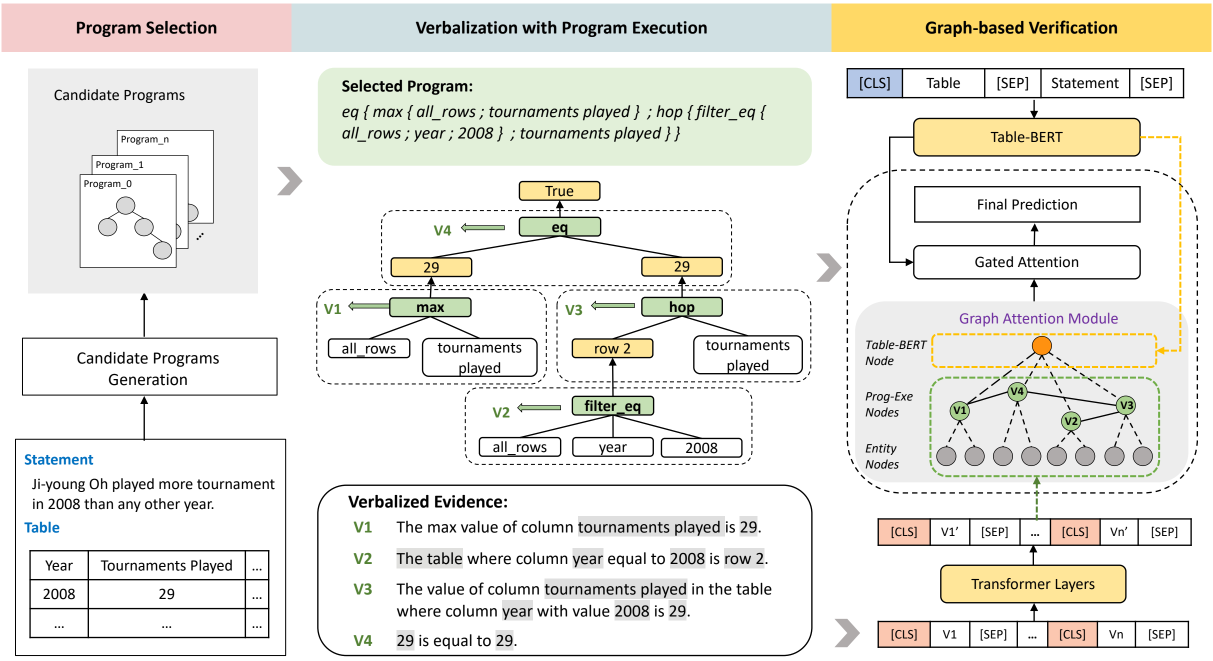

Figure 2: An overview of the proposed framework.

networks (Neelakantan et al., 2016; Jia and Liang, 2016; Liang et al., 2017; Yu et al., 2018; Dong et al., 2019a). Our work leverages symbolic operations inherited in programs produced by neural semantic parsers to enhance fact verification over structured data.

3 Model

We present the proposed framework (ProgVGAT), which centers around *programs* and *execution* to integrate symbolic operations for fact verification. Fig. 2 depicts the overall architecture. This section is organized as follows. We first introduce the task formulation along with program representations in Sec. 3.1. Then, we describe in Sec. 3.2 the program selection module that aims to obtain a semantically relevant program for verification. Built on that, we present our proposed verbalization algorithm and graph attention network to dynamically accumulate evidences embedded in symbolic operations of programs for final verification in Sec. 3.3 and Sec. 3.4.

3.1 Task Formulation and Notations

Formally, given a structured evidence table T and a statement S, the fact verification task aims to predict whether T *entails* S or *refutes* it. The evidence table $T = \{T_{i,j} | i \leq R, j \leq C\}$ has R rows and C columns, and $T_{i,j}$ is the value in the (i, j)-th cell. $T_{i,j}$ can be of different data types, e.g., a word, number, phrase, or even natural language sentence.

Program representation. Given a statement S, a semantic consistent program $z = \{op_i\}_{i=1}^{M}$ is a tree consisting of multiple executable symbolic operations op_i. An example of programs is shown in the center of Fig. 2. An operation $op_i = (op_i.t, op_i.arg)$ contains an operator $op_i.t$ (e.g., *max* in the figure) and arguments $op_i.arg$ relevant to table T (e.g., *all rows* and *tournaments played*), and the execution of an operation yields an output/answer ans (e.g., *29*). Before building the model, we follow the previous work (Chen et al., 2020) and perform rule-based entity linking and latent program search to obtain a set of candidate programs $\mathcal{Z} = \{z_i\}_{i=1}^{N}$. Specifically, entity linking (Nie et al., 2018) detects relevant entities (i.e., cells in evidence table T) in statement S using a set of string matching rules. And the latent program search algorithm finds all valid combinations of pre-defined operations and detected entities by traversing and executing them recursively through the evidence table T.

3.2 Program Selection

Given a statement S, program selection aims to obtain a high quality program z^* from a set of candidate programs $\mathcal{Z} = \{z_i\}_{i=1}^{N}$. Previous work (Chen et al., 2020) optimizes the model via a cross entropy loss:

$$J(\theta) = -\sum_{z \in \mathcal{Z}} \mathbb{1}_{[z]_y} \log p_\theta(z|S,T) \qquad (1)$$

where $\mathbb{1}_{[z]_y}$ is an indicator function which takes the value 1 if the execution result of a program z (i.e., the output of the root; *"True"* in Fig. 2) is consistent with the ground-truth verification label y, otherwise 0. The former type of programs are called *label-consistent* programs and the latter *label-inconsistent* programs. Despite being simple, it ignores that only one of the label-consistent programs is correct and can potentially assign too much credit to spurious programs that execute to get the correct verification labels with incorrect operations during training. Meanwhile, the loss function considers every program in $\mathcal{Z}$ during training and there is only one most relevant program z^* selected in testing phase, creating discrepancies between training and testing.

To remedy these issues, we introduce a margin loss which encourages to select a most positive program (i.e., positive program with maximum semantic similarity score) while maintaining a margin with label-inconsistent programs:

$$J(\theta) = \max\Big(p_\theta(z^{'}_{neg}|S,T) - p_\theta(z^{'}_{pos}|S,T) + \gamma, 0\Big) \qquad (2)$$

where $z^{'}_{neg}$ and $z^{'}_{pos}$ refer to the label-inconsistent program and the label-consistent program with the highest probability in their own categories, respectively. γ is a hyperparameter controlling the margin between the positive instances and negative ones. To measure the semantic similarity between a candidate program z and the corresponding statement S, we leverage pre-trained language model BERT (Devlin et al., 2019) instead of simply training transformer layers as proposed in (Chen et al., 2020). Specifically, given a (S, z) pair, it is prefixed with the `[CLS]` token and suffixed with the `[SEP]` token to form the input of BERT. Then a 1-layer MLP with a sigmoid layer is applied on top of the BERT model to produce the final probability $p_\theta(z|S,T) = \sigma(W_r \boldsymbol{h})$.

Instead of selecting the top program based on Eq. 2, we also tried the exploration strategy proposed in (Guu et al., 2017) to sample a non-top label-consistent program with a small probability. However, this does not further improve the verification performance on the development dataset. We therefore use the first ranked program in the remainder of this paper. Our proposed method relies on the program produced by this section. We further conclude the importance of the program quality in the experimental sections (i.e., Sec.5).

3.3 Verbalization with Program Execution

With the derived program z^* for each (S, T) pair, we propose to verbalize program execution—with operations in a program being recursively executed over the evidence table with a post-order traversal along the program tree. The verbalization algorithm works to convert the execution, including operators, arguments, and execution output, into natural language sentences, to accumulate evidences that are inherently embedded in operations.

Formally, an operation $op_i = (op_i.t, op_i.arg)$ contains an operator $op_i.t$ and arguments $op_i.arg$, and its execution yields an output/answer ans_i. Algorithm 1 describes the verbalization procedure. The post-order traversal over program z^* and the execution of operations can be found in line 3 to line 13. The template-based generation that converts an executed operation (its operation, the arguments, and output) into natural language sentences can be found in line 14. As such, the execution of each operation $\{op_i\}_{i=1}^{M}$ in the program z^* is converted into an evidence sentence $V = \{v_i\}_{i=1}^{M}$. Table 1 lists a few operation templates.* Note that the proposed verbalization can be easily generalized to other domains by extending templates. We leave it as future work for exploring different generation methods, although for structured programs with fixed operations, template-based methods are often very effective already. Fig. 2 gives an example produced by our verbalization algorithm.

3.4 Graph-based Verification Network

We propose *graph attention verification networks*, which is designed to fuse different sources of evidences from verbalized program execution, program structures, together with the original S and table T, to make the final verification decision, shown on the right subfigure of Fig. 2.

3.4.1 Graph Definition

Nodes The graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ contains three types of nodes $\mathcal{V}$ and three types of edges $\mathcal{E}$. The first type of nodes, $(n_0, \ldots, n_{M-1})$, encode verbalized program executions obtained above, called

---

*Full templates are listed in Appendix A.3

Operation	Templates	
	Operation	Operation Results
count, [verb_arg1], ans:string/number	the number of [verb_arg1]	the number of [verb_arg1] is [to_string(ans)]
greater, [verb_arg1, verb_arg2], ans:true/false	[verb_arg1] greater than [verb_arg2]	[arg1's template] [true:is]/[false:is not] greater than [arg2's template]
filter_eq, [verb_arg1, verb_arg2, verb_arg3], ans:rows	[verb_arg1] where column [verb_arg2] equal to [verb_arg3]	[verb_arg1] where column [verb_arg2] equal to [verb_arg3] is row [indices of ans]

Table 1: Examples of generation templates for different operations.

Algorithm 1 Verbalization

Require Statement and evidence table pair (S, T), and parsed program $z^* = \{op_i\}_{i=1}^{M}$; Pre-defined operator $P = \{p_i\}_{i=1}^{R}$; A template function $\mathcal{F}(.)$ maps operation and operation results into sentences.

```
function VERBALIZATION($op, ret$)
    $args = \{\}, verb\_args = \{\}$
    for $a_j$ in arguments of operation $op$ do
        if $a_j$ is an operator in $P$ then
            $arg\_ans, verb\_arg$ = VERBALIZATION($a_j, ret$)
            $args \leftarrow args \cup arg\_ans$
            $verb\_args \leftarrow verb\_args \cup verb\_arg$
        else
            $args \leftarrow args \cup a_j$
            $verb\_args \leftarrow verb\_args \cup str(a_j)$
        end if
    end for
    Apply operation $(op.t, args)$ over evidence table $T$, obtain operation result $ans$
    Apply $\mathcal{F}(op.t, verb\_args, ans)$, obtain verbalized operation result $verb\_ans$ and verbalized operation $verb\_op$
    Update $ret \leftarrow ret \cup verb\_ans$
    Return $ans$, $verb\_op$
Set verbalized program execution $ret = \{\}$
VERBALIZATION($op_1, ret$)
Return $ret$
```

Prog-Exec nodes, shown as green nodes on the right of Fig. 2. M is the number of operations in a program. The second type encodes program entities, called *entity nodes*, shown as grey nodes. As each operation execution o_i consists of arguments and execution output, we construct nodes $(n_M, \ldots, n_{K-2})$ for these entities. The third type of nodes utilize information in original tables and statements. We design a *Table-BERT* node, n_{K-1}, initialized with the output of Table-BERT proposed in (Chen et al., 2020), denoted as the orange node in Fig. 2. In total, we have K nodes, where K varies for different (S, T, z^*) triples.

Edges For a graph $\mathcal{G}$ with K nodes, the adjacency matrix $A \in K \times K$ reflects their connectivity, where $A_{i,j}$ is set to 1 if node n_i and n_j are connected with an edge. Similar to graph nodes, we have three types of edges. We design different attention heads to handle different types of edges/connections as detailed in Section 3.4.3.

The first type of edges connect the nodes of verbalized program execution V based on the program tree structure—we connect node n_i and node n_j, if the corresponding operation o_i is a father or child operation of operation o_j in a program z.[†] The second type of edges connect *Prog-Exec* nodes $\{n_i\}_{i=0}^{M-1}$ with the corresponding entity nodes $(n_M, \ldots, n_{K-2})$. The third type connects *Prog-Exec* nodes, i.e., verbalized symbolic operations and executions, with *Table-BERT node*, which is NLI-based verification performed directly on statement S and T.

3.4.2 Graph Construction and Initialization

For *Table-BERT* node, we utilize the Table-BERT model proposed in (Chen et al., 2020) to obtain the representation:

$$\boldsymbol{h}_{K-1} = f_{BERT}([\widetilde{\boldsymbol{T}}; S]), \tag{3}$$

where $\widetilde{\boldsymbol{T}}$ linearizes table T into sentences; $\boldsymbol{h}_{K-1} \in \mathbb{R}^{F \times 1}$ and F are the number of features in node. We recommend readers to refer to (Chen et al., 2020) for details.

For *Prog-Exec* nodes, instead of directly using the verbalized program executions, the nodes are constructed and initialized as follows to consider context. Given a program z^*, verbalization proposed in Sec. 3.3 generates M sentences $\{v_i\}_{i=1}^{M}$.

[†] We define both directed and undirected graphs; the difference is that in the directed graph, the *Prog_Exec* part of the adjacency matrix is not symmetric again. The experiments on the development set shows these two versions of graphs have similar performance, so in the remainder of the paper, we use the undirected version of the graph.

We use document-level BERT proposed in (Liu and Lapata, 2019) to encode these sentences by first inserting a `[CLS]` token at the beginning of each v_i and a `[SEP]` token at the end of it. The segment embedding is set to E_A when i is odd and E_B when i is even. After applying BERT, we take the corresponding `[CLS]` vector at the top layer (e.g., the `[CLS]` inserted before v_2) to be the representation for the corresponding *Prog-Exec* node (e.g., n_2).

For *entity* nodes, we take the contextualized embeddings at positions corresponding to the entities in the top layer of BERT model as the node representation. For entities with multiple words, an average pooling is applied to produce the final entity representation.

3.4.3 Reasoning with Graph Attentions

Graph Propagation Unlike the standard graph propagation (Velickovic et al., 2018), we model different types of edges in the propagation process. Specifically, we use the following formula to update each node representation $\boldsymbol{h}_i$ in graph $\mathcal{G}$:

$$\boldsymbol{h}_i^{new} = f\big(\Big\Vert_{d=1}^{D} \sigma\big(\sum_{j \in \mathcal{N}_i^d} \alpha_{ij}^d \boldsymbol{W}\boldsymbol{h}_j\big)\big) \tag{4}$$

where

$$e_{ij} = a(\boldsymbol{U}\boldsymbol{h}_i, \boldsymbol{U}\boldsymbol{h}_j), \tag{5}$$

$$\alpha_{ij}^d = \frac{exp(e_{ij})}{\sum_{k=1}^{K} A_{i,k}^d exp(e_{ik})} \tag{6}$$

where $\boldsymbol{U} \in \mathbb{R}^{F \times L}$, $\boldsymbol{W} \in \mathbb{R}^{F \times F}$ are trainable parameters and $a(.)$ denotes shared attention mechanism $\mathbb{R}^L \times \mathbb{R}^L \rightarrow \mathbb{R}$. Note that $||$ refers to the concatenation operation and D denotes number of different types nodes (D is set to 3 in this paper).

To propagate along different types of edges, we extend masked attention with a multi-head mechanism to encode different types of edges in different heads. Particularly, *masked attention* in self-attention mechanism is performed for each type of edges d. The masked attention computes normalized attention coefficients $\alpha_{i,j}^d$ between node n_i and its neighbor n_j under edge type d (i.e., $A_{i,j}^d = 1$ means node i and node j is connected with the edge type d. A^d is the adjacency matrix we constructed above). To aggregate node representation from each head, we concatenate D updated nodes with a feed-forward layer in Eq. 4, yielding the final node representation $\boldsymbol{h}_i^{new}$.

Gated Attention To aggregate information in a graph, we employ a gated attention mechanism to obtain final aggregated representation $\boldsymbol{h}_{final}$ and predict final verification label y as follows:

$$\boldsymbol{h}_{final} = \sum_{i=0}^{M-1} p_i \boldsymbol{h}_i{}^{new}; p_i = \sigma(\boldsymbol{h}_{K-1}^T \boldsymbol{h}_i{}^{new}), \tag{7}$$

$$y = \sigma(\boldsymbol{W_f}([\boldsymbol{h}_{final} \Vert \boldsymbol{h}_{K-1}])) \tag{8}$$

where $\boldsymbol{W_f}$ are trainable parameters, σ is the sigmoid function, and $||$ the concatenation operation.

4 Experiment Setup

Data and Evaluation Metric As discussed above, although (semi-)structured and unstructured text data are ubiquitous in our daily life, performing fact verification across these different formats is relatively new. We conduct our experiments on recently released large-scale dataset TABFACT (Chen et al., 2020).

TABFACT contains 92,283, 12792, and 12779 table-statement pairs for training, validation and testing respectively. Verification on some statements requires higher-order semantics such as *argmax*, the test set is further split into a *simple* and *complex* subset according to verification difficulty. A *small* subset is provided in which the human upper-bound performance is given. Following the existing work, we use *accuracy* as the evaluation metric. Detailed data statistics are listed in Appendix A.1.

Training Details For parameters in all BERT models, the hidden size is set to 768, we use Adam optimizer (Kingma and Ba, 2014) with learning rate 2e-5, warmup step 3000, dropout 0.1. For parameters in graph attention network, the hidden feature dimensions F and L are all set to 768. All codes are implemented with PyTorch (Paszke et al.). All hyper-parameters are decided according to the validation performance.

Compared Systems We compare our models with typical baselines proposed in (Chen et al., 2020). We also present results of a contemporaneous work `LogicalFactChecker` (Zhong et al., 2020) which reports the best performance in the literature. Details of baselines are discussed in related work (Section 2).

5 Results

Overall Performance Table 2 presents the results of different verification models. Our proposed

Model	Val	Test	Test (simple)	Test (complex)	Small Test
Human Performance	-	-	-	-	92.1
Table-BERT-Horizontal-S+T-Concatenate	50.7	50.4	50.8	50.0	50.3
Table-BERT-Vertical-S+T-Template	56.7	56.2	59.8	55.0	56.2
Table-BERT-Vertical-T+S-Template	56.7	57.0	60.6	54.3	55.5
Table-BERT-Horizontal-S+T-Template	66.0	65.1	79.0	58.1	67.9
Table-BERT-Horizontal-T+S-Template	66.1	65.1	79.1	58.2	68.1
LPA-Voting w/o Discriminator	57.7	58.2	68.5	53.2	61.5
LPA-Weighted-Voting	62.5	63.1	74.6	57.3	66.8
LPA-Ranking w/ Discriminator	65.2	65.0	78.4	58.5	68.6
LogicalFactChecker (Zhong et al., 2020)	71.8	71.7	85.4	65.1	74.3
ProgVGAT	**74.9**	**74.4**	**88.3**	**67.6**	**76.2**

Table 2: Performance (accuracy) of different models on TABFACT. For `Table-BERT` baseline, different strategies of linearizing tables to bridge semantic gap with statements. *Horizontal* and *Vertical* refer to horizontally or vertically traverse items in tables respectively. *S* denotes statements, *T* denotes tables, + indicates concatenation order between *S* and *T*. *Concatenate* refers to directly concatenating items in tables. *Template* convert items in tables into sentences with pre-defined templates. For `LPA` baseline, to select one program among all candidates for each statement, they take either a (weighted) voting strategy or a discriminator.

method obtains accuracy of 74.4% on the test set, achieving new state-of-the-art in this dataset.

For `Table-BERT` baseline, it leverages pre-trained language models to measure semantic similarities for table-statement pairs. `LPA` derives a synthesized program best describing the statement-table pair, and executes derived program against semi-structured tables for verification. Our proposed method proposes a verbalization and graph attention network for fact verification. It integrates execution of programs into pre-trained language models, outperforming `Table-BERT` and `LPA` with a large margin.

Compared with `LogicalFactChecker`, our proposed method is built to leverage operation execution evidences and the inherent structures information with verbalization and graph attentions. While `LogicalFactChecker` focuses on pruning irrelevant rows and columns in evidence table with programs and utilizing structures of operations with module networks. Our proposed method achieves better results (74.4%) than `LogicalFactChecker` (71.7%). The result suggests the effectiveness of our proposed method by introducing executed operation results. Symbolic operations performed on evidence tables provide useful information for verification.

Although the proposed model improves the state-of-the-art performance on the entire dataset as well as all subsets, we can see that the *complex* subset of the problem remains hard to solve. On the *small* test set where the human upper-bound performance is provided (92.1%), there is still a large gap between the system and human performance. We hope our work will serve asOther for base for further work on this problem.

Model	Val	Test
Table-BERT w/ prog	70.3	70.0
LogicalFactChecker	71.8	71.7
Table-BERT w/ verb. prog	71.8	71.6
Table-BERT w/ verb. prog exec	72.4	72.2
ProgVGAT	**74.9**	**74.4**

Table 3: Results of different ways of using operations.

Model	Val	Test
ProgVGAT w/o graph attention	73.6	73.4
ProgVGAT	**74.9**	**74.4**

Table 4: Ablation results (accuracy) that shows the effectiveness of our graph attention component.

Effect of Program Operations A key component of our proposed framework is utilizing the executed operation results for verification, in which we introduce a verbalization algorithm to transform the recursive execution of symbolic operations into evidence sentences. We further investigate different ways of leveraging operations: (1) `Table-BERT w/ prog` directly concatenates

			Final Verification		
			Val	Test	ΔTest
LPA	Val	Test	73.3	72.8	-
w/ CE	65.2	65.0			
LPA+ BERT	Val	Test	73.9	73.4	+0.6
w/ CE	67.7	67.3			
LPA +BERT	Val	Test	**74.9**	**74.4**	**+1.6**
w/ Margin loss	**69.4**	**68.5**			

Table 5: Accuracy of different program selection models and corresponding final verification performance based on verbalized evidence derived from each program selection model.

the derived program z^* with the original table as new evidence, and employs `Table-BERT` on the new evidence-statement pair; (2) `Table-BERT w/ verb. prog` differs from `Table-BERT w/ prog` in converting the derived program z into sentences with templates proposed in verbalization algorithm in Sec. 3.3 for verification (3) `Table-BERT w/ verb. prog exec` verbalizes program along with *execution* results using the algorithm proposed in Sec. 3.3.

Table 3 shows the results. Compared to directly concatenate structured program with original Table-BERT, `Table-BERT w/ verb. prog` converts the structured program into natural sentences, and achieves better results. The result demonstrates the importance of eliminating the semantic discrepancy between structured data and natural language in BERT based verification model. `Table-BERT w/ verb. prog exec` leverages executed operation results with the verbalization algorithm and outperforms `Table-BERT w/ verb. prog` as well as `LogicalFactChecker`, The execution output provides complementary clues from evidence tables and improves the verification results. Our proposed `ProgVGAT` further leverages structures in program execution and boost the performance. The results confirm the effectiveness of leveraging symbolic operations with our method.

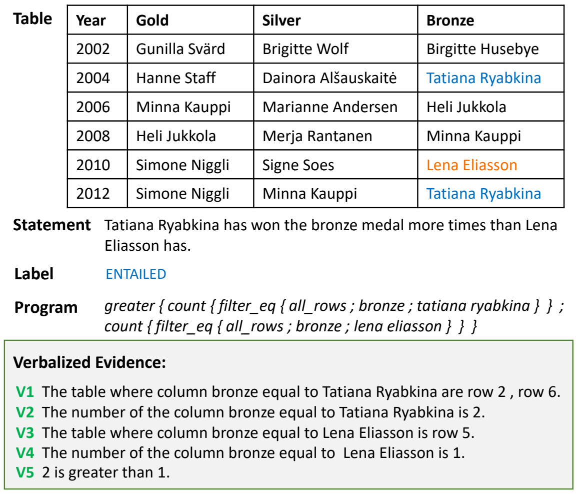
Effect of Graph Attention We investigate the necessity of leveraging structure information in program execution for verification. We present a simpler version of our model by removing the graph attention module and integrating verbalized program execution with gated attention mechanism in Eq. 7. Table 4 presents the results. By removing the graph attention network, the verification accuracy drops 1.3% on the validation set and 1.0% on the test set, respectively. The results show that integrating the structures of programs in the graph attention network is important for verification.

Effect of Derived Programs We investigate the effectiveness of accurate program selection models for final verification. Table 5 represents the results of our model on leveraging different programs produced by different program selection models.

We start by introducing different program selection models in Table 5. `LPA w/ CE` (Chen et al., 2020) applies Transformer encoders without pre-training stage (i.e., BERT) to compute semantic similarity between candidate programs and statements, and optimizes via a cross entropy loss in Eq. 1. It achieves a 65.0% accuracy on the test set. Our proposed program selection denoted as `LPA+BERT w/ Margin loss`, replacing transformer encoders with BERT and optimizing the model with our proposed margin loss, can effectively improve the program accuracy to 68.5%. Comparing with the accuracy of 67.3% obtained by `LPA+BERT w/ CE`, which is optimized with cross entropy loss instead of margin loss, we can conclude that our proposed margin loss plays a positive role in program selection.

Accordingly, we compare the final verification results based on different programs selected by the above models. Our proposed method leverages programs produced by `LPA+BERT w/ Margin loss` obtains better verification results (e.g., 74.4% on test set) compared with using programs derived by `LPA` (e.g., 72.8% on test set). The results indicate more accurate programs can provide more useful operation information and is beneficial for the final verification.

Qualitative Analysis We provide an example, where integrating program execution information with our proposed verbalization and graph attention network can yield the right label. In Fig. 3, the



Table

Year	Gold	Silver	Bronze
2002	Gunilla Svärd	Brigitte Wolf	Birgitte Husebye
2004	Hanne Staff	Dainora Alšauskaitė	Tatiana Ryabkina
2006	Minna Kauppi	Marianne Andersen	Heli Jukkola
2008	Heli Jukkola	Merja Rantanen	Minna Kauppi
2010	Simone Niggli	Signe Soes	Lena Eliasson
2012	Simone Niggli	Minna Kauppi	Tatiana Ryabkina

Statement Tatiana Ryabkina has won the bronze medal more times than Lena Eliasson has.

Label ENTAILED

Program *greater { count { filter_eq { all_rows ; bronze ; tatiana ryabkina } } ; count { filter_eq { all_rows ; bronze ; lena eliasson } } }*

Verbalized Evidence:

V1 The table where column bronze equal to Tatiana Ryabkina are row 2 , row 6.
V2 The number of the column bronze equal to Tatiana Ryabkina is 2.
V3 The table where column bronze equal to Lena Eliasson is row 5.
V4 The number of the column bronze equal to Lena Eliasson is 1.
V5 2 is greater than 1.

Figure 3: An example in qualitative analysis.

statement requires symbolic manipulation on counting bronze medals of two players and compare the number of medals of them. First, program selection produces a semantic-consistent program for the statement and then correctly captures the semantic correlations between the phrase "more times than" and operations $greater$, $count$. With the derived program, a verbalization algorithm executes operations over the table and produces sentences describing useful operation results. For example, "the number of the column bronze equal to Tatiana Ryabkina is 2", "the number of the column bronze equal to Lena Eliasson is 1", and "2 is greater than 1". Then the sentences are integrated into the verification model with the graph attention network to perform the final verification.

6 Conclusions

In this paper, we propose a framework centered around *programs* and *execution* to provide symbolic manipulations for table fact verification. We propose a verbalization technique together with a graph-based verification network to aggregate and fuse evidences inherently embedded in programs and the original tables for fact verification. Moreover, we design a new training strategy adapting margin loss for the program selection module to derive more accurate programs. The experiments show that the proposed model improves the state-of-the-art performance to a 74.4% accuracy on the benchmark dataset TABFACT. Our studies also reveal the importance of accurate program acquisition for improving the performance of table fact verification. In the future, we will investigate the properties of our proposed method on verifying statements with more complicated operations and explore the explainability of the model.

A Appendices

A.1 Statistics of TABFACT Dataset

Table 6 provides the statistics of TABFACT (Chen et al., 2020), a recent large-scale table-based fact verification dataset on which we evaluate our method. Each evidence table comes along with 2 to 20 statements, and consists of 14 rows and 5-6 rows in average.

A.2 Pre-defined Operations in Program Selection

Programs consists of operations, and the definition of operations are listed in Table 7, mainly following (Chen et al., 2020).

A.3 Pre-defined Templates for Verbalization

In our proposed framework, there are 50 pre-defined operations, details are in Table 7. For each operation, we define templates for operation and its executed result. There are three types of executed results: (1) string or number type; (2) boolean type; (3) view or row type, where it is a sub-table or rows extracted from the evidence table.

We represent templates for different types of operations accordingly. The detailed templates are listed in the following Table 8, Table 9 and Table 10.

Split	**Sentence**	**Table**	**Row**	**Col**
Train	92,283	13,182	14.1	5.5
Val	12,792	1,696	14.0	5.4
Test	12,779	1,695	14.2	5.4

Table 6: Statistics of TABFACT and the split of Train/Val/Test.

Operations	**Arguments**	**Output**	**Function**
count	View	Number	Return the number of rows in the View
	View, Header String, Cell String/Number	Bool	Return whether the cell string/number exists under the Header Column of the given View
without	View, Header String, Cell String/Cell Number	Bool	Return whether the cell string/number does not exist under the Header Column of the given view
none	String	Bool	Whether the string represents None, like “None”, “No”, “-”, “No information provided”
before/after	Row, Row	Row	Returns whether row1 is before/after row2
first/second/third/fourth	View, Row	Bool	Returns whether the row is in the first/second/third position of the view
avg/sum/max/min	View, Header String	Number	Returns the average/summation/max/min value under the Header Column of the given view
argmin/argmax	View, Header String	Row	Returns the row with the max/min value under the Header Column of the given view
Hop	Row, Header String	Number/String	Returns the cell value under the Header Column of the given row
diff/add	Number, Number	Number	Perform arithmetic operations on two numbers
greater/less	Number, Number	Bool	Returns whether the first number is greater/less than the second number
Equal/Unequal	String, String/Number, Number	Bool	Compare two numbers or strings to see whether they are the same
filter_eq/ filter_greater/ filter_less/ filter_greater_or_equal/ filter_less_or_equal	View, Header String, Number	View	Returns the subview of the given with the cell values under the Header column greater/less/eq/... against the given number
all_eq/all_greater/ all_less/ all_greater_or_equal/ all_less_or_equal	View, Header String, Number	Bool	Returns the whether all of the cell values under the Header column are greater/less/eq/... against the given number
and/or	Bool, Bool	Bool	Returns the Boolean operation results of two inputs

Table 7: Details of pre-defined operations.

Constrained Fact Verification for FEVER

Abstract

Fact-verification systems are well explored in the NLP literature with growing attention owing to shared tasks like FEVER. Though the task requires reasoning on extracted evidence to verify a claim's factuality, there is little work on understanding the reasoning process. In this work, we propose a new methodology for fact-verification, specifically FEVER, that enforces a closed-world reliance on extracted evidence. We present an extensive evaluation of state-of-the-art verification models under these constraints.

1 Introduction

A rapid increase in the spread of misinformation on the Internet has necessitated automated solutions to determine the validity of a given piece of information. To this end, the Fact Extraction and VERification (FEVER) shared task (Thorne et al., 2018a)[1] introduced a dataset for *evidence-based fact verification*. Given a claim, the task involves extracting relevant evidence sentences from a given Wikipedia dump and assigning a label to the claim by reasoning over the extracted evidence (SUPPORTS / REFUTES / NOTENOUGHINFO).

Several recent works (Liu et al., 2020; Soleimani et al., 2020; Zhao et al., 2020) leverage representations from large pre-trained language models (LMs) like BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2019) to achieve state-of-the-art results on FEVER. However, it is unclear how factual knowledge encompassed in these LMs influences the verification process.

More recently, Lee et al. (2020) developed a fact verification system solely based on large pre-trained LMs and presented their superior zero-shot performance on FEVER compared to a random baseline. This result clearly shows the influence of factual knowledge embedded inside these LMs, but relying entirely on such knowledge directly contrasts to the *evidence-based* paradigm of fact-verification. Such reliance can be problematic, especially with evolving evidence (Wikipedia pages are constantly updated to reflect the latest events). Schuster et al. (2019) illustrate this phenomenon through an example fact, "*Halep failed to ever win a Wimbledon title*", which was valid until July 2019 but not thereafter.

In this work, we propose methods to train fact-verification models that explicitly reason on the available evidence instead of relying on the factual knowledge in pre-trained LMs, thereby emulating a closed-world setting. This is particularly important in the context of the FEVER dataset because of the overlap between the source corpus used for compiling FEVER and the ones commonly used to pre-train LMs (*Wikipedia*).

We build upon the work of Clark et al. (2020) that demonstrated the ability of transformers (BERT, RoBERTa) to function as soft theorem provers. They induce a closed-world reasoning process by fine-tuning on a carefully curated synthetic natural language rulebase. In this work, we transfer this ability to FEVER and gauge the feasibility of such closed-world reasoning. Additionally, we also construct an entity-anonymized version of FEVER following Hermann et al. (2015) for evaluating our proposed models. We construct the anonymized version by masking prominent named entities in the claim-evidence pairs, thereby reducing any reliance on pre-trained factual knowledge.

Our experiments adopt the popular three-stage pipeline of FEVER task, comprising document selection, evidence sentence extraction, and claim verification (Thorne et al., 2018b). We primarily focus on the claim verification stage of FEVER, while using the state-of-the-art document selec-

November 16–20, 2020.

tion and evidence sentences extraction from Liu et al. (2020). Our focus is motivated since only the claim verification step involves a joint (often complicated) reasoning over the extracted evidence. Our main contributions are,

- We propose various pre-training strategies for large pre-trained LMs to induce a closed-world setting during fact verification in FEVER.
- We adapt an existing synthetic natural language rulebase to FEVER by incorporating NOTENOUGHINFO label.
- We create an anonymized version of the FEVER dataset to facilitate investigation into the factual knowledge through named entities.

Our datasets and code are publicly available.[2]

2 Constrained Verification

Traditionally, most FEVER systems rely on large pre-trained language models (LMs) to encode the claim and extracted evidence sentences. Previously, Schuster et al. (2019) studied various reasons for the surprisingly good performance of claim-only classifiers on FEVER and reported dataset idiosyncrasies to be the primary reason as opposed to world knowledge in word embeddings. However, they present only a preliminary analysis of the impact of world knowledge from GloVe embeddings (Pennington et al., 2014). In this work, we present an in-depth analysis because the issue is particularly relevant in the context of large pre-trained LMs. To the best of our knowledge, we are not aware of any other works that look into the impact of embedding's world knowledge on FEVER.

In a nutshell, we model the task under a closed-world setting with the extracted evidence as the only available factual information to the model. Overall, we believe the methods proposed in this paper are general enough to apply to any fact-verification task. However, we show a case study only on FEVER due to its wide-spread popularity.

To this end, we first present an entity-anonymized version of the FEVER dataset and then propose pre-training strategies to enforce the above described closed-world setting on FEVER models.

2.1 Anonymization

A straightforward way to discourage the use of prior factual knowledge in fact-verification systems is to anonymize the named entities. An intuitive way to achieve this is to replace them with a custom list of abstract entity markers. We adapt a related technique from reading comprehension literature (Hermann et al., 2015) to our task. Given a pair of claim and extracted evidence sentences, we first identify the set of named entities from Wiki-titles of evidence sentences. We then replace all the occurrences of these named entities with abstract markers sampled randomly from a predefined list. We present an anonymized FEVER instance in Table 1. We use the resulting anonymized FEVER dataset to evaluate our proposed methods.

Claim	
David Carradine$_{\textbf{ent0}}$ was not in Kung Fu$_{\textbf{ent1}}$	
Evidences	
David Carradine$_{\textbf{ent0}}$	He was known for his leading role as a peace loving Shaolin monk, Kwai Chang Caine, in the 1970s television series Kung Fu$_{\textbf{ent1}}$
Kung Fu (TV series)$_{\textbf{ent1}}$	Kung Fu$_{\textbf{ent1}}$ is an American action adventure martial arts western drama television series starring David Carradine$_{\textbf{ent0}}$

Table 1: Example from Anonymized FEVER dataset. Each evidence constitutes the Wiki-title and a corresponding sentence. The two named entities (ent0, ent1) are highlighted.

2.2 Towards Closed-World FEVER

Clark et al. (2020) analyze the logical reasoning capabilities of transformer-based models on a variety of question-answering and reading comprehension tasks. Given a question and a context comprising of a set of simple facts and rules in natural language, models are expected to reason only based on the provided context, thereby emulating the ability to perform closed-world reasoning. They propose a synthetic training dataset (henceforth referred to as RuleTaker dataset) to fine-tune pre-trained models like RoBERTa. They observe high performances ($\geq$95% accuracy) on the synthetic test set, motivating us to adapt a similar training methodology for FEVER.

Table 2 shows an example context from the RuleTaker dataset. Each question-context pair in this dataset belongs to one of the following types, **Type–A**: provable/disprovable statements, can be labeled by reasoning directly over the context, **Type–B**: unprovable statements, reasoning

$Q2$. Bob is white.	$[F_1, F_2, R_1, R_2, R_3]$	SUPPORTS
$Q3$. Bob is not red.	$[F_1, F_2, R_1, R_2, R_3]$	REFUTES
$Q6$. Fiona is kind.	$[F_1, \cancel{F_2}, R_1, R_2, R_3]$	NOTENOUGHINFO
$Q7$. Bob is white.	$[\cancel{F_1}, F_2, R_1, R_2, R_3]$	NOTENOUGHINFO
$Q9$. Bob is not red.	$[\cancel{F_1}, F_2, R_1, R_2, R_3]$	NOTENOUGHINFO

Table 2: Example from the compiled RuleTaker-CWA and RuleTaker-Skip–fact.

over the context is not sufficient to conclude these statements.[3]

The RuleTaker dataset assigns a TRUE or FALSE label to each question-context pair. Type–A were labeled by reasoning over the context, whereas Type–B were labeled by invoking the closed-world assumption (CWA) ($Q4$, $Q5$ in Table 2). The provided context (facts and rules) constitutes the closed-world setup. Moreover, Type–A are additionally annotated with a proof constituting a reasoning chain over a subset of facts and rules.

We adapt the RuleTaker dataset to FEVER by introducing a new NOTENOUGHINFO label for unprovable question-context pairs. In particular, we construct two FEVER-style RuleTaker datasets, namely RuleTaker-CWA and RuleTaker-Skip–Fact (example in Table 2).

RuleTaker-CWA: We convert all the labels for Type–B pairs into NOTENOUGHINFO ($Q4$, $Q5$ in Table 2) and relabel TRUE and FALSE from Type–A into SUPPORTS and REFUTES respectively ($Q1$, $Q2$, $Q3$ in Table 2).

RuleTaker-Skip–Fact: For each Type–A question, we create a contrastive setting by removing a necessary fact (i.e., required in proof) from the original context. The label for the modified question-context pair becomes NOTENOUGHINFO because the question can no longer be answered under the modified context ($Q6$, $Q7$, $Q8$ in Table 2). We also retain the original Type–A pairs by converting all TRUE and FALSE labels to SUPPORTS and REFUTES respectively ($Q1$, $Q2$, $Q3$ in Table 2). To maintain a balanced dataset, we randomly sample a fraction of newly created NOTENOUGHINFO labels. Note that we only work with Type–A pairs in this variant. Occasionally there could be multiple valid proofs for the same question-context pair. We currently ignore these questions to avoid inconsistencies arising from other valid reasoning methods over the modified context. Table 3 presents the statistics for the train, dev and test splits in the proposed RuleTaker-CWA and RuleTaker-Skip–fact datasets.

Split/Label	SUPPORTS	REFUTES	NOTENOUGHINFO
RuleTaker-CWA			
Train	32034	32034	55000
Validation	4581	4581	7832
Test	9156	9156	15680
RuleTaker-Skip–fact			
Train	27360	27369	25389
Validation	3891	3906	3647
Test	7720	7733	7165

Table 3: Distribution of compiled RuleTaker datasets.

As a natural adaptation, we also considered creating a similar Skip–fact variant of the FEVER dataset. Each claim in FEVER was annotated with potentially many evidence sets, and each evidence set can consist of multiple evidence sentences. Ideally, we need all sentences within single evidence set to validate the claim, i.e., it requires multi-hop reasoning. Unfortunately, we noticed cases where a proper subset of an evidence set is enough to prove/disprove the claim (see Table 4).

2.3 Methodology

We now present the methodology to train constrained fact-verification models for the FEVER shared task. Many state-of-the-art FEVER models use the standard BERT encoder (Devlin et al., 2019) to encode a concatenation of claim and evidence sentences. To enforce closed-world reasoning over available evidence, we first pre-train the BERT encoder on the proposed variants of Rule-

---

[3] Type–A, Type–B correspond to the proof types {proof, inv-proof}, and {rconc, inv-rconc, random, inv-random} respectively, from the original dataset.

Claim
Roman Atwood is a content creator.
(One) Gold Evidence Set
1. (Roman Atwood) Roman Bernard Atwood (born May 28, 1983) is an American YouTube personality, comedian, vlogger and pranker.
2. (Comedian) A popular saying, variously quoted but generally attributed to Ed Wynn, is, "A comic says funny things; a comedian says things funny", which draws a distinction between how much of the comedy can be attributed to verbal content and how much to acting and persona.

Table 4: An example from the FEVER dataset. Wikipedia page titles for the evidence sentences are mentioned in parentheses. Even though the original dataset contains both evidence sentences within a single evidence set, we can label the given claim using just the first evidence sentence. Such cases would result in erroneous labels when creating Skip–fact version of FEVER.

Model	**# labels**	**Test accuracy**
RuleTaker	2	90.5
RuleTaker-CWA	3	92.5
RuleTaker-Skip–fact	3	91.4

Table 5: RuleTaker results on individual in-domain test sets. Note, these are separate test sets.

Taker datasets following Clark et al. (2020).

Firstly, the reasoning models in Clark et al. (2020) were first trained on the RACE multi-choice question answering dataset (Lai et al., 2017) and then fine-tuned on the RuleTaker dataset. In our experiments, we follow the same pipeline (including hyper-parameters) except to replace original RuleTaker dataset with our adaptations, RuleTaker-CWA and RuleTaker-Skip–fact.[4] In Table 5, we present the results of the pretrained RuleTaker-CWA and RuleTaker-Skip–fact on their respective test sets. In general, we notice high performance on the synthetic test sets, indicating the model's ability to rely only on available evidence.

We now utilize the above fine-tuned BERT encoders (CWA, Skip–fact) with two state-of-the-art graph-based reasoning networks for claim verification, KGAT (Liu et al., 2020) and Transformer-XH (Zhao et al., 2020), as well as a robust BERT-based classifier.

BERT–concat: Evidence sentences retrieved before claim verification are concatenated to the claim along with their Wiki-titles and are encoded using a pretrained BERT encoder. The [CLS] representation from the encoder is then directly used for classification.[5]

KGAT (Liu et al., 2020): A kernel-based graph attention network over the evidence graph. Each node in the graph encodes a concatenation of individual evidence sentence (along with Wiki-title) and the claim. Knowledge propagation between the nodes of this graph is achieved using a Gaussian *edge kernel* on a word-word similarity matrix, while individual node importance is measured using a separate *node kernel*. The initial node representations are refined using the above kernels and a single graph attention layer.

Transformer-XH (Zhao et al., 2020): Evidence graph is constructed and initialized in a way similar to KGAT, but the knowledge propagation between the nodes is achieved using special *eXtra-Hop attention* mechanism. For each node, the [CLS] token embedding from BERT is considered as an *attention hub* and is revised using a combination of the extra-hop attention and the traditional *in-sequence* attention.[6]

We compare the above-proposed curricula (CWA, Skip–fact) against a baseline curriculum (Original) where we initialize the verification models with standard pretrained BERT weights (bert-base-cased). We use huggingface transformers (Wolf et al., 2019) in all of our experiments.[7]

3 Experiments

For each of the three models, BERT–concat, Transformer-XH, and KGAT, we show results on the three different training curricula, Original, CWA, and Skip–fact in Table 6. We evaluate all our trained models on three datasets, the official devset of FEVER task (Std.), symmetric FEVER v0.2

---

[4] Note that we use the depth-3ext-NatLang set, which constitutes *depth*=3 dataset augmented with 10% each of *depth*=0,1,2 and crowdsourced natural language. We refer to the original work for more details about the RuleTaker dataset construction process.

[5] We use BertAdam optimizer with learning rate 3e-5, train for ten epochs and choose the best checkpoint based on dev label accuracy

[6] For KGAT and Transformer-XH, we follow the same hyper-parameters as the original work. We refer the readers to the original papers for more details.

[7] `https://huggingface.co/transformers/`

Eval set	BERT–concat			Transformer-XH			KGAT		
	Original	CWA	Skip–fact	Original	CWA	Skip–fact	Original	CWA	Skip–fact

Symm.	**57.5**	51.6	55.1	55.4	51.0	**59.0**	28.0	17.1	14.4
Anon.	73.2	68.0	70.9	70.4	68.1	65.8	**74.3**	70.8	69.1

Table 6: Label Accuracy on Standard (Std.), Symmetric (Symm.) and Anonymized (Anon.) *dev* sets. We highlight the best results in each row (evaluation set).

Eval set	BERT–concat (Anon. train)		
	Original	CWA	Skip–fact
Anon.	**75.7**	73.8	73.6

Table 7: Performance of BERT–concat model trained on anonymized FEVER train dataset. We report the accuracies on anonymized *dev* set.

(Schuster et al., 2019) (Symm.), and our proposed anonymized version of Std. (Anon.). Symmetric FEVER proposed by Schuster et al. (2019) constructs three adversarial claim-evidence pairs based on the original pair from the FEVER dev set.

On most evaluation sets, we found the models trained with Original curriculum performed better than our proposed curricula (CWA, Skip–fact) except on symmetric FEVER where Transformer-XH with Skip–fact does slightly better. Across the models, we notice a considerable drop in performance on Anon. set, validating our hypothesis about existing reliance on factual knowledge. To see the individual impact of the entity-anonymization, we train the BERT–concat model on train split of Anon. FEVER dataset. We observe improvements across the three curricula, with Original still outperforming the proposed curricula (Table 7).

Through our constrained verification setup, we expect the models to reason using only the extracted evidence. The evidence retrieval from Liu et al. (2020) achieves a recall of 94%, indicating the feasibility of reasoning only on extracted evidence in FEVER. With Original outperforming the proposed strategies on both the standard and anonymized FEVER, we find that world knowledge is helpful for FEVER.

Limitations Firstly, our anonymization is a regex-based method and relies only on the entities in Wiki-titles, and this might be insufficient for handling ambiguous titles. Secondly, the Rule-Taker dataset's domain is significantly different from that of the FEVER dataset, thereby presenting a challenge in re-using the pretrained encoder. Additionally, it is not entirely clear as to what constitutes the world (or factual) knowledge for a given task and as highlighted by Clark et al. (2020), effectively combining implicit pretrained knowledge (from encoders) with explicitly stated knowledge (from evidence) remains a challenge.

4 Related Work

We adopted the widely used document selection method from Hanselowski et al. (2018). Many recent state-of-the-art FEVER systems involve reasoning over evidence graphs (Zhou et al., 2019; Zhong et al., 2019; Liu et al., 2020; Zhao et al., 2020) along with competitive LM-based models (Soleimani et al., 2020). Dataset specific idiosyncrasies have been identified in FEVER (Thorne et al., 2019; Schuster et al., 2019) as well as in NLI (Gururangan et al., 2018; Poliak et al., 2018; Naik et al., 2018; McCoy et al., 2019), but is not the focus of this work.

5 Conclusion

We identify a critical issue with existing claim verification systems, especially the recent models that utilize large pre-trained LMs. We propose to perform fact verification under a closed-world setting and present our results on the task of FEVER. While it is hard to evaluate the reliance on implicit pretrained knowledge, our initial results indicate that such reliance is helpful for FEVER.

Abstract

We propose a new formulation for *multilingual entity linking*, where language-specific mentions resolve to a language-agnostic Knowledge Base. We train a dual encoder in this new setting, building on prior work with improved feature representation, negative mining, and an auxiliary entity-pairing task, to obtain a single entity retrieval model that covers 100+ languages and 20 million entities. The model outperforms state-of-the-art results from a far more limited cross-lingual linking task. Rare entities and low-resource languages pose challenges at this large-scale, so we advocate for an increased focus on zero- and few-shot evaluation. To this end, we provide **Mewsli-9**, a large new multilingual dataset[1] matched to our setting, and show how frequency-based analysis provided key insights for our model and training enhancements.

1 Introduction

Entity linking (EL) fulfils a key role in grounded language understanding: Given an ungrounded entity mention in text, the task is to identify the entity's corresponding entry in a Knowledge Base (KB). In particular, EL provides grounding for applications like Question Answering (Févry et al., 2020b) (also via Semantic Parsing (Shaw et al., 2019)) and Text Generation (Puduppully et al., 2019); it is also an essential component in knowledge base population (Shen et al., 2014). Entities have played a growing role in representation learning. For example, entity mention masking led to greatly improved fact retention in large language models (Guu et al., 2020; Roberts et al., 2020).

But to date, the primary formulation of EL outside of the standard monolingual setting has been *cross-lingual*: link mentions expressed in one language to a KB expressed in another (McNamee et al., 2011; Tsai and Roth, 2016; Sil et al., 2018). The accompanying motivation is that KBs may only ever exist in some well-resourced languages, but that text in many different languages need to be linked. Recent work in this direction features progress on low-resource languages (Zhou et al., 2020), zero-shot transfer (Sil and Florian, 2016; Rijhwani et al., 2019; Zhou et al., 2019) and scaling to many languages (Pan et al., 2017), but commonly assumes a single primary KB language and a limited KB, typically English Wikipedia.

We contend that this popular formulation limits the scope of EL in ways that are artificial and inequitable.

First, it artificially simplifies the task by restricting the set of viable entities and reducing the variety of mention ambiguities. Limiting the focus to entities that have English Wikipedia pages understates the real-world diversity of entities. Even within the Wikipedia ecosystem, many entities only have pages in languages other than English. These are often associated with locales that are already underrepresented on the global stage. By ignoring these entities and their mentions, most current modeling and evaluation work tend to side-step underappreciated challenges faced in practical industrial applications, which often involve KBs much larger than English Wikipedia, with a much more significant zero- or few-shot inference problem.

Second, it entrenches an English bias in EL research that is out of step with the encouraging shift toward *inherently multilingual* approaches in natural language processing, enabled by advances in representation learning (Johnson et al., 2017; Pires et al., 2019; Conneau et al., 2020).

Third, much recent EL work has focused on models that rerank entity candidates retrieved by an alias table (Févry et al., 2020a), an approach that works well for English entities with many linked mentions, but less so for the long tail of entities and languages.

---

[1] `http://goo.gle/mewsli-dataset`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7833–7845,
November 16–20, 2020.

To overcome these shortcomings, this work makes the following key contributions:

- Reformulate entity linking as inherently multilingual: link mentions in 104 languages to entities in WikiData, a language-agnostic KB.
- Advance prior dual encoder retrieval work with improved mention and entity encoder architecture and improved negative mining targeting.
- Establish new state-of-the-art performance relative to prior cross-lingual linking systems, with one model capable of linking 104 languages against 20 million WikiData entities.
- Introduce **Mewsli-9**, a large dataset with nearly 300,000 mentions across 9 diverse languages with links to WikiData. The dataset features many entities that lack English Wikipedia pages and which are thus inaccessible to many prior cross-lingual systems.
- Present frequency-bucketed evaluation that highlights zero- and few-shot challenges with clear headroom, implicitly including low-resource languages without enumerating results over a hundred languages.

2 Task Definition

Multilingual Entity Linking (MEL) is the task of linking an entity mention m in some context language l^{c} to the corresponding entity $e \in V$ in a *language-agnostic KB*. That is, while the KB may include textual information (names, descriptions, etc.) about each entity in one or more languages, we make no prior assumption about the relationship between these KB languages $L^{\mathrm{kb}} = \{l_1, \ldots, l_k\}$ and the mention-side language: l^{c} may or may not be in L^{kb}.

This is a generalization of *cross-lingual EL* (XEL), which is concerned with the case where $L^{\mathrm{kb}} = \{l'\}$ and $l^{\mathrm{c}} \neq l'$. Commonly, l' is English, and V is moreover limited to the set of entities that express features in l'.

2.1 MEL with WikiData and Wikipedia

As a concrete realization of the proposed task, we use WikiData (Vrandečić and Krötzsch, 2014) as our KB: it covers a large set of diverse entities, is broadly accessible and actively maintained, and it provides access to entity features in many languages. WikiData itself contains names and short descriptions, but through its close integration with all Wikipedia editions, it also connects entities to rich descriptions (and other features) drawn from the corresponding language-specific Wikipedia pages.

Basing entity representations on features of their Wikipedia pages has been a common approach in EL (e.g. Sil and Florian, 2016; Francis-Landau et al., 2016; Gillick et al., 2019; Wu et al., 2019), but we will need to generalize this to include multiple Wikipedia pages with possibly redundant features in many languages.

2.1.1 WikiData Entity Example

Consider the WikiData Entity `Sí Ràdio`$^{\text{Q3511500}}$, a now defunct Valencian radio station. Its KB entry references Wikipedia pages in three languages, which contain the following descriptions:[2]

- (Catalan) ***Sí Ràdio*** *fou una emissora de ràdio musical, la segona de Radio Autonomía Valenciana, S.A. pertanyent al grup Radiotelevisió Valenciana.*
- (Spanish) ***Nou Si Ràdio*** *(anteriormente conocido como Sí Ràdio) fue una cadena de radio de la Comunidad Valenciana y emisora hermana de Nou Ràdio perteneciente al grupo RTVV.*
- (French) ***Sí Ràdio*** *est une station de radio publique espagnole appartenant au groupe Ràdio Televisió Valenciana, entreprise de radio-télévision dépendant de la Generalitat valencienne.*

Note that these Wikipedia descriptions are not direct translations, and contain some name variations. We emphasize that this particular entity would have been completely out of scope in the standard cross-lingual task (Tsai and Roth, 2016), because it does not have an English Wikipedia page.

In our analysis, there are millions of WikiData entities with this property, meaning the standard setting skips over the substantial challenges of modeling these (often rarer) entities, and disambiguating them in different language contexts. Our formulation seeks to address this.

---

[2] We refer to the first sentence of a Wikipedia page as a description because it follows a standardized format.

2.2 Knowledge Base Scope

Our modeling focus is on using *unstructured textual* information for entity linking, leaving other modalities or structured information as areas for future work. Accordingly, we narrow our KB to the subset of entities that have descriptive text available: We define our entity vocabulary V as all WikiData items that have an associated Wikipedia page in *at least one language*, independent of the languages we actually model.[3] This gives 19,666,787 entities, *substantially more than in any other task settings we have found*: the KB accompanying the entrenched TAC-KBP 2010 benchmark (Ji et al., 2010) has less than a million entities, and although English Wikipedia continues to grow, recent work using it as a KB still only contend with roughly 6 million entities (Févry et al., 2020a; Zhou et al., 2020). Further, by employing a simple rule to determine the set of viable entities, we avoid potential selection bias based on our desired test sets or the language coverage of a specific pretrained model.

2.3 Supervision

We extract a supervision signal for MEL by exploiting the hyperlinks that editors place on Wikipedia pages, taking the anchor text as a linked mention of the target entity. This follows a long line of work in exploiting hyperlinks for EL supervision (Bunescu and Paşca, 2006; Singh et al., 2012; Logan et al., 2019), which we extend here by applying the idea to extract a large-scale dataset of 684 million mentions in 104 languages, linked to WikiData entities. This is at least six times larger than datasets used in prior English-only linking work (Gillick et al., 2019). Such large-scale supervision is beneficial for probing the quality attainable with current-day high-capacity neural models.

3 Mewsli-9 Dataset

We facilitate evaluation on the proposed multilingual EL task by releasing a matching dataset that covers a diverse set of languages and entities.

Mewsli-9 (***M****ultilingual* ***E****ntities in* ***N****ews,* ***li****nked*) contains 289,087 entity mentions appearing in 58,717 originally written news articles from WikiNews, linked to WikiData.[4]

The corpus includes documents in nine languages, representing five language families and six orthographies.[5] Per-language statistics appear in Table 1. Crucially, 11% of the 82,162 distinct target entities in Mewsli-9 *do not have English Wikipedia pages*, thereby setting a restrictive upper bound on performance attainable by a standard XEL system focused on English Wikipedia entities.[6] Even some English documents may contain such mentions, such as the Romanian reality TV show, `Noră pentru mama`$^{\text{Q12736895}}$.

			Entities	
Lang.	**Docs**	**Mentions**	Distinct	$\notin$ EnWiki
ja	3,410	34,463	13,663	3,384
de	13,703	65,592	23,086	3,054
es	10,284	56,716	22,077	1,805
ar	1,468	7,367	2,232	141
sr	15,011	35,669	4,332	269
tr	997	5,811	2,630	157
fa	165	535	385	12
ta	1,000	2,692	1,041	20
en	12,679	80,242	38,697	14
	58,717	289,087	82,162	8,807
en$'$	1801	2,263	1799	0

Table 1: Corpus statistics for Mewsli-9, an evaluation set we introduce for multilingual entity linking against WikiData. Line en$'$ shows statistics for English WikiNews-2018, by Gillick et al. (2019).

WikiNews articles constitute a somewhat different text genre from our Wikipedia training data: The articles do not begin with a formulaic entity description, for example, and anchor link conventions are likely different. We treat the full dataset as a test set, avoiding any fine-tuning or hyperparameter tuning, thus allowing us to evaluate our model's robustness to domain drift.

Mewsli-9 is a drastically expanded version of the English-only WikiNews-2018 dataset by Gillick et al. (2019). Our automatic extraction technique trades annotation quality for scale and diversity, in contrast to the MEANTIME corpus based on WikiNews (Minard et al., 2016). Mewsli-9 intentionally stretches the KB definition beyond English Wikipedia, unlike VoxEL (Rosales-Méndez et al., 2018). Both MEANTIME and VoxEL are limited to a handful of European languages.

---

[3] More details in Appendix C.

[4] `www.wikinews.org`, using the 2019-01-01 snapshot from `archive.org`

[5] Mewsli-9 languages (code, family, script): Japanese ('ja', Japonic, ideograms); German ('de', Indo-European (IE), Latin); Spanish ('es', IE, Latin); Arabic ('ar', Afro-Asiatic, Arabic); Serbian ('sr', IE, Latin & Cyrillic); Turkish ('tr', Turkic, Latin); Persian ('fa', IE, Perso-Arabic); Tamil ('ta', Dravidian, Brahmic); English ('en', IE, Latin).

[6] As of 2019-10-03.

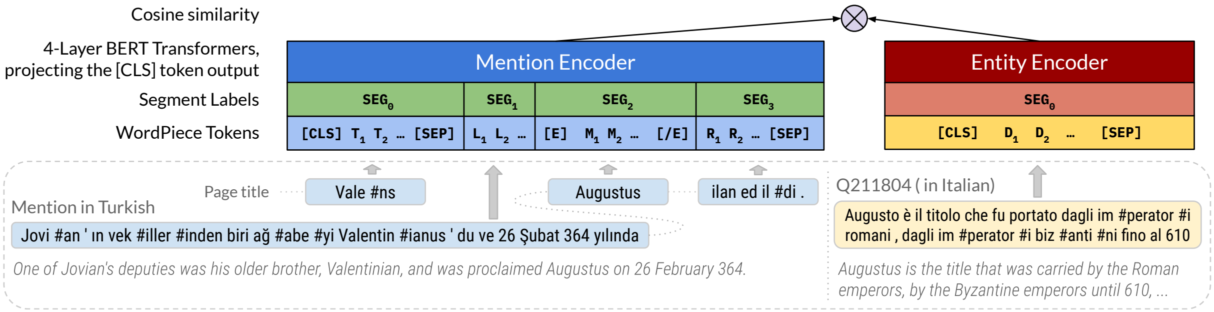

Figure 1: Dual Encoder **Model F** diagram. The input to the *Mention Encoder* is a sequence of WordPiece tokens that includes the document title (T_i), context immediately left of the mention (L_i), the mention span (M_i) demarcated by [E] and [/E] markers, and context immediately right of the mention (R_i). Segment labels (SEG_i) are also used to distinguish the input segments. The input to the (Model F) *Entity Encoder* is simply the WordPiece tokens in the entity description (D_i). As usual, embeddings passed to the first transformer layer are the sum of positional embeddings (not pictured here), the segment embeddings, and the WordPiece embeddings. The example shows a Turkish mention of `Augustus`$^{\text{Q211804}}$ paired with its Italian description.

4 Model

Prior work showed that a dual encoder architecture can encode entities and contextual mentions in a dense vector space to facilitate efficient entity retrieval via nearest-neighbors search (Gillick et al., 2019; Wu et al., 2019). We take the same approach. The dual encoder maps a mention-entity pair (m, e) to a score:

$$s(m, e) = \frac{\phi(m)^T \psi(e)}{\|\phi(m)\| \|\psi(e)\|}, \tag{1}$$

where ϕ and ψ are learned neural network encoders that encode their arguments as d-dimensional vectors (d=300, matching prior work).

Our encoders are BERT-based Transformer networks (Vaswani et al., 2017; Devlin et al., 2019), which we initialize from a pretrained multilingual BERT checkpoint.[7] For efficiency, we only use the first 4 layers, which results in a negligible drop in performance relative to the full 12-layer stack. The WordPiece vocabulary contains 119,547 symbols covering the top 104 Wikipedia languages by frequency—this is the language set we use in our experiments.

4.1 Mention Encoder

The mention encoder ϕ uses an input representation that is a combination of *local context* (mention span with surrounding words, ignoring sentence boundaries) and simple *global context* (document title). The document title, context, and mention span are marked with special separator tokens as well as identifying token type labels (see Figure 1 for details). Both the mention span markers and document title have been employed in related work (Agarwal and Bikel, 2020; Févry et al., 2020a). We use a maximum sequence length of 64 tokens similar to prior work (Févry et al., 2020a), up to a quarter of which are used for the document title. The CLS token encoding from the final layer is projected to the encoding dimension to form the final mention encoding.

4.2 Entity Encoders

We experiment with two entity encoder architectures. The first, called **Model F**, is a featurized entity encoder that uses a fixed-length text description (64 tokens) to represent each entity (see Figure 1). The same 4-layer Transformer architecture is used—without parameter sharing between mention and entity encoders—and again the CLS token vector is projected down to the encoding dimension. Variants of this entity architecture were employed by Wu et al. (2019) and Logeswaran et al. (2019).

The second architecture, called **Model E** is simply a QID-based embedding lookup as in Févry et al. (2020a). This latter model is intended as a baseline. *A priori*, we expect Model E to work well for common entities, less well for rarer entities, and not at all for zero-shot retrieval. We expect Model F to provide more parameter-efficient storage of entity information and possibly improve on zero- and few-shot retrieval.

4.2.1 Entity Description Choice

There are many conceivable ways to make use of entity descriptions from multiple languages. We limit the scope to using one primary description per entity, thus obtaining a single coherent text fragment to feed into the Model F encoder.

---

[7] `github.com/google-research/bert` `multi_cased_L-12_H-768_A-12`

We use a simple data-driven selection heuristic that is based on observed entity usage: Given an entity e, let $n_e(l)$ denote the number of mentions of e in documents of language l, and $n(l)$ the global number of mentions in language l across all entities. From a given source of descriptions—first Wikipedia and then WikiData—we order the candidate descriptions $(t_e^{l_1}, t_e^{l_2}, \dots)$ for e first by the per-entity distribution $n_e(l)$ and then by the global distribution $n(l)$.[8] For the example entity in Section 2.1.1, this heuristic selects the Catalan description because $9/16$ training examples link to the Catalan Wikipedia page.

4.3 Training Process

In all our experiments, we use an 8k batch size with in-batch sampled softmax (Gillick et al., 2018). Models are trained with Tensorflow (Abadi et al., 2016) using the Adam optimizer (Kingma and Ba, 2015; Loshchilov and Hutter, 2019). All BERT-based encoders are initialized from a pretrained checkpoint, but the Model E embeddings are initialized randomly. We doubled the batch size until no further held-out set gains were evident and chose the number of training steps to keep the training time of each phase under one day on a TPU. Further training would likely yield small improvements. See Appendix B for more detail.

5 Experiments

We conduct a series of experiments to gain insight into the behavior of the dual encoder retrieval models under the proposed MEL setting, asking:

- What are the relative merits of the two types of entity representations used in Model E and Model F (embeddings vs. encodings of textual descriptions)?
- Can we adapt the training task and hard-negative mining to improve results across the entity frequency distribution?
- Can a single model achieve reasonable performance on over 100 languages while retrieving from a 20 million entity candidate set?

5.1 Evaluation Data

We follow Upadhyay et al. (2018) and evaluate on the "hard" subset of the Wikipedia-derived test set introduced by Tsai and Roth (2016) for cross-lingual EL against English Wikipedia, **TR2016$^{\textbf{hard}}$**. This subset comprises mentions for which the correct entity did not appear as the top-ranked item in their alias table, thus stress-testing a model's ability to generalize beyond mention surface forms.

Unifying this dataset with our task formulation and data version requires mapping its gold entities from the provided, older Wikipedia titles to newer WikiData entity identifiers (and following intermediate Wikipedia redirection links). This succeeded for all but 233/42,073 queries in TR2016$^{\text{hard}}$—our model receives no credit on the missing ones.

To be compatible with the pre-existing train/test split, we excluded from our training set all mentions appearing on Wikipedia pages in the full TR2016 test set. This was done for all 104 languages, to avoid cross-lingual overlap between train and test sets. This aggressive scheme holds out 33,460,824 instances, leaving our final training set with 650,975,498 mention-entity pairs. Figure 2 provides a break-down by language.

5.2 Evaluating Design Choices

5.2.1 Setup and Metrics

In this first phase of experiments we evaluate design choices by reporting the *differences* in Recall@100 between two models at a time, for conciseness. Note that for final system comparisons, it is standard to use Accuracy of the top retrieved entity (R@1), but to evaluate a dual encoder retrieval model, we prefer R@100 as this is better matched to its likely use case as a candidate generator.

Here we use the TR2016$^{\text{hard}}$ dataset, as well a portion of the 104-language set held out from our training data, sampled to have 1,000 test mentions per language. (We reserve the new Mewsli-9 dataset for testing the final model in Section 5.5.)

Reporting results for 104 languages is a challenge. To break down evaluation results by entity frequency bins, we partition a test set according to the frequency of its gold entities as observed in the training set. This is in line with recent recommendations for finer-grained evaluation in EL (Waitelonis et al., 2016; Ilievski et al., 2018).

We calculate metrics within each bin, and report macro-average over bins. This is a stricter form of the label-based macro-averaging sometimes used, but better highlights the zero-shot and few-shot cases. We also report micro-average metrics, computed over the entire dataset, without binning.

---

[8] The candidate descriptions (but not V) are limited to the 104 languages covered by our model vocabulary—in general, both Wikipedia and WikiData cover more than 300 languages.

Table 2: R@100 differences between pairs of models: (a) model F (featurized inputs for entities) relative to model E (dedicated embedding for each entity); (b) add cross-lingual entity-entity task on top of the mention-entity task for model F; (c) control label balance per-entity during negative mining (versus not).

5.2.2 Entity Encoder Comparison

We first consider the choice of entity encoder, comparing Model F with respect to Model E.

Table 2(a) shows that using the entity descriptions as inputs leads to dramatically better performance on rare and unseen entities, in exchange for small losses on entities appearing more than 100 times, and overall improvements in both macro and micro recall.

Note that as expected, the embedding Model E gives 0% recall in zero-shot cases, as their embeddings are randomly initialized and never get updated in absence of any training examples.

The embedding table of Model E has 6 billion parameters, but there is no sharing across entities. Model F has approximately 50 times fewer parameters, but can distribute information in its shared, compact WordPiece vocabulary and Transformer layer parameters. We can think of these dual encoder models as classifiers over 20 million classes where the softmax layer is either parameterized by an ID embedding (Model E) or an encoding of a description of the class itself (Model F). Remarkably, using a Transformer for the latter approach effectively compresses (nearly) all the information in the traditional embedding model into a compact and far more generalizable model.

This result highlights the value of analyzing model behavior in terms of entity frequency. When looking at the micro-averaged metric in isolation, one might conclude that the two models perform similarly; but the macro-average is sensitive to the large differences in the low-frequency bins.

5.2.3 Auxiliary Cross-Lingual Task

In seeking to improve the performance of Model F on tail entities, we return to the (partly redundant) entity descriptions in multiple languages. By choosing just one language as the input, we are ignoring potentially valuable information in the remaining descriptions.

Here we add an auxiliary task: cross-lingual entity description retrieval. This reuses the entity encoder ψ of Model F to map two descriptions of an entity e to a score, $s(t_e^l, t_e^{l'}) \propto \psi(t_e^l)^T \psi(t_e^{l'})$, where $t_e^{l'}$ is the description selected by the earlier heuristic, and t_e^l is sampled from the other available descriptions for the entity.

We sample up to 5 such cross-lingual pairs per entity to construct the training set for this auxiliary task. This makes richer use of the available multilingual descriptions, and exposes the model to 39 million additional high-quality training examples whose distribution is decoupled from that of the mention-entity pairs in the primary task. The multitask training computes an overall loss by averaging the in-batch sampled softmax loss for a batch of (m, e) pairs and for a batch of (e, e) pairs.

Table 2(b) confirms this brings consistent quality gains across all frequency bins, and more so for uncommon entities. Again, reliance on the micro-average metric alone understates the benefit in this data augmentation step for rarer entities.

5.2.4 Hard-Negative Mining

Training with hard-negatives is highly effective in monolingual entity retrieval (Gillick et al., 2019), and we apply the technique they detail to our multilingual setting.

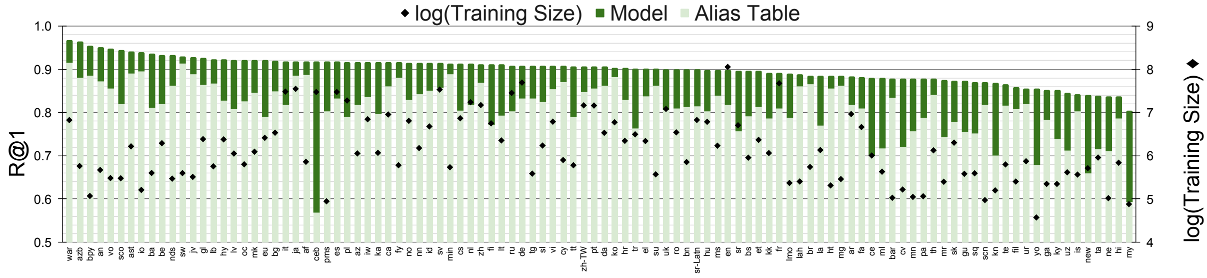

Figure 2: Accuracy of Model F$^+$ on the 104 languages in our balanced Wikipedia heldout set, overlayed on alias table accuracy and Wikipedia training set size. (See Figure B1 in the Appendix for a larger view.)

In its standard form, a certain number of negatives are mined for each mention in the training set by collecting top-ranked but incorrect entities retrieved by a prior model. However, this process can lead to a form of the class imbalance problem as uncommon entities become over-represented as negatives in the resulting data set. For example, an entity appearing just once in the original training set could appear hundreds or thousands of times as a negative example. Instead, we control the ratio of positives to negatives on a per-entity basis, mining up to 10 negatives per positive.

Table 2(c) confirms that our strategy effectively addresses the imbalance issue for rare entities with only small degradation for more common entities. We use this model to perform a second, final round of the adapted negative mining followed by further training to improve on the macro-average further by +.05 (holdout) and +.08 (TR2016$^{\text{hard}}$).

The model we use in the remainder of the experiments combines all these findings. We use Model F with the entity-entity auxiliary task and hard negative mining with per-entity label balancing, referenced as **Model F$^+$**.

5.3 Linking in 100 Languages

Breaking down the model's performance by language (R@1 on our heldout set) reveals relatively strong performance across all languages, despite greatly varying training sizes (Figure 2). It also shows improvement over an alias table baseline on all languages. While this does not capture the relative difficulty of the EL task in each language, it does strongly suggest effective cross-lingual transfer in our model: even the most data-poor languages have reasonable results. This validates our massively multilingual approach.

	Tsai+	**Upad.+**	**Model F$^+$**
Languages	13	5	104
$\lvert V\rvert$	5m	5m	20m
Candidates	20	20	20m
de	0.53	0.55	**0.62**
es	0.54	0.57	**0.58**
fr	0.48	0.51	**0.54**
it	0.48	0.52	**0.56**
Average	0.51	0.54	**0.57**

Table 3: Our best model outperforms previous related non-monolingual models that relied on alias tables and disambiguated among a much smaller set of entities. *Bottom half:* linking accuracy on the TR2016$^{\text{hard}}$ test set. *Top half:* language coverage; entity vocabulary size; and entities disambiguated among at inference time. *Middle columns:* (Tsai and Roth, 2016) and (Upadhyay et al., 2018).

5.4 Comparison to Prior Work

We evaluate the performance of our final retrieval model relative to previous work on two existing datasets, noting that direct comparison is impossible because our task setting is novel.

5.4.1 Cross-Lingual Wikification Setting

We compare to two previously reported results on TR2016$^{\text{hard}}$: the WIKIME model of Tsai and Roth (2016) that accompanied the dataset, and the XELMS-MULTI model by Upadhyay et al. (2018). Both models depend at their core on multilingual word embeddings, which are obtained by applying (bilingual) alignment or projection techniques to pretrained monolingual word embeddings.

As reported in Table 3, our multilingual dual encoder outperforms the other two by a significant margin. To the best of our knowledge, this is the highest accuracy to-date on this challenging evaluation set. (Our comparison is limited to the four languages on which Upadhyay et al. (2018) evaluated their multilingual model.)

	DEER	**Model F^+**
Languages	1	104
Candidates = $\|V\|$	5.7m	20m
R@1	0.92	0.92
R@100	0.98	**0.99**

Table 4: Comparison to DEER model (Gillick et al., 2019) on their English WikiNews-2018 dataset.

This is a strong validation of the proposed approach because the experimental setting is heavily skewed toward the prior models: Both are *rerankers*, and require a first-stage candidate generation step. They therefore only disambiguate among the resulting ≤20 candidate entities (only from English Wikipedia), whereas our model performs retrieval against all 20 million entities.

5.4.2 Out-of-Domain English Evaluation

We now turn to the question of how well the proposed multilingual model can maintain competitive performance in English and generalize to a domain other than Wikipedia. Gillick et al. (2019) provides a suitable comparison point. Their DEER model is closely related to our approach, but used a more light-weight dual encoder architecture with bags-of-embeddings and feed-forward layers without attention and was evaluated on English EL only. On the English WikiNews-2018 dataset they introduced, our Transformer-based multilingual dual encoder matches their monolingual model's performance at R@1 and improves R@100 by 0.01 (reaching 0.99) Our model thus retains strong English performance despite covering many languages and linking against a larger KB. See Table 4.

5.5 Evaluation on Mewsli-9

Table 5 shows the performance of our model on our new Mewsli-9 dataset compared with an alias table baseline that retrieves entities based on the prior probability of an entity given the observed mention string. Table 6 shows the usual frequency-binned evaluation. While overall (micro-average) performance is strong, there is plenty of headroom in zero- and few-shot retrieval.

	Alias Table		**Model F^+**	
Language	R@1	R@10	R@1	R@10
ar	0.89	0.93	0.92	0.98
de	0.86	0.91	0.92	0.97

$[1k, 10k)$	78,519	0.93	0.98	0.93
$[10k, +)$	102,203	0.94	0.99	0.96
micro-avg	289,087	0.89	0.96	0.91
macro-avg		0.70	0.84	0.71

Table 6: Results on the new Mewsli-9 dataset, by entity frequency, attained by our main dual encoder Model F^+, plus reranking its predictions with a Cross-Attention scoring model (CA).

5.5.1 Example Outputs

We sampled the model's correct predictions on Mewsli-9, focusing on cross-lingual examples where entities do not have an English Wikipedia page (Table 7). These examples demonstrate that the model effectively learns cross-lingual entity representations. Based on a random sample of the model's errors, we also show examples that summarize notable error categories.

5.5.2 Reranking Experiment

We finally report a preliminary experiment to apply a cross-attention scoring model (CA) to rerank entity candidates retrieved by the main dual encoder (DE), using the same architecture of Logeswaran et al. (2019). We feed the concatenated mention text and entity description into a 12-layer Transformer model, initialized from the same multilingual BERT checkpoint referenced earlier.

The CA model's CLS token encoding is used to classify mention-entity coherence. We train the model with a binary cross-entropy loss, using posi-

Context 1	. . . Bei den neuen Bahnen handelt es sich um das Model **Tramino** von der polnischen Firma Solaris Bus & Coach. . .

Outcome	***Wrong****: Metonymous mention of* `Central Valley Project`$^{\text{Q2944429}}$ *in English, but model retrieved the more literal match, featurized in Chinese. Metonymy is a known challenging case for EL (Ling et al., 2015).*

Table 7: Correct and mistaken examples observed in error analysis of dual encoder model F^{+} on Mewsli-9.

tives from our Wikipedia training data, taking for each one the top-4 DE-retrieved candidates plus 4 random candidates (proportional to the positive distributions).

We use the trained CA model to rerank the top-5 DE candidates for Mewsli-9 (Table 6). We observed improvements on most frequency buckets compared to DE R@1, which suggests that the model's few-shot capability can be improved by cross-lingual reading-comprehension. This also offers an initial multilingual validation of a similar two-step BERT-based approach recently introduced in a monolingual setting by (Wu et al., 2019), and provides a strong baseline for future work.

6 Conclusion

We have proposed a new formulation for multilingual entity linking that seeks to expand the scope of entity linking to better reflect the real-world challenges of rare entities and/or low resource languages. Operationalized through Wikipedia and WikiData, our experiments using enhanced dual encoder retrieval models and frequency-based evaluation provide compelling evidence that it is feasible to perform this task with a single model covering over a 100 languages.

Our automatically extracted Mewsli-9 dataset serves as a starting point for evaluating entity linking beyond the entrenched English benchmarks and under the expanded multilingual setting. Future work could investigate the use of non-expert human raters to improve the dataset quality further.

In pursuit of improved entity representations, future work could explore the joint use of complementary multi-language descriptions per entity, methods to update representations in a light-weight fashion when descriptions change, and incorporate relational information stored in the KB.

Appendix

A Mewsli-9 Dataset

Available at: `http://goo.gle/mewsli-dataset`

We used an automated process to construct Mewsli-9, exploiting link anchor text to identify naturally occurring entity mentions in WikiNews articles, from its inception to the end of 2018.

From a given WikiNews page dump,[9] we extracted text including link anchors and section headings using a modified version of `wikiextractor`.[10]

To obtain clean article text, we discard page-final sections that merely contain external references, etc. This is done by matching section headings against a small set of hand-collected, language-specific patterns.

Mention candidates are filtered to those remaining links that point to Wikipedia pages in any language (not limited to our 104 languages). These Wikipedia links are redirected if necessary, and resolved to WikiData identifiers to determine the gold entity for a mention. There are many reasons why resolution may fail, including mistakes in the original markup and churn in the data sources over time. The final dataset is limited to (mention, entity) pairs where resolution to WikiData succeeded.

B Training Details and Hyperparameters

All model training was carried out on a Google TPU v3 architecture,[11] using batch size 8192 and a learning rate schedule that uses linear warm-up followed by linear decay to 0.

The first phase of training our dual encoders (DE) with in-batch random negatives encompasses 500,000 steps, which takes approximately one day.

Where hard-negative training is applied, we initialize from the corresponding prior model checkpoint and continue training against the multi-task loss for a further 250,000 steps, which also takes about a day.

Other than the limit to using a 4-layer Transformer stack, our mention encoder and model F entity encoders use the same hyperparameters as mBERT-base, allowing initialization from the publicly available checkpoint—we use the weights of its first 4 layers, in addition to those of the token and positional embeddings.

Table 8: WikiData identifiers used for filtering out Wikimedia-internal entities from our KB definition.

The cross-attention scoring model (CA) in the final preliminary experiment is a full 12-layer Transformer (also mBERT-base), and was trained for 1 million steps, taking just under one day.

The learning rates were 1e-4 (DE) and 1-e5 (CA) and included warm-up phases of 10% (DE) and 1% (CA) of the respective number of training steps.

C Data Preprocessing

We used the 2019-10-03 dump of Wikipedia and WikiData, parsed using in-house tools.[12]

Two filtering criteria are relevant in preprocessing WikiData to define our KB. The first is to exclude items that are a subclass (P279) or instance of (P31) the most common Wikimedia-internal administrative entities, detailed in Table 8. The remaining entities are then filtered to retain only those for which the WikiData entry points to at least one Wikipedia page, in any language, motivated by our objective of using descriptive text as entity features.

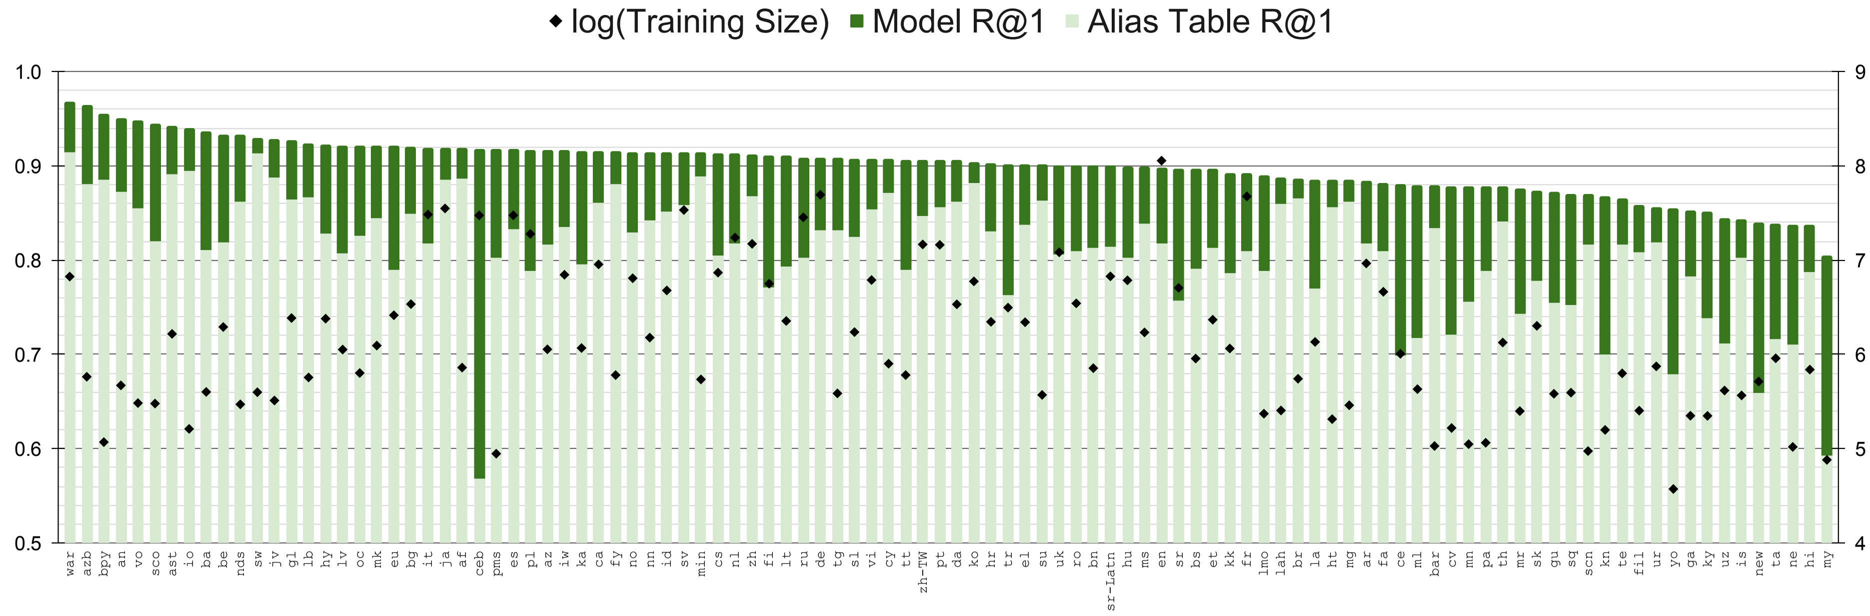

Figure B1: Accuracy (left-axis) of Model F$^+$ on the 104 languages in our balanced Wikipedia heldout set, overlayed on alias table accuracy, and Wikipedia training set size (right-axis). Our Model F$^+$ obtains relatively strong performance across 104 languages and outperforms an alias table baseline in all cases. Although task difficulty is not necessarily comparable between languages, this result suggests effective cross-lingual transfer is happening: even languages with small training sets show reasonable accuracy. *(This is a scaled-up reproduction of Figure 2 from Section 5.3.)*

Abstract

Large scale pre-trained language models have shown groundbreaking performance improvements for transfer learning in the domain of natural language processing. In our paper, we study a pre-trained multilingual BERT model and analyze the OOV rate on downstream tasks, how it introduces information loss, and as a side-effect, obstructs the potential of the underlying model. We then propose multiple approaches for mitigation and demonstrate that it improves performance with the same parameter count when combined with fine-tuning.

1 Background

The advent of large scale language models pre-trained with large unannotated corpora has shown significant advancements in the domain of natural language processing, especially by demonstrating their effectiveness through transfer learning for downstream tasks (Howard and Ruder, 2018; Devlin et al., 2019; Conneau and Lample, 2019; Radford et al.), analogous to ImageNet (Deng et al., 2009) pre-trained backbones in the domain of computer vision. In the domain of natural language processing, new methods have made it possible to use internet corpora as a nearly free source for increasing the amount of data at an unprecedented scale during pre-training.

Additionally, new tokenization methods such as Byte-Pair Encoding (BPE, Sennrich et al. (2016)), WordPiece (Wu et al., 2016), SentencePiece (Kudo and Richardson, 2018), which break the lexicons into smaller subwords, have shown to be effective when applied to alphabetic languages to reduce the size of the vocabulary while increasing the robustness against out-of-vocabulary (OOV) in downstream tasks. This is especially powerful when combined with transfer learning. However, these tokenizers still operate at Unicode character levels - contrary to the names suggesting byte-level (which would completely mitigate OOV, as studied in Gillick et al. (2016)). Hence, the minimum size of the vocabulary is twice the size of all unique characters in the corpus, as subword tokenizers store each character in prefix and suffix form in the vocabulary. As OOV was a much more prevalent problem in the context of lexicon-based methods, there have been many methods, such as dictionary-based postprocessing (Luong et al., 2015) and distributional representation based substitution (Kolachina et al., 2017). Recently this has not been as actively studied in the context of subword tokenization as Latin languages are no longer affected.

For these reasons, when trained against a diverse set of languages, the vocabulary size increases proportionally to the number of languages supported. Existing models have sampled portions of entire corpora or relaxed constraints on character level coverage for these languages, to prevent the vocabulary from growing to an unmanageable scale. As of today, this is an unavoidable trade-off when training multilingual models. This introduces a bottleneck for downstream tasks since any character omitted causes information loss.

Training models for each language is the most straightforward possible mitigation. However, the downside is the cost for pre-training; acquiring a large corpus is a daunting task, and training a large model for many researchers can be financially infeasible. The high upfront cost leaves transfer learning on an open, multilingual model as an economically attractive alternative. Unfortunately, due to corpus imbalance during pre-training, minor languages, especially those with a diverse character set (such as CJK languages), OOV is likely to surface. Our motivation is to improve performance for these languages, without significantly increas-

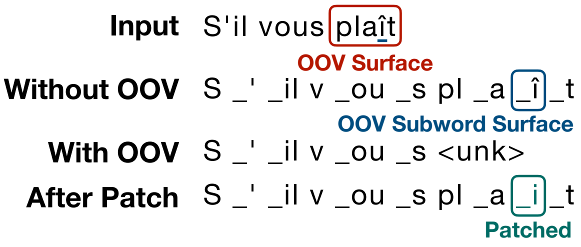

Figure 1: The hierarchy of OOV and the high level process explained through a simplified example in French. In this example, we assume î is a missing subword.

ing the computation cost when using open-source pre-trained models.

In our work, we propose multiple approaches to mitigate OOV during fine-tuning. We compare each approach with no OOV mitigation, along with increasing vocabulary size as a secondary baseline.

2 Approach

The multilingual BERT model **bert-base-multilingual-cased** (Devlin et al., 2019) we used performs two-phase tokenization, first with whitespace followed by WordPiece. The tokenizer was modified to support a secondary vocabulary which points new words to existing words for our experiments, connected to a Transformers library (Wolf et al., 2019) BERT model. The approach consists of three steps.

First, we perform a complete corpus analysis and search for all OOV surfaces by tokenizing the task corpus. An OOV surface in the context of BERT is an entire space tokenized token. Whenever OOV occurs, we keep a record of the entire OOV surface, along with the context.

For each OOV surface, we brute-force search to find the maximally specific OOV subword surface. An OOV subword surface is an actual subword missing in an OOV surface. In this step, we compute a frequency table for both OOV and in-vocabulary subwords for a preference mechanism in the mitigation strategy. We observed that most cases of the OOV subword surface were caused by one character missing in the vocabulary during our experiments, which is a result of incomplete character coverage from the corpora used for pre-training.

Finally, we use this information to build a mitigation strategy for the OOV subwords. Here, we evaluate different algorithms for OOV mitigation, each of which we discuss in the individual method sections below. After applying OOV mitigation, we then optionally perform fine-tuning and evaluate against the baseline.

Substitution to mitigate OOV has been studied in (Kolachina et al., 2017). This method depends on part-of-speech tagging or a secondary corpus and model for similarity computation, which is challenging to apply in a subword model. The significance of our approach is that it works for subword models and it's practical applicability, as only a downstream task corpus and a pre-trained model is required.

2.1 Surrogated Tokens

Surrogates, simply put, is treating a subword missing from the vocabulary to a subword that is already in the vocabulary of a pre-trained model. There are intuitive ways to find substitute words in a word-level setup, the most obvious being choosing a semantically similar word from a thesaurus. In a subword context, this is not as straightforward, as a subword generally has no meaning. In our work, we discuss different surrogate selection processes. The surrogate selection process introduces polysemy as a tradeoff for mitigating OOV. While some of the proposed methods add complexity for generative tasks, it does not increase the model's computation cost as the vocabulary size does not change.

The embeddings between the newly added subword and the surrogate are shared and updated together in the fine-tuning process. The OOV subword frequency table we constructed in the second step of the process above is used to break ties and minimize conflicts. For example, token A and B, both of which are OOV subwords, can end up with the same proposals $\{X, Y\}$ in preference order. In this case, given A has a higher frequency, it gets precedence over B, so the surrogate map becomes $A \rightarrow X$ and $B \rightarrow Y$. Our goal is to refine the proposals to be in a state where one surrogate is assigned to only one OOV token.

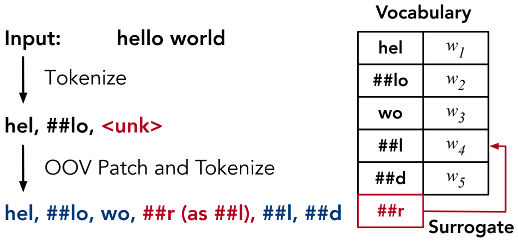

Figure 2: Surrogate vocabulary injection process.

2.1.1 Character Distance

This method selects the surrogate with Unicode codepoint distance, limited to subword tokens within the vocabulary of the same length. In this process, we perform an exhaustive search, formulated as $\underset{w \in W'}{\operatorname{argmin}}(|\operatorname{ord}(v) - \operatorname{ord}(w)|_1$ where v is the OOV subword, and W' is a subset of the vocabulary W which satisfies UTF-8 length equality $|v| = |w|$ for $w \in W$. ord is Unicode ordinal conversion.

The intuition of this method builds on the characteristics of the CJK Unicode blocks, which allow us to cheaply approximate text or semantic similarity through the scalar values of the Unicode codepoints. The properties which we intend to exploit are different depending on the target language. In CJK ideographs, adjacent characters tend to share a radical, hence has a bias towards semantic similarity.

On the other hand, in Korean, phonetically similar characters are adjacent. This approximates edit distance, as a Korean character in Unicode is a combination of multiple sub-characters. This phonetic similarity differs from edit distance, as it tends to disallow edits on the first two components of the character. In the event of a distance tie, we used the candidate with a lower codepoint.

Frequent subword tokens get preferential treatment and hence get surrogates with closer distance to an infrequent token. Once a token has been assigned, it is not re-used as a surrogate.

2.1.2 Unseen Tokens

We select tokens from the in-vocabulary token frequency table, which were never seen in the current task as surrogates. As downstream tasks for evaluation do not require the entire vocabulary, we select random tokens with a frequency of 0 as surrogates.

This method is analogous to increasing the model parameters (via vocabulary size), then pruning back to the original size, but as an in-place operation. Any word previously assigned was held out to prevent re-assignment. As the vocabulary will have a large number of tokens never seen in most downstream tasks, we do not use any frequency preference here.

This method can also be combined with character distance to prefer surrogates with a high distance to assign surrogates in a distant Unicode page to prevent unseen tokens of the same language being used as surrogates.

Figure 3: In character distance, The highlighted character is missing from the vocabulary. Observing the adjacent characters, in CJK ideographs they share a radical, while in Korean they share two subcharacters.

2.1.3 Masked Language Model

First, the masked language model based proposal uses BERT's masked language head to generate surrogate proposals. Each subword OOV surface is replaced with the mask token and passed to the masked LM head with the whole context. The subword token with the highest probability is selected for each context, stored in a frequency table, to select the most common token later. We use the same frequency preference as character distance, which allows frequent OOV subwords to have precedence when selecting surrogates. As with other methods, once a surrogate is assigned, it is held out. Therefore, less frequent words are assigned to the next most locally frequent surrogate. After the entire process is done, OOV subwords that were not assigned a surrogate are assigned to the candidate with the lowest frequency.

2.2 Additional Tokens

Here, we add new tokens to the vocabulary and increase the model size, motivated by Wang et al. (2019). As this increases the network parameters, these are used as a secondary baseline to be compared with surrogates.

2.2.1 Random Initialization

After adding the missing subword to the vocabulary, the embedding is then randomly initialized.

2.2.2 Transfer Initialization

Transfer initialization is done by following the first step of the masked language model task to generate a list of surrogates. We then initialize by

Dataset	O/Tok	O/Sen	Total	%
NSMC	81603	60151	200K	30.1

Twitter	10310	5518	22K	25.1
INEWS	2570	1278	6K	20.1

Table 2: OOV analysis on the four datasets. O/Tok is the number of OOV tokens, O/Sen is the number of sentences with at least one OOV token, and the total sentence count, followed by the ratio of OOV sentences.

copying the embedding vector of the topmost probable candidate of the OOV subword into the newly added OOV subword's slot in the embedding matrix. These two tokens share the same initial embeddings but are expected to diverge through fine-tuning.

3 Datasets

For our experiments, we used four datasets for evaluation. For all tasks, we first learn OOV words, perform fine-tuning, then evaluate. The OOV rates noted for each dataset is the ratio of sentences containing at least one OOV token.

3.1 Naver Sentiment Movie Corpus

The Naver Sentiment Movie Corpus (NSMC) is a Korean sentiment analysis task, containing 200,000 user comments and a corresponding binary label which indicates positive or negative sentiment. The OOV rate was 30.1% due to a large number of typos and also being from a different domain.

3.2 Japanese Twitter Sentiment Analysis

As a second validation target language, we used a Japanese Twitter dataset, which is a sentiment analysis task with five possible labels. The task is 20K Tweets and 2K Tweets, respectively, for training and test. During analysis, we observed that a large portion of the OOV was from emojis, resulting in an OOV rate of 25.1%.

3.3 Chinese News Sentiment Analysis

The INEWS dataset is part of the ChineseGLUE dataset. The input is a short sentence from a news article, and the label is the tone of the article. This is also a sentiment analysis task, with a split of 5K train and 1K validation, and an OOV rate of 20.1%.

3.4 KorQuAD 1.0

KorQuAD 1.0 is a Korean version of the SQuAD (Rajpurkar et al., 2016) reading comprehension task. The task involves answering a question given a passage of text, and consists of 10K passages with 66K questions. The passages are from Wikipedia, which is commonly used as a part of large-scale training corpora. The result of this is a low OOV rate of 5.9%. For this task, task corpus fine-tuning was omitted to prevent the model from memorizing answers.

4 Results

The evaluation was done through the SST-2 GLUE task metrics (Wang et al., 2018) for the sentiment analysis tasks, and EM/F1 evaluation from the SQuAD metrics for KorQuAD, as the two tasks are compatible. Each model used the same dataset and training parameters as the baseline, only with different OOV mitigation methods.

Additionally, while Chinese and Japanese are both scriptio continua languages, BERT's tokenizer treats CJK ideograph text differently and breaks at every character. This makes the affected surface from OOV significantly smaller, resulting in less information loss. For these reasons, we expect to see larger gains in Korean, as the per-character break is not enabled.

4.1 Naver Sentiment Movie Corpus

Due to the larger OOV surface and frequency, we expect to observe a modest increase in the best case compared to the baseline. We can indeed observe that regardless of the mitigation method, OOV mitigation, in general, improves accuracy. The OOV tokens we observed here were from casual writing in user comments, which shifts from the book corpus like domain used for pre-train. This suggests that even without robust, representative embeddings, it is still better than losing information during tokenization. We also hypothesize that because the embeddings initially are not representative of the subword in context, performance improves by domain adaptation through fine-tuning.

4.2 Japanese Twitter Sentiment Analysis

This corpus showed a high OOV rate due to the frequent occurrence of emoji in the text. We observe similar patterns with the results from NSMC. Generally, we see improvements when both OOV mitigation and fine-tuning were done, except for character distance. We observed that character distance assigned surrogates to Korean characters, which may have contributed to this.

Table 3: Results. Acc denotes accuracy. Params denote a parameter increase. FT and NT mean with and without fine-tuning, respectively. Results for KorQuAD are without fine-tuning.

4.3 Chinese News Sentiment Analysis

While we observed a high OOV rate in this dataset, the improvement was negligible. Analyzing the surrogates, we observed that most of the OOV tokens were punctuation or uncommon ideographs, which we expected to, and confirmed to have little effect in the downstream task performance. In particular, we attribute the negligible gains to the nature of the task itself, as it is a news article classification task. While punctuation is an important aspect in tasks such as sentiment classification, classifying articles into categories has a stronger dependency on keywords, which are likely to in-vocabulary.

4.4 KorQuAD 1.0

We did not expect significant improvements due to the low OOV rate, and the results reflect this. While we still saw minor improvements across the board, the difference is incremental at best. The small delta can most likely be attributed to the relatively low OOV rate and omission of fine-tuning.

5 Conclusions

After demonstrating examples (1) and the effects of OOV triggered information loss, we propose multiple methods for mitigating OOV during downstream task fine-tuning. We then demonstrate and compare with no mitigation, mitigation through network modification, and surrogates, which require no network modification, and show how each approach affects downstream tasks. In particular, we show that vocabulary surrogates can provide performance boosts with no additional computation cost, especially when paired with fine-tuning.

We also empirically show that tasks with lower OOV suffer less when compared to languages that do not, as seen in table 1. While our experiments are limited to CJK languages on BERT, we believe the methods proposed are generic and simple to implement and expect the performance gains to also apply to different languages and models.

Table 4: Hyperparameters used to train each of the downstream task models.

A Appendix

A.1 Hyperparameters

We ran our experiments as close as possible to the baseline parameters used by the publicly available benchmark scripts for each task type. This means most of the hyperparameters for all of the evaluation was done as close to the default values as possible. The maximum sequence length was fixed to 512 for all models and tasks.

A.2 Environment

All experiments were executed on a shared rt_G.small instance on the ABCI compute cluster[1]. An rt_G.small node has 6 segregated CPU cores from a Xeon Gold 6148, a Tesla V100 GPU with 16GB VRAM, and 60GBs of memory. The training data and experimental code was streamed from a shared GPFS mount. Each experiment requires a

different amount of compute budget. The longest running experiment finished in 10 hours of wall clock time and the shortest finished in 2 hours of wall clock time. The average runtime for each experiment was approximately 5.5 hours.

On the importance of pre-training data volume for compact language models

Abstract

Recent advances in language modeling have led to computationally intensive and resource-demanding state-of-the-art models. In an effort towards sustainable practices, we study the impact of pre-training data volume on compact language models. Multiple BERT-based models are trained on gradually increasing amounts of French text. Through fine-tuning on the French Question Answering Dataset (FQuAD), we observe that well-performing models are obtained with as little as 100 MB of text. In addition, we show that past critically low amounts of pre-training data, an intermediate pre-training step on the task-specific corpus does not yield substantial improvements.

1 Introduction

Over the past year, pre-trained language models have become the norm in Natural Language Processing. These large-scale Transformer-based (Vaswani et al., 2017) networks considerably advanced the state-of-the-art in language understanding (Devlin et al., 2019) via a two-step process: self-supervised learning on a vast text corpus followed by fine-tuning on a specific downstream task.

Following these advances, the ongoing trend has been to build bigger models with an ever-increasing amount of data (Liu et al., 2019; Raffel et al., 2020; Radford et al., 2019; Brown et al., 2020). However, pre-training models with billions of parameters over hundreds of gigabytes of text requires tremendous computational resources that only a few companies and institutions can afford. Besides, many languages and specific corpora (e.g. legal, scientific) are currently under-resourced. Hence, our goal is to explore model architectures and data volumes lowering the entry barrier to new research and practical applications.

We conduct experiments on French corpora in order to release the first French compact language models and to illustrate the training process in another language than English. Furthermore, we consider the question answering task since compact models may find their purpose in low-latency/fault-tolerant information retrieval systems.

2 Problem statement

We intend to study the impact of pre-training data volume when training compact bidirectional Transformers (Devlin et al., 2019). We assume a scarce resources setting, both in terms of data and computing power. Two key aspects are explored:

- The amount of pre-training data required to train high-performing compact language models.
- The importance of corpus-specific MLM before fine-tuning.

We use the French part of the OSCAR corpora (Ortiz Suarez et al., 2019) for pre-training and the FQuAD dataset [1] (d'Hoffschmidt et al., 2020) for machine reading comprehension fine-tuning. Moreover, the models under consideration are based on the CamemBERT (Martin et al., 2020) language model.

3 Related work

A wealth of work has recently been released (Ganesh et al., 2020) on compressing Transformer-based models (Vaswani et al., 2017; Devlin et al., 2019) through the pre-training of compact models (Turc et al., 2019), distillation (Hinton et al., 2015; Jiao et al., 2019; Sun et al., 2020), pruning (Li et al., 2020; McCarley et al., 2019; Sanh et al., 2020; Fan et al., 2020a) and quantization (Shen et al., 2019;

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7853–7858,
November 16–20, 2020.

Fan et al., 2020b). Nevertheless, absolute performance is not the end goal of this study. Rather, we investigate the training process of compact models in the absence of larger ones to distillate or prune. Furthermore, Sanh et al. (2020) acknowledge the difficulty of speeding up sparse models due to the absence of specialized hardware. Therefore, from an inference speed standpoint, it is currently preferable to train compact models.

Language models have been successfully pre-trained on domain-specific corpora (Beltagy et al., 2019; Lee et al., 2019) and outperform their general-purpose counterparts on targetted downstream tasks. Still, training these models involved large datasets and computational resources out of reach for most.

Multilingual models (Devlin et al., 2019; Lample and Conneau, 2019; Conneau et al., 2020) have been released to alleviate the need for language-specific pre-training. While they offer competitive results, they usually lag behind monolingual models and require larger architectures.

Martin et al. (2020) observed that large models did not improve on evaluation tasks when increasing the amount of pre-training data from 4 GB to 138 GB. They left as future work to question the need for large scale pre-training corpora with other model architectures and tasks.

4 Datasets

4.1 OSCAR

OSCAR [2] (Ortiz Suarez et al., 2019) is a large-scale multilingual open source collection of corpora obtained by language classification and filtering of the Common Crawl corpus [3]. The whole French part amounts to 138 GB of text and it has already been used to train French language models (Martin et al., 2020). In this work, we only extract a sample of 4 GB of shuffled lines.

4.2 FQuAD

FQuAD (d'Hoffschmidt et al., 2020) is a recently introduced open source French native reading comprehension dataset. It consists of 60,000 questions and answers gathered on a set of 1,769 high-quality Wikipedia articles. In many aspects, it is the French equivalent of SQuAD 1.1 (Rajpurkar et al., 2016). Given a question and a paragraph, the task consists in extracting from the paragraph the span of text answering the question.

Model	**Size**	**Time**
CamemBERT$_{\text{SMALL}}$	72 MB	157 ms
CamemBERT$_{\text{BASE}}$	440 MB	705 ms
CamemBERT$_{\text{LARGE}}$	1340 MB	2376 ms

Table 1: Model size and inference time on an Intel Xeon 2.30GHz Quad core CPU with batch size 1 and max sequence length 384 tokens (average over 1000 samples).

We chose FQuAD as the fine-tuning dataset because it allows one to draw a direct parallel with its English counterpart (d'Hoffschmidt et al., 2020) and is one of the largest annotated French datasets. However, question answering is a notoriously difficult task for compact models (McCarley et al., 2019). While distillation has shown to improve their results on the GLUE benchmark (Wang et al., 2018) substantially, machine reading comprehension remains difficult to speed-up without incurring a significant drop in accuracy.

5 CamemBERT$_{\text{SMALL}}$

CamemBERT (Martin et al., 2020) is a multi-layer bidirectional Transformer (Vaswani et al., 2017) with two architectures: base (12 layers, 768 hidden dimensions, 12 attention heads, 110M parameters) and large (24 layers, 1024 hidden dimensions, 16 attention heads, 355M parameters). It is very similar to RoBERTa (Liu et al., 2019). The main differences are the use of whole-word masking and SentencePiece tokenization (Kudo and Richardson, 2018) instead of subword-masking and byte-level Byte-Pair encoding (Sennrich et al., 2016; Radford et al., 2019). RoBERTa itself improves upon BERT by aggregating several modifications on top of the original architecture such as removing the next sentence prediction task, dynamic masking, and training with larger batches on more data.

We introduce CamemBERT$_{\text{SMALL}}$ [4], a CamemBERT-based language model with a small architecture (12 layers, 256 hidden dimensions, 4 attention heads, 17M parameters). The main difference with the original CamemBERT lies in the use of subword-masking. Indeed, the authors later found out that whole-word masking had

[4] The pre-trained models are made available in the Hugging Face collection: `https://huggingface.co/illuin/lepetit`.

Hyperparameter	**Pre-train**	**Fine-tune**
Train steps	200k	30k
Warmup steps	10k	3k
Batch size	128	32
Learning rate	1e-4	1e-4
Adam β_1	0.9	0.9
Adam β_2	0.999	0.999
Weight decay	0.01	0.0
Max gradient norm	1.0	1.0
Dropout	0.1	0.1
Mask percent	15	n/a
Max sequence length	512	384

Table 2: Pre-training and fine-tuning hyperparameters. In the corpus-specific MLM step, we take the same hyperparameters as in pre-training except that we decrease the number of steps to 2.5k and drop the warmup.

at best a marginal impact on downstream task performance.

Apart from inference speed and size considerations, two main factors explain this architectural choice:

- This is the same architecture as ELECTRA$_{\text{SMALL++}}$ (Clark et al., 2020), a recently released compact language model. Even though ELECTRA and CamemBERT differ in many regards (ELECTRA being trained as a discriminator rather than a generator), prior experiments conducted by Clark et al. (2020) give us an acceptable set of hyperparameters when pre-training and fine-tuning the model.
- Turc et al. (2019)'s empirical results suggest that depth should be prioritized over width when pre-training compact models.

Table 1 shows that CamemBERT$_{\text{SMALL}}$ is much smaller and faster than its larger siblings. In a plausible setup for question answering systems, it provides, respectively, a 4.5-fold and 15-fold inference speed-up compared to CamemBERT$_{\text{BASE}}$ and CamemBERT$_{\text{LARGE}}$ while being 6.2 and 18.8 times smaller.

6 Experiments

Six overlapping subsets are built from the 4 GB OSCAR sample. They are denoted as OSC$_{10}$, OSC$_{100}$, OSC$_{500}$, OSC$_{1000}$, OSC$_{2000}$ and OSC$_{4000}$ (the numbers indicating the number of MB). We extract an additional 10 MB sample from the corpus, which serves as a validation set for the self-supervised pre-training task. On the other hand, FQuAD consists of a train/dev split of 50,741 and 5,668 question/context pairs.

For each OSCAR subset, we pre-train a CamemBERT$_{\text{SMALL}}$ model with the standard masked language modeling (MLM) objective. Then we fine-tune the pre-trained models on the question answering task with the same span prediction method as BERT (Devlin et al., 2019). Between those two steps, an optional MLM step over the FQuAD train set is included.

Table 2 shows the pre-training, intermediate MLM (if any) and fine-tuning hyperparameters. Fine-tuning being a brittle process (Dodge et al., 2020), fine-tuning results are averaged over 3 seeds.

The experiments described were implemented using Hugging Face's Transformers library (Wolf et al., 2019) and were conducted on an NVidia V100 16 GB.

7 Analysis

Martin et al. (2020) observed that complex downstream tasks may require more pre-training steps. Since for each OSCAR subset the validation loss is still slowly decreasing after 200k steps, we assume that training longer might increase performance on the difficult question answering task. On the other hand, corpus-specific MLM fine-tuning quickly converged for all models. Table 3 reports the entirety of the results.

7.1 How much data does one need to pre-train a compact language model?

As we increase the amount of pre-training data, perplexity on the OSCAR dev set decreases in every instance but one (OSC$_{4000}$). Nevertheless, aside from OSC$_{10}$, discrepancies are small and the models show almost identical learning curves. OSC$_{10}$ is underperforming in terms of MLM perplexity and question answering F1 score when compared to larger subsets. However, past this smallest dataset, pre-training data volume does not exhibit any strong monotonic relationship with downstream performance. The only OSCAR subset displaying a noticeable performance gap is OSC$_{2000}$, with a +2.46 average F1 score increase over OSCAR$_{100}$. For anchoring, a randomly initialized CamemBERT$_{\text{SMALL}}$ model "fine-tuned" directly on the FQuAD train set achieves an F1 score

Subset	Perplexities	F1 score
OSC$_{10}$	45.20 / 43.34	58.18 (0.60)
OSC$_{100}$	14.22 / 11.91	68.50 (0.25)
OSC$_{500}$	12.75 / 10.58	69.50 (0.41)
OSC$_{1000}$	12.56 / 10.57	69.35 (0.64)
OSC$_{2000}$	12.45 / 10.41	70.96 (0.66)
OSC$_{4000}$	12.49 / 10.35	69.76 (0.61)

(a) Without MLM fine-tuning.

Subset	Perplexities	F1 score
OSC$_{10}$	40.31 / 18.95	62.33 (0.58)
OSC$_{100}$	16.35 / 9.41	69.04 (0.16)
OSC$_{500}$	15.09 / 8.77	70.25 (0.43)
OSC$_{1000}$	14.74 / 8.83	69.84 (0.27)
OSC$_{2000}$	14.72 / 8.75	70.71 (0.08)
OSC$_{4000}$	14.90 / 8.68	69.84 (0.79)

(b) With MLM fine-tuning.

Table 3: Dev OSCAR / FQuAD perplexities and FQuAD F1 score (average token overlap between predicted and ground truth answers) for each pre-training subset.

of only 17.76, i.e. 40 F1 points less than OSC$_{10}$. This result indicates that even if a small amount of pre-training data is available, one should not neglect that step. Regarding larger architectures, CamemBERT$_{\text{BASE}}$ and CamemBERT$_{\text{LARGE}}$ models from Martin et al. (2020) obtain an F1 score of 88 and 92, respectively, after fine-tuning.

Due to computational constraints, we could not investigate smaller or larger datasets as well as a prolonged pre-training phase. It could be the case that for a 200k pre-training steps budget, data volume is not the bottleneck. In fact, additional training steps may be even more beneficial for larger datasets. Nonetheless, a preliminary experiment pushing the pre-training phase of CamemBERT$_{\text{SMALL}}$ on OSC$_{2000}$ to 300k steps revealed that while the MLM loss decreased, the F1 score on the downstream task did not improve.

7.2 Is corpus-specific MLM beneficial?

Again, we observe a contrast between OSC$_{10}$ and larger subsets. OSC$_{10}$ is the only pre-training dataset significantly improving on the downstream task (+4.15 F1) and experiencing a decrease in perplexity on both pre-training and fine-tuning data when complemented with an intermediate MLM step. However, this corpus-specific MLM step is not truly intermediate since FQuAD contexts contain 10MB of raw text. This implies a 2-fold increase in pre-training data rather than a specific domain adaptation step. Therefore, we turn our focus to larger subsets for the rest of this analysis.

In these cases, MLM fine-tuning results in a net FQuAD perplexity decrease at the cost of an OSCAR perplexity increase. Domain shift may be the root cause of this trade-off. Indeed, as there exists a mismatch between pre-training and fine-tuning sets, the language model has to adapt to the specificity of descriptive paragraphs. In addition, perplexity is higher on the OSCAR dev set than on the FQuAD one. This is most likely due to the difficulty of predicting masked words in an heterogeneous web-crawled dataset compared to a set of high quality Wikipedia articles.

For every pre-training subset but one (OSC$_{2000}$), MLM fine-tuning induced a slight F1 score increase on the downstream task. However, these gains are marginal with at most a +0.75 average F1 score increase in the case of OSC$_{500}$. Additional experiments are required to consolidate these findings, especially on larger task-specific datasets such as scientific or legal corpora. In those instances, a greater domain shift would probably legitimate an intermediate MLM fine-tuning step.

8 Conclusion

We investigated the importance of pre-training data volume when training compact Transformer-based models. We made the observation that 100 MB of raw text are sufficient to reach similar performance as with larger datasets on a question answering task, and that corpus-specific self-supervised learning does not bring significant improvements on that particular problem. These preliminary results pave the way for further experiments with other language models, various architectures and new downstream tasks.

Abstract

In this paper, we propose a novel model compression approach to effectively compress BERT by progressive module replacing. Our approach first divides the original BERT into several modules and builds their compact substitutes. Then, we randomly replace the original modules with their substitutes to train the compact modules to mimic the behavior of the original modules. We progressively increase the probability of replacement through the training. In this way, our approach brings a deeper level of interaction between the original and compact models. Compared to the previous knowledge distillation approaches for BERT compression, our approach does not introduce any additional loss function. Our approach outperforms existing knowledge distillation approaches on GLUE benchmark, showing a new perspective of model compression.[1]

1 Introduction

With the prevalence of deep learning, many huge neural models have been proposed and achieve state-of-the-art performance in various fields (He et al., 2016; Vaswani et al., 2017). Specifically, in Natural Language Processing (NLP), pretraining and fine-tuning have become the new norm of most tasks. Transformer-based pretrained models (Devlin et al., 2019; Liu et al., 2019b; Yang et al., 2019; Song et al., 2019; Dong et al., 2019) have dominated the field of both Natural Language Understanding (NLU) and Natural Language Generation (NLG). These models benefit from their "overparameterized" nature (Nakkiran et al., 2020) and contain millions or even billions of parameters, making it computationally expensive and inefficient considering both memory consumption and high latency. This drawback enormously hinders the applications of these models in production.

To resolve this problem, many techniques have been proposed to compress a neural network. Generally, these techniques can be categorized into Quantization (Gong et al., 2014), Weights Pruning (Han et al., 2016) and Knowledge Distillation (KD) (Hinton et al., 2015). Among them, KD has received much attention for compressing pretrained language models. KD exploits a large *teacher* model to "teach" a compact *student* model to mimic the teacher's behavior. In this way, the knowledge embedded in the teacher model can be transferred into the smaller model. However, the retained performance of the student model relies on a well-designed distillation loss function which forces the student model to behave as the teacher. Recent studies on KD (Sun et al., 2019; Jiao et al., 2019) even leverage more sophisticated model-specific distillation loss functions for better performance.

Different from previous KD studies which explicitly exploit a distillation loss to minimize the distance between the teacher model and the student model, we propose a new genre of model compression. Inspired by the famous thought experiment "Ship of Theseus"[2] in Philosophy, where all components of a ship are gradually replaced by new ones until no original component exists, we propose **Theseus Compression** for BERT (**BERT-of-Theseus**), which progressively substitutes modules of BERT with modules of fewer parameters. We call the original model and compressed model *predecessor* and *successor*, in correspondence to the concepts of *teacher* and *student* in KD, respectively. As shown in Figure 1, we first specify a substitute (successor module) for each predecessor module (i.e., modules in the predecessor model). Then, we randomly replace each predecessor module with its

---

November 16–20, 2020.

corresponding successor module by a probability and make them work together in the training phase. After convergence, we combine all successor modules to be the successor model for inference. In this way, the large predecessor model can be compressed into a compact successor model.

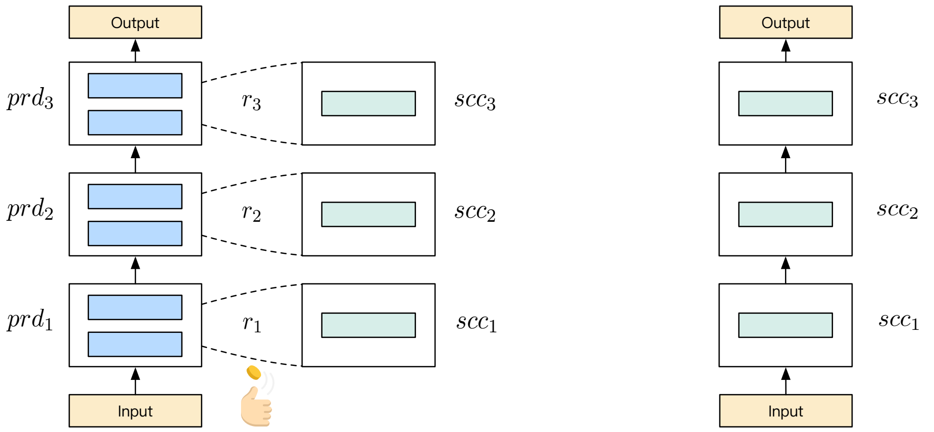
Theseus Compression shares a similar idea with KD, which encourages the compressed model to behave like the original, but holds many merits. First, we only use the task-specific loss function in the compression process. However, KD-based methods use task-specific loss, together with one or multiple distillation losses as its optimization objective. Also, selecting various loss functions and balancing the weights of each loss for different tasks and datasets can be laborious (Sun et al., 2019; Sanh et al., 2019). Second, different from recent work (Jiao et al., 2019), Theseus Compression does not use Transformer-specific features for compression thus is potential to compress a wide spectrum of models. Third, instead of using the original model only for inference in KD, our approach allows the predecessor model to work in association with the compressed successor model, enabling a possible gradient-level interaction. Moreover, the different module permutations mixing both predecessor and successor modules may add extra regularization, similar to Dropout (Srivastava et al., 2014). With a Curriculum Learning (Bengio et al., 2009) driven replacement scheduler, our approach achieves promising performance compressing BERT (Devlin et al., 2019), a large pretrained Transformer model.

To summarize, our contribution is two-fold: (1) We propose a novel approach, Theseus Compression, revealing a new pathway to model compression, with no additional loss function. (2) Our compressed BERT model is $1.94\times$ faster while retaining more than 98% performance of the original model, outperforming other KD-based compression baselines.

2 Related Work

Model Compression Model compression aims to reduce the size and computational cost of a large model while retaining as much performance as possible. Conventional explanations (Denil et al., 2013; Zhai et al., 2016) claim that the large number of weights is necessary for the training of deep neural network but a high degree of redundancy exists after training. Recent work (Frankle and Carbin, 2019) proposes The Lottery Ticket Hypothesis claiming that dense, randomly initialized and feed-forward networks contain subnetworks that can be recognized and trained to get a comparable test accuracy to the original network. Quantization (Gong et al., 2014) reduces the number of bits used to represent a number in a model. Weights Pruning (Han et al., 2016; He et al., 2017) conducts a binary classification to decide which weights to be trimmed from the model. Knowledge Distillation (KD) (Hinton et al., 2015) aims to train a compact model which behaves like the original one. FitNets (Romero et al., 2015) demonstrates that "hints" learned by the large model can benefit the distillation process. Born-Again Neural Network (Furlanello et al., 2018) reveals that ensembling multiple identical-parameterized students can outperform a teacher model. LIT (Koratana et al., 2019) introduces block-wise intermediate representation training. Liu et al. (2019a) distilled knowledge from ensemble models to improve the performance of a single model on NLU tasks. Tan et al. (2019) exploited KD for multi-lingual machine translation. Different from KD-based methods, our proposed Theseus Compression is the first approach to mix the original model and compact model for training. Also, no additional loss is used throughout the whole compression procedure, which simplifies the implementation.

Faster BERT Very recently, many attempts have been made to speed up a large pretrained language model (e.g., BERT (Devlin et al., 2019)). Michel et al. (2019) reduced the parameters of a BERT model by pruning unnecessary heads in the Transformer. Shen et al. (2020) quantized BERT to 2-bit using Hessian information. Also, substantial modification has been made to Transformer architecture. Fan et al. (2020) exploited a structure dropping mechanism to train a BERT-like model which is resilient to pruning. ALBERT (Lan et al., 2020) leverages matrix decomposition and parameter sharing. However, these models cannot exploit ready-made model weights and require a full retraining. Tang et al. (2019) used a BiLSTM architecture to extract task-specific knowledge from BERT. DistilBERT (Sanh et al., 2019) applies a naive Knowledge Distillation on the same corpus used to pretrain BERT. Patient Knowledge Distillation (PKD) (Sun et al., 2019) designs multiple distillation losses between the module hidden states of the teacher and student models. Pretrained Distilla-



(a) Compression Training

(b) Successor Fine-tuning and Inference

Figure 1: The workflow of BERT-of-Theseus. In this example, we compress a 6-layer predecessor $P = \{prd_1, \ldots, prd_3\}$ to a 3-layer successor $S = \{scc_1, \ldots, scc_3\}$. prd_i and scc_i contain two and one layer, respectively. (a) During module replacing training, each predecessor module prd_i is replaced with corresponding successor module scc_i by the probability of p. (b) During successor fine-tuning and inference, all successor modules $scc_{1 \ldots 3}$ are combined for calculation.

tion (Turc et al., 2019) pretrains the student model with a self-supervised masked LM objective on a large corpus first, then performs a standard KD on supervised tasks. TinyBERT (Jiao et al., 2019) conducts the Knowledge Distillation twice with data augmentation. MobileBERT (Sun et al., 2020) devises a more computationally efficient architecture and applies knowledge distillation with a bottom-to-top layer training procedure. PABEE (Zhou et al., 2020b) exploits early exiting to dynamically accelerate the inference of BERT.

3 BERT-of-Theseus

In this section, we introduce module replacing, the technique proposed for BERT-of-Theseus. Further, we introduce a Curriculum Learning driven scheduler to obtain better performance. The workflow is shown in Figure 1.

3.1 Module Replacing

The basic idea of Theseus Compression is very similar to KD. We want the successor model to act like a predecessor model. KD explicitly defines a loss to measure the similarity of the teacher and student. However, the performance vastly relies on the design of the loss function (Hinton et al., 2015; Sun et al., 2019; Jiao et al., 2019). This loss function needs to be combined with task-specific loss (Sun et al., 2019; Koratana et al., 2019). Different from KD, Theseus Compression only requires one task-specific loss function (e.g., Cross Entropy), which closely resembles a fine-tuning procedure. Inspired by Dropout (Srivastava et al., 2014), we propose module replacing, a novel technique for model compression. We call the original model and the target model *predecessor* and *successor*, respectively. First, we specify a successor module for each module in the predecessor. For example, in the context of BERT compression, we let one Transformer layer be the successor module for two Transformer layers. Consider a predecessor model P which has n modules and a successor model S which has n predefined modules. Let $P = \{prd_1, \ldots, prd_n\}$ denote the predecessor model, prd_i and scc_i denote the the predecessor modules and their corresponding substitutes, respectively. The output vectors of the i-th module is denoted as $\mathbf{y}_i$. Thus, the forward operation can be described in the form of:

$$\mathbf{y}_{i+1} = prd_i(\mathbf{y}_i) \tag{1}$$

During compression, we apply module replacing. First, for $(i+1)$-th module, r_{i+1} is an independent Bernoulli random variable which has probability p to be 1 and $1-p$ to be 0.

$$r_{i+1} \sim \text{Bernoulli}(p) \tag{2}$$

Then, the output of the $(i+1)$-th model is calculated as:

$$y_{i+1} = r_{i+1} * scc_i(\mathbf{y}_i) + (1 - r_{i+1}) * prd_i(\mathbf{y}_i) \tag{3}$$

where $*$ denotes the element-wise multiplication, $r_{i+1} \in \{0, 1\}$. In this way, the predecessor modules and successor modules work together in the training. Since the permutation of the hybrid model is random, it adds extra noises as a regularization for the training of the successor, similar to Dropout (Srivastava et al., 2014).

During training, similar to a fine-tuning process, we optimize a regular task-specific loss, e.g., Cross Entropy:

$$L = -\sum_{j \in |X|} \sum_{c \in C} \left[\mathbb{1} \left[\mathbf{z}_j = c \right] \cdot \log P \left(\mathbf{z}_j = c | \mathbf{x}_j \right) \right] \tag{4}$$

where $\mathbf{x}_j \in X$ is the i-th training sample; $\mathbf{z}_j$ is its corresponding ground-truth label; c and C denote a class label and the set of class labels, respectively. For back-propagation, the weights of all predecessor modules are frozen. For both the embedding layer and output layer of the predecessor model are weight-frozen and directly adopted for the successor model in this training phase. In this way, the gradient can be calculated across both the predecessor and successor modules, allowing deeper interaction.

3.2 Successor Fine-tuning and Inference

To make the training and inference processes as close as possible, we further carry out a post-replacement fine-tuning phase to allow all successor modules to work together. After the replacing compression converges, we collect all successor modules and combine them to be the successor model S:

$$\begin{aligned} S &= \{scc_1, \ldots, scc_n\} \\ \mathbf{y}_{i+1} &= scc_i(\mathbf{y}_i) \end{aligned} \tag{5}$$

Since each scc_i is smaller than prd_i in size, the predecessor model P is in essence compressed into a smaller model S. Then, we fine-tune the successor model by optimizing the same loss of Equation 4. The whole procedure including module replacing and successor fine-tuning is illustrated in Figure 2(a). Finally, we use the fine-tuned successor for inference as Equation 5.

3.3 Curriculum Replacement

Although setting a constant replacement rate p can meet the need for compressing a model, we further highlight a Curriculum Learning (Bengio et al., 2009) driven replacement scheduler, which coordinates the progressive replacement of the modules.

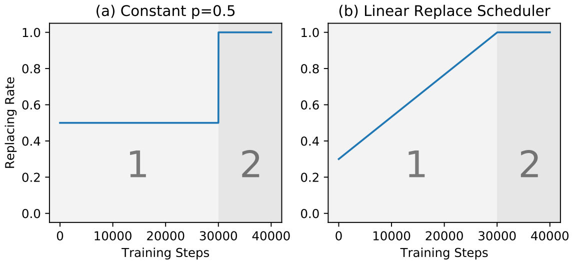


Figure 2: The replacing curves of a constant module replace rate and a replacement scheduler. We use different shades of gray to mark the two phases of Theseus Compression: (1) Module replacing. (2) Successor fine-tuning.

Similar to (Morerio et al., 2017; Zhou et al., 2020a), we devise a replacement scheduler to dynamically tune the replacement rate p.

Here, we leverage a simple linear scheduler $\theta(t)$ to output the dynamic replacement rate p_d for step t.

$$p_d = \min(1, \theta(t)) = \min(1, kt + b) \tag{6}$$

where $k > 0$ is the coefficient and b is the basic replacement rate. The replacing rate curve with a replacement scheduler is illustrated in Figure 2(b).

In this way, we unify the two previously separated training stages and encourage an end-to-end easy-to-hard learning process. First, with more predecessor modules present, the model would more likely to correctly predict thus have a relatively small cross-entropy loss, which is helpful for smoothing the learning process. Then, at a later time of compression, more modules can be present together, encouraging the model to gradually learn to predict with less guidance from the predecessor and steadily transit to the successor fine-tuning stage.

Second, at the beginning of the compression, when $\theta(t) < 1$, considering the average learning rate for all n successor modules, the expected number of replaced modules is $n \cdot p_d$ and the expected average learning rate is:

$$lr' = (np_d/n)lr = (kt + b)lr \tag{7}$$

where lr is the constant learning rate set for the compression and lr' is the equivalent learning rate considering all successor modules. Thus, when applying a replacement scheduler, a warm-up mechanism (Popel and Bojar, 2018) is essentially adopted at the same time, which helps the training of a Transformer.

4 Experiments

In this section, we introduce the experiments of Theseus Compression for BERT (Devlin et al., 2019) compression. We compare BERT-of-Theseus with other compression methods and further conduct experiments to analyze the results.

4.1 Datasets

We evaluate our proposed approach on the GLUE benchmark (Wang et al., 2019; Dolan and Brockett, 2005; Conneau and Kiela, 2018; Socher et al., 2013; Williams et al., 2018; Rajpurkar et al., 2016; Warstadt et al., 2019). Note that we exclude WNLI (Levesque, 2011) following the original BERT paper (Devlin et al., 2019).

The accuracy is used as the metric for SST-2, MNLI-m, MNLI-mm, QNLI and RTE. The F1 and accuracy are used for MRPC and QQP. The Pearson correlation and Spearman correlation are used for STS-B. Matthew's correlation is used for CoLA. The results reported for the test set of GLUE are in the same format as on the official leaderboard. For the sake of comparison with (Sanh et al., 2019), on the development set of GLUE, the result of MNLI is an average on MNLI-m and MNLI-mm; the results on MRPC and QQP are reported with the average of F1 and accuracy; the result reported on STS-B is the average of the Pearson and Spearman correlation.

4.2 Experimental Settings

We test our approach under a task-specific compression setting (Sun et al., 2019; Turc et al., 2019) instead of a pretraining compression setting (Sanh et al., 2019; Sun et al., 2020). That is to say, we use no external unlabeled corpus but only the training set of each task in GLUE to compress the model. The reason behind this decision is that we intend to straightforwardly verify the effectiveness of our generic compression approach. The fast training process of task-specific compression (e.g., no longer than 20 GPU hours for any task of GLUE) computationally enables us to conduct more analytical experiments. For comparison, DistilBERT (Sanh et al., 2019) takes 720 GPU hours to train. Plus, in real-world applications, this setting provides with more flexibility when selecting from different pretrained LMs (e.g., BERT, RoBERTa (Liu et al., 2019b)) for various downstream tasks and it is easy to adopt a newly released model, without a time-consuming pretraining compression. We will also discuss the possibility to use an MNLI model for a general purpose with intermediate transfer learning (Pruksachatkun et al., 2020).

Formally, we define the task of compression as trying to retain as much performance as possible when compressing the officially released BERT-base (uncased)[3] to a 6-layer compact model with the same hidden size, following the settings in (Sanh et al., 2019; Sun et al., 2019; Turc et al., 2019). Under this setting, the compressed model has 24M parameters for the token embedding (identical to the original model) and 42M parameters for the Transformer layers and obtains a $1.94\times$ speed-up for inference.

4.3 Training Details

We fine-tune BERT-base as the predecessor model for each task with the batch size of 32, the learning rate of 2×10^{-5}, and the number of epochs as 4. As a result, we are able to obtain a predecessor model with comparable performance with that reported in previous studies (Sanh et al., 2019; Sun et al., 2019; Jiao et al., 2019).

Afterward, for training successor models, following (Sanh et al., 2019; Sun et al., 2019), we use the first 6 layers of BERT-base to initialize the successor model since the over-parameterized nature of Transformer (Vaswani et al., 2017) could cause the model unable to converge while training on small datasets. During module replacing, We fix the batch size as 32 for all evaluated tasks to reduce the search space. All r variables only sample once for a training batch. The maximum sequence length is set to 256 on QNLI and 128 for the other tasks. We perform grid search over the sets of learning rate lr as $\{$1e-5, 2e-5$\}$, the basic replacing rate b as $\{0.1, 0.3\}$, the scheduler coefficient k making the dynamic replacing rate increase to 1 within the first $\{$1000, 5000, 10000, 30000$\}$ training steps. We apply an early stopping mechanism and select the model with the best performance on the development set. We conduct our experiments on a single Nvidia V100 16GB GPU. The peak memory usage is approximately identical to fine-tuning a BERT-base, since there would be at most 12 layers training at the same time. The training time for each task varies depending on the different sizes of training sets. For example, it takes 20 hours to

Table 1: Comparison of different BERT compression approaches. "CE" and "MSE" stand for Cross Entropy and Mean Square Error, respectively. "KD" indicates the loss is for Knowledge Distillation. "CE_{TASK}", "CE_{MLM}" and "CE_{NSP}" indicate Cross Entropy calculated on downstream tasks, Masked LM pretraining and Next Sentence Prediction, respectively. Other loss functions are described in their corresponding papers.

train on MNLI but less than 30 minutes on MRPC.

4.4 Baselines

As shown in Table 1, we compare the layer numbers, parameter numbers, loss function, external data usage and model agnosticism of our proposed approach to existing methods. We set up a baseline of vanilla Knowledge Distillation (Hinton et al., 2015) as in (Sun et al., 2019). Additionally, we directly fine-tune a truncated 6-layer BERT model (the bottom 6 layers of the original BERT)[4] on GLUE tasks to obtain a natural fine-tuning baseline. Under the setting of compressing 12-layer BERT-base to a 6-layer compact model, we choose BERT-PKD (Sun et al., 2019), PD-BERT (Turc et al., 2019), and DistilBERT (Sanh et al., 2019) as strong baselines. Note that DistilBERT (Sanh et al., 2019) is not directly comparable here since it uses a pretraining compression setting. Both PD-BERT and DistilBERT use external unlabeled corpus. Additionally, we use LayerDrop (Fan et al., 2020) on BERT weights to prune the model on downstream tasks. We do not include TinyBERT (Jiao et al., 2019) since it conducts distillation twice and leverages extra augmented data for GLUE tasks. We also exclude MobileBERT (Sun et al., 2020), due to its redesigned Transformer block and different model size. Besides, in these two studies, the loss functions are not architecture-agnostic thus limit their applications on other types of models.

4.5 Experimental Results

We report the experimental results on the development set of GLUE in Table 2 and submit our predictions to the GLUE test server and obtain the results from the official leaderboard as shown in Table 3. Note that DistilBERT does not report on the test set. The BERT-base performance reported on GLUE development set is the predecessor fine-tuned by us. The results of BERT-PKD on the development set are reproduced by us using the official implementation. In the original paper of BERT-PKD, the results of CoLA and STS-B on the test set are not reported, thus we reproduce these two results. Fine-tuning and Vanilla KD baselines are both implemented by us. All other results are from the original papers.[5] The macro scores here are calculated in the same way as the official leaderboard but are not directly comparable with GLUE leaderboard since we exclude WNLI from the calculation.

Overall, our BERT-of-Theseus retains 98.4% and 98.3% of the BERT-base performance on GLUE development set and test set, respectively. On every task of GLUE, our model dramatically outperforms the fine-tuning baseline, indicating that with the same loss function, our proposed approach can effectively transfer knowledge from the predecessor to the successor. Also, our model obviously outperforms the vanilla KD (Hinton et al., 2015) and Patient Knowledge Distillation (PKD) (Sun et al., 2019), showing its supremacy over the KD-based compression approaches. On MNLI, our model performs better than BERT-PKD but slightly lower than PD-BERT (Turc et al., 2019). However, PD-BERT exploits an additional corpus which provides much more samples for knowledge transferring. Also, we would like to highlight that

---

[4] We also tried the top 6 layers and interleaving 6 layers but both perform worse than the bottom 6 layers.

[5] Please note that the reported results of DistilBERT are different across various versions on arXiv. The results here are from v3, which was the newest version when we composed this paper.

on RTE, our model achieves nearly identical performance to BERT-base and on QQP our model even outperforms BERT-base. To analyze, a moderate model size may help generalize and prevent overfitting on downstream tasks. Notably, on both large datasets with more than 350K samples (e.g., MNLI and QQP) and small datasets with fewer than 4K samples (e.g., MRPC and RTE), our model can consistently achieve good performance, verifying the robustness of our approach.

4.6 Intermediate-Task Transfer Learning

Although our approach achieves good performance under a task-specific setting, it requires more computational resources to fine-tune a full-size predecessor than a compact BERT (e.g., DistilBERT (Sanh et al., 2019)). Pruksachatkun et al. (2020) found that models trained on some datasets can be used for a second-round fine-tuning. Thus, we use MNLI as the intermediate task and release our compressed model by conducting compression on MNLI to facilitate downstream applications. After compression, we fine-tune the successor model on other sentence classification tasks and compare the results with DistilBERT (Sanh et al., 2019) in Table 4. Our model achieves an identical performance on MRPC and outperforms DistilBERT on the other sentence-level tasks. Also, our intermediate-task transfer results also outperform PD-BERT (Turc et al., 2019) on three tasks, indicating that our task-specific model is also competitive for a general purpose through the intermediate-task transfer learning approach.

5 Analysis

In this section, we conduct extensive experiments to analyze our BERT-of-Theseus.

5.1 Impact of Module Replacement

As pointed out in previous work (Fan et al., 2020), different layers of a Transformer play imbalanced roles for inference. To explore the effect of different module replacements, we iteratively use one compressed successor module (constant replacing rate, without successor fine-tuning) to replace its corresponding predecessor module on QNLI, MNLI and QQP, as shown in Table 5. Our results show that the replacement of the last two modules have limited influence on the overall performance while the replacement of the first module significantly harms the performance. To analyze, the linguistic features are mainly extracted by the first

Method	MNLI	MRPC	QNLI	QQP	RTE	SST-2	STS-B
BERT-base (2019)	83.5	89.5	91.2	89.8	71.1	91.5	88.9
DistilBERT (2019)	79.0	**87.5**	85.3	84.9	59.9	90.7	81.2
PD-BERT (2019)	**83.0**	87.2	**89.0**	**89.1**	66.7	91.1	-

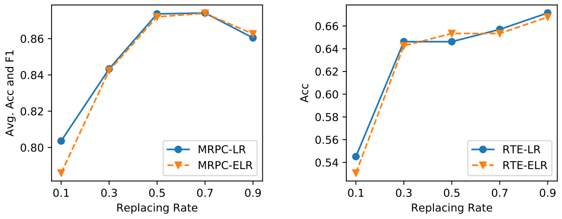
Table 5: Impact of the replacement for different modules on GLUE-dev. $prd_i \rightarrow scc_i$ indicates the replacement of the i-th module from the predecessor.



(a) MRPC

(b) RTE

Figure 3: Performance of different replacing rate on MRPC and RTE. "LR" and "ELR" denote that the learning rate and equivalent learning rate are fixed, respectively.

few layers. Therefore, the reduced representation capability becomes the bottleneck for the following layers.

5.2 Impact of Replacing Rate

We attempt to adopt different replacing rates on GLUE tasks. First, we fix the batch size to be 32 and learning rate lr to be 2×10^{-5} and conduct compression on each task. On the other hand, as we analyzed in Section 3.3, the equivalent learning rate lr' is affected by the replacing rate. To further eliminate the influence of the learning rate, we fix the equivalent learning rate lr' to be 2×10^{-5} and adjust the learning rate lr for different replacing rates by $lr = lr'/p$.

We illustrate the results with different replacing rates on two representative tasks (MRPC and RTE) in Figure 3. The trivial gap between two curves in both figures indicate that the effect of different replacing rates on equivalent learning rate is not the main factor for the performance differences. A replacing rate in the range between 0.5 and 0.7 can always lead to a satisfying performance on all GLUE tasks. However, a significant performance drop can be observed on all tasks if the replacing rate is too small (e.g., $p = 0.1$). On the other hand, the best replacing rate differs across tasks.

5.3 Impact of Replacement Scheduler

To study the impact of our curriculum replacement strategy, we compare the results of BERT-of-Theseus compressed with a constant replacing rate and with a replacement scheduler. The constant replacing rate for the baseline is searched over $\{0.5, 0.7, 0.9\}$. Additionally, we implement an "anti-curriculum" baseline, similar to the one in (Morerio et al., 2017). For each task, we adopt the same coefficient k and basic replacing rate b to calculate the p_d as Equation 6 for both curriculum replacement and anti-curriculum. However, we use $1 - p_d$ as the dynamic replacing rate for anti-curriculum baseline. Thus, we can determine whether the improvement of curriculum replacement is simply due to an inconstant replacing rate or an easy-to-hard curriculum design.

As shown in Table 6, our model compressed with curriculum scheduler consistently outperforms a model compressed with a constant replacing rate. In contrast, a substantial performance drop is observed on the model compressed with an anti-curriculum scheduler, which further verifies the effectiveness and importance of the curriculum replacement strategy.

5.4 Impact of Predecessor Layers

We further replace different numbers of Transformer layers with one layer to verify the effectiveness of Theseus Compression under different settings. We replace 3/4 layers with one Transformer layer, resulting in a 4/3-layer BERT model.

Strategy	CoLA(Δ)	MNLI(Δ)	MRPC(Δ)	QNLI(Δ)	QQP(Δ)	RTE(Δ)	SST-2(Δ)	STS-B(Δ)
Constant Rate	44.4	81.9	87.1	88.5	88.6	66.4	90.6	88.4
Anti-curriculum	42.8 (-1.6)	79.8 (-2.1)	85.6 (-1.5)	87.8 (-0.7)	87.6 (-1.0)	62.4 (-4.0)	88.8 (-1.8)	85.4 (-3.0)
Curriculum	**51.1 (+6.7)**	**82.3 (+0.4)**	**89.0 (+1.9)**	**89.5 (+1.0)**	**89.6 (+1.0)**	**68.2 (+1.8)**	**91.5 (+0.9)**	**88.7 (+0.3)**

Table 6: Comparison of models compressed with a constant replacing rate, a curriculum replacement scheduler and its corresponding anti-curriculum scheduler on GLUE-dev.

Table 7: Experimental results of replacing different numbers of layers with one layer on GLUE-dev. "#Layer" indicates the number of layers in the compressed models.

The results are shown in Table 7. BERT-of-Theseus consistently outperforms the fine-tuned truncated BERT baselines, demonstrating its effectiveness under different settings.

6 Discussion

In this paper, we propose Theseus Compression, a novel model compression approach. We use this approach to compress BERT to a compact model that outperforms other models compressed by Knowledge Distillation. Our work highlights a new genre of model compression and reveals a new path towards model compression.

For future work, we would like to explore the possibility of applying Theseus Compression on heterogeneous network modules. First, many developed in-place substitutes (e.g., ShuffleNet unit (Zhang et al., 2018) for ResBlock (He et al., 2016), Reformer Layer (Kitaev et al., 2020) for Transformer Layer (Vaswani et al., 2017)) are natural successor modules that can be directly adopted in Theseus Compression. Also, it is possible to use a feed-forward neural network to map features between the hidden spaces of different sizes (Jiao et al., 2019) to enable replacement between modules with different input and output sizes. Although our model has achieved good performance compressing BERT, it would be interesting to explore its possible applications in other neural models. As summarized in Table 1, our model does not rely on any model-specific features to compress BERT. Therefore, it is potential to apply Theseus Compression to other large models (e.g., ResNet (He et al., 2016) in Computer Vision). In addition, we would like to conduct Theseus Compression on more types of neural networks including Convolutional Neural Networks and Graph Neural Networks. We will also investigate the combination of our compression-based approach with recently proposed dynamic acceleration method (Zhou et al., 2020b) to further improve the efficiency of pre-trained language models.

Abstract

Deep pretrained language models have achieved great success in the way of pretraining first and then fine-tuning. But such a sequential transfer learning paradigm often confronts the catastrophic forgetting problem and leads to sub-optimal performance. To fine-tune with less forgetting, we propose a recall and learn mechanism, which adopts the idea of multi-task learning and jointly learns pretraining tasks and downstream tasks. Specifically, we introduce a Pretraining Simulation mechanism to recall the knowledge from pretraining tasks without data, and an Objective Shifting mechanism to focus the learning on downstream tasks gradually. Experiments show that our method achieves state-of-the-art performance on the GLUE benchmark. Our method also enables *BERT-base* to achieve better average performance than directly fine-tuning of *BERT-large*. Further, we provide the open-source RECADAM optimizer, which integrates the proposed mechanisms into Adam optimizer, to facility the NLP community.[1]

1 Introduction

Deep Pretrained Language Models (LMs), such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), have significantly altered the landscape of Natural Language Processing (NLP), and a wide range of NLP tasks has been promoted by these pretrained language models. These successes are mainly achieved through *Sequential Transfer Learning* (Ruder, 2019): pretrain a language model on large-scale unlabeled data and then adapt it to downstream tasks. The adaptation step is usually conducted in two manners: fine-tuning or freezing pretrained weights. In practice, fine-tuning is adopted more widely due to its flexibility (Phang et al., 2018; Peters et al., 2019; Lan et al., 2020).

Despite the great success, sequential transfer learning of deep pretrained LMs is prone to catastrophic forgetting during the adaptation step. *Catastrophic forgetting* is a common problem for sequential transfer learning, and it happens when a model forgets previously learned knowledge and overfits to target domains (McCloskey and Cohen, 1989; Kirkpatrick et al., 2017). To remedy the catastrophic forgetting in transferring deep pretrained LMs, existing efforts mainly explore fine-tuning tricks to forget less. ULMFiT (Howard and Ruder, 2018) introduced discriminative fine-tuning, slanted triangular learning rates, and gradual unfreezing for LMs fine-tuning. Lee et al. (2020) reduced forgetting in BERT fine-tuning by randomly mixing pretrained parameters to a downstream model in a dropout-style.

Instead of learning pretraining tasks and downstream tasks in sequence, *Multi-task Learning* learns both of them simultaneously, thus can inherently avoid the catastrophic forgetting problem. Xue et al. (2019) tackled forgetting in automatic speech recognition by jointly training the model with previous and target tasks. Kirkpatrick et al. (2017) proposed Elastic Weight Consolidation (EWC) to overcome catastrophic forgetting when continuous learning multiple tasks by adopting the multi-task learning paradigm. EWC regularizes new task training by constraining the parameters which are important for previous tasks and adapt more aggressively on other parameters. Thanks to the appealing effects on catastrophic forgetting, EWC has been widely applied in various domains, such as game playing (Ribeiro et al., 2019), neural machine translation (Thompson et al., 2019) and reading comprehension (Xu et al., 2019).

However, these multi-task learning methods cannot be directly applied to the sequential transferring regime of deep pretrained LMs. Firstly, multi-task learning methods require to use the data of pre-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7870–7881,
November 16–20, 2020.

training tasks during adaptation, but the pretraining data of LMs is often inaccessible or too large for the adaptation. Secondly, we only care about the downstream task's performance, while multi-task learning also aims to promote performance on pretraining tasks.

In this paper, we propose a recall and learn mechanism to cope with the forgetting problem of fine-tuning the deep pretrained LMs. To achieve this, we take advantage of multi-task learning by adopting LMs pretraining as an auxiliary learning task during fine-tuning. Specifically, we introduce two mechanisms for the two challenges mentioned above, respectively. As for the challenge of data obstacles, we introduce the *Pretraining Simulation* to achieve multi-task learning without accessing to pretraining data. It helps the model recall previously learned knowledge by simulating the pretraining objective using only the pretrained parameters. As for the challenge of learning objective difference, we introduce the *Objective Shifting* to balance new task learning and pretrained knowledge recalling. It allows the model to focus gradually on the new task by shifting the multi-task learning objective to the new task learning.

We also provide Recall Adam (RECADAM) optimizer to integrate the proposed recall and learn mechanism into Adam optimizer (Kingma and Ba, 2015). We release the source code of the RECADAM optimizer implemented in PyTorch (Paszke et al., 2019). It is easy to use and can facilitate the NLP community for better fine-tuning of deep pretrained LMs. Experiments on the GLUE benchmark with the BERT-base model show that the proposed method can significantly outperform the vanilla fine-tuning method. Our method with the BERT-base model can even achieve better average results than directly fine-tuning the BERT-large model. In addition, thanks to the effectiveness of pretrained knowledge recalling, we can initialize the model with random parameters and gain better performance with larger parameter search space than the pretrained initialization. Finally, we achieve state-of-the-art performance on the GLUE benchmark with the ALBERT-xxlarge model.

Our contributions can be summarized as follows: (1) We propose to tackle the catastrophic forgetting problem of fine-tuning the deep pretrained LMs by adopting the idea of multi-task learning and obtain state-of-the-art results on the GLUE benchmark. (2) We propose a recall and learn mechanism with Pretraining Simulation and Objective Shifting to achieve multi-task fine-tuning without data of pretraining tasks. (3) We provide the open-source RECADAM optimizer to facilitate deep pretrained LMs fine-tuning with less forgetting.

2 Background

In this section, we present two transfer learning settings: sequential transfer learning and multi-task learning. They both aim to improve the learning performance by transferring knowledge across multiple tasks, but apply to different scenarios.

2.1 Sequential Transfer Learning

Sequential transfer learning learns source tasks and target tasks in sequence, and transfers knowledge from source tasks to improve the models' performance on target tasks.

It typically consists of two stages: *pretraining* and *adaptation*. During pretraining, the model is trained on source tasks with the loss function Loss_S. During adaptation, the pretrained model is further trained on target tasks with the loss function Loss_T. The standard adaptation methods includes *fine-tuning* and *feature extraction*. Fine-tuning updates all the parameters of the pretrained model, while feature extraction regards the pretrained model as a feature extractor and keeps it fixed during the adaptation phase.

Sequential transfer learning has been widely used recently, and the released deep pretrained LMs have achieved great successes on various NLP tasks (Peters et al., 2018; Devlin et al., 2019; Lan et al., 2020). While the adaptation of the deep pretrained LMs is very efficient, it is prone to *catastrophic forgetting*, where the model forgets previously learned knowledge from source tasks when learning new knowledge from target tasks.

2.2 Multi-task Learning

Multi-task Learning learns multiple tasks simultaneously, and improves the models' performance on all of them by sharing knowledge across these tasks (Caruana, 1997; Ruder, 2017).

Under the multi-task learning paradigm, the model is trained on both source tasks and target tasks with the loss function:

$$\mathrm{Loss}_\mathrm{M} = \lambda \mathrm{Loss}_\mathrm{T} + (1-\lambda)\mathrm{Loss}_\mathrm{S} \quad (1)$$

where $\lambda \in (0,1)$ is a hyperparameter balancing these two tasks. It can inherently avoid catastrophic forgetting because the loss on source tasks Loss_S is always part of the optimization objective.

To overcome catastrophic forgetting (discussed in § 2.1), can we apply the idea of multi-task learning to the adaptation of the deep pretrained LMs? There are two challenges in practice:

1) We cannot get access to the pretraining data to calculate Loss_S during adaptation.
2) The optimization objective of adaptation is Loss_T, while multi-task learning aims to optimize Loss_M, i.e., the weighted sum of Loss_T and Loss_S.

3 Methodology

In this section, we introduce Pretraining Simulation (§ 3.1) and Objective Shifting (§ 3.2) to overcome the two challenges (discussed in § 2.2) respectively. Pretraining Simulation allows the model to learn source tasks without pretraining data, and Objective Shifting allows the model to focus on target tasks gradually. We also introduce the RECADAM optimizer (§ 3.3) to integrate these two mechanisms into the common-used Adam optimizer.

3.1 Pretraining Simulation

As for the first challenge that pretraining data is unavailable, we introduce Pretraining Simulation to approximate the optimization objective of source tasks as a quadratic penalty, which keeps the model parameters close to the pretrained parameters.

Following Elastic Weight Consolidation (EWC; Kirkpatrick et al. 2017; Huszár 2017), we approximate the optimization objective of source tasks with Laplace's Method and assumption of independence among the model parameters. Since EWC requires pretraining data, we further introduce a stronger independence assumption and derive a quadratic penalty, which is independent of the pretraining data. We introduce the detailed derivation process as follows.

From the probabilistic perspective, the learning objective on the source tasks Loss_S would be optimizing the negative log posterior probability of the model parameters θ given data of source tasks D_S:

$$\text{Loss}_\text{S} = -\log p(\theta|D_S)$$

The pretrained parameters θ^* can be assumed as a local minimum of the parameter space, and it satisfies the equation:

$$\theta^* = \arg\min_\theta\{-\log p(\theta|D_S)\}$$

Due to the intractability, the optimization objective $-\log p(\theta|D_S)$ is locally approximated with the Laplace's Method (MacKay, 2003):

$$\begin{aligned}-\log p(\theta|D_S) &\approx -\log p(\theta^*|D_S)\\ &\quad + \frac{1}{2}(\theta-\theta^*)^\top H(\theta^*)(\theta-\theta^*)\end{aligned}$$

where $H(\theta^*)$ is the Hessian matrix of the optimization objective w.r.t. θ and evaluated at θ^*. $-\log p(\theta^*|D_S)$ is a constant term w.r.t. θ, and it can be ignored during optimization.

Since the pretrained model convergences on the source tasks, $H(\theta^*)$ can be approximated with the empirical Fisher information matrix $F(\theta^*)$ (Martens, 2014):

$$F(\theta^*) = \mathbb{E}_{x\sim D_S}[\nabla_\theta \log p_\theta(x) \nabla_\theta \log p_\theta(x)^\top|_{\theta=\theta^*}]$$

$$H(\theta^*) \approx NF(\theta^*) + H_{prior}(\theta^*)$$

where N is the number of i. i. d. observations in D_S, $H_{prior}(\theta^*)$ is the Hessian matrix of the negative log prior probability $-\log p(\theta)$.

Because of the computational intractability, EWC approximate $H(\theta^*)$ by using the diagonal of $F(\theta^*)$ and ignoring the prior Hessian matrix $H_{prior}(\theta^*)$:

$$(\theta-\theta^*)^\top H(\theta^*)(\theta-\theta^*) \approx N\textstyle\sum_i F_i(\theta_i-\theta_i^*)^2$$

where F_i is the corresponding diagonal Fisher information value of the model parameter θ_i.

Since the pretraining data is unavailable, we further approximate $H(\theta^*)$ with a stronger assumption that each diagonal Fisher information value F_i is independent of the corresponding parameter θ_i:

$$(\theta-\theta^*)^\top H(\theta^*)(\theta-\theta^*) \approx NF\textstyle\sum_i (\theta_i-\theta_i^*)^2$$

The final approximated optimization objective of the source tasks is the quadratic penalty between the model parameters and the pretrained parameters:

$$\begin{aligned}\text{Loss}_\text{S} &= -\log p(\theta|D_S)\\ &\approx \frac{1}{2}(\theta-\theta^*)^\top H(\theta^*)(\theta-\theta^*)\\ &\approx \frac{1}{2}(\theta-\theta^*)^\top (NF(\theta^*)+H_{prior}(\theta^*))(\theta-\theta^*)\\ &\approx \frac{1}{2}N\sum_i F_i(\theta_i-\theta_i^*)^2\\ &\approx \frac{1}{2}NF\sum_i (\theta_i-\theta_i^*)^2\\ &= \frac{1}{2}\gamma\sum_i (\theta_i-\theta_i^*)^2\end{aligned}$$

where $\frac{1}{2}\gamma$ is the coefficient of the quadratic penalty.

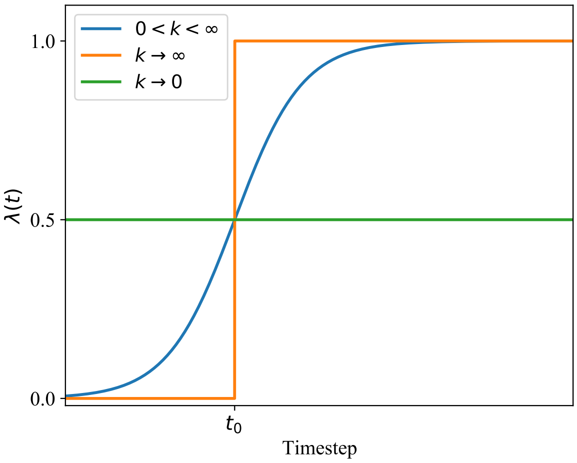

Figure 1: Objective Shifting: we replace the coefficient λ with the annealing function $\lambda(t)$. Fine-tuning and multi-task learning can be regarded as the special cases ($k \to \infty$ and $k \to 0$) of our method.

3.2 Objective Shifting

As for the second challenge that the optimization objective of multi-task learning is inconsistent with adaptation, we introduce Objective Shifting to allow the objective function to gradually shift to Loss_T with the annealing coefficient.

We replace the coefficient λ in the optimization objective of multi-task learning (as shown in Eq. 1) with the annealing function $\lambda(t)$, where t refers to the update timesteps during fine-tuning. The loss function of our method is set to multi-task learning with annealing coefficient:

$$\text{Loss} = \lambda(t)\text{Loss}_\text{T} + (1 - \lambda(t))\text{Loss}_\text{S}$$

Specifically, to better balance the multi-task learning and fine-tuning, $\lambda(t)$ is calculated as the sigmoid annealing function (Bowman et al., 2016; Kiperwasser and Ballesteros, 2018):

$$\lambda(t) = \frac{1}{1 + \exp(-k \cdot (t - t_0))}$$

where k and t_0 are the hyperparameters controlling the annealing rate and timesteps.

As shown in Figure 1, at the beginning of the training process, the model mainly learns general knowledge by focusing more on pretraining tasks. As training progress, the model gradually focuses on target tasks and learns more target-specific knowledge while recalling the knowledge of pretraining tasks. At the end of the training process, the model completely focuses on target tasks, and the final optimization objective is Loss_T.

Fine-tuning and multi-task learning can be regarded as special cases of our method. When $k \to \infty$, our method can be regarded as fine-tuning. The model firstly gets pretrained on source tasks with the Loss_S, then learns the target tasks with the Loss_T. When $k \to 0$, $\lambda(t)$ is a constant function, then our method can be regarded as the multi-task learning. The model learns source tasks and target tasks simultaneously with the loss function $\frac{1}{2}(\text{Loss}_\text{T} + \text{Loss}_\text{S})$.

3.3 RecAdam Optimizer

Adam optimizer (Kingma and Ba, 2015) is commonly used for fine-tuning the deep pretrained LMs. We introduce Recall Adam (RECADAM) optimizer to integrate the quadratic penalty and the annealing coefficient, which are the core factors of the Pretraining Simulation (§ 3.1) and Objective Shifting (§ 3.2) mechanisms respectively, by decoupling them from the gradient updates in Adam optimizer.

Loshchilov and Hutter (2019) observed that L2 regularization and weight decay are not identical for adaptive gradient algorithms such as Adam, and confirmed the proposed AdamW optimizer based on decoupled weight decay could substantially improve Adam's performance in both theoretical and empirical way.

Similarly, it is necessary to decouple the quadratic penalty and the annealing coefficient when fine-tuning the pretrained LMs with Adam optimizer. Otherwise, both the quadratic penalty and annealing coefficient would be adapted by the gradient update rules, resulting in different magnitudes of the quadratic penalty among the model's weights.

The comparison between Adam and RECADAM are shown in Algorithm 1, where SetScheduleMultiplier(t) (Line 11) refers to the procedure (e.g. warm-up technique) to get the scaling factor of the step size.

Line 6 of Algorithm 1 shows how we implement the quadratic penalty and annealing coefficient with the vanilla Adam optimizer. The weighted sum of the gradient of target task objective function $\nabla f(\theta)$ and the gradient of the quadratic penalty $\gamma(\theta - \theta^*)$ get adapted by the gradient update rules, which derives to inequivalent magnitudes of the quadratic penalty among the model's weights, e.g. the weights that tend to have larger gradients $\nabla f(\theta)$ would have the larger second moment v and be

Algorithm 1 Adam and RecAdam

```
1:  given initial learning rate $\alpha \in \mathbb{R}$, momentum factors $\beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 10^{-8}$, pretrained parameter vector $\theta^* \in \mathbb{R}^n$, coefficient of quadratic penalty $\gamma \in \mathbb{R}$, annealing coefficient in objective function $\lambda(t) = 1/(1 + \exp(-k \cdot (t - t_0)), k \in \mathbb{R}, t_0 \in \mathbb{N}$
2:  initialize timestep $t \leftarrow 0$, parameter vector $\theta_{t=0} \in \mathbb{R}^n$, first moment vector $m_{t=0} \leftarrow 0$, second moment vector $v_{t=0} \leftarrow 0$, schedule multiplier $\eta_{t=0} \in \mathbb{R}$
3:  repeat
4:      $t \leftarrow t + 1$
5:      $\nabla f_t(\theta_{t-1}) \leftarrow \text{SelectBatch}(\theta_{t-1})$      ▷ select batch and return the corresponding gradient
6:      $g_t \leftarrow \lambda(t)\ \nabla f_t(\theta_{t-1})\ + (1 - \lambda(t))\gamma(\theta_{t-1} - \theta^*)$
7:      $m_t \leftarrow \beta_1 m_{t-1} + (1 - \beta_1) g_t$      ▷ here and below all operations are element-wise
8:      $v_t \leftarrow \beta_2 v_{t-1} + (1 - \beta_2) g_t^2$
9:      $\hat{m}_t \leftarrow m_t/(1 - \beta_1^t)$      ▷ $\beta_1$ is taken to the power of $t$
10:     $\hat{v}_t \leftarrow v_t/(1 - \beta_2^t)$      ▷ $\beta_2$ is taken to the power of $t$
11:     $\eta_t \leftarrow \text{SetScheduleMultiplier}(t)$      ▷ can be fixed, decay, or also be used for warm restarts
12:     $\theta_t \leftarrow \theta_{t-1} - \eta_t \left( \lambda(t)\ \alpha \hat{m}_t/(\sqrt{\hat{v}_t} + \epsilon)\ + (1 - \lambda(t))\gamma(\theta_{t-1} - \theta^*) \right)$
13: until stopping criterion is met
14: return optimized parameters $\theta_t$
```

penalized by the relatively smaller amount than other weights.

With RECADAM optimizer, we decouple the gradient of the quadratic penalty $\gamma(\theta - \theta^*)$ and the annealing coefficient $\lambda(t)$ in Line 12 of Algorithm 1. In this way, only the gradient of target task objective function $\nabla f(\theta)$ get adapted during the optimization steps, and all the weights of the training model would be more effectively penalized with the same rate $(1 - \lambda(t))\gamma$.

Since the RECADAM optimizer is only one line modification from Adam optimizer, it can be easily used by feeding the additional parameters, including the pretrained parameters and a few hyperparameters of the Pretraining Simulation and Objective Shifting mechanisms.

4 Experiments

4.1 Setup

Model: We conduct the experiments with the deep pretrained language model BERT-base (Devlin et al., 2019) and ALBERT-xxlarge (Lan et al., 2020).

BERT is a deep bi-directional pretrained model based on multi-layer Transformer encoders. It is pretrained on the large-scale corpus with two unsupervised tasks: Masked LM and Next Sentence Prediction, and has achieved significant improvements on a wide range of NLP tasks. We use the BERT-base model with 12 layers, 12 attention heads and 768 hidden dimensions (total 108M parameters).

ALBERT is the latest deep pretrained LM that achieves state-of-the-art performance on several benchmarks. It improves BERT by the parameter reduction techniques and self-supervised loss for sentence-order prediction (SOP). The ALBERT-xxlarge model with 12 layers, 64 attention heads, 128 embedding dimensions and 4,096 hidden dimensions (total 235M parameters) is the current state-of-the-art model released by Lan et al. (2020).

Data: We evaluate our methods on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019).

GLUE is a well-known benchmark evaluating model capabilities for natural language understanding. It includes 9 tasks: Corpus of Linguistic Acceptability (CoLA; Warstadt et al. 2018), Stanford Sentiment Treebank (SST; Socher et al. 2013), Microsoft Research Paraphrase Corpus (MRPC; Dolan and Brockett 2005), Semantic Textual Similarity Benchmark (STS; Cer et al. 2017), Quora Question Pairs (QQP),[2] Multi-Genre NLI (MNLI; Williams et al. 2018), Question NLI (QNLI; Rajpurkar et al. 2016), Recognizing Textual Entailment (RTE; Dagan et al. 2006; Bar Haim et al. 2006; Giampiccolo et al. 2007; Bentivogli et al. 2009) and Winograd NLI (WNLI; Levesque et al. 2011).

Following previous works (Yang et al., 2019; Liu et al., 2019; Lan et al., 2020), we report our single-task single-model results on the dev set of 8 GLUE tasks, excluding the problematic WNLI dataset.[3] We report Pearson correlations for STS, Matthew's correlations for CoLA, the "match" condition (MNLI-m) for MNLI, and accuracy scores

for other tasks.

Implementation: As discussed in § 3.3, we implement the Pretraining Simulation and Objective Shifting techniques with the proposed RECADAM optimizer. We fine-tune the additional output layer with the vanilla Adam optimizer, since it is excluded in the parameters of pretrained LMs. Our methods use random initialization because of the pretrained knowledge recalling implementation, while vanilla fine-tuning initializes the fine-tuning model with the pretrained parameters.

We use the data processing and evaluation script implemented by HuggingFace Transformers library.[4] We fine-tune BERT-base and ALBERT-xxlarge model with the same hyperparameters following Devlin et al. (2019) and Lan et al. (2020), except for the maximum sequence length which we set to 128 rather than 512. For the BERT-base model, we set the learning rate to 2e-5, use the gradient bias correction and select the training step (61,360 on MNLI, 56,855 on QQP, 33,890 on QNLI, 21,050 on SST, 13,400 on CoLA, 9,000 on STS, 11,500 on MRPC, 7,800 on RTE) to improve the fine-tuning stability on each task (Mosbach et al., 2020; Zhang et al., 2020b). We note that we fine-tune on RTE, STS, and MRPC directly using the pretrained LM while the previous works are using an MNLI checkpoint for further performance improvement. As for the hyperparameters of our methods, we set γ in the quadratic penalty to 5,000, and select the best t_0 and k in $\{100, 250, 500, 1{,}000\}$ and $\{0.05, 0.1, 0.2, 0.5, 1\}$ respectively for the annealing coefficient $\lambda(t)$ on each dev set. Following previous works (Liu et al., 2019; Lan et al., 2020), we report the score of 5 differently-seeded runs for each result.

4.2 Results on GLUE

Table 1 shows the single-task single-model results of our RECADAM fine-tuning method comparing to the vanilla fine-tuning method with BERT-base and ALBERT-xxlarge model on the dev set of the GLUE benchmark. We also present the single-task single-model results with the BERT-base model on the test set of the GLUE benchmark in Appendix A.1, where we achieve 1.0% improvement on average.

Results with BERT-base: With the BERT-base model, we outperform the vanilla fine-tuning method on 7 out of 8 tasks of the GLUE benchmark and achieve 1.0% improvement on the average median performance.

Especially for the tasks with smaller training data (<10k), our method can achieve significant improvements (+1.7% on average) compared to the vanilla fine-tuning method. Because of the data scarcity, vanilla fine-tuning on these tasks is potentially brittle and prone to overfitting and catastrophic forgetting problems (Phang et al., 2018; Jiang et al., 2019). With the proposed RECADAM method, we successfully achieve better fine-tuning by learning target tasks while recalling the knowledge of pretraining tasks.

It is interesting to find that compared to the median results with the BERT-large model, we can also achieve better results on more than half of the tasks (e.g., +4.0% on RTE, +0.4% on STS, +1.8% on CoLA, +0.4% on SST, +0.1% on QQP) and better average results (+0.5%) of all the GLUE tasks. Thanks to the less catastrophic forgetting realized by RECADAM, we can get better overall performance with much fewer parameters of the pretrained model.

Results with ALBERT-xxlarge: With the state-of-the-art model ALBERT-xxlarge, we outperform the vanilla fine-tuning method on 5 out of 8 tasks of the GLUE benchmark and achieve the state-of-the-art single-task single-model average median result 90.2% on the dev set of the GLUE benchmark.

Similar to the results with the BERT-base model, We find that our improvements mostly come from the tasks with smaller training data (<10k), and we can improve the ALBERT-xxlarge model's median performance on these tasks by +1.5% on average. Also, compared to the reported results by Lan et al. (2020), we can achieve similar or better median results on RTE (+0.1%), STS (-0.1%), and MRPC (+1.0%) tasks without pretraining on the MNLI task.

Overall, we outperform the average median results of the baseline with the ALBERT-xxlarge model by 0.7%, which is lower than the improvement we gain with the BERT-base model (+1.0%). With advanced model design and pretraining techniques, ALBERT-xxlarge achieves significantly better performance on the GLUE benchmark, which would be harder to be further improved.

Table 2: Comparison of different model initialization strategies: pretrained initialization (PI) and Random Initialization (RI). We report median over 5 runs.

4.3 Analysis

Model Initialization: With our RECADAM method, the model can be initialized with random values, and recall the knowledge of pretraining tasks while learning the new tasks.

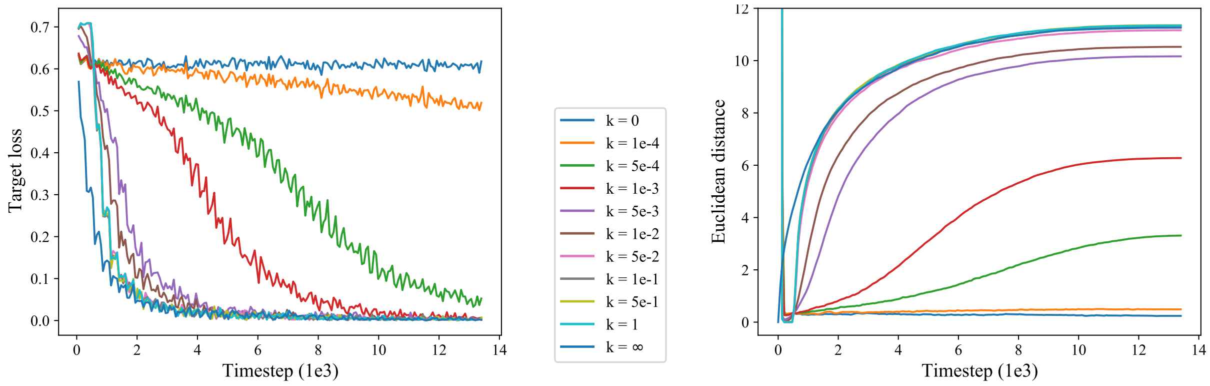
It is interesting to see whether the choice of initialization strategies would impact the performance of our RECADAM method. Table 2 shows the performance comparison of different initialization strategies for RECADAM obtained by the BERT-base model. It shows that RECADAM with both initialization strategies can outperform the vanilla fine-tuning method on all four tasks. For the target task STS, the model with pretrained initialization can achieve the same result as random initialization. For the other tasks (e.g., CoLA, MRPC, RTE), the models with random initialization can achieve better performance. It is because the randomly initialized model can benefit from a larger parameter search space. By contrast, with pretrained initialization, the search space would be limited to around the pretraining model, making it harder for the model to escape poor local minima and gain better performance on the new tasks.

Forgetting Analysis: As introduced in § 3.2, we realize multi-task fine-tuning with the Objective Shifting technique, which allows the model's learning objective to shift from the source tasks to the target tasks gradually. The hyperparameter k controls the rate of the objective shifting.

Figure 2 shows the learning curves of our fine-tuning methods with different k value obtained by BERT-base model trained on CoLA dataset. As discussed in § 3.2, Fine-tuning and multi-task learning can be regarded as the special cases ($k \to \infty$ and $k \to 0$) of our method.

As shown in Figure 2a, with the larger shifting rate k, the model can converge quickly on the target task. As k decreases, it takes a longer time for the model to converge on the target task because of the slower shifting from the pretrained knowledge recalling to target task learning.

Figure 2b shows the pretrained knowledge forgetting during the fine-tuning process. We measure the pretrained knowledge forgetting by the Euclidean distance between the weights of the fine-tuning model and the pretrained model. With vanilla fine-tuning ($k \to \infty$), the Euclidean distance begins at zero and increases as the model learns the target task. With a modest shifting rate k, at the very early timesteps, the Euclidean distance drops sharply because of the random initialization and pretrained knowledge recalling. Then the curve rises with the growth rate slowing down because of the target task learning. As k decreases, thanks to more iterations of pretrained knowledge recalling, the model can achieve less forgetting at the end of



(a) Training loss on the target task

(b) Knowledge forgetting from the source tasks

Figure 2: Learning curves obtained by BERT-base model trained with different objective shifting rate k on CoLA.

the fine-tuning.

Overall, our methods provide a bridge between fine-tuning and multi-task learning. With smaller k, the model achieves less knowledge forgetting from the source tasks but risks not converging completely on the target task. With a good balance between the pretrained knowledge recalling and new task learning, our methods can consistently outperform the vanilla fine-tuning by not only converging on target tasks but also less forgetting from source tasks.

5 Related Works

Catastrophic forgetting has been observed as a great challenge issue in sequential transfer learning, especially in the continuous learning paradigm (McCloskey and Cohen, 1989; French, 1999; Goodfellow et al., 2013; De Lange et al., 2019). Many methods have been proposed to avoid catastrophic forgetting (Kirkpatrick et al., 2017; Li and Hoiem, 2017; Rebuffi et al., 2017; Mallya and Lazebnik, 2018). We focus on regularization-based methods (Kirkpatrick et al., 2017; Li and Hoiem, 2017) which recall the previous knowledge with an regularization term, because they don't require the storage of the pretraining data, and are flexible on the new tasks. Regularization-based methods can be further divided into data-focused and prior-focused methods. Data-focused methods regularize the new task learning by knowledge distillation from the pretrained model (Hinton et al., 2015; Li and Hoiem, 2017; Zhang et al., 2020a). Prior-focused methods regard the distribution of the pretrained parameters as prior when learning the new task (Kirkpatrick et al., 2017; Zenke et al., 2017; Xuhong et al., 2018; Aljundi et al., 2018). We adopted the idea of prior-focused methods because they enable the model to learn more general knowledge from the pretrained parameters more efficiently. While the prior-focused methods, such as EWC (Kirkpatrick et al., 2017) and its variants (Schwarz et al., 2018; Liu et al., 2018), don't directly access to the pretraining data, they need some pretraining knowledge which is not available in our setting. Therefore, we further approximate to a quadratic penalty which is independent with the pretraining data given the pretrained parameters.

Catastrophic forgetting in NLP has raised increased attention recently (Mou et al., 2016; Arora et al., 2019; Chronopoulou et al., 2019). Many approaches have been proposed to overcome the forgetting problem in various domains, such as machine translation (Miceli-Barone et al., 2017; Thompson et al., 2019) and reading comprehension (Xu et al., 2019). As sequential transfer learning widely used for NLP tasks (Howard and Ruder, 2018; Devlin et al., 2019; Liu et al., 2019; Lan et al., 2020), previous works explore many fine-tuning tricks to reduce catastrophic forgetting for adaptation of the deep pretrained LMs (Howard and Ruder, 2018; Sun et al., 2019; Zhang et al., 2019; Chen et al., 2019; Jiang et al., 2019; Lee et al., 2020). In this paper, we bring the idea of multi-task learning which can inherently avoid catastrophic forgetting, and achieve consistent improvement with the proposed RECADAM optimizer.

6 Conclusion

In this paper, we propose to tackle the catastrophic forgetting in transferring deep pretrained language models by bridging two transfer learning paradigms: sequential fine-tuning and multi-task learning. To cope with the absence of pretraining data during the joint learning of the pretraining task, we introduce a Pretraining Simulation mechanism to learn the pretraining task without data. Then we introduce the Objective Shifting mechanism to better balance the learning of the pretraining and downstream tasks. Experiments demonstrate the superiority of our method in transferring deep pretrained language models, and we provide the open-source RECADAM optimizer by integrating the proposed mechanisms into Adam optimizer to facilitate better usage of deep pretrained language models.

A.1 Test Results on GLUE Tasks

As shown in § 4.2, we report both the median and the maximum scores over five runs for the vanilla fine-tuning method and our RECADAM fine-tuning method on the dev set of the GLUE benchmark. The results with the BERT-base model show that we outperform the baseline method by 1.0% on the average median performance and 1.1% on the average maximum performance.

To confirm our best model's generalization on the dev set, we present the single-task single-model results with the BERT-base model on the test set of the GLUE benchmark in Table 3. Similar to the performance on the dev set, we achieve the same or better results on 7 out of 8 tasks of the GLUE benchmark and achieves 1.0% improvement on average.

Compared to the results (+0.3% on average) on the tasks with larger training data (>10k), we obtain more significant improvement (+1.7% on average) on the tasks with smaller training data (<10k). It is consistent with our findings on the dev results (discussed in § 4.2), which shows the generalization and effectiveness of the proposed RECADAM method.

Abstract

Recent advances in NLP demonstrate the effectiveness of training large-scale language models and transferring them to downstream tasks. *Can fine-tuning these models on tasks other than language modeling further improve performance?* In this paper, we conduct an extensive study of the transferability between 33 NLP tasks across three broad classes of problems (text classification, question answering, and sequence labeling). Our results show that transfer learning is more beneficial than previously thought, especially when target task data is scarce, and can improve performance even with low-data source tasks that differ substantially from the target task (e.g., part-of-speech tagging transfers well to the DROP QA dataset). We also develop *task embeddings* that can be used to predict the most transferable source tasks for a given target task, and we validate their effectiveness in experiments controlled for source and target data size. Overall, our experiments reveal that factors such as data size, task and domain similarity, and task complexity all play a role in determining transferability.

1 Introduction

With the advent of methods such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), the dominant paradigm for developing NLP models has shifted to transfer learning: first, pretrain a large language model, and then fine-tune it on the target dataset. Prior work has explored whether fine-tuning on intermediate source tasks before the target task can further improve this pipeline (Phang et al., 2018), but the conditions for successful transfer remain opaque, and choosing arbitrary source tasks can even adversely impact downstream performance (Wang et al., 2019b). Our work has two main contributions: (1) we perform a large-scale empirical study across 33 different datasets to shed light on the transferability between NLP tasks, and (2) we develop *task embeddings* to predict which source tasks to use for a given target task.

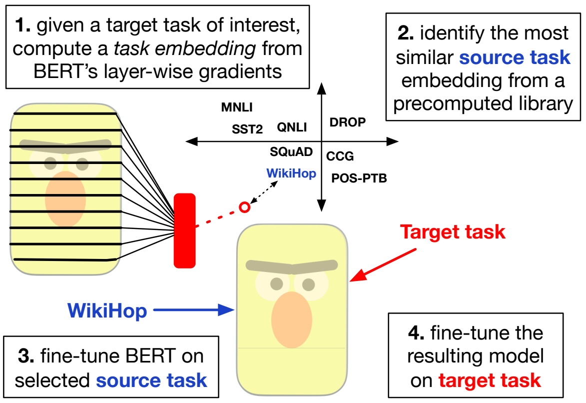

Figure 1: A demonstration of our task embedding pipeline. Given a target task, we first compute its task embedding and then identify the most similar source task embedding (in this example, WikiHop) from a precomputed library via cosine similarity. Finally, we perform intermediate fine-tuning of BERT on the selected source task before fine-tuning on the target task.[1]

Our study includes over 3,000 combinations of tasks and data regimes within and across three broad classes of problems (text classification, question answering, and sequence labeling), which is considerably more comprehensive than prior work (Wang et al., 2019a; Talmor and Berant, 2019a; Liu et al., 2019a). Our results show that transfer learning is more beneficial than previously thought (Wang et al., 2019b), especially for low-data target tasks, and even low-data source tasks that are on the surface very different than the target task can result in transfer gains. While previous work has recommended using the amount of labeled data as a criterion to select source

tasks (Phang et al., 2018), our analysis suggests that the similarity between the source and target tasks and domains are crucial for successful transfer, particularly in data-constrained regimes.

Motivated by these results, we move on to a more practical research question: *given a particular target task, can we predict which source tasks (out of some predefined set) will yield the largest transfer learning improvement, especially in low-data settings?* We address this challenge by learning embeddings of tasks that encode their individual characteristics (Figure 1). More specifically, we process all examples from a dataset through BERT and compute a task embedding based on the model's gradients with respect to the task-specific loss, following recent meta-learning work in computer vision (Achille et al., 2019). We empirically demonstrate the practical value of these task embeddings for selecting source tasks (via simple cosine similarity) that effectively transfer to a given target task. To the best of our knowledge, this is the first work that builds explicit representations of NLP tasks to investigate transferability.

We publicly release our task library, which consists of pretrained models and task embeddings for the 33 NLP tasks we study, along with a codebase that computes task embeddings for new tasks and identifies source tasks that will likely yield positive transferability.[2]

2 Exploring task transferability

To shed light on the transferability between different NLP tasks,[3] we perform an empirical study with 33 tasks across three broad classes of problems: text classification/regression (CR), question answering (QA), and sequence labeling (SL).[4] In each experiment, we follow the STILTs pipeline of Phang et al. (2018) by taking a pretrained BERT model,[5] fine-tuning it on an intermediate *source* task, and then fine-tuning the resulting model on a *target* task. We explore in-class and out-of-class transfer in both data-rich and data-constrained regimes and demonstrate that positive transfer can occur in a more diverse array of settings than previously thought (Wang et al., 2019b).

Task	**|Train|**
text classification/regression (CR)	
SNLI (Bowman et al., 2015)	570K
MNLI (Williams et al., 2018)	393K
QQP (Iyer et al., 2017)	364K
QNLI (Wang et al., 2019b)	105K
SST-2 (Socher et al., 2013)	67K

Chunk (Tjong Kim Sang and Buchholz, 2000)	9K

Table 1: Datasets used in our experiments, grouped by task class and sorted by training dataset size.

2.1 Experimental setup

We denote a dataset $D = \{(x^i, y^i)\}_{i=1}^n$, with n total examples of inputs x and associated outputs y. Each input x, which can be either a single text or a concatenation of multiple text segments (e.g., a question-passage pair), is represented as:

$$\text{[CLS]}\ w_1^1\ w_2^1\ \ldots w_{L_1}^1\ \text{[SEP]}\ w_1^2\ w_2^2\ \ldots w_{L_2}^2,$$

where w_j^i is token i of the j^{th} segment, [CLS] is a special symbol for classification output, and [SEP] is a special symbol to separate any text segments if they exist. Finally, each task is solved by applying a classification layer over either the final [CLS] token representation (for CR) or the entire sequence

---

[2] Library and code available at `http://github.com/tuvuumass/task-transferability`.

[3] We define a *task* as a (dataset, objective function) pair.

[4] We divide tasks into classes based on how they are modeled; there is considerable in-class linguistic diversity.

[5] We use BERT-Base Uncased, which has 12 layers, 768-d hidden size, 12 heads, and 110M total parameters.

of final layer token representations (for QA or SL). For both stages of fine-tuning, we follow Devlin et al. (2019) by backpropagating into all model parameters for a fixed number of epochs.[6] While individual task performance can likely be further improved with more involved hyperparameter tuning for each experimental setting, we standardize hyperparameters across each of the three classes to cut down on computational expense, following prior work (Phang et al., 2018; Wang et al., 2019b).

2.1.1 Datasets & data regimes

Table 1 lists the 33 datasets in our study.[7] We select these datasets by mostly following prior work: nine of the eleven CR tasks come from the GLUE benchmark (Wang et al., 2019b); all eleven QA tasks are from the MultiQA repository (Talmor and Berant, 2019b); and all eleven SL tasks were used by Liu et al. (2019a). We consider all possible pairs of source and target datasets;[8] while some training datasets contain overlapping examples (e.g., SQuAD-1 and 2), we evaluate our models on target development sets, which do not contain overlap.

For each (source, target) dataset pair, we perform transfer experiments in three data regimes to examine the impact of data size on Source → Target transfer: Full → Full , Full → Limited , and Limited → Limited. In the Full training regime, all training data for the associated task is used for fine-tuning. In the Limited setting, we artificially limit the amount of training data by randomly selecting 1K training examples without replacement, following Phang et al. (2018); since fine-tuning BERT can be unstable on small datasets (Devlin et al., 2019), we perform 20 random restarts for each experiment and report the mean.[9]

We measure the impact of transfer learning by computing the *relative transfer gain* given a source task s and target task t. More concretely, if a baseline model that is directly fine-tuned on the target dataset (without any intermediate fine-tuning) achieves a performance of p_t, while a transferred model achieves a performance of $p_{s \to t}$, the relative transfer gain is defined as: $g_{s \to t} = \dfrac{p_{s \to t} - p_t}{p_t}$.

Full → Full			
↓src,tgt→	CR	QA	SL
CR	6.3 (11)	3.4 (10)	0.3 (10)
QA	3.2 (10)	9.5 (11)	0.3 (9)

Full → Limited			
	CR	QA	SL
CR	56.9 (11)	36.8 (10)	2.0 (10)
QA	44.3 (11)	63.3 (11)	5.3 (11)
SL	45.6 (11)	39.2 (6)	20.9 (11)
Limited → Limited			
	CR	QA	SL
CR	23.7 (11)	7.3 (11)	1.1 (11)
QA	37.3 (11)	49.3 (11)	4.2 (11)
SL	29.3 (10)	30.0 (8)	10.2 (11)

Table 2: A summary of our transfer results for each combination of the three task classes in the three data regimes. Each cell represents the relative gain of the *best* source task in the source class (row) for a given target task, averaged across all of target tasks in the target class (column). In parentheses, we additionally report the number of target tasks (out of 11) for which at least one source task results in a positive transfer gain. The diagonal cells indicate in-class transfer.

2.2 Analyzing the transfer results

Table 2 contains the results of our transfer experiments across each combination of classes and data regimes.[10] In each cell, we first compute the transfer gain of the *best* source task for each target task in a particular class, and then average across all target tasks in the same class. We summarize our findings as follows:

- Contrary to prior belief, transfer gains are possible even when the source dataset is small.
- Out-of-class transfer succeeds in many cases, some of which are unintuitive.
- Factors other than source dataset size, such as the similarity between source and target tasks, matter more in low-data regimes.

In the rest of this section, we analyze each of these three findings in more detail.

---

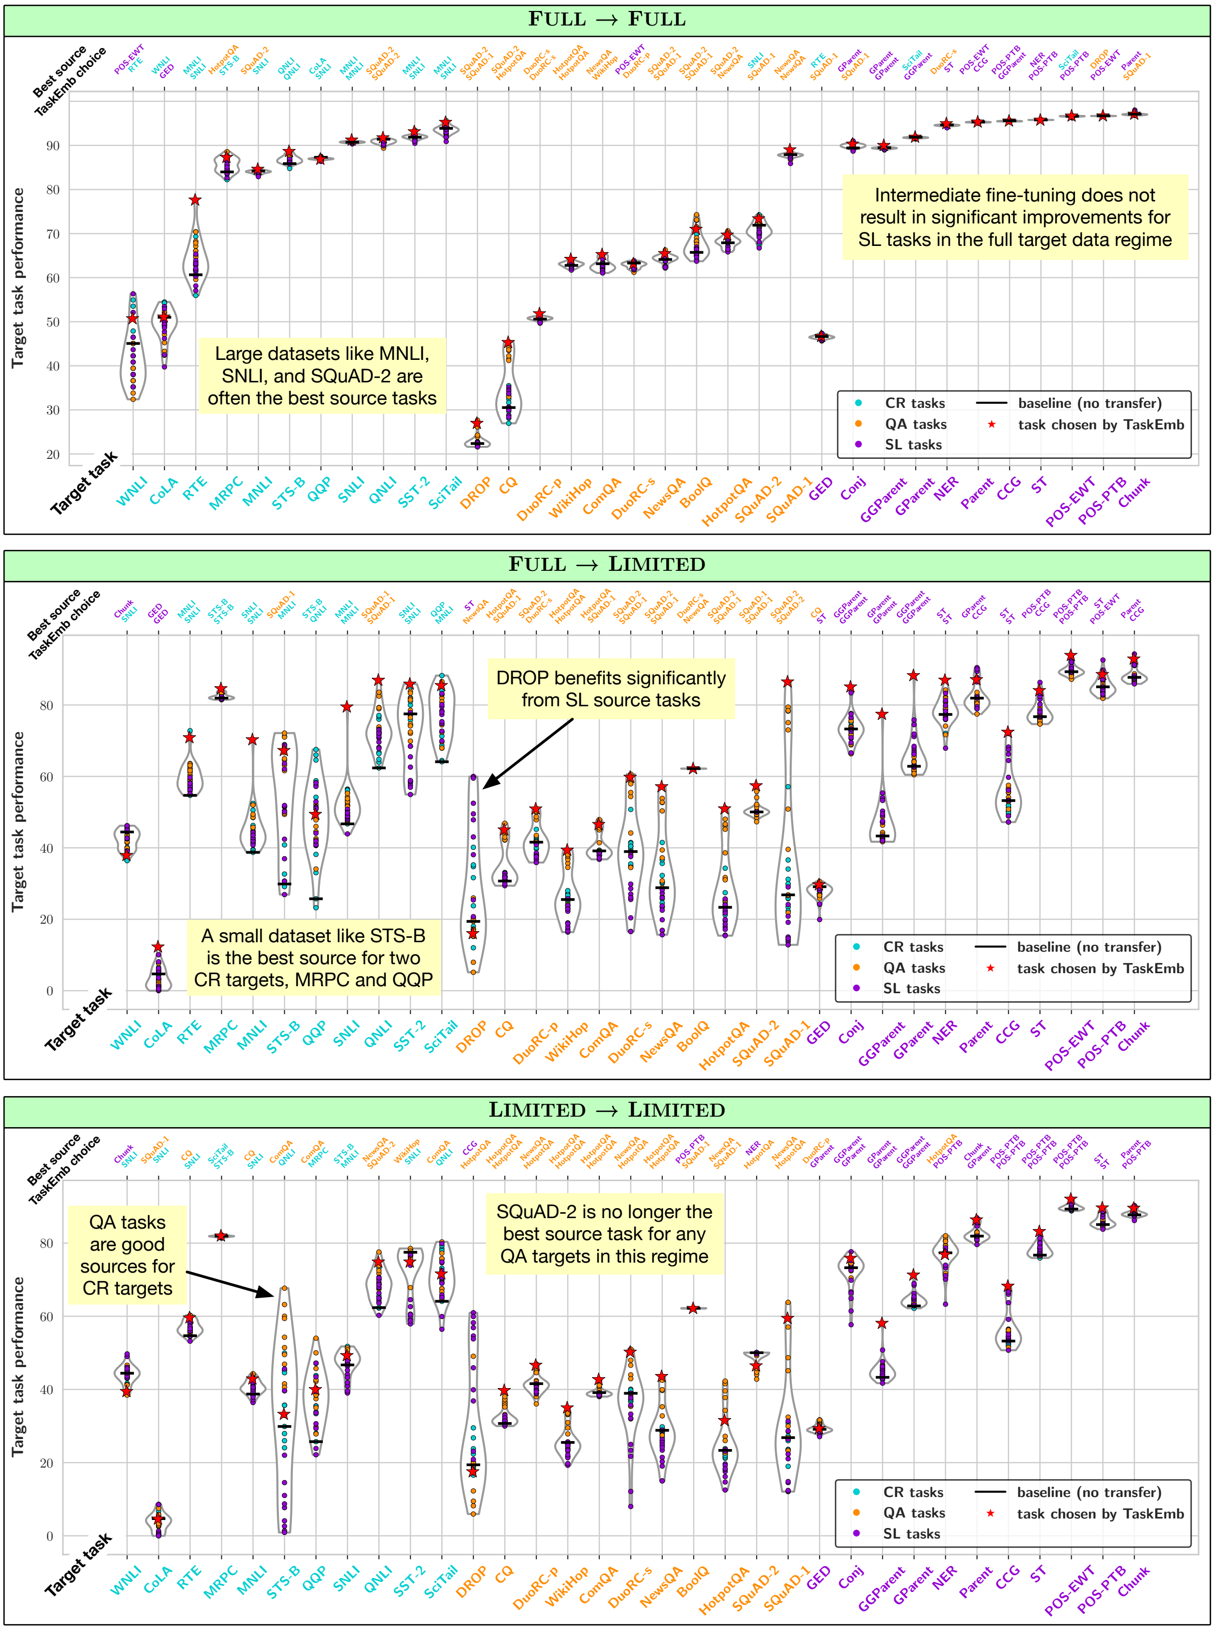
[6] We fine-tune all CR and QA tasks for three epochs, and SL tasks for six epochs, using the Transformers library (Wolf et al., 2019) and its recommended hyperparameters.

[7] Appendix A.1 contains more details about dataset characteristics and their associated evaluation metrics.

[8] All experiments conducted on a GPU cluster operating on renewable energy.

[9] See Appendix B for variance statistics. We resample 1K examples for each restart; for tasks with fewer than 1K training examples, we use the full training dataset.

[10] See Appendix B for tables for each individual task.



Large datasets like MNLI, SNLI, and SQuAD-2 are often the best source tasks

Intermediate fine-tuning does not result in significant improvements for SL tasks in the full target data regime

DROP benefits significantly from SL source tasks

A small dataset like STS-B is the best source for two CR targets, MRPC and QQP

QA tasks are good sources for CR targets

SQuAD-2 is no longer the best source task for any QA targets in this regime

Figure 2: In these plots (best viewed in zoom with color), each violin corresponds to a target task in the specified data regime. Each point inside a violin represents an individual source task; its color denotes task class, and its y-coordinate denotes target task performance after transfer. Above each violin, we provide the *best* source task (highest point within the violin) and TASKEMB's top-ranked source task (the red star). The horizontal black line in each violin represents the baseline target task performance of BERT without intermediate fine-tuning. **TASKEMB generally selects source tasks that yield positive transfer, and often selects the best source task.**

In-class transfer: The diagonal of each block of Table 2 shows the results for in-class transfer, in which source tasks are from the same class as the target task. Across all three data regimes, most target tasks benefit from in-class transfer, and the average transfer gain is larger for CR and QA tasks than for SL tasks. Changing the data regimes significantly impacts the average transfer gain, which is lowest in the FULL → FULL regime (+5.4% average relative gain across all tasks) and highest in the FULL → LIMITED regime (+47.0%). In general, tasks with fewer training examples benefit the most from transfer, such as RTE (+17.0 accuracy points) and CQ (+14.9 F1), and the best source tasks in the FULL → FULL regime tend to be data-rich tasks such as MNLI, SNLI, and SQuAD-2 (Figure 2).[11]

Out-of-class transfer: We switch gears now to out-of-class transfer, in which the source task comes from a different class than the target task. The off-diagonal entries of each block of Table 2 summarize our results. In general, we observe that most tasks benefit from out-of-class transfer, although the magnitude of the transfer gains is lower than for in-class transfer, and that CR and QA tasks benefit more than SL tasks (similar to our in-class transfer results). While some of the results are intuitive (e.g., SQuAD is a good source task for QNLI, which is an entailment task built from QA pairs), others are more difficult to explain (using part-of-speech tagging as a source task for DROP results in huge transfer gains in limited target regimes).

Large source datasets are not always best for data-constrained target tasks: Phang et al. (2018) observe that source data size is a good heuristic to obtain positive transfer gain. In the FULL → LIMITED regime, we find to the contrary that the largest source datasets do not always result in the largest transfer gains. For CR tasks, MNLI/SNLI are the best sources for only four targets (three of which are entailment tasks), compared to seven in FULL → FULL . STS-B, which is much smaller than MNLI and SNLI, is the best source for MRPC and QQP, while MRPC, an even smaller dataset, is the best source for STS-B. As STS-B, QQP, and MRPC are all sentence similarity and paraphrase tasks, this result suggests that the similarity between the source and target tasks matters more for data-constrained targets. We observe similar task similarity patterns for QA (the best source for WikiHop is the other multi-hop QA task, HotpotQA) and SL (POS-PTB is the best source for POS-EWT, the only other POS tagging task). However, the large SQuAD-2 dataset is almost always the best source within QA. Another important factor especially apparent in our QA tasks is domain similarity (e.g., SQuAD and several other datasets were all built from Wikipedia).

When does transfer work with data-constrained sources? We now turn to the LIMITED → LIMITED regime, which eliminates the source data size confound. For CR, STS-B is the best source for six targets out of 11, including four entailment tasks (MNLI, QNLI, SNLI, SciTail), whereas MNLI/SNLI are the best sources for only two tasks (RTE, WNLI). This result suggests that source/target task similarity, which we found to be a factor for the FULL → LIMITED , is not the only important factor for effective transfer in data-constrained scenarios. We hypothesize that the complexity of the source task can also play a role: perhaps regression objectives (as used in STS-B) are more useful for transfer learning than classification objectives (MNLI/SNLI). Unknown factors may also play a role: in QA, SQuAD-2 is no longer the best source for any targets, while NewsQA is the best source for five tasks.

3 Predicting task transferability

The above analysis suggests that no single factor (e.g., data size, task and domain similarity, task complexity) is predictive of transfer gain across all of our settings. *Given a novel target task, how can we identify the single source task that maximizes transfer gain?* One straightforward but extremely expensive approach is to enumerate every possible (source, target) task combination. Work on multi-task learning within NLP offers a more practical alternative by developing feature-based models to identify task and dataset characteristics that are predictive of task synergies (Bingel and Søgaard, 2017). Here, we take a different approach, inspired by recent computer vision methods (Achille et al., 2019), by computing *task embeddings* from layer-wise gradients of BERT. Our approach generally outperforms baseline methods that use the data size heuristic (Phang et al., 2018) and the gradients of the learning curve (Bingel and Søgaard, 2017) in terms of selecting the most transferable source tasks across settings.

---

[11] As in Phang et al. (2018), we find that intermediate fine-tuning reduces variance across random restarts (Appendix B).

3.1 Task embedding methods

We develop two methods for computing task embeddings from BERT. The first, TEXTEMB, is computed by pooling BERT's representations across an entire dataset, and as such captures properties of the text and domain. The second, TASKEMB, relies on the correlation between the fine-tuning loss function and the parameters of BERT, and encodes more information about the type of knowledge and reasoning required to solve the task.

TEXTEMB: As our analysis indicates that domain similarity is a relevant factor for transfer, we first explore a simple method based on averaging BERT token-level representations of the inputs. Given a dataset D, we process each input sample x^i through the pretrained BERT model without any finetuning and compute $\boldsymbol{h}_x$, the average of final layer token-level representations. The final task embedding is the average of these pooled vectors over the entire dataset: $\sum_{x \in D} \frac{\boldsymbol{h}_x}{|D|}$. This method captures linguistic properties of the input text x and does not depend on the training labels y.

TASKEMB: Ideally, we want a way of capturing task similarity beyond just input properties represented by TEXTEMB. Following the methodology of TASK2VEC (Achille et al., 2019), which develops task embeddings for meta-learning over vision tasks, we create representations of tasks derived from the Fisher information matrix (or simply *Fisher*). The Fisher captures the curvature of the loss surface (the sensitivity of the loss to small perturbations of model parameters), which intuitively tells us which of the model parameters are most useful for the task and thus provides a rich source of knowledge about the task itself.

To begin, we fine-tune BERT on the training dataset of a given task; the model without the final task-specific layer forms our *feature extractor*. Next, we feed the entire training dataset into the model and compute the task embedding based on the Fisher of the feature extractor's parameters (weights) θ, i.e., the expected covariance of the gradients of the log-likelihood with respect to θ:

$$F_\theta = \mathop{\mathbb{E}}_{x,y \sim P_\theta(x,y)} \nabla_\theta \log P_\theta(y|x) \nabla_\theta \log P_\theta(y|x)^T.$$

In our experiments, we compute the *empirical Fisher*, which uses the training labels instead of sampling from $P_\theta(x,y)$:

$$F_\theta = \frac{1}{n} \sum_{i=1}^{n} \left[\nabla_\theta \log P_\theta(y^i|x^i) \nabla_\theta \log P_\theta(y^i|x^i)^T \right],$$

and only consider the diagonal entries to reduce computational complexity. Additionally, we consider the Fisher F_ϕ with respect to the feature extractor's outputs (activations) ϕ, which encodes useful features about the inputs to solve the task. The diagonal F_ϕ is averaged over the input tokens and over the entire dataset.[12]

We explore task embeddings derived from the diagonal Fisher of different components of BERT, including the token embeddings, multi-head attention, feed-forward network, and the layer output, performing layer-wise averaging. Since our base model is BERT, this method may result in high-dimensional task embeddings (from 768-d to millions of dimensions). While one can optionally perform dimensionality reduction (e.g., through PCA), all of our experiments are conducted directly on the original task embeddings.

3.2 Task embedding evaluation

We investigate whether a high similarity between two different task embeddings correlates with a high degree of transferability between those two tasks. Our evaluation centers around the meta-task of selecting the best source task for a given target task. Specifically, given a target task, we rank all the other source tasks in our library in descending order by the cosine similarity[13] between their task embeddings and the target task's embedding. This ranking is evaluated using two metrics: (1) the average rank ρ of the source task with the highest absolute transfer gain from Section 2's experiments, and (2) the Normalized Discounted Cumulative Gain (NDCG; Järvelin and Kekäläinen, 2002), a common information retrieval measure that evaluates the quality of the entire ranking, not just the rank of the best source task.[14] The NDCG

---

[12] While Fisher matrices are theoretically more comparable when the feature extractor is fixed during fine-tuning, as done in TASK2VEC, we find empirically that TASKEMB computed from a fine-tuned task-specific BERT result in better correlations to task transferability in data-constrained scenarios. We leave further exploration of this phenomenon to future work.

[13] We leave the exploration of asymmetric similarity metrics to future work.

[14] We use NDCG instead of Spearman correlation, as the latter penalizes top-ranked and bottom-ranked mismatches with the same weight.

at position p is defined as: $\text{NDCG}_p = \frac{\text{DCG}_p(R_{pred})}{\text{DCG}_p(R_{true})}$, where R_{pred}, R_{true} are the predicted and gold rankings of the source tasks, respectively; and $\text{DCG}_p(R) = \sum_{i=1}^{p} \frac{2^{rel_i} - 1}{\log_2(i+1)}$, where rel_i is the relevance (target performance) of the source task with rank i in the evaluated ranking R.[15] An NDCG of 100% indicates a perfect ranking.

Aggregating similarity signals from embedding spaces: For our TASKEMB approach, we aggregate rankings from all of the different components of BERT rather than evaluate each component-specific ranking separately.[16] We expect that task embeddings derived from different components might contain complementary information about the task, which motivates this decision. Concretely, given a target task t, assume that $r_{1:c}$ are the rank scores assigned to a source task s by c different components of BERT. Then, the aggregated score is computed according to the reciprocal rank fusion algorithm (Cormack et al., 2009): $\text{RRF}(s) = \sum_{i=1}^{c} \frac{1}{60 + r_i}$. We also use this approach to aggregate rankings from TEXTEMB and TASKEMB, which results in TEXT + TASK.

3.3 Baseline methods

DATASIZE: To measure the effect of data size, we compare rankings derived from TEXTEMB and TASKEMB to DATASIZE, a heuristic baseline that ranks all source tasks by the number of training examples.

CURVEGRAD: We also consider CURVEGRAD, a baseline that uses the gradients of the loss curve of BERT for each task. Bingel and Søgaard (2017) find such learning curve features to be good predictors of gains from multi-task learning. They suggest that multi-task learning is more likely to work when the main tasks quickly plateau (small negative gradients) while the auxiliary tasks continue to improve (large negative gradients). Following the setup in Bingel and Søgaard (2017), we fine-tune BERT on each source task for a fixed number of steps (i.e., 10,000) and compute the gradients of the loss curve at 10, 20, 30, 50 and 70 percent of the fine-tuning process. Given a target task, we rank all the source tasks in descending order by the gradients and aggregate the rankings using the reciprocal rank fusion algorithm.

3.4 Source task selection experiments

The average performance of selecting the best source task across target tasks using different methods is shown in Table 3.[17] Here, we provide an overview and analysis of these results.

Baselines: DATASIZE is a good heuristic when the full source training data is available, but it struggles in all out-of-class transfer scenarios as well as on SL tasks, for which most datasets contain roughly the same number of examples (Table 1).[18] CURVEGRAD lags far behind DATASIZE in most cases, though its performance is better on SL tasks in the FULL → FULL regime. This indicates that CURVEGRAD cannot reliably predict the most transferable source tasks in our transfer scenarios.

TEXTEMB and TASKEMB improve transferability prediction: Table 3 shows that TEXTEMB performs better than DATASIZE on average, especially within the limited data regimes. Interestingly, TEXTEMB underperforms significantly on CR tasks compared to QA and SL. We theorize that this effect is partly due to the relative homogeneity of the QA and SL datasets (i.e., many QA datasets use Wikipedia while many SL tasks are extracted from the Penn Treebank) compared to the more diverse CR datasets. If TEXTEMB captures mainly domain similarity, then it may struggle when that is not a relevant transfer factor.

TASKEMB can substantially boost the quality of the rankings, frequently outperforming the other methods across different classes of problems, data regimes, and transfer scenarios. These results demonstrate that the task similarity between the computed embeddings is a robust predictor of effective transfer. The ensemble of TEXT + TASK

---

[15] In our experiments, we set p to the number of source tasks in each setting.

[16] We observe that rankings derived from certain components are more useful than others (e.g., token embeddings are crucial for classification), but aggregating across all components generally outperforms individual ones.

[17] In the LIMITED settings, we report the mean results across random restarts.

[18] All methods obtain a higher NDCG score on SL tasks in the FULL → FULL regime because there is little difference in target task performance between source tasks here (see Figure 2), and thus the rankings are not penalized heavily.

Table 3: To evaluate our embedding methods, we measure the average rank (ρ) that they assign to the best source task (i.e., the one that results in the largest transfer gain) across target tasks, as well as the average NDCG measure of the overall ranking's quality. In parentheses, we show the number of source tasks in each setting. Combining the complementary signals in TaskEmb and TextEmb consistently decreases ρ (lower is better) and increases NDCG across all settings, and both methods in isolation generally perform better than the baseline methods.

results in further slight improvements, but the small magnitude of these gains suggests that TaskEmb partially encodes domain similarity. For Limited → Limited , where the DataSize heuristic does not apply, TaskEmb still performs strongly, although not as well as in the full source data regimes. Figure 2 shows that TaskEmb usually selects the best or near the best available source task for a given target task across data regimes.

Understanding the task embedding spaces: What kind of information is encoded by TaskEmb and TextEmb? Figure 3 visualizes the different task spaces in the Full → Full regime using the Fruchterman-Reingold force-directed placement algorithm (Fruchterman and Reingold, 1991).[19]

The task space of TextEmb (Figure 3, top) shows that datasets with similar sources are near one another: in QA, tasks built from web snippets are closely linked (CQ and ComQA), while in SL, tasks extracted from Penn Treebank are clustered together (CCG, POS-PTB, Parent, GParent, GGParent, Chunk, and Conj). Additionally, the SQuAD datasets are strongly linked to QNLI, which was created by converting SQuAD questions. TaskEmb captures domain information to some extent (Figure 3, bottom), but it also encodes task similarity: for example, POS-PTB is closer to POS-EWT, another part-of-speech tagging task that uses a different data source. Neither method captures some unintuitive cases in low-data regimes, such as STS-B's high transferability to CR target tasks, or that DROP benefits most from SL tasks in low-data regimes (see Tables 9, 10, 27, and 28 in Appendix B). Our methods clearly do not capture all of the factors that influence task transferability, which motivates the future development of more sophisticated task embedding methods.

4 Related Work

We build on existing work in exploring and predicting transferability across tasks.

Transferability between NLP tasks: Sharing knowledge across different tasks, as in multi-

---

[19] An alternative to dimensionality reduction algorithms for better preservation of the data's topology; see Appendix A.2.

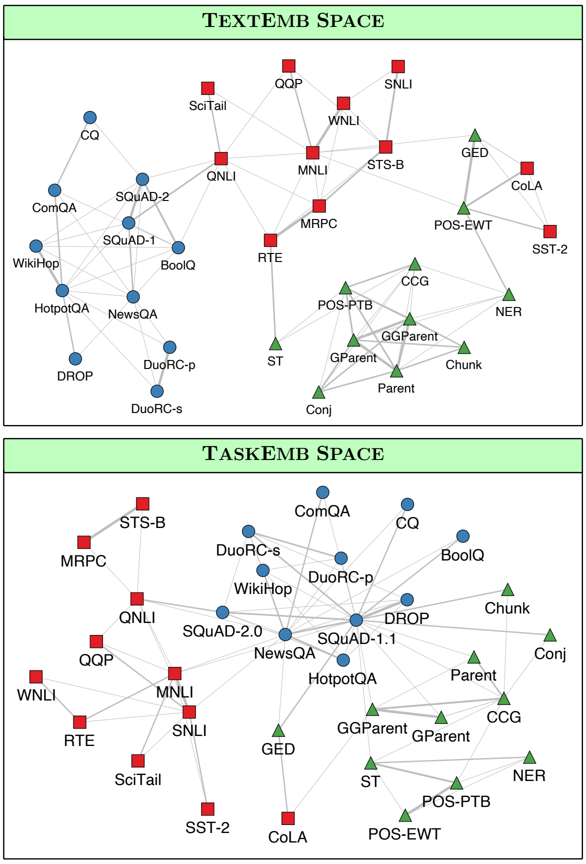

Figure 3: A 2D visualization of the task spaces of TextEmb and TaskEmb. TextEmb captures domain similarity (e.g., the Penn Treebank SL tasks are highly interconnected), while TaskEmb focuses more on task similarity (the two part-of-speech tagging tasks are interconnected despite their domain dissimilarity).

task/transfer learning, often improves over standard single-task learning (Ruder, 2017). Within multi-task learning, several works (e.g., Luong et al., 2016; Liu et al., 2019b; Raffel et al., 2020) combine multiple tasks for better regularization and transfer. More related to our work, Phang et al. (2018) explore intermediate fine-tuning and find that transferring from data-rich source tasks boosts target task performance for text classification, while Liu et al. (2019a) observe transfer gains between related sequence labeling tasks. Expanding from single to multi-source transfer, Talmor and Berant (2019a) show that pretraining on multiple datasets improves generalization on QA tasks. Nevertheless, exploiting synergies between tasks remains difficult, with many combinations of tasks negatively impacting downstream performance (Bingel and Søgaard, 2017; McCann et al., 2018; Wang et al., 2019a), and the factors that determine successful transfer still remain murky. Concurrent work indicates that intermediate tasks that require high-level inference and reasoning abilities tend to work best (Pruksachatkun et al., 2020).

Identifying beneficial task relationships: To predict transferable tasks, some methods (Martínez Alonso and Plank, 2017; Bingel and Søgaard, 2017) rely on features derived from dataset characteristics and learning curves. However, manually designing such features is time-consuming and may not generalize well across classes of problems (Kerinec et al., 2018). Recent work on *task embeddings* in computer vision offers a more principled way to encode tasks for meta-learning (Zamir et al., 2018; Achille et al., 2019; Yan et al., 2020). Taskonomy (Zamir et al., 2018) models the underlying structure among tasks to reduce the need for supervision, while Task2Vec (Achille et al., 2019) uses a frozen feature extractor pretrained on ImageNet to represent tasks in a topological space (analogous to our approach's reliance on BERT). Finally, recent work in NLP augments a generative model with an embedding space for modeling latent skills (Cao and Yogatama, 2020).

5 Conclusion

We conduct a large-scale empirical study of the transferability between 33 NLP tasks across three broad classes of problems. We show that the benefits of transfer learning are more pronounced than previously thought, especially when target training data is limited, and we develop methods that learn vector representations of tasks that can be used to reason about the relationships between them. These *task embeddings* allow us to predict source tasks that will likely improve target task performance. Our analysis suggests that data size, the similarity between the source and target tasks and domains, and task complexity are crucial for effective transfer, particularly in data-constrained regimes.

Acknowledgments

We thank Yoshua Bengio and researchers at Microsoft Research Montreal for valuable feedback on this project. We also thank the anonymous reviewers, Kalpesh Krishna, Nader Akoury, Shiv Shankar, and the rest of the UMass NLP group for their helpful comments. We are grateful to Alon Talmor and Nelson Liu for sharing the QA and SL datasets. Finally, we thank Peter Potash for additional experimentation efforts. Vu and Iyyer were supported by an Intuit AI Award for this project.

A Additional details for experimental setup

A.1 Tasks & datasets

In this work, we experiment with 33 datasets across three broad classes of problems (text classification/regression, question answering, and sequence labeling). Below, we briefly describe the datasets, and summarize their characteristics in Table 4.

Text classification/regression (eleven tasks): We use the nine GLUE datasets (Wang et al., 2019b), including grammatical acceptability judgments (**CoLA**; Warstadt et al., 2019); sentiment analysis (**SST-2**; Socher et al., 2013); paraphrase identification (**MRPC**; Dolan and Brockett, 2005); semantic similarity with STS-Benchmark (**STS-B**; Cer et al., 2017) and Quora Question Pairs[20] (**QQP**); natural language inference (NLI) with Multi-Genre NLI (**MNLI**; Williams et al., 2018), SQuAD (Rajpurkar et al., 2016) converted into Question-answering NLI (**QNLI**; Wang et al., 2019b), Recognizing Textual Entailment 1,2,3,5 (**RTE**; Dagan et al., 2005, et seq.), and the Winograd Schema Challenge (Levesque, 2011) recast as Winograd NLI (**WNLI**). Additionally, we include the Stanford NLI dataset (**SNLI**; Bowman et al., 2015) and the science QA dataset (Khot et al., 2018) converted into NLI (**SciTail**). We report F1 scores for QQP and MRPC, Spearman correlations for STS-B, and accuracy scores for the other tasks. For MNLI, we report the average score on the "matched" and "mismatched" development sets.

Question answering (eleven tasks): We use eleven QA datasets from the MultiQA (Talmor and Berant, 2019a) repository[21], including the Stanford Question Answering datasets **SQuAD-1** and **SQuAD-2** (Rajpurkar et al., 2016, 2018); **NewsQA** (Trischler et al., 2017); **HotpotQA** (Yang et al., 2018) – the version where the context includes 10 paragraphs retrieved by an information retrieval system; Natural Yes/No Questions dataset (**BoolQ**; Clark et al., 2019); Discrete Reasoning Over Paragraphs dataset (**DROP**; Dua et al., 2019) – we only use the extractive examples in the original dataset but evaluate on the entire development set, following Talmor and Berant (2019a); **WikiHop** (Welbl et al., 2018); DuoRC Self (**DuoRC-s**) and DuoRC Paraphrase (**DuoRC-p**) datasets (Saha et al., 2018) where the questions are taken from either the same version or a different version of the document from which the questions were asked, respectively; ComplexQuestions (**CQ**; Bao et al., 2016; Talmor et al., 2017); and **ComQA** (Abujabal et al., 2019) – contexts are not provided but the questions are augmented with web snippets retrieved from Google search engine (Talmor and Berant, 2019a). We report F1 scores for all QA tasks.

Sequence labeling (eleven tasks): We experiment with eleven sequence labeling tasks used by Liu et al. (2019a), including CCG supertagging with CCGbank (**CCG**; Hockenmaier and Steedman, 2007); part-of-speech tagging with the Penn Treebank (**POS-PTB**; Marcus et al., 1993) and the Universal Dependencies English Web Treebank (**POS-EWT**; Silveira et al., 2014); syntactic constituency ancestor tagging, i.e., predicting the constituent label of the parent (**Parent**), grandparent (**GParent**), and great-grandparent (**GGParent**) of each word in the PTB phrase-structure tree; semantic tagging task (**ST**; Bjerva et al., 2016; Abzianidze et al., 2017); syntactic chunking with the CoNLL 2000 shared task dataset (**Chunk**; Tjong Kim Sang and Buchholz, 2000); named entity recognition with the CoNLL 2003 shared task dataset (**NER**; Tjong Kim Sang and De Meulder, 2003); grammatical error detection with the First Certificate in English dataset (**GED**; Yannakoudakis et al., 2011; Rei and Yannakoudakis, 2016); and conjunct identification, i.e., identifying the tokens that comprise the conjuncts in a coordination construction, with the coordination annotated PTB dataset (**Conj**; Ficler and Goldberg, 2016). We report F1 scores for all SL tasks.

Table 4: Datasets used in our experiments and their characteristics, grouped by task class and sorted by training dataset size.

A.2 Fruchterman-Reingold force-directed placement algorithm

The Fruchterman-Reingold force-directed placement algorithm (Fruchterman and Reingold, 1991) simulates a space of nodes (in our setup, tasks) as a system of atomic particles/celestial bodies, exerting attractive forces on one another. In our setup, the algorithm resembles molecular/planetary simulations: the transferability between tasks specify the forces that are used to place the tasks towards each other in order to minimize the energy of the system. The force between a pair of tasks (t_1, t_2) is defined as: $f(t_1, t_2) = \frac{1}{r_{\rightarrow t_2}(t_1)} + \frac{1}{r_{\rightarrow t_1}(t_2)}$, where $r_{\rightarrow t}(s)$ is the rank of the source task s in the list of source tasks to transfer to the target task t.

B Full results for fine-tuning and transfer learning across tasks

For both fine-tuning and transfer learning, we use the same architecture across tasks, apart from the task-specific output layer. The feature extractor, i.e., BERT, is pretrained while the task-specific output layer is randomly initialized for each task. All the parameters are fine-tuned end-to-end. An alternative approach is to keep the feature extractor frozen during fine-tuning. We find that fine-tuning the whole model for a given task leads to better performance in most cases, except for WNLI and DROP, possibly because of their adversarial nature (see Tables 5, 6, and 7). In our experiments, we follow the fine-tuning recipe of (Devlin et al., 2019), i.e., only fine-tuning for a fixed number of t epochs for each class of problems. We develop our infrastructure using the HuggingFace's Transformers (Wolf et al., 2019) and its recommended hyperparameters for each class.

We show the full results for fine-tuning and transfer learning across tasks from Table 5 to Table 34. Below, we describe the setting for these tables in more detail:

In Tables 5, 6, and 7, we report the results of fine-tuning BERT (without any intermediate fine-tuning) on the 33 NLP tasks studied in this work. We perform experiments in two data regimes: FULL and LIMITED. In the FULL regime, all training data for the associated task is used while in the LIMITED setting, we artificially limit the amount of training data by randomly selecting 1K training examples without replacement, following Phang et al. (2018). For each experiment in the LIMITED regime, we perform 20 random restarts (1K examples are resampled for each restart) and report the mean and standard deviation. We show the results after each training epoch t.

For our transfer experiments, we consider every possible pair of (source, target) tasks within and across classes of problems in the three data regimes described in 2.1.1, which results in 3267 combinations of tasks and data regimes. We follow the transfer recipe of Phang et al. (2018) by first fine-tuning BERT on the source task (intermediate fine-tuning) before fine-tuning on the target task. For both stages, we only perform training for a fixed number t of epochs, following previous work (Devlin et al., 2019; Phang et al., 2018). For each task, we use the same value of t as in our fine-tuning experiments.

From Table 8 to Table 16, we show our in-class transfer results for each combination of (source, target) tasks, in which source tasks come from the same class as the target task. In each table, rows denote source tasks while columns denote target tasks. Each cell represents the target task performance of the transferred model from the associated source task to the associated target task. The orange-colored cells along the diagonal indicate the results of fine-tuning BERT on target tasks without any intermediate fine-tuning. Positive transfers are shown in blue and the best results are highlighted in bold (blue). For transfer results in the LIMITED setting, we report the mean and standard deviation across 20 random restarts.

Finally, from Table 17 to Table 34, we present our out-of-class transfer results, in which source tasks come from a different class than the target task. In each table, results are shown in a similar way as above, except that the orange-colored row Baseline shows the results of fine-tuning BERT on target tasks without any intermediate fine-tuning.

Abstract

Leveraging large amounts of unlabeled data using Transformer-like architectures, like BERT, has gained popularity in recent times owing to their effectiveness in learning general representations that can then be further fine-tuned for downstream tasks to much success. However, training these models can be costly both from an economic and environmental standpoint. In this work, we investigate how to effectively use unlabeled data: by exploring the task-specific semi-supervised approach, Cross-View Training (CVT) and comparing it with task-agnostic BERT in multiple settings that include domain and task relevant English data. CVT uses a much lighter model architecture and we show that it achieves similar performance to BERT on a set of sequence tagging tasks, with lesser financial and environmental impact.

1 Introduction

Exploiting unlabeled data to improve performance has become the foundation for many natural language processing tasks. The question we investigate in this paper is how to effectively use unlabeled data: in a task-agnostic or a task-specific way. An example of the former is training models on language model (LM) like objectives on a large unlabeled corpus to learn general representations, as in ELMo (Embeddings from Language Models) (Peters et al., 2018) and BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019). These are then reused in supervised training on a downstream task. These pre-trained models, particularly the ones based on the Transformer architecture (Vaswani et al., 2017)[1] have achieved state-of-the-art results in a variety of NLP tasks, but come at a great cost financially and environmentally (Strubell et al., 2019; Schwartz et al., 2019).

In contrast, Cross-View Training (CVT) (Clark et al., 2018) is a semi-supervised approach that uses unlabeled data in a *task-specific* manner, rather than trying to learn general representations that can be used for many downstream tasks. Inspired by self-learning (McClosky et al., 2006; Yarowsky, 1995) and multi-view learning (Blum and Mitchell, 1998; Xu et al., 2013), the key idea is that the primary prediction module, which has an unrestricted view of the data, trains on the task using labeled examples, and makes task-specific predictions on unlabeled data. The auxiliary modules, with restricted views of the unlabeled data, attempt to replicate the primary module predictions. This helps to learn better representations for the task.

We present an experimental study that investigates different task-agnostic and task-specific approaches to use unsupervised data and evaluates them in terms of performance as well as financial and environmental impact. On the one hand, we use BERT in three different settings: 1) standard BERT setup in which BERT pretrained on a generic corpus is fine-tuned on a supervised task; 2) pre-training BERT on domain and/or task relevant unlabeled data and fine-tuning on a supervised task (Pretrained BERT); and 3) continued pretraining of BERT on domain and/or task relevant unlabeled data followed by fine-tuning on a supervised task (Adaptively Pretrained BERT) (Gururangan et al., 2020). On the other hand, we use CVT based on a much lighter architecture (CNN-BiLSTM) which uses domain and/or task relevant unlabeled data in a *task-specific* manner. We experiment on several tasks framed as a sequence labeling problem: opinion target expression detection, named entity recognition and slot-labeling.

November 16–20, 2020.

Task	Labeled Data	Unlabeled Data
OTE	SE16-R Train: 2000; Test: 676	Yelp-R: ∼32.5M
	SE14-L Train: 3045; Test: 800	Amazon-E: ∼95M
NER	CONLL-2003 Train: 14987; Test: 3684	CNN-DM: ∼4M
	CONLL-2012 Train: 59924; Test: 8262	
Slot-labeling	MIT-Movies Train: 9775; Test: 2443	IMDb: ∼ 271K

Table 1: Number of sentences in unlabeled data and default train-test splits of the labeled datasets, for the various tasks.

We find that the CVT-based approach using less unlabeled data achieves similar performance with BERT-based models, while being superior in terms of financial and environmental cost as well.

2 Background, Tasks and Datasets

Before presenting the models and their training setups, we discuss the relevant literature and introduce the tasks and datasets used for our experiments. We focus on three tasks: opinion target expression (OTE) detection; named entity recognition (NER), and slot-labeling, each of which can be modeled as a sequence tagging problem (Xu et al., 2018; Liu et al., 2019a; Louvan and Magnini, 2018). The IOB sequence tagging scheme (Ramshaw and Marcus, 1999) is used for each of these tasks.

Related Work. The usefulness of continued training of large transformer-based models on domain/task-related unlabeled data has been shown recently (Gururangan et al., 2020; Rietzler et al., 2019; Xu et al., 2019), with a varied use of terminology for the process. Xu et al. (2019) and Rietzler et al. (2019) show gains of further tuning BERT using in-domain unlabeled data and refer to this as Post-training, and LM finetuning, respectively. More recently, Gururangan et al. (2020) use the term Domain-Adaptive Pretraining and show benefits over RoBERTa (Liu et al., 2019b). There have also been efforts to reduce model sizes for BERT, such as DistilBERT (Sanh et al., 2019), although these come at significant losses in performance.

Opinion Target Expression (OTE) Detection: An integral component of fine-grained sentiment analysis is the ability to identify segments of text towards which opinions are expressed. These segments are referred to as Opinion Target Expressions or OTEs. An example of this task is provided in Figure 1. The commonly used *labeled* datasets for Opinion Target Expression (OTE) detection are those released as part of SemEval Aspect-based Sentiment shared tasks: SemEval-2014 Laptops (Pontiki et al., 2014) (**SE14-L**) and SemEval-2016 Restaurants (Pontiki et al., 2016) (**SE16-R**). These consist of reviews from the laptop and restaurant domains, respectively, with OTEs annotated for each sentence of a review. We use the provided train-test splits but further split the training data randomly into 90% training and 10% validation sets. As *unlabeled* data that is similar to the domain and task, we extract restaurant reviews from the Yelp[2] dataset (Yelp-R) and reviews of electronics products from Amazon Product Reviews dataset[3] (Amazon-E) (see Table 1).

Named Entity Recognition (NER): NER is the task of identifying and categorizing named entities from unstructured text into pre-defined categories such as Person (PER), Location (LOC), Organization (ORG) etc. Figure 1 contains an example of this task. CONLL-2003 (Tjong Kim Sang and De Meulder, 2003) and CONLL-2012 (OntoNotes v5.0) (Pradhan et al., 2012) are the commonly used *labeled* datasets to build and evaluate performance for Named Entity Recognition models (Lample et al., 2016; Ma and Hovy, 2016; Akbik et al., 2018, inter-alia). We focus on the English parts of these datasets. CONLL-2003 contains annotations for Reuters news for 4 entity types (Person, Location, Organization, and Miscellaneous). CONLL-2012 dataset contains 18 entity types, consisting of various genres (weblogs, news, talk shows, etc.) with newswire being majority. We use the provided train, validation and test splits for these datasets. As newswire is the predominant genre in these

datasets, as we use stories from the CNN and Daily Mail datasets[4] (**CNN-DM**) as an unlabeled dataset from the news genre (see Table 1).

Slot-labeling: Slot-labeling is a key component of Natural Language Understanding (NLU) in dialogue systems, which involves labeling words of an utterance with pre-defined attributes - slots. For this task, we use the widely-used MIT-Movie dataset[5] as labeled data which contains queries related to movie information, with 12 slot labels such as Plot, Actor, Director, etc.. An example from this dataset is demonstrated in Figure 1. We use the default train-test split, and create a validation set by randomly selecting 10% of the training samples. IMDb Movie review dataset (**IMDb**) is used as in-domain unlabeled data (Maas et al., 2011) (see Table 1).

3 Models and Experimental Setup

We describe the various models we compare in this work and the experimental setup for each of them. Experiments are geared towards comparing the performance accuracy of the models, while also measuring impact on the environment and the resources required for training these models. Details on model architecture and training are provided in Appendix A.

Cross-View Training (CVT) CVT is a semi-supervised approach proposed by Clark et al. (2018) that leverages unlabeled data in a task-specific manner. The underlying model is a two-layer CNN-BiLSTM sentence encoder followed by a linear layer and a softmax per prediction module. There are two kinds of prediction modules - *primary* and *auxiliary*. CVT alternates between learning from labeled and unlabeled data during training. The key idea is that the primary prediction module, which has an unrestricted view of the data, trains on the task using labeled examples, and makes task-specific predictions on unlabeled data. The auxiliary modules, with different restricted views of the unlabeled data, attempt to mimic the predictions of the primary module. Standard cross-entropy loss is minimized when learning from labeled examples, while for unlabeled examples, KL-Divergence (Kullback and Leibler, 1951) between the predicted primary and auxiliary probability distributions is minimized (see (Clark et al., 2018) for more details). We demonstrate the training strategy in Figure 2. Thus, the model is trained to produce consistent results despite seeing partial views of the input - thereby improving underlying representations.

Results for SemEval2016 Restaurants Dataset

Table 2: Model performance for OTE detection task. The *same* unlabeled dataset is used for training CVT, Pre-BERT$_{\text{Base}}$ and APBERT$_{\text{Base}}$, and **Unlabeled Data** indicates the approximate number of sentences seen by each model during training, until convergence criteria is met. **Wiki+Books** and **Amazon-L** refer to English cased Wikipedia and Books Corpus, and Amazon Laptop Reviews, respectively. Xu et al. (2018) propose DE-CNN, the SOTA baseline for the task. They do not specify the sizes of the unlabeled data used.

We use Glove 840B.300d embeddings (Pennington et al., 2014) instead of Glove 6B.300d embeddings used by the authors for a larger vocabulary coverage. For each of the labeled datasets (Section 2), we use the corresponding domain/task-relevant unlabeled data to train a sequence tagging model

[5] `https://groups.csail.mit.edu/sls/downloads/movie/`

for 400K steps, with early stopping enabled using validation set convergence.

$\textbf{BERT}_{\textbf{Base}}$ BERT (Devlin et al., 2019) has achieved state-of-the-art results on many NLP tasks. The key innovation lies in the use of bi-directional Transformers as well as the Masked Language Model (MLM) and Next Sentence Prediction (NSP) objectives used during training. Learning happens in two steps: 1) training the model on a very large generic dataset (using the two objectives above); 2) fine-tuning the learned representations on a downstream task in a supervised fashion. For our experiments we use $\text{BERT}_{\text{Base}}$, which has 12 layers, 768 hidden dimensions per token and 12 attention heads and is pre-trained on the cased English Wikipedia and Books Corpus data (**Wiki+Books**). In order to fine-tune on the downstream sequence tagging task, the model we use consists of the $\text{BERT}_{\text{Base}}$ encoder, followed by a dropout layer and a classification layer that classifies each token into B-*label*, I-*label*, O, where $label \in \{label_i, label_{i+1}, ..., label_n\}$. Cross-entropy loss is the loss function used.

Pretrained $\textbf{BERT}_{\textbf{Base}}$ (Pre-$\textbf{BERT}_{\textbf{Base}}$) In this setup, we use $\text{BERT}_{\text{Base}}$ architecture and pre-train it from scratch on the domain/task relevant unlabeled data. Each training step trains on a batch of size 256. A validation set is created from each unlabeled dataset by random sampling (details in Appendix A). The convergence criteria is set to be validation MLM accuracy improvement ≥ 0.05 when evaluated every 30K steps. We then perform the second step of fine-tuning on the downstream task data, as in the regular BERT setup.

Adaptively Pretrained $\textbf{BERT}_{\textbf{Base}}$(AP$\textbf{BERT}_{\textbf{Base}}$) Here, we start with $\text{BERT}_{\text{Base}}$ trained on the generic unlabeled dataset (English Wikipedia and Book Corpus) and continue pretraining on the corresponding domain/task-relevant unlabeled data (Section 2). Inspired by the nomenclature in (Gururangan et al., 2020), we refer to this model as Adaptively Pretrained $\text{BERT}_{\text{Base}}$. Further, we perform fine-tuning on the downstream task data, as with the previous BERT models.

4 Results

We present here metrics-based and resource-based comparison of CVT and BERT models on all tasks. State-of-the-art (SOTA) baselines are included for reference.

Results on CONLL-2003 dataset

Model	Unlabeled Data	Mean F1
CVT	CNN-DM (∼17M)	92.26±0.11
$\text{BERT}_{\text{Base}}$	Wiki+Books (∼192M)	91.22±0.21
Pre-$\text{BERT}_{\text{Base}}$	CNN-DM (∼146M)	85.54±0.19
AP$\text{BERT}_{\text{Base}}$	CNN-DM (∼138M)	88.02±0.18
Cloze	Wiki+Books (∼192M)	**93.5**

Results on CONLL-2012 dataset

Model	Unlabeled Data	Mean F1
CVT	CNN-DM (∼18M)	89.26±0.1
$\text{BERT}_{\text{Base}}$	Wiki+Books (∼192M)	89.0±0.23
Pre-$\text{BERT}_{\text{Base}}$	CNN-DM (∼146M)	84.20±0.19
AP$\text{BERT}_{\text{Base}}$	CNN-DM (∼138M)	85.88±0.17
BERT-MRC+DSC	Wiki+Books (∼192M)	**92.07**

Table 3: Model performance for NER. The *same* unlabeled dataset is used for training CVT, Pre-$\text{BERT}_{\text{Base}}$ and AP$\text{BERT}_{\text{Base}}$, and **Unlabeled Data** indicates the approximate number of sentences seen by each model during training, until convergence criteria is met. Cloze (Baevski et al., 2019) and BERT-MRC+DSC (Li et al., 2019) are SOTA baselines for CONLL-2003 and CONLL-2012, respectively, for this task. Baevski et al. (2019) also use subsampled Common Crawl and News Crawl datasets but do not provide exact splits for these.

Performance Metrics We report mean F1 (with standard deviation) on the labeled test splits for each task over 5 randomized runs, and compare the models using statistical significance tests over these runs. Further, we report the approximate number of unlabeled sentences seen by each model. Table 2 shows the results for the OTE detection task. Here, out of the 3 BERT-based variations, the best result is achieved by the AP$\text{BERT}_{\text{Base}}$ model across both SemEval datasets. For SemEval2016 Restaurants, we find the mean F1 from the AP$\text{BERT}_{\text{Base}}$ model to be comparable to that of CVT (p-value 0.26). Both models outperform the SOTA baseline. For SemEval2014 Laptops, AP$\text{BERT}_{\text{Base}}$ is found to have a statistically significant (p-value 0.04) higher F1 than CVT, and both models outperform SOTA.

In Tables 3 and 4, we present F1 results on NER and Slot-labeling task, respectively. For all 3 datasets, we find CVT to outperform all BERT models (statistically significant for CONLL-2003 and MIT Movies dataset, at p-values 0.0086 and 0.0085, respectively). For these tasks, $\text{BERT}_{\text{base}}$ outperforms AP$\text{BERT}_{\text{Base}}$ models. Furthermore, CVT outperforms SOTA for Slot-labeling task.

These results show that the CVT model, using unlabeled data in a task-specific manner, is more robust across different tasks and types of unlabeled data.

Model	Unlabeled Data	Mean F1
CVT	IMDb (∼24.1M)	**88.16±0.12**
$\text{BERT}_{\text{Base}}$	Wiki+Books (∼192M)	86.91±0.36
$\text{Pre-BERT}_{\text{Base}}$	IMDb (∼30.7M)	85.77±0.57
$\text{APBERT}_{\text{Base}}$	IMDb (∼30M)	86.78±0.1
HSCRF + softdict	-	87.41

Table 4: Model performance for Slot-labeling. The *same* unlabeled dataset is used for training CVT, Pre-$\text{BERT}_{\text{Base}}$ and $\text{APBERT}_{\text{Base}}$, and **Unlabeled Data** indicates the approximate number of sentences seen by each model during training, until convergence criteria is met. HSCRF + softdict (Louvan and Magnini, 2018) is the SOTA baseline for this task.

For OTE detection, the unlabeled data is closely related to both domain and task, while for NER and Slot-labeling, the unlabeled data is related to genre (newswire) and domain (movies), but not necessarily to the specific tasks. In line with the findings of Gururangan et al. (2020), Adaptive Pre-training shows best results when using unlabeled data that is domain and task relevant (superior results for the OTE task). It is also worth noting that CVT requires significantly smaller amount of unlabeled data than the BERT models (Tables 2, 3 and 4).

Model	HW	Hours	Cost	Power	CO_2
CVT	1/8	56	172	14.82	14.14
$\text{Pre-BERT}_{\text{Base}}$	8/64	85	2081	273.62	261.04
$\text{APBERT}_{\text{Base}}$	8/64	80	1958	260.63	248.64

Table 5: Estimated CO_2 emissions and computational cost for CVT and BERT models, using models trained on Yelp Restaurants (Yelp-R) as an example. These computations hold for other tasks and datasets discussed in this work. *HW* (hardware) refers to #GPUs/#CPUs used. *Cost* refers to approximate cost in USD. *Power* stands for total power consumption (in kWh) as combined GPU, CPU and DRAM consumption, multiplied by Power Usage Effectiveness (PUE) coefficient to account for additional energy needed for infrastructure support (Strubell et al., 2019). *CO_2* represents CO_2 emissions in pounds.

Resource Cost Table 5 shows computational cost and environmental impact by means of estimated CO_2 emissions occurring during training. We use the procedure described by Strubell et al. (2019). Tesla V100 GPUs are used for training. For computational cost, we refer to the average cost per hour for the training instances used.[6] To compute energy consumed, we query the NVIDIA System Management Interface [7] multiple times during training, to note the average GPU power consumption. For CPU and DRAM power usage, we use Linux's turbostat package.[8] The models trained using Yelp Restaurants unlabeled data are used as an example in Table 5, but the same computations hold for other models. Note that we do not perform initial pretraining of $\text{BERT}_{\text{base}}$ nor pretrain the Glove 840B.300d embeddings used in CVT, but these come at a one-time cost that we consider constant. Worth noting though, that $\text{BERT}_{\text{base}}$ pretraining is more expensive than Glove pretraining. As is evident, training the CVT model incurs much less financial cost than the corresponding BERT models (∼11x lower than $\text{APBERT}_{\text{base}}$), while also emitting lesser CO_2 emissions (∼18x lower than $\text{APBERT}_{\text{base}}$).[9]

5 Conclusion & Future Work

We compare the task-specific semi-supervised method, CVT, with a task-agnostic semi-supervised approach, BERT (with and without adaptive pretraining), on a variety of problems that can be modeled as sequence tagging tasks. We find that the CVT-based approach is more robust than BERT-based models across tasks and types of unsupervised data available to them. Furthermore, the financial and environmental costs incurred are also significantly lower using CVT as compared to BERT.

As part of future work, we will explore CVT on other sequence-labeling tasks such as chunking, elementary discourse unit segmentation and argumentative discourse unit segmentation, thus moving beyond entity-level spans. Moreover, other supervised tasks such as classification could also be studied in this context. Furthermore, we intend to implement CVT as a training strategy over Transformers (BERT) and compare it with Adaptively-Pretrained BERT.

[8] `http://manpages.ubuntu.com/manpages/xenial/man8/turbostat.8.html`

[9] If we consider just fine-tuning $\text{BERT}_{\text{Base}}$ on the supervised data of the downstream task (OTE detection on SemEval2016 Restaurants Data) the numbers corresponding to Table 5 are: HW: 1/8, Hours: 0.283, Cost: 0.87, Power: 0.094, CO_2: 0.09. Although fine-tuning BERT on the downstream task (using supervised data) is relatively cheap, and one could amortize the cost of pre-training BERT over a large number of such tasks, this requires an understanding of what the number and type of such tasks are.

A Appendices

A.1 Source Code and Data Preprocessing Steps

For CVT, we use the official author-provided codebase.[10] The unlabeled datasets are preprocessed to have one sentence per line using NLTK's sentence tokenizer [11], as required by the model. For BERT pretraining, we use GluonNLP's open-source code.[12] For each unlabeled dataset, we create a randomly sampled validation set of about 30K samples during these experiments. Unlabeled data is processed to be in the required format.[13]

A.2 Model Hyperparameters, Training Details and Validation F1

Here, we enlist the hyperparameters used for each model, and describe the training process. conlleval is used as the evaluation metric for each of the models.[14]

CVT: A batch-size of 64 is used for both labeled and unlabeled data. We use character embeddings of size 50, with char CNN filter widths of [2,3,4], and 300 char CNN filters. Encoder LSTMs have sizes 1024 and 512, respectively for the 1st and 2nd layer, with a projection size of 512. Dropout of 0.5 for labeled examples and 0.8 for unlabeled examples is used. Base learning rate of 0.5 is used, with an adaptive learning rate scheme, using SGD with Momentum as the optimizer.

Pretrained BERT$_{\text{Base}}$ (Pre-BERT$_{\text{Base}}$) and Adaptive Pretraining BERT$_{\text{Base}}$ (APBERT$_{\text{Base}}$): Batch-size of 256 is used during training. Number of steps for gradient accumulation is set to 4. BERTAdam is used as optimizer. Base learning rate used of 0.0001 is used, which is adaptive w.r.t. the number of steps. Maximum input sequence length is set to 512.

Table 6: Validation Set Metrics for all Models

Steps at which Pre-BERT$_{\text{Base}}$ models converge are ∼1.02M for Yelp Restaurants and Amazon Electronics, ∼570K for CNN DailyMail, ∼119K for IMDb. Model convergence steps for APBERT$_{\text{Base}}$were ∼960K for Yelp-R, ∼930K for Amazon-E, ∼539K for CNN-DM, ∼117K for IMDb.

BERT$_{\text{Base}}$ Sequence Tagging model: Batch size for *supervised* fine-tuning on the downstream task is 10. We perform manual hyperparameter tuning over learning rate (0.00001, 0.0001 and 0.001) and dropout (0.0 to 0.5 in steps of 0.1). Validation F1 is used to select the best set of hyper-parameters which were learning rate of 0.00001, dropout of 0.0 for NER and Slot-labeling, and 0.1 for OTE detection.

We demonstrate mean validation set F1 numbers for each task and dataset in Table 6.

Cold-start Active Learning through Self-supervised Language Modeling

Abstract

Active learning strives to reduce annotation costs by choosing the most critical examples to label. Typically, the active learning strategy is contingent on the classification model. For instance, uncertainty sampling depends on poorly calibrated model confidence scores. In the cold-start setting, active learning is impractical because of model instability and data scarcity. Fortunately, modern NLP provides an additional source of information: pre-trained language models. The pre-training loss can find examples that surprise the model and should be labeled for efficient fine-tuning. Therefore, we treat the language modeling loss as a proxy for classification uncertainty. With BERT, we develop a simple strategy based on the masked language modeling loss that minimizes labeling costs for text classification. Compared to other baselines, our approach reaches higher accuracy within less sampling iterations and computation time.

1 Introduction

Labeling data is a fundamental bottleneck in machine learning, especially for NLP, due to annotation cost and time. The goal of active learning (AL) is to recognize the most relevant examples and then query labels from an oracle. For instance, policymakers and physicians want to quickly fine-tune a text classifier to understand emerging medical conditions (Voorhees et al., 2020). Finding labeled data for medical text is challenging because of privacy issues or shortage in expertise (Dernoncourt and Lee, 2017). Using AL, they can query labels for a small subset of the most relevant documents and immediately train a robust model.

Modern transformer models dominate the leaderboards for several NLP tasks (Devlin et al., 2019; Yang et al., 2019). Yet the price of adopting transformer-based models is to use more data. If these models are not fine-tuned on enough examples, their accuracy drastically varies across different hyperparameter configurations (Dodge et al., 2020). Moreover, computational resources are a major drawback as training one model can cost thousands of dollars in cloud computing and hundreds of pounds in carbon emissions (Strubell et al., 2019). These problems motivate further work in AL to conserve resources.

Another issue is that traditional AL algorithms, like uncertainty sampling (Lewis and Gale, 1994), falter on deep models. These strategies use model confidence scores, but neural networks are poorly calibrated (Guo et al., 2017). High confidence scores do not imply high correctness likelihood, so the sampled examples are not the most uncertain ones (Zhang et al., 2017). Plus, these strategies sample one document on each iteration. The single-document sampling requires training the model after each query and increases the overall expense.

These limitations of modern NLP models illustrate a twofold effect: they show a greater need for AL *and* make AL more difficult to deploy. Ideally, AL could be most useful during low-resource situations. In reality, it is impractical to use because the AL strategy depends on warm-starting the model with information about the task (Ash and Adams, 2019). Thus, a fitting solution to AL for deep classifiers is a *cold-start* approach, one that does not rely on classification loss or confidence scores.

To develop a cold-start AL strategy, we should extract knowledge from pre-trained models like BERT (Devlin et al., 2019). The model encodes syntactic properties (Tenney et al., 2019), acts as a database for general world knowledge (Petroni et al., 2019; Davison et al., 2019), and can detect out-of-distribution examples (Hendrycks et al., 2020). Given the knowledge already encoded in pre-trained models, the annotation for a new task

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7935–7948,
November 16–20, 2020.

should focus on the information missing from pre-training. If a sentence contains many words that perplex the language model, then it is possibly unusual or not well-represented in the pre-training data. Thus, the self-supervised objective serves as a surrogate for classification uncertainty.

We develop ALPS (Active Learning by Processing Surprisal), an AL strategy for BERT-based models.[1] While many AL methods randomly choose an initial sample, ALPS selects the first batch of data using the masked language modeling loss. As the highest and most extensive peaks in Europe are found in the Alps, the ALPS algorithm finds examples in the data that are both surprising and substantial. To the best of our knowledge, ALPS is the first AL algorithm that only relies on a self-supervised loss function. We evaluate our approach on four text classification datasets spanning across three different domains. ALPS outperforms AL baselines in accuracy and algorithmic efficiency. The success of ALPS highlights the importance of self-supervision for cold-start AL.

2 Preliminaries

We formally introduce the setup, notation, and terminology that will be used throughout the paper.

Pre-trained Encoder Pre-training uses the language modeling loss to train encoder parameters for generalized representations. We call the model input $x = (w_i)_{i=1}^{l}$ a "sentence", which is a sequence of tokens w from a vocabulary $\mathcal{V}$ with sequence length l. Given weights W, the encoder h maps x to a d-dimensonal hidden representation $h(x; W)$. We use BERT (Devlin et al., 2019) as our data encoder, so h is pre-trained with two tasks: masked language modeling (MLM) and next sentence prediction. The embedding $h(x; W)$ is computed as the final hidden state of the `[CLS]` token in x. We also refer to $h(x; W)$ as the BERT embedding.

Fine-tuned Model We fine-tune BERT on the downstream task by training the pre-trained model and the attached sequence classification head. Suppose that f represents the model with the classification head, has parameters $\theta = (W, V)$, and maps input x to a C-dimensional vector with confidence scores for each label. Specifically, $f(x; \theta) = \sigma(V \cdot h(x; W))$ where σ is a softmax function.

Let D be the labeled data for our classification task where the labels belong to set $\mathcal{Y} = \{1, ..., C\}$. During fine-tuning, we take a base classifier f with weights W_0 from a pre-trained encoder h and fine-tune f on D for new parameters θ_t. Then, the predicted classification label is $\hat{y} = \arg\max_{y \in \mathcal{Y}} f(x; \theta_t)_y$.

Algorithm 1 AL for Sentence Classification

```
Require: Inital model $f(x;\theta_0)$ with pre-trained encoder $h(x;W_0)$, unlabeled data pool $\mathcal{U}$, number of queries per iteration $k$, number of iterations $T$, sampling algorithm $\mathcal{A}$
$\mathcal{D} = \{\}$
for iterations $t = 1, \ldots, T$ do
    if $\mathcal{A}$ is cold-start for iteration $t$ then
        $M_t(x) = f(x;\theta_0)$
    else
        $M_t(x) = f(x;\theta_{t-1})$
    $\mathcal{Q}_t \leftarrow$ Apply $\mathcal{A}$ on model $M_t(x)$, data $\mathcal{U}$
    $\mathcal{D}_t \leftarrow$ Label queries $\mathcal{Q}_t$
    $\mathcal{D} = \mathcal{D} \cup \mathcal{D}_t$
    $\mathcal{U} = \mathcal{U} \setminus \mathcal{D}_t$
    $\theta_t \leftarrow$ Fine-tune $f(x;\theta_0)$ on $\mathcal{D}$
return $f(x;\theta_T)$
```

AL for Sentence Classification Assume that there is a large unlabeled dataset $U = \{(x_i)\}_{i=1}^{n}$ of n sentences. The goal of AL is to sample a subset $D \subset U$ efficiently so that fine-tuning the classifier f on subset D improves test accuracy. On each iteration t, the learner uses strategy $\mathcal{A}$ to acquire k sentences from dataset U and queries for their labels (Algorithm 1). Strategy $\mathcal{A}$ usually depends on an acquisition model M_t (Lowell and Lipton, 2019). If the strategy depends on model warm-starting, then the acquisition model M_t is f with parameters θ_{t-1} from the previous iteration. Otherwise, we assume that M_t is the pre-trained model with parameters θ_0. After T rounds, we acquire labels for Tk sentences. We provide more concrete details about AL simulation in Section 5.

3 The Uncertainty–Diversity Dichotomy

This section provides background on prior work in AL. First, we discuss two general AL strategies: uncertainty sampling and diversity sampling. Then, we explain the dichotomy between the two concepts and introduce BADGE (Ash et al., 2020), a SOTA method that attempts to resolve this issue. Finally, we focus on the limitations of BADGE and other AL strategies to give motivation for our work.

---

[1] `https://github.com/forest-snow/alps`

Dasgupta (2011) describes uncertainty and diversity as the "two faces of AL". While uncertainty sampling efficiently searches the hypothesis space by finding difficult examples to label, diversity sampling exploits heterogeneity in the feature space (Xu et al., 2003; Hu et al., 2010; Bodó et al., 2011). Uncertainty sampling requires model warm-starting because it depends on model predictions, whereas diversity sampling can be a cold-start approach. A successful AL strategy should integrate both aspects, but its exact implementation is an open research question. For example, a naïve idea is to use a fixed combination of strategies to sample points. Nevertheless, Hsu and Lin (2015) experimentally show that this approach hampers accuracy. BADGE optimizes for both uncertainty and diversity by using confidence scores and clustering. This strategy beats uncertainty-based algorithms (Wang and Shang, 2014), sampling through bandit learning (Hsu and Lin, 2015), and CORESET (Sener and Savarese, 2018), a diversity-based method for convolutional neural networks.

3.1 BADGE

The goal of BADGE is to sample a diverse and uncertain batch of points for training neural networks. The algorithm transforms data into representations that encode model confidence and then clusters these transformed points. First, an unlabeled point x passes through the trained model to obtain its predicted label $\hat{y}$. Next, a **gradient embedding** g_x is computed for x such that it embodies the gradient of the cross-entropy loss on $(f(x;\theta), \hat{y})$ with respect to the parameters of the model's last layer. The gradient embedding is

$$(g_x)_i = (f(x;\theta)_i - \mathbb{1}(\hat{y} = i))h(x;W). \quad (1)$$

The i-th block of g_x is the hidden representation $h(x;W)$ scaled by the difference between model confidence score $f(x;\theta)_i$ and an indicator function $\mathbb{1}$ that indicates whether the predictive label $\hat{y}$ is label i. Finally, BADGE chooses a batch to sample by applying k-MEANS++ (Arthur and Vassilvitskii, 2006) on the gradient embeddings. These embeddings consist of model confidence scores and hidden representations, so they encode information about both uncertainty and the data distribution. By applying k-MEANS++ on the gradient embeddings, the chosen examples differ in feature representation and predictive uncertainty.

3.2 Limitations

BADGE combines uncertainty and diversity sampling to profit from advantages of both methods but also brings the downsides of both: reliance on warm-starting and computational inefficiency.

3.2.1 Model Uncertainty and Inference

Dodge et al. (2020) observe that training is highly unstable when fine-tuning pre-trained language models on small datasets. Accuracy significantly varies across different random initializations. The model has not fine-tuned on enough examples, so model confidence is an unreliable measure for uncertainty. While BADGE improves over uncertainty-based methods, it still relies on confidence scores $f(x;\theta)_i$ when computing the gradient embeddings (Equation 1). Also, it uses labels inferred by the model to compensate for lack of supervision in AL, but this inference is inaccurate for ill-trained models. Thus, warm-start methods may suffer from problems with model uncertainty or inference.

3.2.2 Algorithmic Efficiency

Many diversity-based methods involve distance comparison between embedding representations, but this computation can be expensive, especially in high-dimensional space. For instance, CORESET is a farthest-first traversal in the embedding space where it chooses the farthest point from the set of points already chosen on each iteration (Sener and Savarese, 2018). The embeddings may appropriately represent the data, but issues, like the "curse of dimensionality" (Beyer et al., 1999) and the "hubness problem" (Tomasev et al., 2013), persist. As the dimensionality increase, the distance between any two points converges to the same value. Moreover, the gradient embeddings in BADGE have dimensionality of Cd for a C-way classification task with data dimensionality of d (Equation 1). These issues make distance comparison between gradient embeddings less meaningful and raises costs to compute those distances.

4 A Self-supervised Active Learner

Cold-start AL is challenging because of the shortage in labeled data. Prior work, like BADGE, often depend on model uncertainty or inference, but these measures can be unreliable if the model has not trained on enough data (Section 3.2.1). To overcome the lack of supervision, what if we apply self-supervision to AL? For NLP, the language modeling task is self-supervised because the label

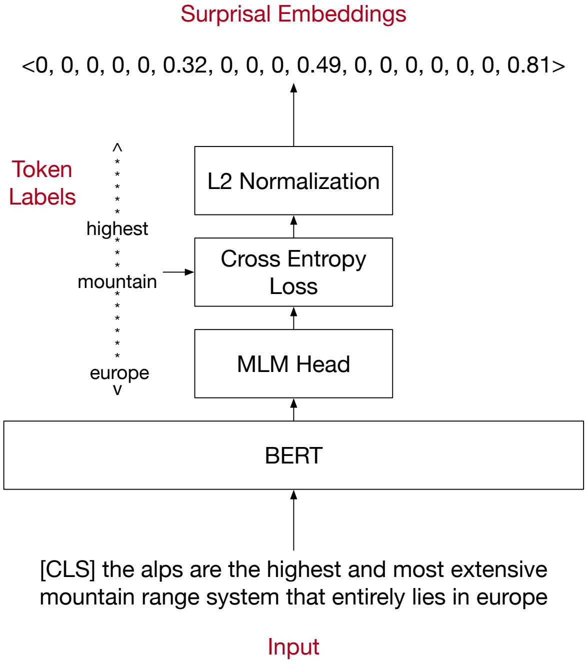

Figure 1: To form surprisal embedding s_x for sentence x, we pass in unmasked x through the BERT MLM head and compute cross-entropy loss for a random 15% subsample of tokens against the target labels. The unsampled tokens have entries of zero in s_x. ALPS clusters these surprisal embeddings to sample sentences for AL.

for each token is the token itself. If the task has immensely improved transfer learning, then it may reduce generalization error in AL too.

For our approach, we adopt the uncertainty-diversity BADGE framework for clustering embeddings that encode information about uncertainty. However, rather than relying on the classification loss gradient, we use the MLM loss to bootstrap uncertainty estimates. Thus, we combine uncertainty and diversity sampling for cold-start AL.

4.1 Masked Language Modeling

To pre-train BERT with MLM, input tokens are randomly masked, and the model needs to predict the token labels of the masked tokens. BERT is bidirectional, so it uses context from the left and right of the masked token to make predictions. BERT also uses next sentence prediction for pre-training, but this task shows minimal effect for fine-tuning (Liu et al., 2019). So, we focus on applying MLM to AL. The MLM head can capture syntactic phenomena (Goldberg, 2019) and performs well on psycholinguistic tests (Ettinger, 2020).

Algorithm 2 Single iteration of ALPS

```
Require: Pre-trained encoder $h(x; W_0)$, unlabeled data pool $\mathcal{U}$, number of queries $k$
for sentences $x \in \mathcal{U}$ do
    Compute $s_x$ with MLM head of $h(x; W_0)$
$\mathcal{M} = \{s_x \mid x \in \mathcal{U}\}$
$\mathcal{C} \leftarrow k$-MEANS cluster centers of $\mathcal{M}$
$\mathcal{Q} = \{\arg\min_{x \in \mathcal{U}} \|c - s_x\| \mid c \in \mathcal{C}\}$
return $\mathcal{Q}$
```

4.2 ALPS

Surprisal Embeddings Inspired by how BADGE forms gradient embeddings from the classification loss, we create **surprisal embeddings** from language modeling. For sentence x, we compute surprisal embedding s_x by evaluating x with the MLM objective. To evaluate MLM loss, BERT randomly masks 15% of the tokens in x and computes cross-entropy loss for the masked tokens against their true token labels. When computing surprisal embeddings, we make one crucial change: *none of the tokens are masked when the input is passed into* BERT. However, we still randomly choose 15% of the tokens in the input to evaluate with cross-entropy against their target token labels. The unchosen tokens are assigned a loss of zero as they are not evaluated (Figure 1).

These decisions for not masking input (Appendix A.1) and evaluating only 15% of tokens (Appendix A.2) are made because of experiments on the validation set. Proposition 1 provides insight on the information encoded in surprisal embeddings. Finally, the surprisal embedding is l_2-normalized as normalization improves clustering (Aytekin et al., 2018). If the input sentences have a fixed length of l, then the surprisal embeddings have dimensionality of l. The length l is usually less than the hidden size of BERT embeddings.

Proposition 1. *For an unnormalized surprisal embedding s_x, each nonzero entry $(s_x)_i$ estimates $I(w_i)$, the surprisal of its corresponding token within the context of sentence x.*

Proof. Extending notation from Section 2, assume that m is the MLM head, with parameters $\phi = (W, Z)$, which maps input x to a $l \times |\mathcal{V}|$ matrix $m(x; \phi)$. The ith row $m(x; \phi)_i$ contains prediction scores for w_i, the ith token in x. Suppose that w_i is the jth token in vocabulary $\mathcal{V}$. Then, $m(x; \phi)_{i,j}$ is the likelihood of predicting w_i correctly.

Now, assume that context is the entire input x and define the language model probability p_m as,

$$p_m(w_i \mid x) = m(x; \phi)_{i,j}. \tag{2}$$

Salazar et al. (2020) have a similar definition as Equation 2 but instead have defined it in terms of the masked input. We argue that their definition can be extended to the unmasked input x. During BERT pre-training, the MLM objective is evaluated on the `[MASK]` token for 80% of the time, random token for 10% of the time, and the original token for 10% of the time. This helps maintain consistency across pre-training and fine-tuning because `[MASK]` never appears in fine-tuning (Devlin et al., 2019). Thus, we assume that m estimates occurrence of tokens within a maskless context as well.

Next, the information-theoretic surprisal (Shannon, 1948) is defined as $I(w) = -\log p(w \mid c)$, the negative log likelihood of word w given context c. If w_i is sampled and evaluated, then the ith entry of the unnormalized surprisal embedding is,

$$\begin{aligned}(s_x)_i &= -\log m(x; \phi)_{i,j} = -\log p_m(w_i \mid x)\\ &= I(w_i).\end{aligned}$$

□

Proposition 1 shows that the surprisal embeddings comprise of estimates for token-context surprisal. Intuitively, these values can help with AL because they highlight the information missing from the pre-trained model. For instance, consider the sentences: "this is my favorite television show" and "they feel ambivalent about catholic psychedelic synth folk music". Tokens from the latter have higher surprisal than those from the former. If this is a sentiment classification task, the second sentence is more confusing for the classifier to learn. The surprisal embeddings indicate sentences challenging for the pre-trained model to understand and difficult for the fine-tuned model to label.

The most surprising sentences contain many rare tokens. If we only train our model on the most surprising sentences, then it may not generalize well across different examples. Plus, we may sample several atypical sentences that are similar to each other, which is often an issue for uncertainty-based methods (Kirsch et al., 2019). Therefore, we incorporate clustering in ALPS to maintain diversity.

k-MEANS Clustering After computing surprisal embeddings for each sentence in the unlabeled pool, we use k-MEANS to cluster the surprisal embeddings. Then, for each cluster center, we select the sentence that has the nearest surprisal embedding to it. The final set of sentences are the queries to be labeled by an oracle (Algorithm 2). Although BADGE uses k-MEANS++ to cluster, experiments show that k-MEANS works better for surprisal embeddings (Appendix A.3).

5 Active Sentence Classification

We evaluate ALPS on sentence classification for three different domains: sentiment reviews, news articles, and medical abstracts (Table 1). To simulate AL, we sample a batch of 100 sentences from the training dataset, query labels for this batch, and then move the batch from the unlabeled pool to the labeled dataset (Algorithm 1). The initial encoder $h(x; \theta_0)$, is an already pre-trained, BERT-based model (Section 5.2). In a given iteration, we fine-tune the base classifier $f(x; \theta_0)$ on the labeled dataset and evaluate the fine-tuned model with classification micro-F_1 score on the test set. We do not fine-tune the model $f(x; \theta_{t-1})$ from the previous iteration to avoid issues with warm-starting (Ash and Adams, 2019). We repeat for ten iterations, collecting a total of 1,000 sentences.

5.1 Baselines

We compare ALPS against warm-start methods (Entropy, BADGE, FT-BERT-KM) and cold-start methods (Random, BERT-KM). For FT-BERT-KM, we use BERT-KM to sample data in the first iteration. For other warm-start methods, data is randomly sampled in the first iteration.

Entropy Sample k sentences with highest predictive entropy measured by $\sum_{i=1}^{C}(f(x;\theta)_i)\ln(f(x;\theta)_i)^{-1}$ (Lewis and Gale, 1994; Wang and Shang, 2014).

BADGE Sample k sentences based on diversity in loss gradient (Section 3.1).

BERT-KM Cluster pre-trained, l_2-normalized BERT embeddings with k-MEANS and sample the nearest neighbors of the k cluster centers. The algorithm is the same as ALPS except that BERT embeddings are used.

FT-BERT-KM This is the same algorithm as BERT-KM except the BERT embeddings $h(x; W_{t-1})$ from the previously fine-tuned model are used.

Dataset	Domain	Train	Dev	Test	# Labels
AG NEWS	News articles	110,000	10,000	7,600	4
IMDB	Sentiment reviews	17,500	7,500	25,000	2
PUBMED 20k RCT	Medical abstracts	180,040	30,212	30,135	5
SST-2	Sentiment reviews	60,615	6,736	873	2

Table 1: Sentence classification datasets used in experiments.

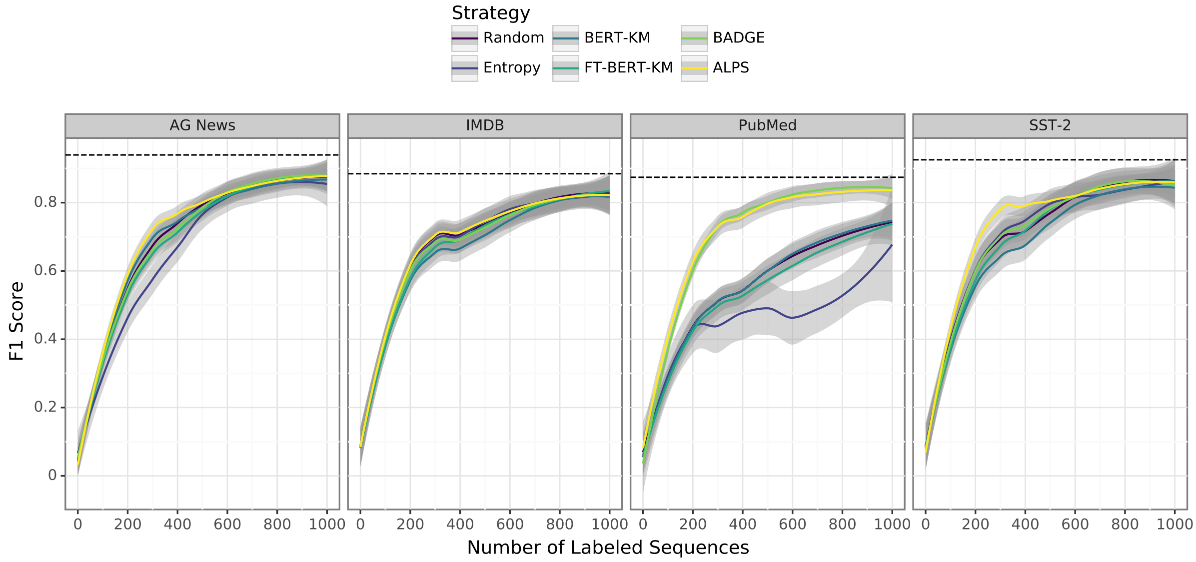

Figure 2: Test accuracy of simulated AL over ten iterations with 100 sentences queried per iteration. The dashed line is the test accuracy when the model is fine-tuned on the entire dataset. Overall, models trained with data sampled from ALPS have the highest test accuracy, especially for the earlier iterations.

5.2 Setup

For each sampling algorithm and dataset, we run the AL simulation five times with different random seeds. We set the maximum sequence length to 128. We fine-tune on a batch size of thirty-two for three epochs. We use AdamW (Loshchilov and Hutter, 2019) with learning rate of 2e-5, $\beta_1 = 0.9$, $\beta_2 = 0.999$, and a linear decay of learning rate.

For IMDB (Maas et al., 2011), SST-2 (Socher et al., 2013), and AG NEWS (Zhang et al., 2015), the data encoder is the uncased BERT-Base model with 110M parameters.[2] For PUBMED (Dernoncourt and Lee, 2017), the data encoder is SCIBERT, a BERT model pre-trained on scientific texts (Beltagy et al., 2019). All experiments are run on GeForce GTX 1080 GPU and 2.6 GHz AMD Opteron 4180 CPU processor; runtimes in Table 2.

5.3 Results

The model fine-tuned with data sampled by ALPS has higher test accuracy than the baselines (Figure 2). For AG NEWS, IMDB, and SST-2, this is true in earlier iterations. We often see the most gains in the beginning for crowdsourcing (Felt et al., 2015). Interestingly, clustering the fine-tuned BERT embeddings is not always better than clustering the pre-trained BERT embeddings for AL. The fine-tuned BERT embeddings may require training on more data for more informative representations.

For PUBMED, test accuracy greatly varies between the strategies. The dataset belongs to a specialized domain and is class-imbalanced, so naïve methods show poor accuracy. Entropy sampling has the lowest accuracy because the classification entropy is uninformative in early iterations. The models fine-tuned on data sampled by ALPS and BADGE have about the same accuracy. Both methods strive to optimize for uncertainty and diversity, which alleviates problems with class imbalance.

	AG NEWS	PUBMED
Random	<1	<1
Entropy	7	10
ALPS	14	24
BADGE	23	70
BERT-KM	28	58
FT-BERT-KM	33	79

Table 2: Average runtime (minutes) per sampling iteration during AL simulation for large datasets. BADGE, FT-BERT-KM, and BERT-KM take much longer to run.

Our experiments cover the first ten iterations because we focus on the cold-start setting. As sampling iterations increase, test accuracy across the different methods converges. Both ALPS and BADGE already approach the model trained on the full training dataset across all tasks (Figure 2). Once the cold-start issue subsides, uncertainty-based methods can be employed to further query the most confusing examples for the model to learn.

6 Analyzing ALPS

Sampling Efficiency Given that the gradient embeddings are computed, BADGE has a time complexity of $\mathcal{O}(Cknd)$ for a C-way classification task, k queries, n points in the unlabeled pool, and d-dimensional BERT embeddings. Given that the surprisal embeddings are computed, ALPS has a time complexity of $\mathcal{O}(tknl)$ where t is the fixed number of iterations for k-MEANS and l is the maximum sequence length. In our experiments, $k = 100$, $d = 768$, $t = 10$, and $l = 128$. In practice, t will not change much, but n and C could be much higher. For large dataset PUBMED, the average runtime per iteration is 24 minutes for ALPS and 70 minutes for BADGE (Table 2). So, ALPS can match BADGE's accuracy more quickly.

Diversity and Uncertainty We estimate diversity and uncertainty for data sampled across different strategies. For diversity, we look at the overlap between tokens in the sampled sentences and tokens from the rest of the data pool. A diverse batch of sentences should share many of the same tokens with the data pool. In other words, the sampled sentences can represent the data pool because of the substantial overlap between their tokens. In our simulations, the entire data pool is the training dataset (Section 5). So, we compute the Jaccard similarity between $\mathcal{V}_D$, set of tokens from the sampled sentences $\mathcal{D}$, and $\mathcal{V}_{D'}$, set of tokens from the unsampled sentences $\mathcal{U} \setminus \mathcal{D}$,

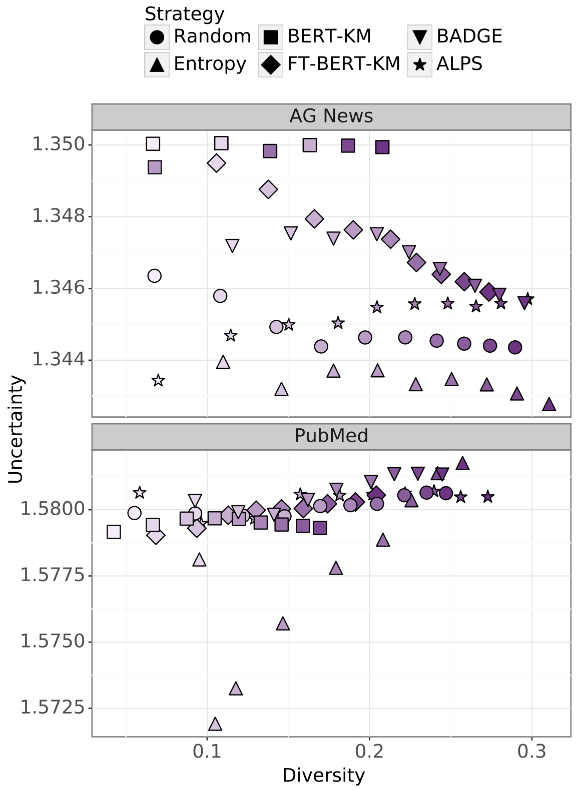

Figure 3: Plot of diversity against uncertainty estimates from AL simulations for AG NEWS and PUBMED. Each point represents a sampled batch of sentences from the AL experiments. The shape indicates the strategy used to sample the sentences. The color indicates the sample iteration. The lightest color corresponds to the first iteration and the darkest color represents the tenth iteration. While uncertainty estimates are similar across different batches, ALPS shows a consistent increase in diversity without drops in uncertainty.

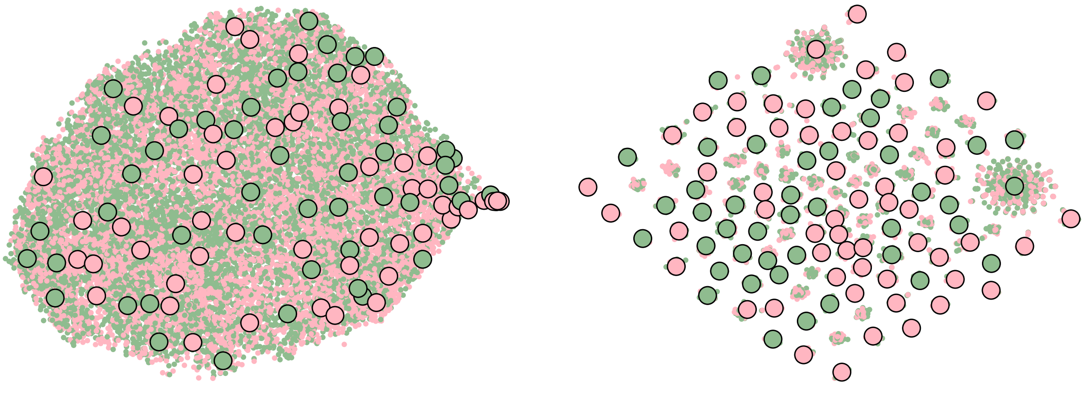
$$G_d(\mathcal{D}) = J(\mathcal{V}_D, \mathcal{V}_{D'}) = \frac{|\mathcal{V}_D \cap \mathcal{V}_{D'}|}{|\mathcal{V}_D \cup \mathcal{V}_{D'}|}. \quad (3)$$

If G_d is high, this indicates high diversity because the sampled and unsampled sentences have many tokens in common. If G_d is low, this indicates poor diversity and representation.

To measure uncertainty, we use $f(x, \theta_*)$, the classifier trained on the full training dataset. In our experiments, classifier $f(x, \theta_*)$ has high accuracy (Figure 2) and inference is stable after training on many examples. Thus, we can use the logits from the classifier to understand its uncertainty toward a particular sentence. First, we compute predictive entropy of sentence x when evaluated by model $f(x, \theta_*)$. Then, we take the average of predictive



(a) BERT embeddings with k-MEANS centers (b) Surprisal embeddings with k-MEANS centers

Figure 4: T-SNE plots of BERT embeddings and surprisal embeddings for each sequence in the IMDB training dataset. The enlarged points are the centers determined by k-MEANS (left) and k-MEANS++ (right). The points are colored according to their classification labels. In both sets of embeddings, we cannot clearly separate the points from their labels, but the distinction between clusters in surprisal embeddings seems more obvious.

entropy over all sentences in a sampled batch $\mathcal{D}$. We use the average predictive entropy to esimate uncertainty of the sampled sentences,

$$G_u(\mathcal{D}) = \frac{1}{|\mathcal{D}|} \sum_{x \in \mathcal{D}} \sum_{i=1}^{C} (f(x;\theta_*)_i) \ln(f(x;\theta_*)_i)^{-1}. \tag{4}$$

We compute G_d and G_u for batches sampled in the AL experiments of AG NEWS and PUBMED. Diversity is plotted against uncertainty for batches sampled across different iterations and AL strategies (Figure 3). For AG NEWS, G_d and G_u are relatively low for ALPS in the first iteration. As iterations increase, samples from ALPS increase in diversity and decrease minimally in uncertainty. Samples from other methods have a larger drop in uncertainty as iterations increase. For PUBMED, ALPS again increases in sample diversity without drops in uncertainty. In the last iteration, ALPS has the highest diversity among all the algorithms.

Surprisal Clusters Prior work use k-MEANS to cluster feature representations as a cold-start AL approach (Zhu et al., 2008; Bodó et al., 2011). Rather than clustering BERT embeddings, ALPS clusters surprisal embeddings. We compare the clusters between surprisal embeddings and BERT embeddings to understand the structure of the surprisal clusters. First, we use t-SNE (Maaten and Hinton, 2008) to plot the embeddings for each sentence in the IMDB training set (Figure 4). The labels are not well-separated for both embedding sets, but the surprisal embeddings seem easier to cluster. To quantitively measure cluster quality, we use the Silhouette Coefficient for which larger values indicate desirable clustering (Rousseeuw, 1987). The surprisal clusters have a coefficient of 0.38, whereas the BERT clusters have a coefficient of only 0.04.

These results, along with the classification experiments, show that naïvely clustering BERT embeddings is not suited for AL. Possibly, more complicated clustering algorithms can capture the intrinsic structure of the BERT embeddings. However, this would increase the algorithmic complexity and runtime. Alternatively, one can map the feature representations to a space where simple clustering algorithms work well. During this transformation, important information for AL must be preserved and extracted. Our approach uses the MLM head, which has already been trained on extensive corpora, to map the BERT embeddings into the surprisal embedding space. As a result, simple k-MEANS can efficiently choose representative sentences.

Single-iteration Sampling In Section 5, we sample data iteratively (Algorithm 1) to fairly compare the different AL algorithms. However, ALPS does not require updating the classifier because it only depends on the pre-trained encoder. Rather than sampling data in small batches and re-training the model, ALPS can sample a batch of k sentences in one iteration (Algorithm 2). Between using ALPS iteratively and deploying the algorithm for a single iteration, the difference is insignificant (Table 3). Plus, sampling 1,000 sentences only takes about 97 minutes for PUBMED and 7 minutes for IMDB.

Dataset	k	Iterative	Single
IMDB	200	0.63 ± 0.04	0.61 ± 0.03
	500	0.74 ± 0.05	0.76 ± 0.04
	1000	0.82 ± 0.01	0.82 ± 0.01
PUBMED	200	0.63 ± 0.03	0.64 ± 0.03
	500	0.80 ± 0.02	0.82 ± 0.01
	1000	0.84 ± 0.00	0.84 ± 0.00

Table 3: Test accuracy on IMDB and PubMed between different uses of ALPS for various k, the number of sentences to query. We compare using ALPS iteratively (Iterative) as done in Section 5 with using ALPS to query all k sentences in one iteration (Single). The test accuracy does not change much, showing that ALPS is flexible to apply in different settings.

With this flexibility in sampling, ALPS can accommodate different budget constraints. For example, re-training the classifier may be costly, so users want a sampling algorithm that can query k sentences all at once. In other cases, annotators are not always available, so the number of obtainable annotations is unpredictable. Then, users would prefer an AL strategy that can query a variable number of sentences for any iteration. These cases illustrate practical needs for a cold-start algorithm like ALPS.

7 Related Work

Active learning has shown success in tasks, such as named entity recognition (Shen et al., 2004), word sense disambiguation (Zhu and Hovy, 2007), and sentiment analysis (Li et al., 2012). Wang and Shang (2014) are the first to adapt prior AL work to deep learning. However, popular heuristics (Settles, 2009) for querying individual points do not work as well in a batch setting. Since then, more research has been conducted on batch AL for deep learning. Zhang et al. (2017) propose the first work on AL for neural text classification. They assume that the classifier is a convolutional neural network and use expected gradient length (Settles et al., 2008) to choose sentences that contain words with the most label-discriminative embeddings. Besides text classification, AL has been applied to neural models for semantic parsing (Duong et al., 2018), named entity recognition (Shen et al., 2018), and machine translation (Liu et al., 2018).

ALPS makes use of BERT, a model that excels at transfer learning. Other works also combine AL and transfer learning to select training data that reduce generalization error. Rai et al. (2010) measures domain divergence from the source domain to select the most informative texts in the target domain. Wang et al. (2014) use AL to query points for a target task through matching conditional distributions. Additionally, combining word-level and document-level annotations can improve knowledge transfer (Settles, 2011; Yuan et al., 2020).

In addition to uncertainty and diversity sampling, other areas of deep AL focus on Bayesian approaches (Siddhant and Lipton, 2018; Kirsch et al., 2019) and reinforcement learning (Fang et al., 2017). An interesting research direction can integrate one of these approaches with ALPS.

8 Conclusion

Transformers are powerful models that have revolutionized NLP. Nevertheless, like other deep models, their accuracy and stability require fine-tuning on large amounts of data. AL should level the playing field by directing limited annotations most effectively so that labels complement, rather than duplicate, unsupervised data. Luckily, transformers have generalized knowledge about language that can help acquire data for fine-tuning. Like BADGE, we project data into an embedding space and then select the most representative points. Our method is unique because it only relies on self-supervision to conduct sampling. Using the pre-trained loss guides the AL process to sample diverse and uncertain examples in the cold-start setting. Future work may focus on finding representations that encode the most important information for AL.

A Appendices

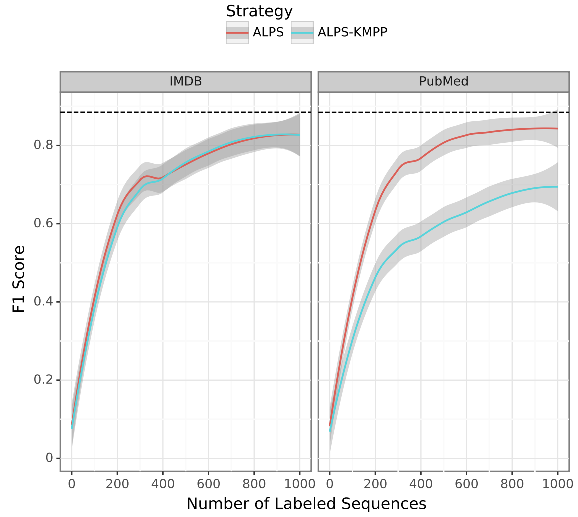

Figure 5: Comparing validation accuracy between using k-MEANS and k-MEANS++ to select centroids in the surprisal embeddings. Using k-MEANS reaches higher accuracy.

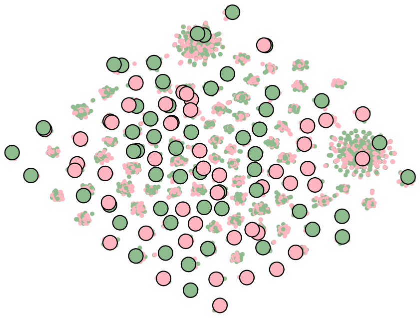
A.1 Token Masking

In our preliminary experiments on the validation set, we notice improvement in accuracy after passing in the original input with no masks (Table 4). The purpose of the `[MASK]` token during pretraining is to train the token embeddings to learn context so that it can predict the token labels. Since we are not training the token embeddings to learn context, masking the tokens does not help much for AL. We use AL for fine-tuning, so the input should be in the same format for AL and fine-tuning. Otherwise, there is a mismatch between the two stages.

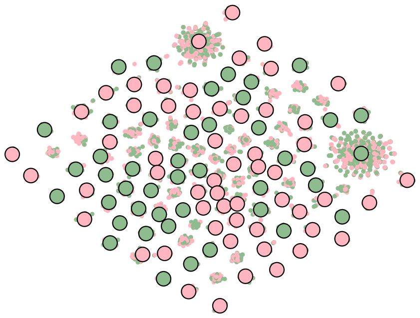
A.2 Token Sampling for Evaluation

When BERT evaluates MLM loss, it only focuses on the masked tokens, which are from a 15% random subsample of tokens in the sentence. We experiment with varying this subsample percentage on the validation set (Table 4). We try sampling 10%, 15%, 20%, and 100%. Overall, we notice that mean accuracy are roughly the same, but variance in accuracy across different runs is slightly higher for percentages other than 15%.

After the second AL iteration, we notice that accuracy mean and variance between the different token sampling percentages converge. So, the token sampling percentage makes more of a difference in early stages of AL. Devlin et al. (2019) show that the difference in accuracy between various mask strategies is minimal for fine-tuning BERT. We believe this can also be applied to what we have observed for ALPS.



(a) Surprisal embeddings with k-MEANS++ centers



(b) Surprisal embeddings with k-MEANS centers

Figure 6: T-SNE plots of surprisal embeddings for IMDB training data. The centers are either picked by k-MEANS++ (right) or k-MEANS (left). There is less overlap between the centers with k-MEANS compared to k-MEANS++. So, using k-MEANS is better for exploiting diversity in the surprisal embedding space.

A.3 k-MEANS vs. k-MEANS++

The state-of-the-art baseline BADGE applies k-MEANS++ on gradient embeddings to select points to query. Initially, we also use k-MEANS++ on the surprisal embeddings but validation accuracy is only slightly higher than random sampling. Since k-MEANS++ is originally an algorithm for robust initialization of k-MEANS, we instead apply k-MEANS on the surprisal embeddings. As a result, we see more significant increase in accuracy over baselines, especially for PubMed (Figure 5). Additionally, the T-SNE plots show that k-MEANS selects centers that are further apart compared to the ones chosen by k-MEANS++ (Figure 6). This shows that k-MEANS can help sample a more diverse batch of data.

	IMDB		SST-2	
	$k = 100$	$k = 200$	$k = 100$	$k = 200$
ALPS	0.60 ± 0.03	$\mathbf{0.69 \pm 0.04}$	$\mathbf{0.57 \pm 0.06}$	$\mathbf{0.64 \pm 0.04}$
ALPS-tokens-0.1	$\mathbf{0.61 \pm 0.05}$	0.63 ± 0.11	0.56 ± 0.07	0.63 ± 0.04
ALPS-tokens-0.2	0.55 ± 0.07	0.65 ± 0.05	$\mathbf{0.57 \pm 0.05}$	0.63 ± 0.05
ALPS-tokens-1.0	0.59 ± 0.05	0.65 ± 0.07	0.56 ± 0.05	0.62 ± 0.05
ALPS-masked	0.59 ± 0.03	0.63 ± 0.09	0.56 ± 0.03	0.60 ± 0.02

Table 4: Comparison of validation accuracy between the variants of ALPS to sample data for IMDB and SST-2 in the first two iterations. ALPS-tokens-p varies the percentage p of tokens evaluated with MLM loss when computing surprisal embeddings. ALPS-masked passes in the input with masks as originally done in pre-training. Overall, we observe that ALPS has higher mean and smaller variance in accuracy.

Table 5: Sample sentences from AG News and PubMed while using ALPS and Random in the first iteration. For ALPS, highlighted tokens are the ones that have a nonzero entry in the surprisal embedding. Compared to random sampling, ALPS samples sentences with more diverse content.

A.4 Sample Sentences

Section 6 quantitatively analyzes diversity of ALPS. Here, we take a closer look at the kind of sentences that are sampled by ALPS. Table 5 compares sentences that are chosen by ALPS and random sampling in the first AL iteration. The tokens highlighted are the ones evaluated with surprisal loss. Random sampling can fall prey to data idiosyncracies. For example, AG News has sixty-two articles about the German golfer Bernhard Langer, and random sampling picks multiple articles about him on one of five runs. For PubMed, many sentences labeled as "methods" are simple sentences with a short, independent clause. While random sampling chooses many sentences of this form, ALPS seems to avoid this problem. Since the surprisal embedding encodes the fluctuation in information content across the sentence, ALPS is less likely to repeatedly choose sentences with similar patterns in surprisal. This may possibly diversify syntactic structure in a sampled batch.

Active Learning for BERT: An Empirical Study

Abstract

Real world scenarios present a challenge for text classification, since labels are usually expensive and the data is often characterized by class imbalance. Active Learning (AL) is a ubiquitous paradigm to cope with data scarcity. Recently, pre-trained NLP models, and BERT in particular, are receiving massive attention due to their outstanding performance in various NLP tasks. However, the use of AL with deep pre-trained models has so far received little consideration. Here, we present a large-scale empirical study on active learning techniques for BERT-based classification, addressing a diverse set of AL strategies and datasets. We focus on practical scenarios of binary text classification, where the annotation budget is very small, and the data is often skewed. Our results demonstrate that AL can boost BERT performance, especially in the most realistic scenario in which the initial set of labeled examples is created using keyword-based queries, resulting in a biased sample of the minority class. We release our research framework, aiming to facilitate future research along the lines explored here.

1 Introduction

Automatic text classification is a well studied problem in Natural Language Processing (NLP), with great practical importance and numerous real world applications (Aggarwal and Zhai, 2012). There are two major hurdles to developing effective text classifiers in practice, as well as to developing classifiers in other domains – the lack of labeled data, and class imbalance (Japkowicz and Stephen, 2002). Text classifiers often require high quantities of labeled data for model training. However, collecting such labeled data is a notoriously expensive and time-consuming process, and shortage of labeled data is exacerbated when the desired class has a relatively low prior in the data. In such a scenario, even going through the burden of labeling a random sample may yield an insufficient number of positive instances to properly train a classifier. Our focus in this work is on this challenging coupled setup, frequently encountered by real-world users – where labeled data is scarce *and* the prior of the desired class is small.

A classical approach for coping with limited annotation resources is Active Learning (AL) (Cohn et al., 1996). In this paradigm, one assumes that unlabeled data are abundant, and the goal is to focus the expensive labeling process on the most informative instances. Many AL strategies have been proposed, aiming to minimize the labeling burden, or if taken from a different perspective – maximize the value of labeling a small set of examples. Importantly, the usefulness of an AL strategy naturally depends on the classification scheme with which it is coupled. A successful AL approach for a Naive Bayes classifier may not be that effective for a modern deep-learning algorithm such as CNN, and vice versa.

A more recent relevant development is the introduction of pre-trained NLP models (cf. Qiu et al., 2020), which have been shown to substantially improve state-of-the-art results in numerous NLP tasks. A prominent example is the BERT model (Devlin et al., 2018), which has received massive attention from the NLP research community since its inception. However, the use of AL with deep pre-trained models for text classification – and BERT in particular – has so far received surprisingly little consideration. Thus, while recent papers have demonstrated the value of AL for various deep-learning text classification schemes (Shen et al., 2017; Zhang et al., 2017; Siddhant and Lipton, 2018; Prabhu et al., 2019), the potential of AL combined with BERT is yet to be explored. First, given the unique properties of pre-trained models,

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7949–7962,
November 16–20, 2020.

and the expectation that such models will yield adequate performance even with small amounts of training data, it is unclear *a priori* whether – and to what extent – established AL paradigms can further enhance their classification performance. Moreover, more recent Deep AL strategies, such as Core-Set (Sener and Savarese, 2017) and Dropout (Gal and Ghahramani, 2016), were developed in the vision domain for CNNs. The value of these strategies on top of the BERT transformer architecture remains unclear.

Our goal in this work is threefold. We study the potential of (i) various AL strategies; (ii) in conjunction with BERT, an arguably outstanding text classification scheme; (iii) within a highly challenging – yet common – real-world scenario of class imbalance and scarce labeled data. To address this goal, we conduct a systematic study, considering traditional and advanced AL strategies coupled with BERT for a wide range of datasets. We focus on three scenarios: A *balanced* setting, serving as a reference, where the prior of the class of interest is not too small; the more challenging *imbalanced* setting, where the class prior is $\leq 15\%$ but we assume a way to obtain an unbiased set of positive samples to be used for initial training; and finally, the *imbalanced-practical* setting, which is similar to the imbalanced one, but takes a step further towards a truly practical setup, in which there is no access to an unbiased positive sample. Instead, we assume the user has access to a *biased* sample, hopefully enriched with positive examples, obtained by issuing simple queries of keywords associated with the positive class.

Our results convey that AL strategies can boost BERT performance, under the challenging setting of a small annotation budget and highly skewed data, especially in the more practical real-world settings. We release our research framework[1] , including access to all datasets, an implementation of multiple AL strategies, and an associated automatic evaluation framework, aiming to facilitate further research along the lines explored here.

2 Related Work

AL has been widely used in many fields to successfully decrease the labeling effort involved in the training process. A good summary of active learning works prior to the advances in deep learning can be found in Settles (2009). Advances in deep learning have given rise to extensive research into deep active learning, which aims to adapt the classic AL framework to the special properties of DNNs. Deep AL presents some specific challenges. Since DNNs are computationally heavy, training a new model whenever a single training sample is added is highly impractical. This requires a shift to batch mode active learning, where a batch of examples is queried at every iteration. Moreover, the tendency of the softmax layer to over-confidence has led to the development of various uncertainty-based strategies tailored to the special properties of DNNs (Gal and Ghahramani, 2016).

Most of the works in deep active learning focus on image classification with convolutional neural networks (Sener and Savarese, 2017; Gal and Ghahramani, 2016; Gissin and Shalev-Shwartz, 2019). Recent papers have demonstrated the value of deep active learning for text classification (Zhang et al., 2017; Siddhant and Lipton, 2018; Prabhu et al., 2019; Lowell et al., 2018), but in general did not study AL for BERT. One exception is Zhang and Zhang (2019) who applied an ensemble of AL strategies to BERT for the task of intent classification. However, this work focuses on a single task, and does not address the effect of small and imbalanced data. Additionally, Shelmanov et al. (2019) and Liu et al. (2020) focused on particular variants of BERT (BioBERT and BERT-CRF) and studied a single or two specific tasks, with a small collection of AL strategies. To the best of our knowledge, this work is the first to systematically explore advanced strategies like Core-Set (Sener and Savarese, 2017), Dropout (Gal and Ghahramani, 2016), Expected Gradient Length (Huang et al., 2016) and Discriminative Active Learning (Gissin and Shalev-Shwartz, 2019) for BERT, in various settings and a diversity of tasks.

3 Empirical Evaluation

3.1 Data

We consider 10 datasets (see Table 1) that cover a variety of domains, and for each we select one target class as our classification goal, thus creating a set of binary classification tasks. Three datasets are originally skewed, i.e., the target class prior is $\leq 15\%$: Wiki Attack (Wulczyn et al., 2017), which annotates Wikipedia discussions for offensive con-

Table 1: Dataset details: size, target (positive) class, and its prior in the dataset.

tent;[2] ISEAR (Shao et al., 2015), which annotates personal reports for emotion; and TREC (Li and Roth, 2002) which considers the answer type of questions. In four datasets the target class prior is $20\% - 50\%$: AG's News (Zhang et al., 2015), which categorizes news articles; CoLA (Warstadt et al., 2018), which annotates sentences for grammatical acceptability; Subjectivity (Pang and Lee, 2004), which classifies movie snippets into subjective or objective; and Polarity (Pang and Lee, 2005), which includes sentiment analysis on movie reviews. In addition, we enriched the imbalanced datasets by creating imbalanced versions of three balanced datasets via sub-sampling the target class instances towards a prior of 10% (Table 1, rows 1–3).

Each dataset was split into train, dev, and test sets, keeping the original split, if exists, and otherwise applying a $70\%/10\%/20\%$ split, respectively. For large datasets, we limit the sizes to $15K/3K/3K$ respectively by randomly sampling from each set. The complete details along with links to all datasets are provided in Appendix A.

3.2 Experimental setup

We apply pool-based active learning (Settles, 2009) in batch mode, using BERT as the classification model. Seven selection strategies are examined over the 10 fully labeled binary classification datasets described above. The use of fully labeled datasets enables simulating manual labeling (Yang and Loog, 2018). Per dataset, we use its train set as the initial *pool* of examples from which instances are selected for labeling.

We assume an initial annotation budget that enables labeling 100 examples, used to create an initial seed L. In some setups, L may contain additional instances without their ground truth labels, and in general the way L is selected depends on the experimental scenario, as described below. We denote by U the instances in the pool that do not belong to L.

For a given AL strategy, a single experiment starts with the seed L, used to train BERT as the initial classifier (iteration 0). Next, we conduct 5 iterations. In each, the AL strategy selects a batch of 50 unlabeled instances from U that are added to L along with their true labels, and BERT is trained over these expanded data. Note, the BERT fine-tuning in each iteration is done from scratch, to avoid overfitting data from previous rounds, as suggested in Hu et al. (2018). In each experiment, all AL strategies start with the same initial seed. The reported results are the average over 5 different experiments, i.e., 5 different initial seeds.

For each AL strategy, we consider the following three scenarios:

Balanced: Here, the positive class prior is not very low, hence a randomly selected sample is expected to have a sufficient number of positive examples. Correspondingly, the seed L is simply defined as 100 instances sampled at random from the pool. We apply this scenario to datasets with $20\% - 50\%$ of positive labels.[3]

For datasets with a positive class label $\leq 15\%$, a random seed of 100 instances led to unstable BERT runs (data not shown), presumably due to the combination of small and highly skewed training data resulting from such random selection. Hence, for these imbalanced datasets, we consider the two scenarios described below. In both cases, we expand the initial set of 100 labeled examples with another set of 100 instances, selected at random from the remaining data, which are all added to L with a negative label. In other words, the low prior of the positive class naturally implies high prior of the negative class, enabling to expand the fully labeled 100 instances with an additional set of 100 instances that are – weakly – labeled as negative examples (without the need for additional annotation budget). Hence, in both scenarios described below, L contains a total of 200 examples.

Imbalanced: Here, the 100 fully labeled examples are drawn at random from the positive examples in the dataset, hence all 100 are indeed positive, and

---

[2] This data set contains offensive language. IBM abhors use of such language and any form of discrimination.

[3] Although not all these datasets are strictly balanced, we chose this name for brevity of presentation.

are further an unbiased sample of the positive class. In this setting we assume high-precision heuristics that enable generating a relatively unbiased sample; but in many real-world cases such heuristics may not exist, or are expected to have limited coverage and would not enable sampling at will[4]. Thus, such heuristics cannot be assumed to yield a large training set, but may nevertheless be used for obtaining a small initial seed in an active learning setting.

Imbalanced-practical: In this scenario, we simulate a more realistic setting in which a user attempts to obtain as many positive examples as possible using the budget of 100 annotations. To this end, we design a simple keyword-based query for each dataset, which aims to retrieve a set of instances enriched with positive examples, using words assumed to be associated with the positive class. We opted for keyword-based queries as they are often used in practice in real-world scenarios. We apply the query to the pool, and randomly draw 100 instances from the query result, which are then added to the seed with their ground truth labels. Note that these 100 examples are expected to be enriched with positive examples, yet in a biased manner, since by construction, all examples match the query we started with. Specifically, this scenario was tested on four datasets for which a simple string (or sub-string) match query with enough hits could be defined: (i) for the *fear* class in ISEAR the query is [*fear* or *afraid* or *scared* or *scary*] (*fear*, for example, can also capture *fearsome*); (ii) for the TREC *location* class, [*Where* or *countr* or *cit*] (matching *cit* captures both the singular and plural of city); (iii) for the Wiki *attack* class, [*[A-Z]!*] (capturing a word ending with an upper case letter which is immediately followed by an exclamation mark, e.g., *IDIOT!*), and (iv) for the AG's News-imb *world* class the query is a list of countries and territories separated by 'or'. It is likely that better queries could be defined. However, our goal here was to simulate a realistic setting in which a user relies on a relatively simple heuristic, and to examine the behavior of AL with BERT when initiated with a potentially biased seed.

3.3 Active Learning Strategies

We consider several AL strategies for choosing the batch of 50 instances to label in each iteration. In addition, as a baseline, we consider a **Random** strategy, where batch instances are chosen at random from the unlabeled set.

- **Least Confidence** (**LC**, Lewis and Gale, 1994): selects instances for which the model is least certain according to the max-entropy decision rule.
- **Monte Carlo Dropout** (**Dropout**, Gal and Ghahramani, 2016): Similar to LC, but instance uncertainty is calculated using Monte Carlo Dropout on 10 inference cycles, with the max-entropy acquisition function[5].
- **Perceptron Ensemble** (**PE**): Selects instances with highest uncertainty – similarly to LC – but averaging over an ensemble of models. Here, we use a light-weight ensemble strategy to overcome the unrealistic computational cost required for training an ensemble of BERT models. PE is composed of 10 perceptrons which are trained to solve the original task using L, where the perceptron inputs are the CLS vectors of the fine-tuned BERT model.
- **Expected Gradient Length** (**EGL**, Huang et al., 2016): selects instances with the largest expected gradient norm, as they are expected to wield a large influence on the model. The expectation is computed over the posterior distribution of labels for the example according to the trained model.
- **Core-Set** (Sener and Savarese, 2017): selects instances that best cover the dataset in the learned representation space (CLS), using the greedy method described in Sener and Savarese (2017).
- **Discriminative Active Learning** (**DAL**, Gissin and Shalev-Shwartz, 2019): This approach aims to select instances that make L most representative of the entire pool. We follow the exact method used in Gissin and Shalev-Shwartz (2019).

We chose these strategies as spanning the leading state-of-the-art approaches in the AL domain: uncertainty-sampling (LC and Dropout), uncertainty-sampling using ensemble methods (PE), expected model change (EGL), and diversity sampling (DAL and Core-Set).

3.4 Implementation Details

Overall, the results presented here consist of 2,520 fine-tuning experiments (14 dataset-scenario combinations $\times$ 5 initial seeds $\times$ (1 base model + (7 selection strategies $\times$ 5 iterations)). In order to run multiple experiments in parallel, experiments were performed on Intel$^{\circledR}$ Xeon CPU E5-2699 v4

---

[4] For instance, for the task of classifying emotional situations, the prefix "This is a situation where I felt afraid:" indicates that the following sentence belongs to the *fear* class, but is expected to be rare within the corpus.

[5] other functions were shown to yield similar results (Gissin and Shalev-Shwartz, 2019)

Random	LC	Dropout	EGL	Core-Set	DAL	PE
< 1	84	840	1106	98	167	370

Table 2: Runtimes (in seconds) for a single iteration for different AL strategies, assuming 7,000 unlabeled examples.

@ 2.20GHz, with 88 CPUs and 748 GB of RAM. BERT training and inference were performed on Nvidia® Tesla K80 GPUs (single GPU per run).

Table 2 lists AL batch selection runtimes for different AL strategies. Runtimes for all strategies except Random are dominated by BERT inference, as BERT model outputs are used in selecting batch instances. Notably, two strategies demand longer inference times: EGL due to the gradient calculation, and Dropout due to the larger number of inference cycles (×10).

3.5 BERT Training Details

In each fine-tuning run, $\text{BERT}_{\text{BASE}}$ (110M paramaters) was trained for 5 epochs, using a learning rate of 5×10^{-5}, and keeping the best model based on its performance on the dev set. In practice, dev sets may be unavailable, particularly under a limited annotation budget. Using a dev set to reduce variance and noise between runs helps stabilize the results, but importantly, we verified that ignoring the dev data and setting a constant number of epochs yields qualitatively similar, albeit noisier, results. Our experiments showed that increasing the batch size had a substantial effect on improving the stability of BERT results. However, due to memory limitations of the GPU, increasing the batch size comes at the expense of the maximal sequence length. We empirically determined that setting the batch size to 50, and the maximal sequence length to 100 tokens (after WordPiece tokenization), yielded the best results. We otherwise used the default settings in the TensorFlow implementation of BERT.

3.6 AL Research Framework

Our open-source framework allows a user to experiment with the active learning strategies in (§3.3) and evaluate their performance over the datasets in (§3.1). The framework also supports adding new AL strategies, making it easy to evaluate their potential.

Strategy	Balanced	Imbalanced	Imbalanced practical
Core-Set	10^{-2}	$< 10^{-5}$	$< 10^{-8}$
Dropout	$< 10^{-3}$	$< 10^{-8}$	$< 10^{-8}$
EGL	$---$	$< 10^{-4}$	$< 10^{-8}$
LC	$< 10^{-5}$	$< 10^{-9}$	$< 10^{-7}$
DAL	$< 10^{-2}$	$< 10^{-5}$	$< 10^{-6}$
PE	$---$	$< 10^{-2}$	$< 10^{-6}$

Table 3: Wilcoxon test p-values (after Bonferroni correction) for different AL strategies compared to Random. $---$ denotes insignificant results ($p \geq 0.05$).

4 Results

We report results for the AL strategies (§3.3) in three experimental scenarios (§3.2). Following the standard in the field, we use accuracy as the classification metric for the balanced scenario, and F1[6] for the imbalanced and imbalanced-practical scenarios, where the prior for positives is relatively low.

Figure 1 depicts the classification quality (accuracy or F1) per iteration for each dataset, for the relevant scenarios. For clarity of presentation, we only plot the Random baseline and three strategies that represent the different approaches. As can be seen in the full figure in the Appendix (Figure 3), the other strategies behave similarly.

In most datasets, all AL strategies performed better than the Random baseline, even in cases where the baseline results were already very good, e.g., AG's News and Subjectivity. Interestingly, the largest improvements were observed in the *imbalanced-practical* scenario. Here, the AL strategies improve the F1 of the Random baseline by a large margin of $4 - 8\%$ on average. These results demonstrate that AL can indeed enhance BERT results when the annotation budget is small, especially for datasets having a low prior for positive examples, as is the case in many real-world settings.

To check the significance of the differences, we calculate the Wilcoxon p-value[7] for every AL strategy compared to the Random baseline, per scenario, and perform a Bonferroni correction to adjust for the multiple strategies examined. To calculate the p-value for a strategy S per scenario, we compare the classification metric for all pairs (S_{dik}, R_{dik}) such that R is the Random baseline results, $d \in D$, where D is the set of datasets in-

---

[6] computed at the default threshold of 0.5

[7] We chose Wilcoxon p-value because of its non-parametric nature.

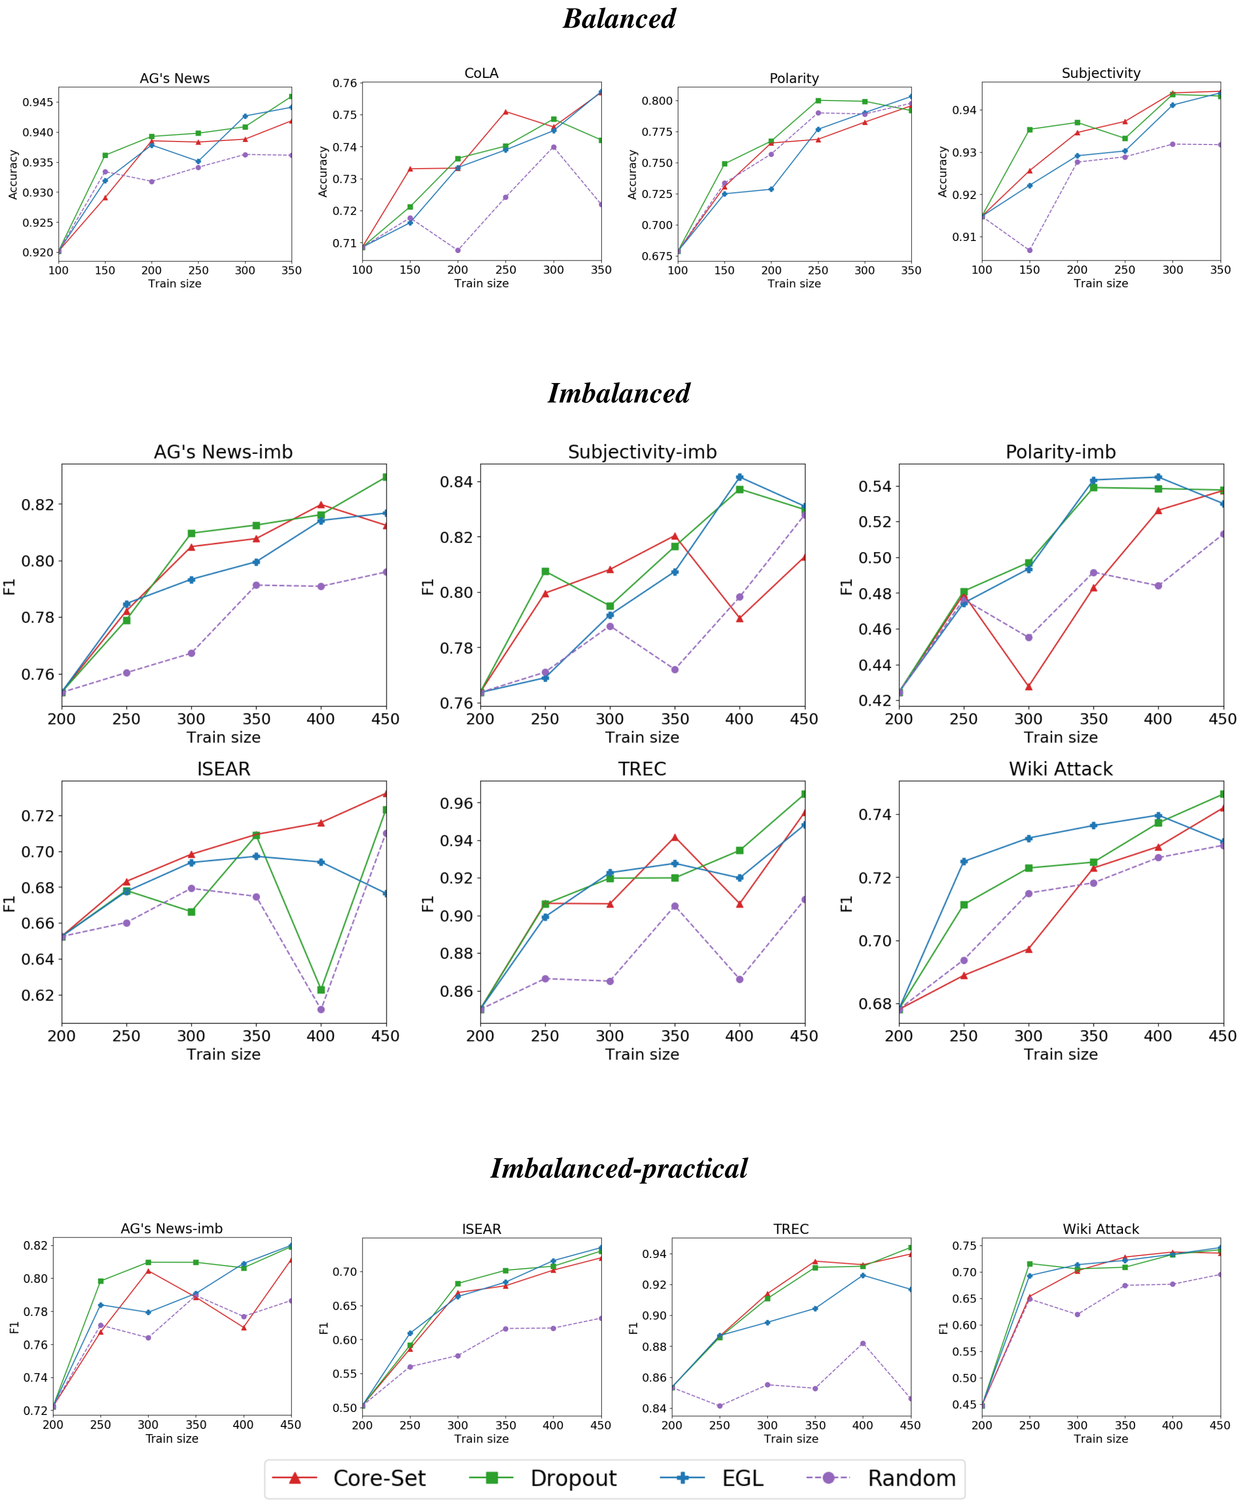

Figure 1: AL strategies compared to the Random baseline in the *balanced* (top row), *imbalanced* (two middle rows) and *imbalanced-practical* (bottom row) scenarios. Train size indicates the size of L, where each iteration adds 50 samples.

cluded in the scenario, $i = (1...5)$ is the iteration index, and $k = (1...5)$ is the experiment number. As can be seen in Table 3, all the examined AL strategies significantly and consistently outperform the Random baseline when the dataset is highly skewed (*imbalanced* and *imbalanced-practical* scenarios). All strategies except PE and EGL also outperform the baseline for the *balanced* scenario.

While AL strategies improve over the Random baseline, apparently no single strategy consistently outperforms all its counterparts. This finding echoes Lowell et al. (2018), who studied AL for text classification and sequence tagging in non-BERT models, and demonstrated the brittleness and inconsistency of AL results. For significance analysis, we calculate the p-value for every pair of strategies per scenario in a similar manner to the one described above per strategy versus Random, correcting for the multiple pairs examined, and indeed find no overall significant performance difference between any pair of AL strategies. Note, however, that some AL strategies are more efficient than others with respect to runtime - see Table 2.

As may be expected, using a seed with positive labels obtained by a query, which is naturally biased towards instances that satisfy the query, typically results in an initial model with lower F1, compared to starting with an unbiased set of positive examples (compare iteration 0 per dataset in Figure 1 between the *imbalanced-practical* and *imbalanced* scenarios). Interestingly, though, after several iterations, the AL strategies seem to bridge the gap and end up with similar classification performance in both scenarios. We further examined whether the increase in F1 for the imbalanced scenarios is driven by an increase in precision or recall. We find that in the *imbalanced-practical* scenario, the improvement in F1 is completely dominated by an increase in recall, supporting the notion that the AL strategies enable the model to extrapolate and generalize beyond the biased sample obtained by the query[8]. In contrast, in the *imbalanced* scenario the increase in F1 is mostly driven by an increase in precision. For the precision and recall curves, see Figures 4 and 5 in the Appendix.

To conclude, our analyses suggest two results that were not trivial to begin with. Applying AL to BERT can further boost the performance of this top performing model. Furthermore, even when initiated with a biased seed of positive examples – as may often occur in practice – AL strategies can swiftly generalize from this seed and significantly improve the model recall, ending up with overall strong F1 performance.

5 Analysis

We perform a comparative analysis of the different AL strategies, aiming to better understand their relative advantages and disadvantages, and provide some insights that may lead to improved AL strategies in future work.

To enable an appropriate comparison, this analysis is performed after the initial BERT model is trained and each AL strategy has selected 50 examples for labeling. Correspondingly, all strategies select examples from the same unlabeled set U while using outputs from the same BERT model. We measure two batch properties which are known in the literature to impact AL effectiveness:

Diversity: Choosing a batch of diverse examples is often better than choosing one containing very similar and perhaps redundant examples. Following Zhdanov (2019), we define the Diversity of a set B as:

$$D(B) = \left(\frac{1}{|U|} \sum_{x_i \in U} \min_{x_j \in B} d(x_i, x_j) \right)^{-1} \quad (1)$$

where x_i denotes the representation of the [CLS] token of example i obtained by the model which was trained using L, and $d(x_i, x_j)$ denotes the Euclidean distance between x_i and x_j.

Representativeness: A known issue with AL strategies, especially the uncertainty-based ones, is their tendency to select outlier examples that do not properly represent the overall data distribution. We thus examine the representativeness of the selected batches. We rely on the KNN-density measure proposed by Zhu et al. (2008), in which the density of an example is quantified by the average distance between the example in question and its K most similar examples (i.e., K nearest neighbors) within U, based on the [CLS] representations as above. An example with high density degree is less likely to be an outlier. We define the representativeness of a batch as one over the average KNN-density of its instances using the Euclidean distance with $K = 10$.

The diversity and representativeness of the different strategies are depicted in Figure 2, where for

---

[8] The low recall of the queries can be seen in Table 5 in the Appendix.

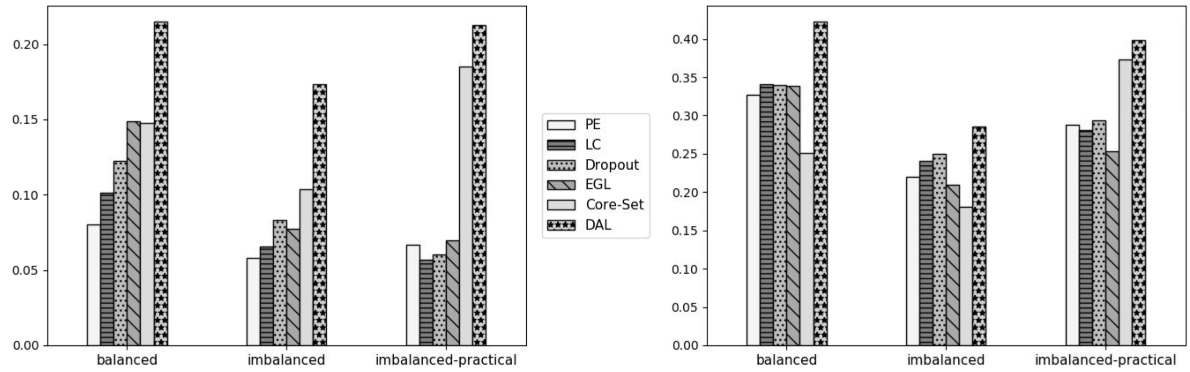

Figure 2: Diversity (left) and Representativeness (right) of the batches selected by the different AL strategies in each of the three scenarios.

each scenario we average results over all datasets and seed selections. As expected, the batch-aware strategies, DAL and Core-Set, which were designed to increase diversity, are characterized by the most diverse batches, with DAL achieving the highest diversity values, demonstrating the success of using mini-queries (Gissin and Shalev-Shwartz, 2019) to reduce redundancy of the selected examples. In contrast, the other strategies tend to select less diverse batches, i.e., they are prone to choose redundant examples, especially in the *imbalanced-practical* scenario. Thus, combining these approaches with methods that encourage diversity (e.g., He et al., 2014; Zhdanov, 2019; Ash et al., 2019) can potentially lead to further improvement in their resultant prediction performance. In terms of representativeness, DAL, which is a representativeness-driven method, again consistently leads across the scenarios. In contrast, the tendency of the greedy core-set version to select outliers (Sener and Savarese, 2017), is indeed reflected in its relatively low representativeness scores. Interestingly, this is not the case for the *imbalanced-practical* scenario. This result can be attributed to the high bias of L towards query matches, which results in poor representativeness of L, which in turn leaves the main ”responsibility” for representing the dataset on the batch examples selected from U. A deeper investigation of this result is left for further investigation. Other strategies have low representativeness scores compared to DAL, implying that they can be improved by combining them with techniques for encouraging representativeness and avoiding outliers.

A popular approach for improving classification quality is combining several, preferably complementary, AL strategies. In order to find pairs of strategies with high synergistic potential, we measured the overlap between the batches selected by each pair of strategies. Our analysis shows that for all pairs of strategies, the expected batch overlap is relatively low, and does not exceed 15%. In general, overlap was higher in the imbalanced scenarios, probably due to the general incentive to select positive examples, which are rare in the data. Also, the overlap within the uncertainty-based strategies was generally quite high. Nevertheless, the highest overlap between batches was between EGL (which is not an uncertainty-based approach) and LC. We leave for future work to try a combination of strategies with low overlap as a way to improve classification even further.

6 Conclusions

The recent emergence of pre-trained models, with BERT as a prominent example, is reshaping the NLP arena (Qiu et al., 2020). The promise embodied in these models is their ability to exploit massive unlabeled textual data to learn versatile, arguably universal language representations. These representations, in turn, are proven to be effective for a multitude of downstream NLP tasks.

A parallel line of research, dating back nearly three decades, is the notion of AL, aiming to minimize labeling burden within the supervised learning paradigm. The pairing of these two influential threads raises non-trivial questions. For example, BERT arguably attains excellent performance with relatively little labeled data, used to fine-tune this pre-trained model for a concrete task. It is not obvious to begin with, to what extent AL strategies can be used to outperform this already high bar.

To the best of our knowledge, the present work provides the first systematic study in this context, while focusing on the prevalent problem of text classification. Moreover, we further focus our attention on a scenario well known to many practitioners – and notoriously difficult from a learning perspective – that of building a classifier when the class of interest is scarce in the data at hand. Aiming to further bridge the gap between research and practice, in our *imbalanced-practical* mode we simulate a user within this challenging scenario, armed only with simple queries to define the labeled seed that will bootstrap the AL process. Our results demonstrate the potential of AL on top of BERT, especially in this latter scenario. Notably, a training data seed resulting from a simple query is expected to capture only limited, and perhaps somewhat obvious, aspects of the class under consideration. Our study shows that the initial BERT model indeed suffers from poor prediction performance, mainly due to low recall values. However, while the random AL baseline is limited in its ability to help BERT emerge from this poor initial model, AL strategies turn out to be very helpful. Using the AL pipeline, BERT improves its recall by a large margin, generalizing beyond the narrow data it was initially exposed to.

This work focused on various binary classification tasks. A natural future direction is to conduct a similar empirical investigation of AL over BERT in the context of multi-class classification and regression tasks. It would also be interesting to investigate the realm of larger annotation budgets, and more recent BERT variants (Liu et al., 2019; Lan et al., 2019). Finally, the present work focused on existing AL strategies, which were mostly developed in the vision domain for CNNs. The development of novel AL methods, that are tailored for pre-trained models such as BERT, seems like an important direction for future work. We hope that the experimental results and analyses reported here, as well as the release of the research framework we developed, would be instrumental for these and other future studies.

Transformer Based Multi-Source Domain Adaptation

Dustin Wright and **Isabelle Augenstein**

Abstract

In practical machine learning settings, the data on which a model must make predictions often come from a different distribution than the data it was trained on. Here, we investigate the problem of *unsupervised multi-source domain adaptation*, where a model is trained on labelled data from multiple source domains and must make predictions on a domain for which no labelled data has been seen. Prior work with CNNs and RNNs has demonstrated the benefit of mixture of experts, where the predictions of multiple domain expert classifiers are combined; as well as domain adversarial training, to induce a domain agnostic representation space. Inspired by this, we investigate how such methods can be effectively applied to large pretrained transformer models. We find that domain adversarial training has an effect on the learned representations of these models while having little effect on their performance, suggesting that large transformer-based models are already relatively robust across domains. Additionally, we show that mixture of experts leads to significant performance improvements by comparing several variants of mixing functions, including one novel mixture based on attention. Finally, we demonstrate that the predictions of large pretrained transformer based domain experts are highly homogenous, making it challenging to learn effective functions for mixing their predictions.

1 Introduction

Machine learning practitioners are often faced with the problem of evolving test data, leading to mismatches in training and test set distributions. As such, the problem of *domain adaptation* is of particular interest to the natural language processing community in order to build models which are robust this shift in distribution. For example, a model may be trained to predict the sentiment of product reviews for DVDs, electronics, and kitchen goods, and must utilize this learned knowledge to predict the sentiment of a review about a book (Figure 1). This paper is concerned with this setting, namely *unsupervised multi-source domain adaptation*.

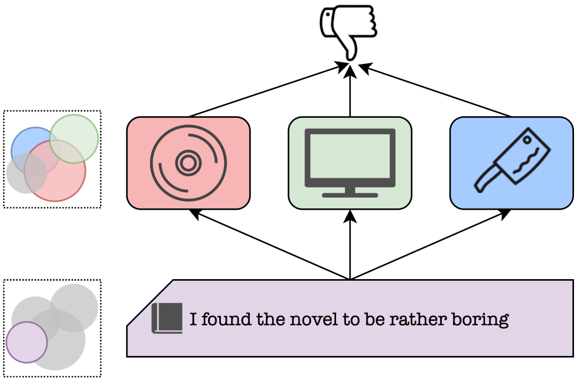

Figure 1: In multi-source domain adaptation, a model is trained on data drawn from multiple parts of the underlying distribution. At test time, the model must make predictions on data from a potentially non-overlapping part of the distribution.

Multi-source domain adaptation is a well studied problem in deep learning for natural language processing. Prominent techniques are generally based on data selection strategies and representation learning. For example, a popular representation learning method is to induce domain invariant representations using unsupervised target data and domain adversarial learning (Ganin and Lempitsky, 2015). Adding to this, mixture of experts techniques attempt to learn both domain specific and global shared representations and combine their predictions (Guo et al., 2018; Li et al., 2018; Ma et al., 2019). These methods have been primarily studied using convolutional nets (CNNs) and recurrent nets (RNNs) trained from scratch, while the NLP community has recently begun to rely more and more on large pretrained transformer (LPX) models e.g. BERT (Devlin et al., 2019). To date

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7963–7974,
November 16–20, 2020.

there has been some preliminary investigation of how LPX models perform under domain shift in the single source-single target setting (Ma et al., 2019; Han and Eisenstein, 2019; Rietzler et al., 2020; Gururangan et al., 2020). What is lacking is a study into the effects of and best ways to apply classic multi-source domain adaptation techniques with LPX models, which can give insight into possible avenues for improved application of these models in settings where there is domain shift.

Given this, we present a study into unsupervised multi-source domain adaptation techniques for large pretrained transformer models. Our main research question is: do mixture of experts and domain adversarial training offer any benefit when using LPX models? The answer to this is not immediately obvious, as such models have been shown to generalize quite well across domains and tasks while still learning representations which are not domain invariant. Therefore, we experiment with four mixture of experts models, including one novel technique based on attending to different domain experts; as well as domain adversarial training with gradient reversal. Surprisingly, we find that, while domain adversarial training helps the model learn more domain invariant representations, this does not always result in increased target task performance. When using mixture of experts, we see significant gains on out of domain rumour detection, and some gains on out of domain sentiment analysis. Further analysis reveals that the classifiers learned by domain expert models are highly homogeneous, making it challenging to learn a better mixing function than simple averaging.

2 Related Work

Our primary focus is multi-source domain adaptation with LPX models. We first review domain adaptation in general, followed by studies into domain adaptation with LPX models.

2.1 Domain Adaptation

Domain adaptation approaches generally fall into three categories: *supervised* approaches (e.g. Daumé (2007); Finkel and Manning (2009); Kulis et al. (2011)), where both labels for the source and the target domain are available; *semi-supervised* approaches (e.g. Donahue et al. (2013); Yao et al. (2015)), where labels for the source and a small set of labels for the target domain are provided; and lastly *unsupervised* approaches (e.g. Blitzer et al. (2006); Ganin and Lempitsky (2015); Sun et al. (2016); Lipton et al. (2018)), where only labels for the source domain are given. Since the focus of this paper is the latter, we restrict our discussion to unsupervised approaches. A more complete recent review of unsupervised domain adaptation approaches is given in Kouw and Loog (2019).

A popular approach to unsupervised domain adaptation is to induce representations which are invariant to the shift in distribution between source and target data. For deep networks, this can be accomplished via domain adversarial training using a simple gradient reversal trick (Ganin and Lempitsky, 2015). This has been shown to work in the multi-source domain adaptation setting too (Li et al., 2018). Other popular representation learning methods include minimizing the covariance between source and target features (Sun et al., 2016) and using maximum-mean discrepancy between the marginal distribution of source and target features as an adversarial objective (Guo et al., 2018).

Mixture of experts has also been shown to be effective for multi-source domain adaptation. Kim et al. (2017) use attention to combine the predictions of domain experts. Guo et al. (2018) propose learning a mixture of experts using a point to set metric, which combines the posteriors of models trained on individual domains. Our work attempts to build on this to study how multi-source domain adaptation can be improved with LPX models.

2.2 Transformer Based Domain Adaptation

There are a handful of studies which investigate how LPX models can be improved in the presence of domain shift. These methods tend to focus on the data and training objectives for single-source single-target unsupervised domain adaptation. The work of Ma et al. (2019) shows that curriculum learning based on the similarity of target data to source data improves the performance of BERT on out of domain natural language inference. Additionally, Han and Eisenstein (2019) demonstrate that domain adaptive fine-tuning with the masked language modeling objective of BERT leads to improved performance on domain adaptation for sequence labelling. Rietzler et al. (2020) offer similar evidence for task adaptive fine-tuning on aspect based sentiment analysis. Gururangan et al. (2020) take this further, showing that significant gains in performance are yielded when progressively fine-tuning on in domain data, followed by task data,

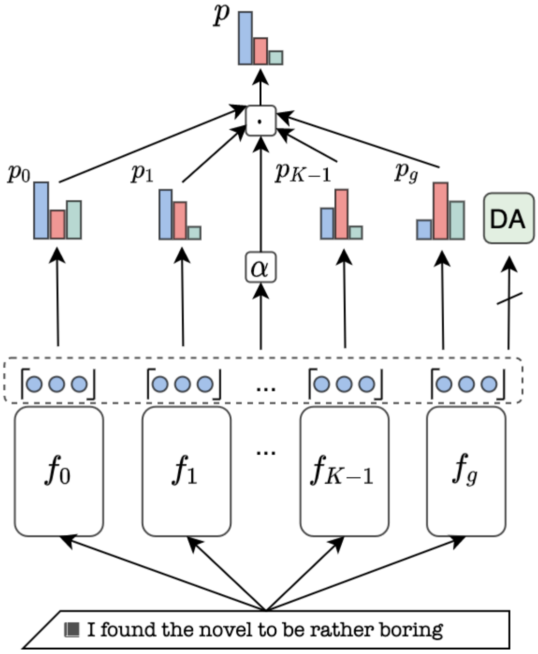

Figure 2: The overall approach tested in this work. A sample is input to a set of expert and one shared LPX model as described in §3.1. The output probabilities of these models are then combined using an attention parameter alpha (§3.1.1, §3.1.2, §3.1.3, §3.1.4). In addition, a global model f_g learns domain invariant representations via a classifier `DA` with gradient reversal (indicated by the slash, see §3.2).

using the masked language modeling objective of RobERTa. Finally, Lin et al. (2020) explore whether domain adversarial training with BERT would improve performance for clinical negation detection, finding that the best performing method is a plain BERT model, giving some evidence that perhaps well-studied domain adaptation methods may not be applicable to LPX models.

What has not been studied, to the best of our knowledge, is the impact of domain adversarial training via gradient reversal on LPX models on natural language processing tasks, as well as if mixture of experts techniques can be beneficial. As these methods have historically benefited deep models for domain adaptation, we explore their effect when applied to LPX models in this work.

3 Methods

This work is motivated by previous research on domain adversarial training and mixture of domain experts for domain adaptation. In this, the data consists of K source domains $\mathcal{S}$ and a target domain $\mathcal{T}$. The source domains consist of labelled datasets $D_s, s \in \{1, ..., K\}$ and the target domain consists only of unlabelled data U_t. The goal is to learn a classifier f, which generalizes well to $\mathcal{T}$ using only the labelled data from $\mathcal{S}$ and optionally unlabelled data from $\mathcal{T}$. We consider a base network $f_z, z \in \mathcal{S} \cup \{g\}$ corresponding to either a domain specific network or a global shared network. These f_z networks are initialized using LPX models, in particular DistilBert (Sanh et al., 2019).

3.1 Mixture of Experts Techniques

We study four different mixture of expert techniques: simple averaging, fine-tuned averaging, attention with a domain classifier, and a novel sample-wise attention mechanism based on transformer attention (Vaswani et al., 2017). Prior work reports that utilizing mixtures of domain experts and shared classifiers leads to improved performance when having access to multiple source domains (Guo et al., 2018; Li et al., 2018). Given this, we investigate if mixture of experts can have any benefit when using LPX models.

Formally, for a setting with K domains, we have set of K different LPX models $f_k, k \in \{0...K-1\}$ corresponding to each domain. There is also an additional LPX model f_g corresponding to a global shared model. The output predictions of these models are $p_k, k \in \{0...K-1\}$ and p_g, respectively. Since the problems we are concerned with are binary classification, these are single values in the range $(0, 1)$. The final output probability is calculated as a weighted combination of a set of domain expert probabilities $\bar{\mathcal{K}} \subseteq \mathcal{S}$ and the probability from the global shared model. Four methods are used for calculating the weighting.

3.1.1 Averaging

The first method is a simple averaging of the predictions of domain specific and shared classifiers. The final output of the model is

$$p_A(x, \bar{\mathcal{K}}) = \frac{1}{|\bar{\mathcal{K}}|+1} \sum_{k \in \bar{\mathcal{K}}} p_k(x) + p_g(x) \qquad (1)$$

3.1.2 Fine Tuned Averaging

As an extension to simple averaging, we fine tune the weight given to each of the domain experts and global shared model. This is performed via randomized grid search evaluated on validation data, after the models have been trained. A random integer between zero and ten is generated for each of the models, which is then normalized to a set of probabilities α_F. The final output probability is then given as follows.

$$p_F(x) = \sum_{k \in \bar{\mathcal{K}}} p_k(x) * \alpha_F^{(k)}(x) + p_g(x) * \alpha_F^{(g)}(x) \tag{2}$$

3.1.3 Domain Classifier

It was recently shown that curriculum learning using a domain classifier can lead to improved performance for single-source domain adaptation (Ma et al., 2019) when using LPX models. Inspired by this, we experiment with using a domain classifier as a way to attend to the predictions of domain expert models. First, a domain classifier f_C is trained to predict the domain of an input sample x given $\mathbf{r}_g \in \mathbb{R}^d$, the representation of the `[CLS]` token at the output of a LPX model. From the classifier, a vector α_C is produced with the probabilities that a sample belongs to each source domain.

$$\alpha_C = f_C(x) = \text{softmax}(\mathbf{W}_C \mathbf{r}_g + b_C) \tag{3}$$

where $\mathbf{W}_C \in \mathbb{R}^{d \times K}$ and $b_C \in \mathbb{R}^K$. The domain classifier is trained before the end-task network and is held static throughout training on the end-task. For this, a set of domain experts f_k are trained and their predictions combined through a weighted sum of the attention vector α_C.

$$p_C(x) = \sum_{k \in S} p_k(x) * \alpha_C^{(k)}(x) \tag{4}$$

where the superscript (k) indexes into the α_C vector. Note that in this case we only use domain experts and not a global shared model. In addition, the probability is always calculated with respect to each source domain.

3.1.4 Attention Model

Finally, a novel parameterized attention model is learned which attends to different domains based on the input sample. The attention method is based on the scaled dot product attention applied in transformer models (Vaswani et al., 2017), where a global shared model acts as a query network attending to each of the expert and shared models. As such, a shared model f_g produces a vector $\mathbf{r}_g \in \mathbb{R}^d$, and each domain expert produces a vector $\mathbf{r}_k \in \mathbb{R}^d$. First, for an input sample x, a probability for the end task is obtained from the classifier of each model yielding probabilities p_g and $p_k, k \in 0...K-1$. An attention vector α_X is then obtained via the following transformations.

$$\mathbf{q} = \mathbf{g}\mathbf{Q}^T \tag{5}$$

$$\mathbf{k} = \begin{bmatrix} \mathbf{r}_1 \\ \vdots \\ \mathbf{r}_K \\ \mathbf{r}_g \end{bmatrix} \mathbf{K}^T \tag{6}$$

$$\alpha_X = \text{softmax}(\mathbf{q}\mathbf{k}^T) \tag{7}$$

where $\mathbf{Q} \in \mathbb{R}^{d \times d}$ and $\mathbf{K} \in \mathbb{R}^{d \times d}$. The attention vector α_X then attends to the individual predictions of each domain expert and the global shared model.

$$p_X(x, \bar{\mathcal{K}}) = \sum_{k \in \bar{\mathcal{K}}} p_k(x) * \alpha_X^{(k)}(x) + p_g(x) * \alpha_X^{(g)}(x) \tag{8}$$

To ensure that each model is trained as a domain specific expert, a similar training procedure to that of Guo et al. 2018 is utilized, described in §3.3.

3.2 Domain Adversarial Training

The method of domain adversarial adaptation we investigate here is the well-studied technique described in Ganin and Lempitsky (2015). It has been shown to benefit both convolutional nets and recurrent nets on NLP problems (Li et al., 2018; Gui et al., 2017), so is a prime candidate to study in the context of LPX models. Additionally, some preliminary evidence indicates that adversarial training might improve LPX generalizability for single-source domain adaptation (Ma et al., 2019).

To learn domain invariant representations, we train a model such that the learned representations maximally confuse a domain classifier f_d. This is accomplished through a min-max objective between the domain classifier parameters θ_D and the parameters θ_G of an encoder f_g. The objective can then be described as follows.

$$\mathcal{L}_D = \max_{\theta_D} \min_{\theta_G} -d \log f_d(f_g(x)) \tag{9}$$

where d is the domain of input sample x. The effect of this is to improve the ability of the classifier to determine the domain of an instance, while encouraging the model to generate maximally confusing representations via minimizing the negative loss. In practice, this is accomplished by training the model using standard cross entropy loss, but reversing the gradients of the loss with respect to the model parameters θ_G.

3.3 Training

Our training procedure follows a multi-task learning setup in which the data from a single batch comes from a single domain. Domains are thus shuffled on each round of training and the model is optimized for a particular domain on each batch.

For the attention based (§3.1.4) and averaging (§3.1.1) models we adopt a similar training algorithm to Guo et al. (2018). For each batch of training, a meta-target t is selected from among the source domains, with the rest of the domains treated as meta-sources $\mathcal{S}' \in \mathcal{S} \setminus \{t\}$. Two losses are then calculated. The first is with respect to all of the meta-sources, where the attention vector is calculated for only those domains. For target labels y_i and a batch of size N with samples from a single domain, this is given as follows.

$$\mathcal{L}_s = -\frac{1}{N}\sum_i y_i \log p_X(x, \mathcal{S}') \qquad (10)$$

The same procedure is followed for the averaging model p_A. The purpose is to encourage the model to learn attention vectors for out of domain data, thus why the meta-target is excluded from the calculation.

The second loss is with respect to the meta-target, where the cross-entropy loss is calculated directly for the domain expert network of the meta-target.

$$\mathcal{L}_t = -\frac{1}{N}\sum_i y_i \log p_t(x) \qquad (11)$$

This allows each model to become a domain expert through strong supervision. The final loss of the network is a combination of the three losses described previously, with λ and γ hyperparameters controlling the weight of each loss.

$$\mathcal{L} = \lambda\mathcal{L}_s + (1-\lambda)\mathcal{L}_t + \gamma\mathcal{L}_D \qquad (12)$$

For the domain classifier (§3.1.3) and fine-tuned averaging (§3.1.2), the individual LPX models are optimized directly with no auxiliary mixture of experts objective. In addition, we experiment with training the simple averaging model directly.

4 Experiments and Results

We focus our experiments on text classification problems with data from multiple domains. To this end, we experiment with sentiment analysis from Amazon product reviews and rumour detection from tweets. For both tasks, we perform cross-validation on each domain, holding out a single domain for testing and training on the remaining domains, allowing a comparison of each method on how well they perform under domain shift. The code to reproduce all of the experiments in this paper can be found here[1].

Sentiment Analysis Data The data used for sentiment analysis come from the legacy Amazon Product Review dataset (Blitzer et al., 2007). This dataset consists of 8,000 total tweets from four product categories: books, DVDs, electronics, and kitchen and housewares. Each domain contains 1,000 positive and 1,000 negative reviews. In addition, each domain has associated unlabelled data. Following previous work we focus on the transductive setting (Guo et al., 2018; Ziser and Reichart, 2017) where we use the same 2,000 out of domain tweets as unlabelled data for training the domain adversarial models. This data has been well studied in the context of domain adaptation, making for easy comparison with previous work.

Rumour Detection Data The data used for rumour detection come from the PHEME dataset of rumourous tweets (Zubiaga et al., 2016). There are a total of 5,802 annotated tweets from 5 different events labelled as rumourous or non-rumourous (1,972 rumours, 3,830 non-rumours). Methods which have been shown to work well on this data include context-aware classifiers (Zubiaga et al., 2017) and positive-unlabelled learning (Wright and Augenstein, 2020). Again, we use this data in the transductive setting when testing domain adversarial training.

4.1 Baselines

What's in a Domain? We use the model from Li et al. (2018) as a baseline for sentiment analysis. This model consists of a set of domain experts and one general CNN, and is trained with a domain adversarial auxiliary objective.

Mixture of Experts Additionally, we present the results from Guo et al. (2018) representing the most recent state of the art on the Amazon reviews dataset. Their method consists of domain expert classifiers trained on top of a shared encoder, with predictions being combined via a novel metric which considers the distance between the mean representations of target data and source data.

Table 1: Experiments for sentiment analysis in (D)VD, (E)lectronics, (K)itchen and housewares, and (B)ooks domains and rumour detection for different events ((C)harlie(H)ebdo, (F)erguson, (G)erman(W)ings, (O)ttawa(S)hooting, and (S)ydneySiege) using leave-one-out cross validation. Results are averaged across 5 random seeds. The results for sentiments analysis are in terms of accuracy and the results for rumour detection are in terms of F1.

Zubiaga et al. 2017 Though not a domain adaptation technique, we include the results from Zubiaga et al. 2017 on rumour detection to show the current state of the art performance on this task. The model is a CRF, which utilizes a combination of content and social features acting on a timeline of tweets.

4.2 Model Variants

A variety of models are tested in this work. Therefore, each model is referred to by the following.

Basic Basic DistilBert with a single classification layer at the output.

Adv-X DistilBert with domain adversarial supervision applied at the X'th layer (§3.2).

Independent-Avg DistilBert mixture of experts averaged but trained individually (not with the algorithm described in §3.3).

Independent-FT DistilBert mixture of experts averaged with mixing attention fine tuned after training (§3.1.2), trained individually.

MoE-Avg DistilBert mixture of experts using averaging (§3.1.1).

MoE-Att DistilBert mixture of experts using our novel attention based technique (§3.1.4).

MoE-Att-Adv-X DistilBert mixture of experts using attention and domain adversarial supervision applied at the X'th layer.

MoE-DC DistilBert mixture of experts using a domain classifier for attention (§3.1.3).

4.3 Results

Our results are given in Table 1. Similar to the findings of Lin et al. (2020) on clinical negation, we see little overall difference in performance from both the individual model and the mixture of experts model when using domain adversarial training on sentiment analysis. For the base model, there is a slight improvement when domain adversarial supervision is applied at a lower layer of the model, but a drop when applied at a higher level. Additionally, mixture of experts provides some benefit, especially using the simpler methods such as averaging.

For rumour detection, again we see little performance change from using domain adversarial training, with a slight drop when supervision is applied at either layer. The mixture of experts methods overall perform better than single model methods, suggesting that mixing domain experts is still effective when using large pretrained transformer models. In this case, the best mixture of experts methods are simple averaging and static grid search for mixing weights, indicating the difficulty in learning an effective way to mix the predictions of domain experts. We elaborate on our findings further in §5. Additional experiments on domain adversarial training using Bert can be found in Table 2 in §A, where we similarly find that domain adversarial training leads to a drop in performance on both datasets.

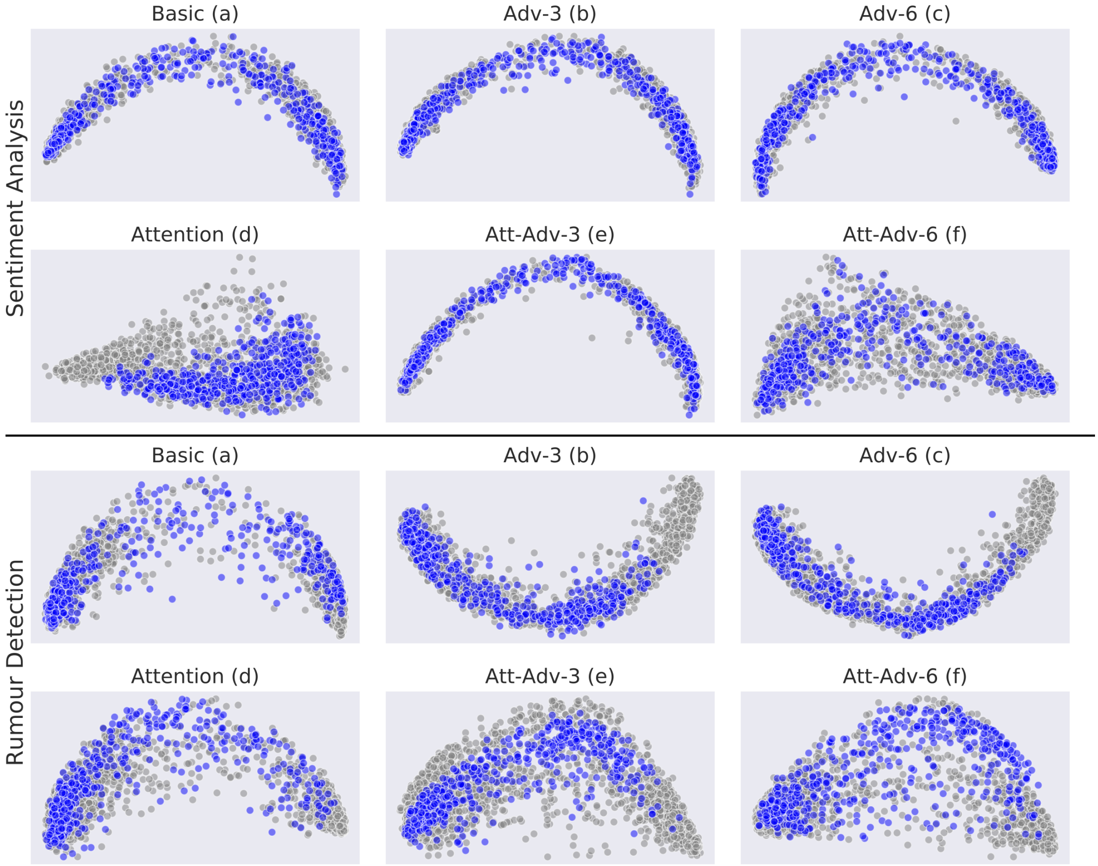

Figure 3: Final layer DistilBert embeddings for 500 randomly selected examples from each split for each tested model for sentiment data (top two rows) and rumour detection (bottom two rows). The blue points are out of domain data (in this case from Kitchen and Housewares for sentiment analysis and Sydney Siege for rumour detection) and the gray points are in domain data.

5 Discussion

We now discuss our initial research questions in light of the results we obtained, and provide explanations for the observed behavior.

5.1 What is the Effect of Domain Adversarial Training?

We present PCA plots of the representations learned by different models in Figure 3. These are the final layer representations of 500 randomly sampled points for each split of the data. In the ideal case, the representations for out of domain samples would be indistinguishable from the representations for in domain data.

In the case of basic DistilBert, we see a slight change in the learned representations of the domain adversarial models versus the basic model (Figure 3 top half, a-c) for sentiment analysis. When the attention based mixture of experts model is used, the representations of out of domain data cluster in one region of the representation space (d). With the application of adversarial supervision, the model learns representations which are more domain agnostic. Supervision applied at layer 6 of DistilBert (plot f) yields a representation space similar to the version without domain adversarial supervision. Interestingly, the representation space of the model with supervision at layer 3 (plot e) yields representations similar to the basic classifier. This gives some potential explanation as to the similar performance of this model to the basic classifier on this split (kitchen and housewares). Overall, domain adversarial supervision has some effect on performance, leading to gains in both the basic classifier and the mixture of experts model for this split. Additionally, there are minor improvements overall for the basic case, and a minor drop in performance with the mixture of experts model.

The effect of domain adversarial training is more pronounced on the rumour detection data for the basic model (Figure 3 bottom half, a), where the rep-

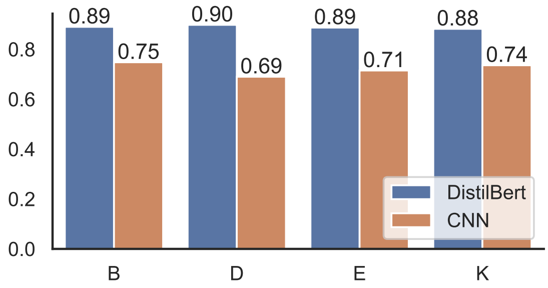

Figure 4: Comparison of agreement (Krippendorff's alpha) between domain expert models when the models are either DistilBert or a CNN. Predictions are made on unseen test data by each domain expert, and agreement is measured between their predictions ((B)ooks, (D)VD, (E)lectronics, and (K)itchen). The overall agreement between the DistilBert experts is greater than the CNNs, suggesting that the learned classifiers are much more homogenous.

resentations exhibit somewhat less variance when domain adversarial supervision is applied. Surprisingly, this leads to a slight drop in performance for the split of the data depicted here (Sydney Siege). For the attention based model, the variant without domain adversarial supervision (d) already learns a somewhat domain agnostic representation. The model with domain adversarial supervision at layer 6 (f) furthers this, and the classifier learned from these representations perform better on this split of the data. Ultimately, the best performing models for rumour detection do not use domain supervision, and the effect on performance on the individual splits are mixed, suggesting that domain adversarial supervision can potentially help, but not in all cases.

5.2 Is Mixture of Experts Useful with LPX Models?

We performed experiments with several variants of mixture of experts, finding that overall, it can help, but determining the optimal way to mix LPX domain experts remains challenging. Simple averaging of domain experts (§3.1.1) gives better performance on both sentiment analysis and rumour detection over the single model baseline. Learned attention (§3.1.4) has a net positive effect on performance for sentiment analysis and a negative effect for rumour detection compared to the single model baseline. Additionally, simple averaging of domain experts consistently outperforms a learned sample by sample attention. This highlights the difficulty in utilizing large pretrained transformer models to learn to attend to the predictions of domain experts.

Comparing agreement To provide some potential explanation for why it is difficult to learn to attend to domain experts, we compare the agreement on the predictions of domain experts of one of our models based on DistilBert, versus a model based on CNNs (Figure 4). CNN models are chosen in order to compare the agreement using our approach with an approach which has been shown to work well with mixture of experts on this data (Guo et al., 2018). Each CNN consists of an embedding layer initialized with 300 dimensional FastText embeddings (Bojanowski et al., 2017), a series of 100 dimensional convolutional layers with widths 2, 4, and 5, and a classifier. The end performance is on par with previous work using CNNs (Li et al., 2018) (78.8 macro averaged accuracy, validation accuracies of the individual models are between 80.0 and 87.0). Agreement is measured using Krippendorff's alpha (Krippendorff, 2011) between the predictions of domain experts on test data.

We observe that the agreement between DistilBert domain experts on test data is significantly higher than that of CNN domain experts, indicating that the learned classifiers of each expert are much more similar in the case of DistilBert. Therefore, it will potentially be more difficult for a mixing function on top of DistilBert domain experts to gain much beyond simple averaging, while with CNN domain experts, there is more to be gained from mixing their predictions. This effect may arise because each DistilBert model is highly pre-trained already, hence there is little change in the final representations, and therefore similar classifiers are learned between each domain expert.

6 Conclusion

In this work, we investigated the problem of multi-source domain adaptation with large pretrained transformer models. Both domain adversarial training and mixture of experts techniques were explored. While domain adversarial training could effectively induce more domain agnostic representations, it had a mixed effect on model performance. Additionally, we demonstrated that while techniques for mixing domain experts can lead to improved performance for both sentiment analysis and rumour detection, determining a beneficial mixing of such experts is challenging. The best method we tested was a simple averaging of the domain experts, and we provided some evidence as to why this effect was observed. We find that LPX models may be better suited for data-driven techniques such as that of Gururangan et al. (2020), which focus on inducing a better prior into the model through pretraining, as opposed to techniques which focus on learning a better posterior with architectural enhancements. We hope that this work can help inform researchers of considerations to make when using LPX models in the presence of domain shift.

A BERT Domain Adversarial Training Results

Additional results on domain adversarial training with Bert can be found in Table 2.

B Reproducibility

B.1 Computing Infrastructure

All experiments were run on a shared cluster. Requested jobs consisted of 16GB of RAM and 4 Intel Xeon Silver 4110 CPUs. We used a single NVIDIA Titan X GPU with 12GB of RAM.

B.2 Average Runtimes

The average runtime performance of each model is given in Table 3. Note that different runs may have been placed on different nodes within a shared cluster, thus why large time differences occurred.

B.3 Number of Parameters per Model

The number of parameters in each model is given in Table 4.

B.4 Validation Performance

The validation performance of each tested model is given in Table 5.

B.5 Evaluation Metrics

The primary evaluation metrics used were accuracy and F1 score. For accuracy, we used our implementation provided with the code. The basic implementation is as follows.

$$\text{accuracy} = \frac{tp + tn}{tp + fp + tn + fn}$$

We used the sklearn implementation of `precision_recall_fscore_support` for F1 score, which can be found here: https://scikit-learn.org/stable/modules/generated/sklearn.metrics.precision_recall_fscore_support.html. Briefly:

$$p = \frac{tp}{tp + fp}$$

$$r = \frac{tp}{tp + fn}$$

$$F1 = \frac{2 * p * r}{p + r}$$

where tp are true positives, fp are false positives, and fn are false negatives.

B.6 Hyperparameters

We performed and initial hyperparameter search to obtain good hyperparameters that we used across models. The bounds for each hyperparameter was as follows:

- Learning rate: [0.00003, 0.00004, 0.00002, 0.00001, 0.00005, 0.0001, 0.001].
- Weight decay: [0.0, 0.1, 0.01, 0.005, 0.001, 0.0005, 0.0001].
- Epochs: [2, 3, 4, 5, 7, 10].
- Warmup steps: [0, 100, 200, 500, 1000, 5000, 10000].
- Gradient accumulation: [1,2]

We kept the batch size at 8 due to GPU memory constraints and used gradient accumulation instead. We performed a randomized hyperparameter search for 70 trials. Best hyperparameters are chosen based on validation set performance (accuracy for sentiment data, F1 for rumour detection data). The final hyperparameters selected are as follows:

- Learning rate: 3e-5.
- Weight decay: 0.01.
- Epochs: 5.
- Warmup steps: 200.
- Batch Size: 8
- Gradient accumulation: 1

Additionally, we set the objective weighting parameters to $\lambda = 0.5$ for the mixture of experts models and $\gamma = 0.003$ for the adversarial models, in line with previous work (Guo et al., 2018; Li et al., 2018).

Abstract

Deep neural networks have become the standard approach to building reliable Natural Language Processing (NLP) applications, ranging from Neural Machine Translation (NMT) to dialogue systems. However, improving accuracy by increasing the model size requires a large number of hardware computations, which can slow down NLP applications significantly at inference time. To address this issue, we propose a novel vector-vector-matrix architecture (VVMA), which greatly reduces the latency at inference time for NMT. This architecture takes advantage of specialized hardware that has low-latency vector-vector operations and higher-latency vector-matrix operations. It also reduces the number of parameters and FLOPs for virtually all models that rely on efficient matrix multipliers without significantly impacting accuracy. We present empirical results suggesting that our framework can reduce the latency of sequence-to-sequence and Transformer models used for NMT by a factor of four. Finally, we show evidence suggesting that our VVMA extends to other domains, and we discuss novel hardware for its efficient use.

1 Introduction

Artificial neural networks have become increasingly popular over the last decade as they excel in tasks such as object detection and speech recognition (LeCun et al., 2015), which are becoming more commonplace with the use of self-driving cars and virtual assistants. The rapid development of deep neural networks has also made them the dominant approach for natural language processing (NLP) applications, ranging from neural machine translation (NMT) (Bahdanau et al., 2015; Klein et al., 2017; Wu et al., 2016) and text summarization (Rush et al., 2015; Nallapati et al., 2016; Liu et al., 2018) to virtual assistants such as Apple Siri, Amazon Alexa, and Google Home.

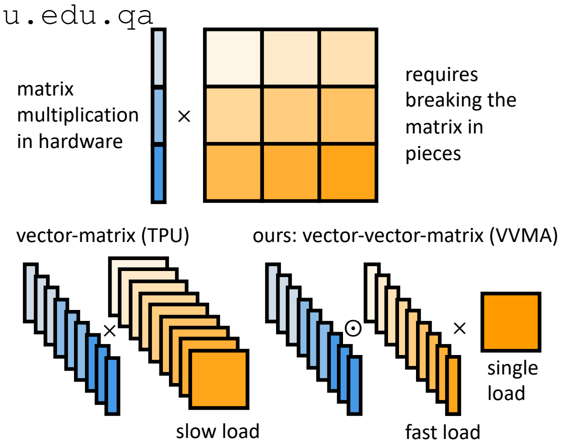

Figure 1: TPU vs. VVMA. Top: to multiply a vector by a matrix, the hardware tiles up the matrix. Bottom left: the TPU loads each piece. Bottom right: the VVMA loads a single piece (for broadcasting) and adds diagonals for element-wise multiplication, which is faster.

Unfortunately, neural networks are slow for training, inference and use due to their vast computational complexity. Several approaches have been proposed to address these issues including (*a*) quantization and pruning, (*b*) efficient models with less computational demand, and (*c*) specialized hardware accelerators (Sze et al., 2017). While direction (*a*) has been well-studied (LeCun et al., 1990; Han et al., 2016b,a; Guo, 2018; Quinn and Ballesteros, 2018), and can be considered complementary to (*b*,*c*), optimizing the combination of (*b*) and (*c*) has not been considered, to the best of our knowledge. Thus, here we propose a novel *vector-vector-matrix architecture* (VVMA) that compresses neural networks, while optimizing for hardware performance at inference time. Therefore, we optimize (*b*) and (*c*), without conflicting with (*a*), i.e., using quantization and pruning can potentially further boost the efficiency of our framework. Figure 1 illustrates this VVMA in contrast to a traditional vector-matrix architecture.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7975–7984,
November 16–20, 2020.

Moreover, the inherently sequential nature of many NLP tasks can increase the latency at inference time. Constrained by their memory bandwidth and footprint, modern accelerators rely on large batch sizes to avoid under-utilization. However, it is not always possible to increase the batch size if conclusions have to be inferred quickly, e.g., for real-time inference. For example, the matrix multiply unit of state-of-the-art accelerators, such as Google's Tensor Processing Unit (TPU), will "stall" when translating a single sentence, thus increasing the overall latency (Jouppi et al., 2017).

Our architecture can improve the TPU and other AI accelerators for *small-batch inference*. Thus, unlike other methods for compressing neural networks, the VVMA is designed to take advantage of the dataflow and the architecture of certain kinds of hardware accelerators such as the TPU.

Our contributions are as follows:

- We tailor an efficient model to state-of-the-art hardware accelerators.
- We provide an efficient vector-vector-matrix architecture (VVMA) framework for inference with small batch sizes.
- We use VVMAs to speed up inference in the computationally expensive Neural Machine Translation (NMT) task by a factor of four without losing much in terms of quality.
- We highlight promising applications of the VVMA in other deep learning domains and novel Artificial Intelligence (AI) accelerators.

The rest of this paper is organized as follows: In Section 2, we elaborate on directions (*b*) and (*c*), and we relate them to VVMAs. In Section 3, we motivate VVMAs as a faster improvement of the TPU's architecture and dataflow at inference time, and we then analyze our framework in its universality, including tips for efficient implementation of VVMAs. As a proof of concept, in Section 4 we demonstrate empirical inference speed-ups for NMT using Seq2seq-LSTM and Transformer models, which are both notorious for their computational complexity. We also show ablation studies and extensions to other tasks. In Section 5, we explore novel accelerators that can benefit from VVMAs. Finally, we offer concluding remarks in Section 6, and we point to possible directions for future work.

2 Background

Here, we look at efficient models from the software and the hardware side, and we discuss the advantages of merging them in a *co-design* manner. We further discuss the importance of wall-clock speed versus floating point operations and why from this perspective our weight sharing matrices will decrease inference rather than training time.

2.1 Efficient Models from the Software Side for Training and Inference

Efficient model architectures can decrease the complexity of neural networks. Some techniques to achieve this are described in (Chen et al., 2015; Zhang et al., 2018; Gao et al., 2018).

Zhang et al. (2018) added a new type of layer, a *channel shuffle layer*, to neural networks that use group convolution. By shuffling the data between layers, they reduced the number of parameters in the other layers while retaining similar accuracy. Gao et al. (2018) used a technique similar to group convolution, but applied it to recurrent neural networks. They used shuffling operations with a group recurrent neural network and showed improvements for NMT and text summarization.

Chen et al. (2015) compressed a weight matrix into a learned vector of weights. They used a hash function to map entries in the weight matrix to elements in the vector. As a result, many matrix entries share a single weight in the vector.

As Transformers are becoming the standard building block for NLP tasks, there is a growing effort to make them efficient, since their inference time scales as $O(N^2)$, where N is the number of input tokens. Child et al. (2019) proposed Sparse Transformers with $O(N\sqrt{N})$ complexity. Likewise, Sukhbaatar et al. (2019) developed Adaptive Attention Span and Kitaev et al. (2020) proposed Reformer using locality-sensitive hashing, and achieved $O(N \log N)$ complexity. See (Ganesh et al., 2020) for a broader overview.

In a similar fashion, our VVMA is an efficient model because it reduces the computational complexity at inference time without much decrease in performance. However, unlike the above models, VVMAs focus on the low levels of execution: the VVMA is an architecture that speeds up matrix multiplications. Thus, it is an efficient model that relates to hardware accelerators directly and it is universal, as matrix multiplication is the dominant computational factor for neural network inference.

2.2 Efficient Models from the Hardware Side

As we have mentioned above, successful NLP applications have been based on a variety of neural network models: recurrent and convolutional neural networks, memory-augmented networks, attention mechanism, Transformers, etc. These models were designed to solve numerous tasks ranging from language modeling and named entity recognition to NMT and other sequence modeling and sequence generation tasks. Most of the computation in such models is matrix multiplication both at inference and at training time, which is expensive. Therefore, specialized hardware accelerators for neural networks have been designed, focusing on making matrix multiplication efficient.

Note that the above techniques assume general hardware, i.e., they do not utilize the specific dataflow or architecture of an AI accelerator to improve efficiency. Yet, several such accelerators have been developed recently, e.g., the Horizon Robotics Brain Processing Unit, Graphcore Intelligence Processing Unit, NVIDIA Tensor Core, and Google Tensor Processing Unit (TPU).

A *matrix-matrix* architecture is a hardware unit that takes two matrices and multiplies them, e.g., NVIDIA Tensor Core. A *vector-matrix* architecture such as Google's TPU multiplies a vector and a matrix. As shown in Figure 1, the VVMA *vector-vector-matrix* architecture takes two vectors and a matrix, and it multiplies element-wise the first vector by the second vector, and then multiplies the resulting vector by the matrix.

Furthermore, VVMAs are optimized for certain AI accelerators, such as the TPU architecture. We specifically take advantage of the dataflow of the matrix multiply unit in the TPU, which is described in (Jouppi et al., 2017). This matrix multiply unit allows to re-use weights for multiple batches of data, while also using a systolic loop to perform matrix multiplication extremely fast. Therefore, we reduce the computational complexity of the "matrix" component in the TPU's vector-matrix unit, but we also maintain representational accuracy by inserting an extra "vector" part to get the vector-vector-matrix unit. By switching to this unit, we introduce a trade-off by increasing the efficiency of the model while decreasing its flexibility and generalization power. Likewise, we expect to have comparable accuracy to other compression techniques while also providing even faster performance at inference time.

2.3 Trade-Off between Flexibility and Efficiency at Inference Time

While every neural network requires a certain budget of floating point operations for a target computation, how fast such computations are in practice depends not on the size of this budget but rather on the number of wall clocks needed in order to cover all floating point operations. Thus, it is important to combine the software and the hardware advances in a co-design manner to optimize an efficient model for the correct metric: wall clocks.

Designed to optimize for the number of wall clocks, our VVMA introduces an extra vector component that maintains accuracy, but increases the computational complexity. We achieve this in part by optimizing our VVMA to specifically take advantage of the TPU architecture and dataflow. This creates a trade-off between flexibility and efficiency, e.g., the more we reuse weights, the more we have to compensate for the model accuracy.

Neural networks that are specifically designed to work in conjunction with certain AI accelerators will encounter a similar trade-off. That is, the more a neural network is tuned for efficiency, the less flexibility for change the model will have (Han et al., 2015). Nonetheless, we find regimes that suppress this trade-off and yield faster neural networks inference with VVMA. Thus, we believe that our VVMAs provide enough flexibility to be useful in a variety of existing neural architectures.

Training is the process of using (large) datasets to learn specific weights in neural networks. This process is usually very computationally expensive and can take days or months to complete. Once a neural network has finished training, the set of weights that were learned through the training process can remain fixed while making predictions. This process of using a fixed set of weights to make predictions with a neural network is called *inference* (Sze et al., 2017). Training can be done faster when parallelizing the process and increasing the amount of data fed into the network at a given time. This roughly translates to increasing the throughput of the training process. However, when performing inference on a single data point, the latency of making predictions seems to dominate the runtime (Jouppi et al., 2017). The VVMA we propose can be used specifically to decrease the latency of a neural network. Likewise, we expect this technique to be used to decrease inference time rather than to decrease training time.

3 Architecture

In this section, we present our approach to constructing a VVMA, including implementation details that are necessary to use VVMAs in practice.

3.1 Motivation

Google announced their first application-specific AI accelerator called the *Tensor Processing Unit* (TPU) in 2016. As described by Jouppi et al. (2017), the TPU uses a systolic loop to perform matrix multiplications (Jouppi et al., 2017), which are the most demanding computations in deep neural networks. Let W be an $n \times n$ weight matrix and x be an n-dimensional input vector. In order to perform Wx on the TPU, we must first break up W and x into $k \times k$ sections, where $k \times k$ is the size of the matrix multiply unit:

$$Wx = \begin{bmatrix} W_{1,1} & W_{1,2} & \cdots \\ W_{2,1} & W_{2,2} & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \end{bmatrix}. \quad (1)$$

Here, $W_{i,j}$ is a $k \times k$ block of W, and x_j is a k-dimensional block of x. Likewise, the TPU must load each block $W_{i,j}$ onto the matrix multiply unit before multiplying it by x_j. Loading a $k \times k$ block takes $O(k)$ clocks on the TPU. After loading a block $W_{i,j}$ onto the TPU, it takes $O(2k + t)$ clocks to multiply t k-dimensional vectors x_j by the matrix $W_{i,j}$. So, the total number of clocks to multiply t n-dimensional vectors x by W is

$$O\left(\frac{n^2}{k^2}(k + 2k + t)\right). \quad (2)$$

Note the large latency for single-batch inference, i.e., for $t = 1$. In order to decrease it, we tweak the weight matrix W, so that we only have to load a single $k \times k$ block M onto the matrix multiply unit. We then perform vector operations to each x_j in order to make up for the extra parameters that are lost by re-using the same $k \times k$ matrix M. Figure 2 shows an illustration of this process.

With this new procedure, the total number of clocks to multiply t n-dimensional vectors by the larger matrix is given by

$$O\left(k + 2k + \frac{n^2 t}{k^2}\right). \quad (3)$$

We can see that this new procedure significantly decreases the total number of clocks for single-batch inference with $t = 1$.

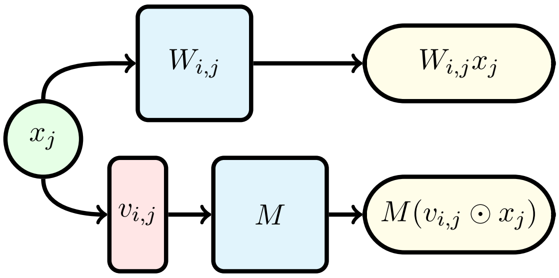

Figure 2: Illustration of how we can save time by sharing a weight matrix M. The top path shows the traditional dataflow, where each $W_{i,j}$ must be loaded onto the matrix multiply unit. The bottom path shows our approach, where M is loaded onto the matrix multiply unit only once. We then add a vector-vector operation $v_{i,j} \odot x_j$ before doing the matrix multiplication, where $\odot$ denotes element-wise multiplication.

3.2 Vector-Vector-Matrix Architecture

We construct the VVMA as follows. Let W be a large $n \times n$ weight matrix and let M be a smaller $k \times k$ weight matrix. First, we tile M into a larger matrix, so that its size is greater than or equal to the weight matrix W. Then, we multiply each copy of M by a unique diagonal matrix. Mathematically, we replace W with a structured matrix as shown below:

$$\begin{bmatrix} MD_{1,1} & MD_{1,2} & \cdots \\ MD_{2,1} & MD_{2,2} & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix}, \quad (4)$$

where M is a shared $k \times k$ weight matrix and $D_{i,j}$ is a diagonal $k \times k$ weight matrix.

We use the diagonal matrices $D_{i,j}$ in order to introduce variation to each of the copies of M. We found that this is necessary for a VVMA to be able to effectively replace the original matrix W. Each of the entries in the matrix M is shared in multiple blocks of the new matrix, thus decreasing the total number of parameters compared to the original weight matrix W. Moreover, each of the entries of M as well as the entries in each diagonal matrix $D_{i,j}$ are learned as part of the training process.

Even though each entry $D_{i,j}$ is mathematically represented as a matrix in Equation 4, we can also see it as a k-dimensional vector $v_{i,j}$. We can then perform the matrix multiplication $D_{i,j}x$ as an element-wise multiplication $v_{i,j} \odot x_j$, as shown in Figure 2.

Task	Model	Architecture	# Params	BLEU	# Clocks	FLOPs

Table 1: Comparing the original Seq2seq-LSTM and Transformer models to such with VVMAs. Shown are the number of parameters, the BLEU score, and the estimated number of clock cycles and floating point operations.

3.3 Implementation Details

In order to implement equation 4 as a trainable matrix, we found that it was inefficient to actually construct the entire matrix representation. Instead, it was better to take advantage of broadcasting, which allows us to element-wise multiply tensors of different shapes. Likewise, we use broadcasting to multiply the input vector x by a larger diagonal tensor D. We then perform a matrix multiplication with the broadcasted vector and the matrix M. Thus, our program constructs a single $k \times k$ matrix M, and it does so only once rather than actually tiling it as shown in equation 4. We further found that a more aggressive gradient clipping was needed when training Seq2seq-LSTM models that use VVMAs; otherwise, the gradient grew extremely large and as a result eventually overflowed. We believe that this is because gradients accumulate as we propagate them back to a single small matrix M.

4 Results

In this section, we present empirical results showing that VVMAs can substitute different types of weight matrices in neural networks (NNs). Specifically, we use our VVMAs in Seq2seq-LSTM and Transformer NMT. We report some theoretical speedups that VVMAs provide when using a TPU-style architecture. We then present a small ablation study where we modify our VVMAs by removing the diagonal terms $D_{i,j}$ or by varying the value of k. We also compare VVMA to standard low-rank approximations. Finally, we show that our technique extends to language modelling with Transformer-XL, and beyond NLP tasks.

Unless otherwise noted, all results in this section use VVMAs with $k = 32$. That is, the matrix W in the neural network is replaced with a VVMA that uses a 32×32 matrix M along with 32×32 diagonal matrices $D_{i,j}$ as shown in equation 4.

4.1 Neural Machine Translation

We tested our VVMAs on NMT: we integrated them as part of Seq2seq-LSTM and Transformer models, as they are most commonly used today.

4.1.1 Sequence-to-Sequence Models

For the Seq2seq-LSTM models (Cho et al., 2014; Sutskever et al., 2014), we slightly modified the code by Luong et al. (2017), and we ran it on the two benchmarks provided in the repository. In particular, we used WMT datasets to train German-English and English-German models. We further used IWSLT datasets to train Vietnamese-English and English-Vietnamese models. We prepared the datasets according to the instructions found in the repository. For the German-English and English-German models, we used newstest2015 for testing.

Both models are Seq2seq models with LSTM layers and attention mechanism. We used four VVMAs for the LSTM cells: for the forget gate, for the input gate, for the output gate, and for the cell state vector. We also used VVMAs for the matrices in the attention mechanism.

For the Seq2seq-LSTM models, we decreased the gradient clipping value from 5 to 1 in order to prevent the gradient from overflowing. We also decreased the batch size to 32, to fit the models on a single GPU. We trained for 340,000 iterations for German-English and English-German, and 48,000 for Vietnamese-English and English-Vietnamese.

The results comparing the original models with models that use VVMAs are shown in Table 1. We can see that the BLEU scores decrease when using VVMAs, which should be expected given that the overall number of parameters in the model decreased noticeably. Overall, when taking into account the number of parameters, the observed decrease in the BLEU scores is very reasonable.

4.1.2 Transformer Models

For the Transformer models (Vaswani et al., 2017), we replaced the matrices in the feed-forward layers with VVMAs.[1] We trained these models on WMT datasets for German-English and English-German translation. We prepared the datasets according to the instructions found in the repository that we modified. We used the base Transformer models with a hidden size of 512 (rather than the big models, which have a hidden size of 1024). We trained these models with a batch size of 2048 for 6 epochs.

In Table 1, we present our results on the Transformer models with VVMAs. We achieved reasonable BLEU scores compared to the original Transformer. For German-English, the original model had 61.4M parameters and an uncased test BLEU score of 29.66. The VVMA model had 37M parameters and a BLEU score of 28.5. For English-German, the original model had 61.4M parameters and a BLEU score of 24.57. The VVMA model had 37M parameters and a BLEU score of 23.13. To recap, each matrix in these models was replaced by VVMAs except for the embedding and the projection matrices. We found that restricting these with the VVMA constraints had a sizable negative impact on performance.

4.2 Theoretical Speedups

We also calculated two measures for the inference time of the models described in Section 4.1: (*i*) the estimated number of clock cycles, and (*ii*) the number of floating point operations (FLOPs). Both roughly correspond to the real time needed to perform the inference at run time. We computed the former for a TPU-style architecture with one matrix multiply unit of size $k \times k$, and we estimated the latter for the original and the VVMA models using Equations 2 and 3 with $k = 32$, $t = 1$, and sequence lengths of 25. Note that the vector-vector operation before M takes zero extra clock cycles, as illustrated in Figures 1 and 2.

This happens because we pipeline these vector-vector processes as we feed the data into the matrix multiply unit. Moreover, we initialize these operations while loading weights into the matrix multiply unit. We used a TensorFlow profiling tool in order to measure the number of FLOPs in our models. Looking at Table 1, we can see that the original Seq2seq-LSTM models require three to four times more clock cycles and roughly twice as many FLOPs compared to the VVMA models.

For the Transformer models with VVMAs, we saw less noticeable speed-ups. For similar accuracy, the estimated number of clock cycles and FLOPs were roughly 1.7 and 1.5 times more in the original Transformer models compared to models with VVMAs. This is expected since we use VVMAs only in the feed-forward layers. We tried to use VVMAs for the attention layers as well, but this led to larger decrease in accuracy, due to the significant reduction in the number of parameters.

As the Transformer is already getting noticeable impact in industrial settings, e.g., for machine translation and Web search, there is active research in developing more efficient Transformer architectures (Sanh et al., 2019; Kitaev et al., 2020; Beltagy et al., 2020; Zaheer et al., 2020). Thus, with each new version of a Transformer architecture, new VVMA experiments would be needed in order to measure the potential improvements in efficiency that VVMA would yield.

4.3 Ablation Study

Next, we performed an ablation study for the Seq2seq-LSTM models described in Section 4.1 for the English-Vietnamese machine translation task. In particular, we slightly modified the VVMAs in the Seq2seq-LSTM models by removing the diagonal terms $D_{i,j}$ or by changing the value of k.

Here, we trained with a batch size of 32 for 48,000 steps. In order to prevent the gradient from overflowing, we needed to multiply the shared matrix M by a scaling factor of 0.1 when removing the diagonal terms $D_{i,j}$. The results are shown in Table 2. We can see that removing the diagonal terms significantly decreases the BLEU scores for our models, while changing the value of k has no significant impact. Additionally, Figure 3 presents BLEU scores as the number of clock increases. We can see that compared to their original counterparts, VVMA models do not yield degradation in performance when then number of clocks gets large.

Architecture	k	**Diags**	**# Params**	**BLEU**	**# Clocks**	**FLOPs**
Original	N/A	N/A	27.5M	25.34	34.8M	54.9M
VVMA	32	T	17.1M	24.42	10.3M	34.1M
VVMA	32	F	16.7M	15.62	10.3M	33.8M
VVMA	16	T	17.4M	24.76	22.7M	34.8M
VVMA	64	T	16.9M	23.96	5.0M	33.9M

Table 2: Ablation study for English-Vietnamese NMT with Seq2seq-LSTM models. Here, k is the size of M in VVMAs, Diags shows whether diagonal terms are present (T=true, F=false), then follow the number of parameters, BLEU score, number of clocks and FLOPs. Original's clock is on a TPU with a block size of 32.

Architecture	k	**# Params**	**# Clocks**	**PPL**
Original	N/A	151.1M	99.4M	24.05
VVMA	32	138.2M	67.0M	30.70
VVMA	64	138.1M	35.9M	30.55
QRNN	N/A	151.0M	N/A	33.0

Table 3: Language modeling on WikiText-103 using Transformer-XL with and without VVMA, as well as using QRNN. (Original: TPU with a block size of 32.)

n **/ Fit** ($\times 10^3$)	**VVMA**	**Low-rank**	**Optimal**
1,024	3.0	2.9	2.9
2,048	6.1	5.9	5.8
4,096	12.2	11.9	11.7

Table 4: VVMA's closeness of fit to a target matrix is comparable to that of (*i*) standard low-rank approximation and (*ii*) optimal approximation, but it is orders of magnitude faster at inference time.

4.4 Comparison to Standard Low-Rank Approximation

First, note that the rank of VVMA is maximum k for a $k \times k$ sharing matrix. To prove that, we can represent the matrix in equation 4 as a product of matrices of maximal rank k. Then, we can use the property that $\operatorname{rank}(AB) \leq \min(\operatorname{rank}(A), \operatorname{rank}(B))$.

Second, we compare to low-rank approximation. We fix $k = 128$ and we choose $n =$1,024; 2,048; 4,096. We sample a random matrix and we fit VVMA parametrization to it using Adam (Kingma and Ba, 2015) with a learning rate of 0.0001 ran for $30,000$ steps, and using the Frobenius norm as a loss. We do the same experiment with $UV^\top$ low-rank rank-p approximation, where p is chosen to match the number of parameters in VVMA. Additionally, we use Eckart–Young–Mirsky's theorem to get the Optimal low-rank fit. Table 4 shows some Frobenius norm losses from these experiments. We can see that VVMA's expressiveness is comparable to standard low-rank approximation; note, however, that standard low-rank approximation does not yield the inference speedups of VVMA.

4.5 Extension to Language Modelling

Even though the main focus of this paper is the contribution of VVMA to neural machine translation, we also demonstrate that VVMA is compatible to state-of-the-art language modelling architectures. For that purpose, we perform an experiment on WikiText-103 (Merity et al., 2017) using the Transformer-XL model (Dai et al., 2019).

In this experiment, we directly integrate VVMA into the Transformer-XL architecture, keeping all hyper-parameter values as in the original Transformer-XL paper (Dai et al., 2019), except for reducing the batch size to 30, in order to fit the optimization on two GPUs. We chose to replace the weights of the attention mechanism with VVMA. Replacing the weights of the positional feed-forward layers drastically decreases the number of parameters, which yields poor performance, as Transformer-XL's perplexity is sensitive to the number of parameters. We present our results in Table 3, where we can see that VVMA with a block size of 256 yields reasonable performance, and the perplexity decreases noticeably with the reduction of parameters.

4.6 Extension to Other Areas

We further extended our VVMAs beyond NLP, to image classification. We modified the convolutional filters in ResNet (He et al., 2016) to use VVMAs and we trained on CIFAR-10.[2] We prepared the CIFAR-10 dataset following the instructions in the repository we modified. We trained all ResNet models with a batch size of 128 for 250 epochs. Figure 3 bottom shows the accuracy of the ResNet models as a function of the number of parameters. We can see that the ResNet models with VVMAs outperform the original ResNet models when keeping the number of parameters fixed.

---

[2] We modified code from `github.com/tensorflow/models/tree/master/official/resnet`

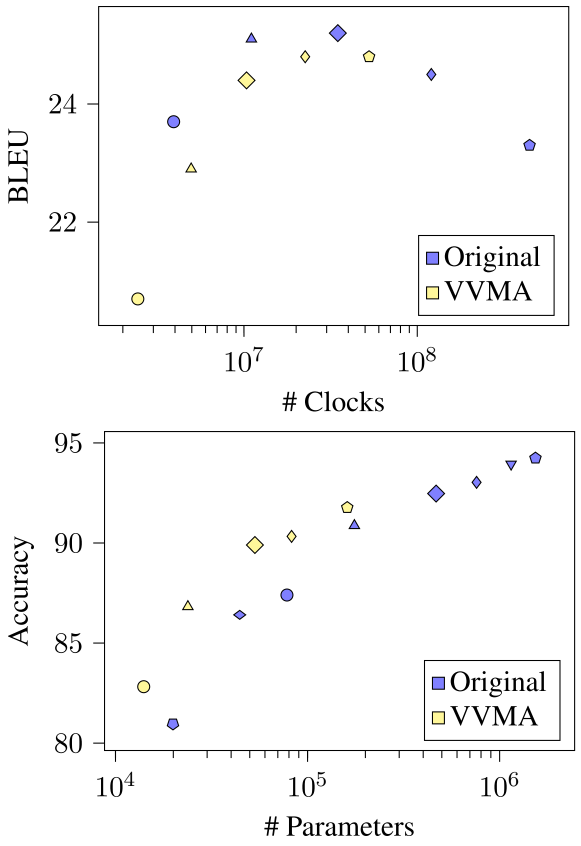

Figure 3: BLEU scores and validation accuracy as a function of the number of trainable parameters in the original and in the VVMA Seq2seq-LSTM models for English-Vietnamese (top) and ResNet (He et al., 2016) models on CIFAR-10 (bottom). The number of parameters is varied by changing the depth and the size of the hidden state. Unique shapes with different colors refer to the same Seq2seq-LSTM model, with the original model in blue and the VVMA model in yellow.

5 Discussion

Below, we discuss new AI hardware that could optimize inference for neural networks via VVMAs. This hardware would decrease latency at inference time rather than decreasing the training time.

Tensor Processing Unit. As mentioned above, Google's Tensor Processing Units (TPU) has a dedicated matrix multiply unit (Jouppi et al., 2017). We believe that a modified version of the TPU could take advantage of VVMAs. The necessary modifications would be relatively simple. As illustrated in Figure 2, we would add a dedicated vector-vector unit before the matrix multiply unit, and we would pipeline it and initialize it at the same time as the matrix multiply unit. As seen in Section 4.2, this would noticeably decrease the number of inference clock cycles in Seq2seq-LSTM models.

Tensor Cores. NVIDIA's newest GPUs have dedicated matrix multiply units called *Tensor Cores*, which can perform 4×4 matrix multiplications in a single clock cycle (Markidis et al., 2018). Adding vector-vector units before each Tensor Core would make them more efficient for VVMAs. The largest speedup would come from the time spent loading matrices from the memory into the Tensor Cores. For instance, if multiple Tensor Cores share the same matrix elements, this would decrease the latency when performing inference.

Optical Processing Unit. A newer, more experimental architecture, is to use VVMAs with optical computing. Shen et al. (2017) proposed to use an Optical Processing Unit (OPU) to perform matrix multiplications at the speed of light. Likewise, it is possible to use an OPU in order to accelerate inference on a neural network. Note, however, that the OPU would run into some of the same problems that the TPU has. That is, there will be a large delay when loading the matrix weights from the memory onto the OPU. Thus, we propose to add an electronic vector-vector unit before the OPU, which would be pipelined and initialized as weights are loaded onto the OPU. This extra unit will not increase the overall latency of a system that uses an OPU because the input vectors will still need to be fetched from the digital electronic memory. Likewise, performing vector-vector operations with the input data will not significantly increase the latency of the entire system.

6 Conclusion and Future Work

We have proposed a novel vector-vector-matrix architecture for low-latency inference, and we have demonstrated theoretical and empirical speed-ups for Seq2seq-LSTM and Transformer models, with application to neural machine translation, language modeling, and image classification. We hope that this work would bring the novel concept of AI *co-design* (between software and hardware) to the domain of NLP applications.

In future work, we plan to optimize the low-level code and to develop new hardware to deploy VVMAs in real-world applications. Distilling models to their VVMA counterparts would be an interesting experiment, and potentially an orthogonal enhancement to pre-existing frameworks (Sanh et al., 2019). VVMAs could also be an orthogonal contribution to other factorizations of NLP models, such as in (Lan et al., 2020).

The importance of fillers for text representations of speech transcripts

Tanvi Dinkar[1]*, **Pierre Colombo**[1,2]*,

Abstract

While being an essential component of spoken language, fillers (e.g. "um" or "uh") often remain overlooked in Spoken Language Understanding (SLU) tasks. We explore the possibility of representing them with deep contextualised embeddings, showing improvements on modelling spoken language and two downstream tasks — predicting a speaker's stance and expressed confidence.

1 Introduction

Disfluencies are interruptions in the regular flow of speech, such as pausing silently, repeating words, or interrupting oneself to correct something said previously (Fraundorf et al., 2018). They commonly occur in spoken language, as spoken language is rarely fluent. *Fillers* are a type of disfluency that can be a sound ("um" or "uh") filling a pause in an utterance or conversation.

Recent work has shown that contextualised embeddings pre-trained on large written corpora can be fine-tuned on smaller spoken language corpora to learn structures of spoken language (Tran et al., 2019). However, for NLP tasks, fillers and all disfluencies are typically removed in pre-processing, as NLP models achieve highest accuracy on syntactically correct utterances. This contradicts linguistic studies, which show that fillers are an essential and informative part of spoken language (Clark and Fox Tree, 2002; Yoshida and Lickley, 2010; Brennan and Williams, 1995; Corley et al., 2007; Stolcke and Shriberg, 1996).

So far, the information carried by fillers has only been studied using hand crafted features, for example in Le Grezause (2017); Saini (2017); Dinkar et al. (2020). Besides, Barriere et al. (2017) show that pre-trained word embeddings such as Word2vec (Mikolov et al., 2013), have poor representation of spontaneous speech words such as "uh", as they are trained on written text and do not carry the same meaning as when used in speech. We address the matter of representing fillers with deep contextualised word representations (Devlin et al., 2019), and investigate their usefulness in NLP tasks for spoken language, without handcrafting features.

Hence, the present work is motivated by the following observations: (1) Fillers play an important role in spoken language. For example, a speaker can use fillers to inform the listener about the linguistic structure of their utterance, such as in their (difficulties of) selection of appropriate vocabulary while informing the listener about a pause in their upcoming speech stream (Clark and Fox Tree, 2002). (2) Fillers and prosodic cues have also been linked to a speaker's *Feeling of Knowing (FOK)* or *expressed confidence*, that is, a speaker's certainty or commitment to a statement (Smith and Clark, 1993). Brennan and Williams (1995) observed that fillers and prosodic cues contribute to the listener's perception of the speaker's expressed confidence in their utterance, which they refer to as the *Feeling of Another's Knowing (FOAK)*, also observed by (Wollermann et al., 2013). (3) Recent work has shown that fillers have been successful in *stance* prediction (stance referring to the subjective spoken attitude towards something) (Le Grezause, 2017).

Aim of this work: We want to verify that these observations are still valid when

we represent fillers in an automatic and efficient way. Hence, our contributions are as follows: (1) Fillers contain useful information that can be leveraged by deep contextualised embeddings to better model spoken language and thus should not be removed. In addition, we study which filler representation strategies are best suited to our task of Spoken Language Modelling (SLM) and investigate the learnt positional distribution of fillers. (2) We show that in a spontaneous speech corpus of spoken monologues, fillers are a discriminative feature in predicting the perception of expressed confidence of the speaker, and perception of a speaker's stance (which we measure by sentiment).

2 Models and Data description

2.1 Model Description

For our work, we consider the two fillers "uh" and "um" (see subsection 2.2). To obtain contextualised word embeddings for fillers, we use bidirectional encoder representations from transformers (BERT) (Devlin et al., 2019), as it has achieved SOTA performance on several NLP benchmarks and are better than Word2Vec for word sense disambiguation by integrating context (Bartunov et al., 2015).

2.1.1 Spoken Language Modelling

For SLM, we use the masked language modelling objective (MLM). It consists of masking some words of the input tokens at random, and then predicting these masked tokens. The MLM objective is classically used to pretrain and then fine-tune BERT. Here, we use this MLM objective to fine-tune a pretrained BERT on a spoken language corpus (see subsection 2.2). Each experiment requires a token representation strategy $\mathcal{T}_i$ and a pre-processing strategy $\mathcal{P}_{Si}$ (additional details are given in the algorithm 1 in Supplementary).

The **token representation strategies** are particularly important for our task, for BERT to learn the distribution of fillers. The three token representation strategies $(\mathcal{T}_1, \mathcal{T}_2, \mathcal{T}_3)$, are described as follows: In $\mathcal{T}_1$, no special treatment is done to the fillers[1], i.e BERT will use its a priori knowledge of the fillers "uh" or "um" to model the language. In $\mathcal{T}_2$, "uh" and "um" are distinguished from other tokens by a special filler tag, and are represented as two different tokens respectively; this strategy aims at forcing BERT to learn a new embedding that focuses both on the position and the context of the fillers. In $\mathcal{T}_3$, both fillers are represented as the same token, suggesting that they have the same pragmatic meaning and are interchangeable. A concrete example is given in Table 1.

Pre-processing strategies, $(\mathcal{P}_{S1}, \mathcal{P}_{S2}, \mathcal{P}_{S3})$, are as follows: In $\mathcal{P}_{S1}$, the sentences have all fillers removed, both during training and inference. In $\mathcal{P}_{S2}$, the sentences have the fillers kept during training, but are removed at inference. In $\mathcal{P}_{S3}$, the fillers are kept both during training and inference. For each pre-processing and token representation strategy, we optionally fine-tune BERT using the same Masked Language Model (MLM) objective as in the original paper (Devlin et al., 2019). Note, if we do not fine-tune, the training dataset $(\mathcal{D}_{train})$ is not used and therefore $\mathcal{P}_{S1}$ and $\mathcal{P}_{S2}$ are equivalent. For language modelling we report the perplexity (ppl) measure to evaluate the quality of the model.

2.1.2 Confidence and Sentiment Prediction

In both our confidence prediction and sentiment analysis task, our goal is to predict a label of confidence/sentiment using our BERT text representations that include fillers. Formally, our confidence/sentiment predictor is obtained by adding a Multi-Layer Perceptron (MLP) on top of a BERT, which has been optionally fine-tuned using the MLM. The MLP is trained by minimising the mean squared error (MSE) loss (additional details are given in algorithm 2 in Supplementary). We keep the same token representation and pre-processing strategies from Section 2.1.1.

2.2 Data Description

We use the Persuasive Opinion Mining (POM) dataset (Park et al., 2014), a dataset of 1000 English monologue videos. Speakers recorded themselves giving a movie review, freely available on ExpoTV.com. The movies were rated from 1 star (most negative) to 5 stars (most

---

[1] It is interesting to note that BERT provides embedding for "uh" or "um" despite being trained on written text (Wikipedia, BooksCorpus (Zhu et al., 2015), Word Benchmark (Chelba et al., 2014).

$\mathcal{T}_1$	[‘umm’, ‘things’, ‘that’, ‘uh’, ‘you’, ‘usually’, ‘wouldn’, “”, ‘t’, ‘find’, ‘funny’, ‘were’, ‘in’, ‘this’, ‘movie’, ‘.’]
$\mathcal{T}_2$	[‘[$FILLER_{UMM}$]’, ‘things’, ‘that’, ‘[$FILLER_{UHH}$]’, ‘you’, ‘usually’, ‘wouldn’, “”, ‘t’, ‘find’, ‘funny’, ‘were’, ‘in’, ‘this’, ‘movie’, ‘.’]
$\mathcal{T}_3$	[‘[FILLER]’, ‘things’, ‘that’, ‘[FILLER]’, ‘you’, ‘usually’, ‘wouldn’, “”, ‘t’, ‘find’, ‘funny’, ‘were’, ‘in’, ‘this’, ‘movie’, ‘.’]

Table 1: Filler representation using different token representation strategies

positive). Annotators were asked to label the video for high-level attributes. For confidence, annotators (3 per video) were asked "How confident was the reviewer?", and had to each give a label respectively; from 1 (not confident) to 7 (very confident), after watching the entire review. Similarly for sentiment, the annotators were asked "How would you rate the sentiment expressed by the reviewer towards this movie?", and were asked to give a label from 1 (strongly negative) to 7 (strongly positive).

We choose this dataset for the following reasons: (1) The corpus has been manually transcribed with fillers "uh" and "um", where ≈ 4% of the speech consists of fillers (for comparison, the Switchboard (Godfrey et al., 1992) dataset of human-human dialogues, consists of ≈ 1.6% of fillers (Shriberg, 2001)). Sentence markers have been manually transcribed, with the practice of the filler being annotated sentence-initially, if the filler occurs between sentences. (2) The dataset consists of monologues, where the speaker is conscious of an *unseen* listener, but dialogue-related disfluencies (such as backchannels) are not present, allowing us to concentrate on fillers of the narratives of the speaker (Swerts, 1998). (3) Only reviews with a 1-2 star or a 5 star rating were chosen for annotation, to clearly demarcate sentiment/stance polarity. (4) *FOAK*, which we measure by the given label of confidence, has been annotated with high inter-annotator agreement (Krippendorff's alpha = 0.73).

Details can be found in the supplementary material and in Park et al. (2014). Confidence labels are obtained by taking the root mean square (RMS) value of the labels given by the 3 annotators[2]. Sentiment labels are calculated by taking the mean of the 3 labels, which were obtained from Zadeh (2018a)[3].

3 Experiments and Analysis

3.1 Information contained by fillers can be leveraged to model spoken language.

Language Modelling with fillers. We compare the perplexity of the LM with different pre-processing strategies with a fixed token representation $\mathcal{T}_1$. Results are reported in Table 2(a). We compare $\mathcal{P}_{S1}$,$\mathcal{P}_{S2}$ $\mathcal{P}_{S3}$ with or without fine-tuning and observe that adding fillers, both during training and inference, leads to a model with lower perplexity and a perplexity reduction of at least 10%. Hence, fillers contain information that can be leveraged by BERT.

As shown, the fine-tuning procedure reduces the perplexity of the language model. Even without fine-tuning, we observe that $\mathcal{P}_{S3}$ outperforms $\mathcal{P}_{S1}/\mathcal{P}_{S2}$, as the perplexity reduces when adding fillers. This suggests that BERT has a priori knowledge of spoken language, in terms of fillers.

Hence, fillers can be leveraged to reduce uncertainty of BERT for SLM. This is not an expected result, as intuitively, one might think that the perplexity would reduce when fillers are excluded from both training and inference, due to the fact that the utterance is shorter and "simplified". The fact that $\mathcal{P}_{S3}$ outperforms the other pre-processing methods also suggests that the MLM procedure is an effective way to learn this information.

Best Token representation: We observe that $\mathcal{T}_1$ outperforms the other representations in a fine-tuning setting, as shown in Table 2(b). Given the restricted size of our data and the dimension of the BERT embeddings (768), it is better to keep the existing representations (with $\mathcal{T}_1$), than adding and learning new representations from scratch.

---

[2] Though the inter-annotator agreement for confidence is high, we choose RMS as a way to handle disagreement between annotators. For example, annotation labels $\{3, 5, 7\}$ would result in mean value of 5, not highlighting that one annotator found the reviewer particularly confident. The RMS value however (≈ 5.3), slightly enhances the high confidence label.

[3] A toolkit for multimodal analysis. Please refer to the **Usage** and the **Supported Datasets** sections, which include instructions to download the data.

Fine.	Setting	Token.	Ppl
w/o	$\mathcal{P}_{S1}$	$\mathcal{T}_1$	22
	$\mathcal{P}_{S2}$	$\mathcal{T}_1$	22
	$\mathcal{P}_{S3}$	$\mathcal{T}_1$	**20**
w	$\mathcal{P}_{S1}$	$\mathcal{T}_1$	5.5
	$\mathcal{P}_{S2}$	$\mathcal{T}_1$	5.6
	$\mathcal{P}_{S3}$	$\mathcal{T}_1$	**4.6**

(a)

Setting	Token.	Ppl

	$\mathcal{P}_{S3}$	**1.24**	**1.22**

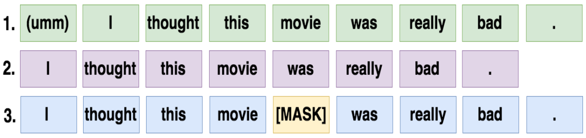
(c)

Table 2: From left to right, the (a) LM Task, (b) Best token representation, (c) MSE of Confidence (FOAK) and the Sentiment (Sent) prediction task. Wilcoxon test (10 runs with different seeds) has been performed. Highlighted results exhibit significant differences (p-value < 0.005). Data split is fixed according to Zadeh (2018b) and results are given on the test set (see supplementary materials for for additional details).

Interestingly, $\mathcal{T}_2$ and $\mathcal{T}_3$ perform the same. This can be explained by "um" and "uh" being only distinguished in duration (Clark and Fox Tree, 2002), the hypothesis being that "uh" is used for a shorter pause in speech; which cannot not be reflected in text. Given these results, we fix $\mathcal{T}_1$ as the token representation strategy for the rest of the experiments.

Learnt Positional distribution of fillers: We additionally test whether our model has learnt information about the placement of fillers. We use fine-tuned BERT on $\mathcal{D}_{train}$ with fillers to see where the model estimates the most probable position of the fillers (which we call $\mathcal{LM}_{fillers}$) to be. Given a sentence S of length L, we insert after word j the mask token ('[MASK]') to obtain the corrupted sentence $\widetilde{S}$[4]. We compute the probability of the appearance of a filler in position $j+1$ according to the LM, which corresponds to $P([MASK] = filler|\widetilde{S})$, as illustrated by Figure 1. Formally, we plot the average of the probability of the masked word to be a filler given its position in the sentence, as shown in Figure 2. We observe that the fine-tuned BERT on $\mathcal{D}_{train}$ with fillers ($\mathcal{LM}_{fillers}$) predicts with high probability fillers occurring at the first position in the sentence (please refer to Table 5 supplementary for example sentences). This is consistent with the actual distribution of fillers in the dataset, as can be seen in Figure 2. The fine-tuned BERT on $\mathcal{D}_{train}$ without fillers ($\mathcal{LM}_{nofillers}$) predicts a constant low probability. Given the available segmentation of sentence boundaries (fine-grained discourse annotations are not available), it is interesting to note that our model was able to capture similar positional distribution of fillers that are reported in Swerts (1998); Shriberg (2001); Swerts and Geluykens (1994); Yoshida and Lickley (2010).

In this section we show that although BERT uses contextualised word embeddings, the information contained in fillers can be leveraged to achieve a better modelling of spoken language.



1. (umm) I thought this movie was really bad .
2. I thought this movie was really bad .
3. I thought this movie [MASK] was really bad .

Figure 1: Predicting the probability of a filler, where 1. Raw input, 2. Pre-processed text with the filler removed, and 3. Illustrates the [MASK] procedure for predicting the probability of a filler at position 5.

3.2 Fillers are a discriminative feature for *FOAK* and *stance* prediction.

We observe the impact that fillers have on two downstream tasks, a novel FOAK prediction task, and a ubiquitous sentiment analysis task. Psycholinguistic studies have observed the link between fillers and expressed confidence (Smith and Clark, 1993; Brennan and Williams, 1995; Wollermann et al., 2013). Previous research on the link between fillers and their relation to a speaker's expressed confidence has been confined to a narrow range of QA tasks (Schrank and Schuppler, 2015). Fillers have also been linked to stance prediction (Le Grezause, 2017),

---

[4] For clarity we abuse the notation and remove dependence in j.

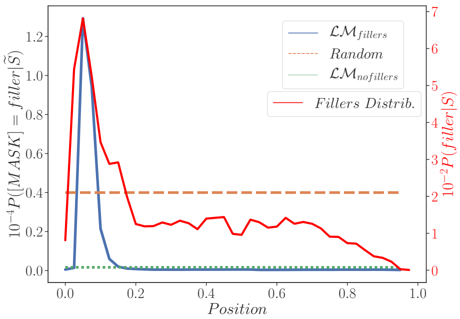


Figure 2: Predicting the position of fillers. *Fillers Distrib.* stands for the actual filler distribution in the dataset. *Random* stands for the random predictor which predicts $P([MASK] = filler|\widetilde{S}) = \frac{2}{|\mathcal{V}|}$ where $|\mathcal{V}|$ is the size of the vocabulary, and 2 represents both fillers.

which we measure using sentiment. We show that in a spontaneous speech corpus of spoken monologues, fillers can play a role in predicting both the perception of the speaker's expressed confidence and speaker's stance.

In Table 2(c) we observe that both with and without fine-tuning the $\mathcal{P}_{S3}$ decreases the MSE compared to $\mathcal{P}_{S1}$ and $\mathcal{P}_{S2}$. $\mathcal{P}_{S1}$ and $\mathcal{P}_{S2}$ have similar MSE because fillers are not added during the inference phase. We observe that $\mathcal{P}_{S2}$ leads to higher MSE, possibly because of the discrepancy created between $\mathcal{D}_{train}^{labelled}$ and $\mathcal{D}_{test}^{labelled}$. This shows that fillers can be a discriminative feature in both FOAK and stance (Le Grezause, 2017) prediction, apart from overt lexical cues [5].

Does the addition of fillers always improve the results for downstream spoken language tasks? In the subsection 3.1, we show that by including fillers , the MLM achieves a lower perplexity. An assumption one could make based on the work by Radford et al. (2019), is that with this model, the results for any further downstream task would be improved by the presence of fillers. However, we observe that to predict the persuasiveness of the speaker (using the high level attribute of persuasiveness annotated in the dataset (Park et al., 2014)), following the same procedure as outlined in subsubsection 2.1.2, that fillers, in fact, are not a discriminative feature.

4 Conclusion

When working with deep contextualised representations of transcribed spoken language, we showed that retaining fillers can improve results, both when modelling language and on a downstream task (FOAK and stance prediction). Besides, we propose and compare various token representation and pre-processing strategies in order to integrate fillers. We plan to extend these results by studying the mixing of such textual filler-oriented representations with acoustic representations, and further investigate the representation of fillers learnt during pre-training.

Supplementary

Model

Detailed algorithms: In algorithm 1 and algorithm 2, we provide additional details of the procedure used for the language modelling task and confidence prediction task. For stance prediction, the procedure is the same as for confidence.

Algorithm 1: Spoken Language Modelling

```
Input  : $\mathcal{P}_{Si}$, $\mathcal{T}_i$, Pret. BERT $\mathcal{LM}$
Output : $(\mathcal{LM}, Perplexity)$
$(\mathcal{D}_{train}, \mathcal{D}_{dev}, \mathcal{D}_{test}) \leftarrow$ (train, dev, test set) according to $(\mathcal{P}_{Si}, \mathcal{T}_i)$
if Do Finetuning then
    $\mathcal{LM} \leftarrow \mathcal{LM}(\mathcal{D}_{train})$ using $(MLM)$.
end
Evaluate: $Perplexity \leftarrow \mathcal{LM}$ on $\mathcal{D}_{test}$
```

Algorithm 2: Confidence prediction

```
Input  : $\mathcal{P}_{Si}$, $\mathcal{T}_i$, $\mathcal{LM}$ from algorithm 1
Output : $(CONF_p, MSE)$
$(\mathcal{D}^{labelled}_{train}, \mathcal{D}^{labelled}_{dev}, \mathcal{D}^{labelled}_{test}) \leftarrow$ (train, dev, test set) according to $(\mathcal{P}_{Si}, \mathcal{T}_i)$
$CONF_p \leftarrow \mathcal{LM} + MLP$
$CONF_p \leftarrow CONF_p(\mathcal{D}^{labelled}_{train})$ using $(MSE)$.
Evaluate: $MSE \leftarrow CONF_p$ on $\mathcal{D}_{test}$
```

Example of token representation strategies: Our token representation strategies are built on the tokenizer introduced by Devlin et al. (2019) and used the Sentence Piece algorithm (Kudo and Richardson, 2018). An example is given in Table 3.

Dataset: Additional details

We highlight relevant information about the dataset in Table 4. The count of each "uh" and "um" filler is roughly the same. After discarding some videos due to missing labels, only 100 of them do not contain fillers. We use the original standard training, testing and validation folds provided in the CMU-Multimodal SDK (Zadeh, 2018b).

The process of transcription of fillers is described in (Park et al., 2014). The transcriptions were carried out via Amazon Mechanical Turk, using 18 native English speaking workers based in the United States. These workers were from the same pool of workers used to annotate the videos for high level attributes. Each transcription was then reviewed and edited by in-house experienced transcribers for accuracy.

In Table 5 we give example sentences extracted from the POM dataset. In these examples, we can observe that the fillers are commonly located sentence-initially. Note, the corpus annotates "uh" and "um" as "uhh" and "umm" respectively, reflected in our examples taken from the dataset.

Hyper-parameters for our experiments

All the hyper-parameters have been optimised on the validation set based on the minimum of the training loss (MSE for confidence/sentiment prediction and perplexity for LM) accuracy computed on the last tag of the sequence. We used Adam optimizer (Kingma and Ba, 2015) with a learning rate of $10^{-}5$, which is updated using a polynomial decay. The gradient norm is clipped to 5.0, weight decay is set to 10^{-6}, and dropout (LeCun et al., 2015) is set to 0.2. Models have been implemented in PyTorch and trained on a v100 using the same procedure as in (Colombo et al., 2019, 2020; Witon et al., 2018).

Token.	Output Tokenizer
Raw	(umm) It’s an interesting movie to say the least.
T1	[‘umm’, ‘it’, “”, ‘s’, ‘an’, ‘interesting’, ‘movie’, ‘to’, ‘say’, ‘the’, ‘least’, ‘.’]
T2	[‘[$FILLER_{UMM}$]’, ‘it’, “”, ‘s’, ‘an’, ‘interesting’, ‘movie’, ‘to’, ‘say’, ‘the’, ‘least’, ‘.’]
T3	[‘[FILLER]’, ‘it’, “”, ‘s’, ‘an’, ‘interesting’, ‘movie’, ‘to’, ‘say’, ‘the’, ‘least’, ‘.’]

Table 3: Additional example of the different token representation strategies

Description	**Value**

(umm) The movie itself is a lot like Saving Private Ryan and Band of Brothers.
(uhh) Morgan Freeman is great in this movie, and **(uhh)** so is Tim Robbins.
(umm) You’ll only like it if you’re into kid of strange, bizarre humor.
It’s just **(uhh)** pretty obvious stuff you know.
But **(umm)** a lot of the movie didn’t really make sense.
(umm) It’s really funny, there there’s (stutter) some really funny parts in it.
(umm) But, I recommend watching this movie it’s really good.
(umm) The acting is only so-so.
And so **(umm)** I wouldn’t really recommend it.
(umm) Yeah, but that’s it.

Table 5: Some samples from the dataset. As can be seen, many of the fillers occur sentence-initially.

The role of context in neural pitch accent detection in English

Abstract

Prosody is a rich information source in natural language, serving as a marker for phenomena such as contrast. In order to make this information available to downstream tasks, we need a way to detect prosodic events in speech. We propose a new model for pitch accent detection, inspired by the work of Stehwien et al. (2018), who presented a CNN-based model for this task. Our model makes greater use of context by using full utterances as input and adding an LSTM layer. We find that these innovations lead to an improvement from 87.5 percent to 88.7 percent accuracy on pitch accent detection on American English speech in the Boston University Radio News Corpus, a state-of-the-art result. We also find that a simple baseline that just predicts a pitch accent on every content word yields 82.2 percent accuracy, and we suggest that this is the appropriate baseline for this task. Finally, we conduct ablation tests that show pitch is the most important acoustic feature for this task and this corpus.

1 Introduction

Prosody is a rich information source with the potential to improve performance in many spoken NLP tasks (Roesiger et al., 2017; Niemann et al., 1998). In order to make prosodic information available to downstream tasks, many models have been proposed to predict which words in an utterance carry *pitch accents*—word-level prosodic prominences signaled by a deviation from the speaker's usual pitch, duration, intensity, or some combination of these three features. Identifying pitch accents is helpful since they are often used to signal important or unexpected information. For example, pitch accents in English typically fall on content words, which are generally more informative. When a pitch accent falls on a function word, it indicates that it is unusually informative, as in the sentence, *They ran out of toilet paper even **before** the quarantine*, where *before* is more informative because it contrasts with what might be a default assumption (e.g., *during*).

Previous pitch accent prediction models include rule-based models (Brenier et al., 2005), traditional machine learning models (Wightman and Ostendorf, 1994; Levow, 2005; Gregory and Altun, 2004), and neural models (Fernandez et al., 2017; Stehwien and Vu, 2017; Stehwien et al., 2018). Stehwien and Vu (2017) and Stehwien et al. (2018) (henceforth, SVS18) showed that neural methods can perform comparably to traditional methods using a relatively small amount of speech context—just a single word on either side of the target word. However, since pitch accents are deviations from a speaker's average pitch, intensity, and duration, we hypothesize that, as in some non-neural models (e.g. Levow 2005; Rosenberg and Hirschberg 2009), a wider input context will allow the model to better determine the speaker's baseline for these features and therefore improve its ability to detect deviations. In addition, we hypothesize that a recurrent model (rather than the CNN used by SVS18) will also improve performance, since it is better adapted to processing long-distance dependencies.

In this paper, we test these hypotheses by building a new neural pitch accent prediction model that takes in prosodic speech features, text features, or both. Our main contribution is showing that these context-enhancing innovations in the speech-only model improve performance on a corpus of American English speech, yielding higher accuracy than SVS18 and all previous models on this dataset. We also find that a baseline of simply labeling all content words with pitch accents is very robust, matching the performance of the text-only model. We argue that this more robust content-word baseline is the correct baseline for this task. We find that our speech-only model is able to outperform this baseline by detecting some of the cases where a speaker deviates from the predictions of the content-word baseline, and we provide

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7994–8000,
November 16–20, 2020.

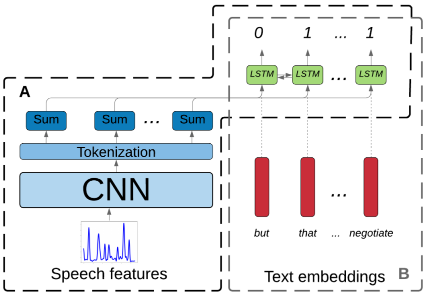

Figure 1: The combined speech+text model. Box A outlines the speech-only model components, while box B outlines the text-only model.

an analysis of which acoustic features yield the most benefit.

2 Models

We build models to predict which words carry a pitch accent, given input of either prosodic speech features, text features, or both. The variants are shown in Figure 1 and described below. All models are implemented in PyTorch (Paszke et al., 2019).[1]

We also describe the ways in which we varied the amount of context available to the speech-only model in particular.

Speech-only model. Like SVS18's model, our speech encoder begins with several CNN layers that take a series of frames $f_1, f_2, ..., f_n$ as input, where each frame f_i is a vector of 6 acoustic-prosodic features (see §3). These frames are encoded by the CNN, which reduces the overall number of frames by passing a kernel over the input with a stride of size 2, resulting in frames $f'_1, f'_2, ..., f'_k$. However, rather than predicting the label for a single token at a time, as SVS18 do, our model labels the whole sequence at once. In order to divide the output of the CNN into word tokens, we use the token timestamps provided in the corpus to divide the frames at places corresponding to word boundaries in the input, similar to the approach taken in Tran et al. (2018). Each resulting subdivision of the frames $[f'_i, f'_{i+1}, ..., f'_j]$ contains different numbers of frames, since tokens are of various lengths. To obtain token representations of identical size, we sum across all frames for a given token: $t_j = sum(f'_i, f'_{i+1}, ..., f'_k)$. Each token embedding $t_1, ..., t_m$ is then passed into a bidirectional LSTM, and finally a feed forward layer that outputs a prediction for each token. The model's hyperparameters are described in detail in Appendix A.3.

Our full model takes an entire utterance as input and predicts all labels at once, but we also experiment with using only three or one token(s) as input. In these cases, the model only predicts the label for the central input token. The three-token scenario is designed to be most similar to SVS18's model.

Text-only model. The text-only model is a simple bidirectional LSTM. An embedding for each token is passed to the BiLSTM and a prediction is made at each timestep. We followed SVS18 in using pretrained 300d GloVe word embeddings (Pennington et al., 2014), although using pre-trained embeddings did not improve performance much over randomly initialized embeddings.

Speech+text model. The speech-only and text-only models both include a bidirectional LSTM, so for the combined model, we just concatenate the embedding for each token generated by the CNN encoder with the pretrained text embedding for that token before passing them to the LSTM.

Baselines. In addition to a majority class baseline, we also report results on a content-word baseline, where all content words (non-stopwords as identified by NLTK) are labelled as carrying a pitch accent. We also report a duration-only baseline, where the input features to the speech-only model are all replaced with the value 1—so the model can only tell how many frames each token contains.

3 Data and experimental setup

We train and test all models using data from the Boston University Radio News Corpus (hereafter BURNC)[2], a speech corpus of General American English that is partially annotated with prosodic information. The annotated subsection of the corpus that we use includes five speakers, three female, and two male, all of them trained radio journalists reading pre-written news segments. This kind of read speech from trained speakers is different from spontaneous speech and so the conclusions we reach here can only confidently be applied to this genre. The data we use amount to approximately 2.75 hours of speech, consisting of 1721 utterances. These come from a total of 398 news segments. There are 28,489 word tokens, 15,544 of which carry pitch accents. Though this is a limited amount of data, this corpus is one of very few corpora with available prosodic annotations and enables us to compare with previous studies that use this resource, including SVS18.

---

[1] https://github.com/ekayen/prosody_detection

[2] https://catalog.ldc.upenn.edu/LDC96S36

For the speech-only model, we follow SVS18 in using the OpenSMILE toolkit (Eyben et al., 2013) to extract six features, which fall into three broad categories: pitch features (smoothed F0), intensity features (RMS energy, loudness), and voicing features (zero-crossing rate, voicing probability, and harmonics-to-noise ratio). These features are extracted from frames of varying sizes (following Schuller et al. (2013)), and frames are offset by 10ms. The speech-only model has no access to phone-level or spectral information that might allow it to make predictions based on word identity. The transcription of the speech in this corpus includes marked breaths, which we use to segment the corpus into utterances. Note that there are no explicit correlates of duration in this feature set, though the model has access to the absolute duration of each token via the number of input frames per token. In future, we could follow Tran et al. (2018) by giving an explicit feature for the duration of a given token normalized by the average duration of that token in the corpus.

For the text-only model, we follow SVS18 in removing contractions (e.g. *we'll* ⟶ *we*), though we diverge in leaving hyphenated tokens in place (e.g. *eighty-eight* remains *eighty-eight*).

We perform tenfold cross-validation of all experiments and report the average performance. For a detailed description of how we divided data into train, development, and test sets for cross-validation, see Appendix A.2. In order to test for repeatability, we furthermore initialize our model architecture with five distinct random seeds and repeat the tenfold cross-validation procedure for each of these five model initializations. Our reported test set results are the average performance of all these five model initializations. We report accuracy as our primary metric since this task is a balanced binary classification task. We train for 25 epochs and we report the highest development set accuracy of these 25 epochs. We use this same epoch to report test set accuracy.

4 Results and discussion

Development set results from the speech-only model using different input contexts and architectures are shown in Table 1. The results confirm our hypotheses that it should help to include more input context (full utterances rather than only three tokens as in SVS18) and to use an LSTM to permit better use of that context. Note that our full utterance CNN-only model actually has more parameters than the CNN+LSTM model (~14m, vs. ~12m), so the improvements of the latter are not due to model size. The underperformance of the CNN-only model also cannot be attributed to overfitting, since the CNN+LSTM model was more overfit to the training set than the CNN-only model (93.8 percent accuracy vs. 91.7 percent accuracy after 25 epochs).

Context	**Architecture**	**Acc (%)**
Full utterance	CNN+LSTM	89.1
	CNN only	87.9
Three tokens	CNN+LSTM	88.6
	CNN only	87.3
One token	CNN only	85.5

Table 1: Development set accuracy of speech-only model variants using different input contexts and architectures. Greater input context helps, and including LSTM layers works better than just CNN layers.

	Speech	**Text**	**Sp+text**
Our model	**88.4**	**82.2**	**89.1**
SVS18	87.1	78.5	87.5
Content-word		82.2	
Duration-only	81.2		

Table 2: Test set accuracy of our CNN+LSTM model, compared to the CNN-only baseline of SVS18, a baseline where all content words are labelled as accented, and a baseline where the speech model is given only duration information. The majority baseline performance is 54.4 percent.

In contrast, development set experiments with the text-only model found little effect of context or architecture (see Appendix A.1), and indeed even our best text-only model is not much better than the content-word baseline, which in turn outperforms SVS18's text-only model (as shown in Table 2 for

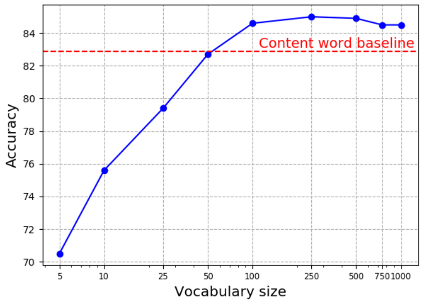

Figure 2: Ablation of vocabulary size in text-only model.

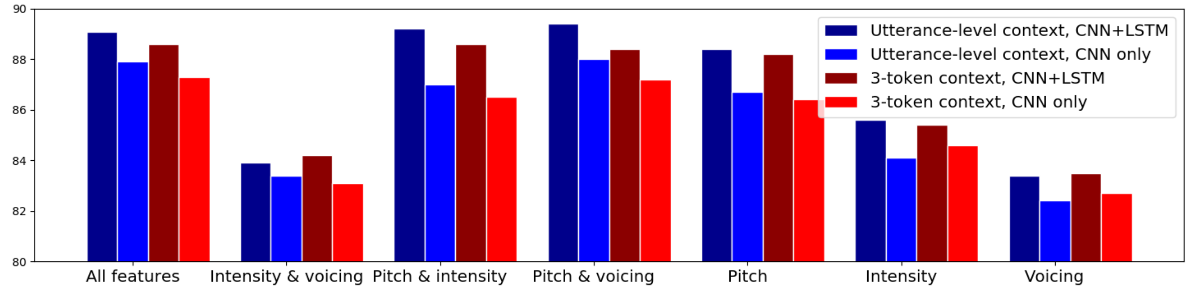

Figure 3: Ablation of prosodic features in speech-only model. Labels on the x-axis indicate which features were available to the model.

the test set and Appendix A.1 for the dev set). This suggests that although text-only context might help identify pitch accented words in principle, even powerful neural models are not well able to exploit the right information (or perhaps require discourse level context, which we did not provide). This conclusion is further supported by an additional analysis where we progressively reduced the vocabulary size of the text-only model from 3000 down to 5. As shown in Figure 2, we found that performance was steady until vocabulary dropped below 100 words (with the rest labelled as 'UNK'). This strongly suggests that either word frequency or the strongly correlated content/function word distinction are the main source of information for the text-only model. Of course, absolute word duration is also strongly correlated with frequency and content/function, and we note that the duration-only speech model also achieves a similar accuracy to the content-word baseline (Table 2).

Overall, our best speech-only model outperforms the previous work (SVS18) as well as the text-only model and baselines on the test set (See Table 2), and combining speech plus text yields a small additional improvement. Our analysis shows in particular that the speech-only model outperforms the text-only model in places where the speaker's realization deviates from the content-word baseline: the speech-only model can correctly detect some pitch accents that fall on function words (as in (1a) *that*; pitch accents are labeled as *1*) or unaccented content words (as in (1b) *Mary*).

(1) a. Input: *but that would require the union*
Speech: 0 1 0 1 0 1
Text: 0 0 0 1 0 1

b. Input: *she agrees with Mary Conroy*
Speech: 0 1 0 0 1
Text: 0 1 0 1 1

If we only consider these tokens where the speaker's production deviates from the content-word baseline, the speech-only model achieves 66.7 percent accuracy, vs. only 38.2 percent for the text-only model.

	Our model (speech + text)	**Stehwien & Vu 2017** (speech only)
f1a	**89.43**	85.6
f2b	**88.14**	82.9
f3a	**89.65**	83.5
m1b	**85.05**	81.4
m2b	84.42	**84.8**

Table 3: Speaker-independent results of the speech+text model, identified by speaker IDs in BURNC. We compare to the speech-only model of Stehwien and Vu (2017).

In addition to the evaluations described above, where all utterances are randomly assigned to train, development, and test sets, we do speaker-independent evaluation of the speech+text model. That is, we hold out a single speaker for testing and use all the other speakers for training and development. These results are shown in Table 3. We do not have published results of a speech+text model evaluated in this test condition to compare to. However, we can compare to the results of the speech-only model of Stehwien and Vu (2017). We find that our model outperforms theirs on all speakers except the speaker identified as *m2b*. The reasons for this underperformance are unclear.

4.1 Speech feature ablation tests

The duration-only baseline shown in Table 2 shows that the speech model is able to perform quite well given only information about token length, without access to prosodic features, but that these prosodic features are still used in achieving the speech-only model's performance.

In order to determine the relative importance of various prosodic features, we group the prosodic features into those related to pitch (smoothed F0), intensity (RMS energy, loudness), and voicing (harmonics-to-noise ratio, zero-crossing rate, voicing probability), and ablate one or two sets of features at a time. We test these models by training them with full utterance context and with more a limited three-token context, as well as with the full CNN+LSTM architecture and the more limited CNN-only architecture. The results of these experiments on the development set can be seen in Figure 3.

Pitch seems to play the biggest role of these features, with its ablation leading to the lowest performance in all cases. Voicing appears to be the weakest feature set, actually harming model performance in one case: intensity and voicing features combined underperform intensity features alone.

All three groups of prosodic features seem equally dependent on the inclusion of context, with the removal of the LSTM and restriction to a three-token context leading to proportionally similar drops in performance. This supports our hypothesis that acoustic correlates of prosody cannot be evaluated in isolation: a high pitch or intensity is only meaningfully high compared to some lower pitch or intensity.

5 Conclusions

This work demonstrates some important principles for predicting pitch accent from text and speech. First, we show that a speech-only model benefits from having utterance-level context. Second, we show that both the text and the speech-only model derive at least some of their performance from being able to distinguish function words from content words. In fact, our BiLSTM-based text model can hardly outperform a content-word baseline. Finally, we show that a speech-only model can successfully predict pitch accent in cases where a text-only model cannot, and that combining text and speech provides only a tiny benefit. These results indicate that the speech-only model uses information available in the prosodic features to surpass the content-word baseline, and that knowing the actual words doesn't provide much further useful information.

	CNN only	82.8
One token	CNN only	84.3

Table 5: Text model development set results with different context and architectures.

A.2 Cross-validation procedure

The process we used for tenfold cross-validation was as follows. If we had a corpus with a total of 100 utterances, we would shuffle the utterances, and designate utterances 1-10 as the test set. From the remaining 90 utterances, we randomly designate 10 as development and 80 as training, which gives us our first train/development/test split. Next, we select utterances 11-20 as the test set, and select the development and training sets from the remaining 90 utterances. We repeat this process till we have created 10 distinct train/development/test splits, each with a unique test set. To cross-validate a model, we train and evaluate it on all 10 of these data splits. We use the development portions to optimize hyperparameters, as well as to determine where to stop training for each split.

A.3 Model hyperparameters

We train the model for a total of 25 epochs of approximately 1400 training examples, using a batch size of 64. The speech and speech+text models take a total of about 200 seconds to train on average, with each epoch taking around 8 seconds to train on a single Titan X-equivalent GPU. The text model takes about 75 seconds to train, with an average of 3 seconds per epoch. Evaluation on the entire development set (about 200 instances) takes an average of 2 seconds to run for the speech and speech+text models, and 1 second for the text model.

Hyperparameter	Possible values	Selected values
CNN layers	2, 3, 4	3
LSTM layers	2, 3	2
Dropout	0, 0.2, 0.5, 0.7	0.5
Weight decay	0, 10e-5, 10e-4	10-e5
Filter width	9, 11, 13, 15, 17, 19, 21, 23	11
Post-tokenization	sum, max	sum

Table 6: Possible and selected values for each hyperparameter considered in the search. The 'post-tokenization' hyperparameter corresponds to the method used to collapse the token representations — max pooling or summing across all frames.

We perform a hyperparameter search on the combined model, using the resulting hyperparameters for all input configurations (text, speech, speech+text). The possible values of each hyperparameter are as shown in Table 6, with each hyperparameter configuration being chosen at random from these values. The selected value for the hyperparameter is shown in the right column. We ran 96 distinct hyperparameter configurations, picking the configuration with the highest accuracy on the development set. The average performance on the development set over the search space was 83.5 percent accuracy, with a variance of 0.005 and a standard error of 0.007.

Other hyperparameters are selected manually without searching: we use 128 kernels in the first CNN layer, with 256 kernels in all subsequent CNN layers, and use a stride length of 2 throughout all CNN layers. The LSTM layers each have a hidden size of 128. We use a learning rate of 0.001 with PyTorch's Adam optimizer (Paszke et al., 2019). We set the text-only model to have a vocabulary size of 3000 types, which is approximately 80 percent of the total types present in the corpus.

Many of our hyperparameter experiments focused on changes to the CNN that should allow it to process a wider swath of the input at once: adjusting filter width, and adjusting the number of CNN layers. Neither change showed significant positive effect, and both were harmful when taken to the extreme. As can be seen in Figure 4, given a constant depth of 3 CNN layers, the very narrowest kernels underperformed, but widening the kernel did not consistently produce better performance, and eventually degraded performance. Likewise, adding CNN layers—which increases the number of frames of the input data being viewed by the final CNN layer—was actively harmful to performance beyond depths of 3 layers.

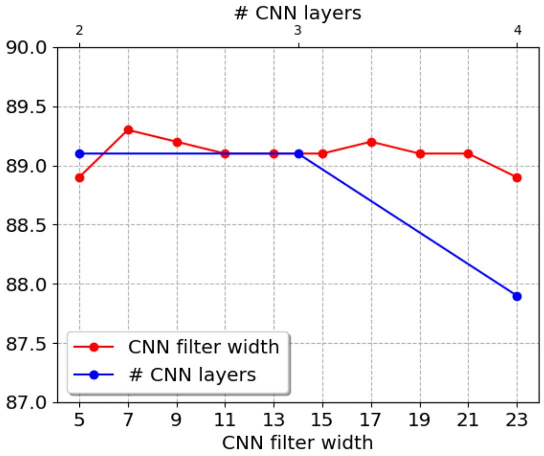

Figure 4: The performance of the speech-only model given different CNN hyperparameters, tested on a development set using tenfold cross-validation. When varying CNN filter width, the CNN layers were kept invariant at 3; when varying the number of CNN layers, the filter width was kept invariant at 11 frames.

VolTAGE: Volatility Forecasting via Text Audio Fusion with Graph Convolution Networks for Earnings Calls

Abstract

Natural language processing has recently made stock movement forecasting and volatility forecasting advances, leading to improved financial forecasting. Transcripts of companies' earnings calls are well studied for risk modeling, offering unique investment insight into stock performance. However, vocal cues in the speech of company executives present an underexplored rich source of natural language data for estimating financial risk. Additionally, most existing approaches ignore the correlations between stocks. Building on existing work, we introduce a neural model for stock volatility prediction that accounts for stock interdependence via graph convolutions while fusing verbal, vocal, and financial features in a semi-supervised multi-task risk forecasting formulation. Our proposed model, VolTAGE, outperforms existing methods demonstrating the effectiveness of multimodal learning for volatility prediction.

1 Introduction

Motivation Financial risk modeling is of great interest to capital market participants for making sound investment decisions. Stock volatility is a vital indicator of a company's risk profile (Poon and Granger, 2003; Yang et al., 2020). The stock market presents various opportunities that increasingly attract investors, who utilize the market's potential to generate profits, wherein stock volatility is a vital risk modeling factor. One underexplored, yet crucial event that leads to significant fluctuations in stock volatility, is the earnings conference call. These calls are held periodically by publicly traded companies' executives to summarize and prognosticate company's performance (Qin and Yang, 2019). Harnessing the interplay between the multimodal verbal and vocal cues in earnings calls can help better analyze the impact these calls may have on financial markets and forecast stock volatility (Dichev and Tang, 2009; Yang et al., 2020).

Challenges While stock trading presents unparalleled investment opportunities, accurately predicting the rise and fall of stock prices has numerous challenges (Campbell et al., 1997). Conventional research in finance revolves around using historical stock data to develop statistical models and recurrent neural networks (RNNs) capable of forecasting price trends (Kristjanpoller et al., 2014; Zheng et al., 2019). They are influenced by many factors ranging from public opinion to the movements of other related stocks (Malkiel, 2003). Recent advances in deep learning present a promising prospect in multimodal stock forecasting by analyzing online news (Hu et al., 2018), and social media (Guo et al., 2018) to learn latent patterns affecting stock prices (Jiang, 2020). However, the challenging aspect in stock forecasting is that most existing work treats stock movements to be independent of each other, contrary to true market function (Diebold and Yılmaz, 2014). Additionally, existing research has not leveraged the rich audio signals in company executives' speech, which could indicate the emotional and affective state of the speakers, and provide insights into company performance. More recently, the use of audio processing for earnings calls has gained an interest in both financial and linguistic research (Burgoon et al., 2015; Jiang and Pell, 2017).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8001–8013,
November 16–20, 2020.

Multimodal approaches can extract complementary information from multiple modalities to improve financial modeling, MDRM (Qin and Yang, 2019), and HTML (Yang et al., 2020) validate the premise of such approaches for volatility forecasting. Additionally, advances in graph-based deep learning (Kipf and Welling, 2017) have led to the rise of graph neural networks (GNNs) that can model the relationships between related stocks (Feng et al., 2019). Publicly available online company information can be used to identify connections between stocks that might influence each other, such as those having the same CEO or belonging to the same industry. Financial tasks are often correlated, thus making multi-task learning a promising choice for financial forecasting.

Contributions Building on advances in the intersection of financial research, graph neural networks, and natural language processing, we present VolTAGE: **Vol**atility forecasting via **T**ext-**A**udio fusion with **G**raph convolution networks for **E**arnings calls. VolTAGE comprises a set of neural components to capture cross-modal signals from earnings calls transcripts, CEO speech, inter stock dependence graphs, and numerical financial features. First, VolTAGE combines the verbal-vocal coherence between earnings calls transcripts and speech via an inter-modal multi-utterance attention mechanism. The fused features are then fed to a graph convolution network (GCN) to simultaneously solve two homogeneous stock volatility tasks - average volatility (main task) and single-day volatility prediction (auxiliary task), in a semi-supervised fashion. Through a set of comparative, qualitative, and ablation experiments on real-world S&P 500 index data, we show VolTAGE's utility of augmenting vocal and verbal cues with graph-based features in a multi-task setup.

Ethical Considerations and Limitations Examining a CEO's speech and tone in earnings calls is a well-studied phenomenon in financial literature (Crawford Camiciottoli, 2011; Qin and Yang, 2019). Our work focuses only on calls for which companies publicly release transcripts and audio recordings. The data used in our study corresponds to earnings calls of S&P 500 companies. We acknowledge the presence of gender bias in our study, given the imbalance in the gender ratio of CEOs of S&P 500 companies. We also acknowledge the demographic bias in our study, as the S&P 500 companies are organizations listed in the US, and may not generalize directly to non-native speakers.

2 Background

Extensive studies have shown the utility of employing historical financial data (Jones, 2017; Dichev and Tang, 2009) for volatility prediction, yet financial forecasting using multiple modalities remains an underexplored avenue. While newer work focuses on data across multiple modalities, there exist drawbacks and understudied approaches to improve current methods, which we describe next.

Volatility Forecasting Forecasting stock volatility is a crucial pillar across multiple financial domains and has focused on numerous academic studies. Volatility is a key indicator of uncertainty and is a decisive variable to many investment decisions and portfolio creations. Previous work in this domain has mainly relied on numerical features (Liu and Chen, 2019; Nikou et al., 2019), such as macroeconomic indicators (Hoseinzade et al., 2019). This includes discrete (GARCH (Duan, 1995), rolling regression (Peng et al., 2018)), continuous (Andersen, 2007), and neural approaches (Kogan et al., 2009). This comprehensive work illustrates the significance of volatility in investment, security valuation, and risk management.

Natural Language Processing and Finance Extensive studies incorporating related text information have proven successful in financial forecasting tasks. Mohan et al. (2019); Tan et al. (2019) utilized financial news articles to improve the accuracy of stock price predictions. Hu et al. (2018) propose a hybrid attention network to predict the stock trend based on the related sequential news articles. Researchers have also observed the influence of textual data in online media on stock markets (Bollen et al., 2011; Mittermayer and Knolmayer, 2006). Si et al. (2014) showed sentiment analysis based on social media is predictive of each stock's market. However, utilizing multimodal sources of information remains an underexplored avenue in financial forecasting.

Speech Processing and Finance Newer studies (Qin and Yang, 2019; Yang et al., 2020) illustrate the gains obtained using vocal cues from the CEO's earnings conference calls for volatility prediction. Yet, the majority of the current work does not utilize speech based data. The audio features add greater context and provide psycho-linguistic signaling about the speaker's emotional state (Jiang and Pell, 2017). Qin and Yang (2019) illustrated that late fusion of audio and text features from earnings calls could be used to forecast stock volatility following the earnings call. The verbose quarterly earnings calls (Wang and Hua, 2014) act as a medium of voluntary disclosure (Tasker, 1998), thereby resulting in significant stock movements (Ding et al., 2015), yet the majority of existing approaches do not focus on such highly volatile macro activities, where the market microstructure is highly uncertain (Rogers et al., 2009). During these macro events, the stock returns' predictability can be improved since the disclosure of informed investors influences volatility spreads (Atilgan, 2014). Although multiple sources of information are crucial, not all modalities contribute equally (Akhtar et al., 2019). Noise in one modality can be detrimental in such multimodal frameworks (Morris-Drake et al., 2016).

Multimodality and Finance The Efficient Market Hypothesis (Malkiel, 2003) illustrates the success of multimodal data sources for predictive financial tasks. The more recent multimodal HTML (Yang et al., 2020) is a transformer-based model that uses BERT (Devlin et al., 2019) for textual modeling, and the same hand-crafted audio features as MDRM, in an early fusion formulation. Both MDRM and HTML assume stocks' independence and do not exploit these relations between stock movements. Relations like the same industrial base and co-ownership also result in related stock movements (Feng et al., 2019). Recent works exploit stock relations through graph neural networks (Kipf and Welling, 2017; Veličković et al., 2018) for stock movement prediction (Kim et al., 2019; Sawhney et al., 2020).

Building on these gaps in existing literature, we propose VolTAGE for volatility prediction.

3 Forecasting Stock Volatility

Following Kogan et al. (2009) and Qin and Yang (2019) we define stock volatility as a regression task. For a given stock, with a close price of p_i on trading day i, we calculate the average log volatility over n days following the earnings call as:

$$v_{[0,n]} = \ln\left(\sqrt{\frac{\sum_{i=1}^{n}(r_i - \bar{r})^2}{n}}\right) \tag{1}$$

where, the return price r_i is defined as $\frac{p_i}{p_{i-1}} - 1$ and $\bar{r}$ is the mean of the return price over the period from day-0 to day-n. Additionally, for our auxiliary task we define the single-day log volatility using the daily log absolute returns as follows:

$$v_n = \ln\left(\left|\frac{p_n - p_{n-1}}{p_{n-1}}\right|\right) \tag{2}$$

Problem Statement Given an earning call e, comprising of an audio A, and aligned text T, and stock prices $p_{[0,n]}$, we aim to learn a predictive regression function $f(e_{\{T,A\}}) \rightarrow v_{[0,n]}$.

4 VolTAGE: Architecture and Learning

Below, we describe both the individual components and joint optimization of VolTAGE, and present an overview of the architecture in Figure 1.

4.1 Verbal Cues: Transcript Encoding

We use FinBERT[1] (Araci, 2019) as a sentence encoder, which is a pre-trained language model based on BERT, for language modeling specific to the financial domain. Recent works (Araci, 2019; Keith and Stent, 2019) in this domain indicate the benefits of using a language model pre-trained on financial corpora and retrofitting pre-computed embeddings, achieving considerable performance gains; thereby giving us a strong ground to incorporate the same. FinBERT has been pre-trained on 46,000 documents of financial news articles and has shown state-of-the-art performance on FiQA[2] and Financial PhraseBank benchmarks (Malo et al., 2013).

Formally, we represent the transcript utterances of each call as $(t_1, t_2, ..., t_K)$, where t_i is the i^{th} text utterance and K is the number of sentences, which are encoded as follows:

$$s_i = \text{FinBERT}(t_i) \tag{3}$$

We then pass the sequence of these sentence representations to a BiLSTM as:

$$\overrightarrow{T_t^{(f)}} = \text{BiLSTM}^{(f)}(s_t, T_{t-1}^{(f)}) \tag{4}$$

$$\overleftarrow{T_t^{(b)}} = \text{BiLSTM}^{(b)}(s_t, T_{t+1}^{(b)}) \tag{5}$$

$$T_t = [\overrightarrow{T_t^{(f)}}, \overleftarrow{T_{T-t}^{(b)}}] \tag{6}$$

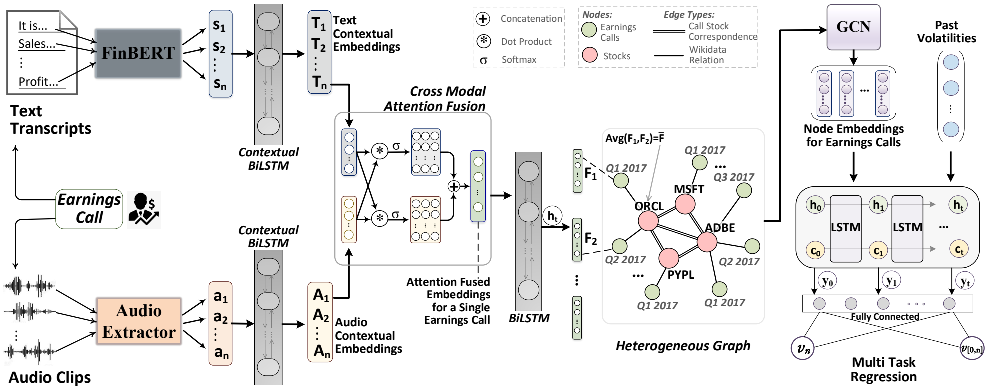

Figure 1: VolTAGE architecture overview: feature extraction, semi-supervised learning and multi-task regression.

4.2 Vocal Cues: Audio Call Encoding

Audio-based features provide prosodic cues related to the affective state of speakers (Montacié and Caraty, 2018). Capturing the emotional valence of the CEO can alter the understanding of the underlying linguistic utterances in an earnings call (Schröder et al., 2001). We extract a set of 26 acoustic features from each aligned audio clip at a sampling rate of $10ms$ for each sentence. These feature time series were then summarized by statistical functions such as mean, median, min, and max to yield a fixed dimensional representation for each sentence. We extend the feature sets of previous works (Qin and Yang, 2019; Yang et al., 2020). These features have shown to be correlated to the speaker's affective states such as stress and anxiety (APQ 11 Shimmer, DDA Shimmer) (Li et al., 2007; Mongia and Sharma, 2014), vocal pace reflecting inconsistencies in vocal cues (ratio of voiced to unvoiced frames in audio) (Přibil and Přibilová, 2009; Viswanathan et al., 2012) and deception (pitch) (Burgoon et al., 2015). We extracted these 26 features from each audio utterance using Praat (Boersma and Van Heuven, 2001).

Text-Audio Alignment Following Qin and Yang (2019), we use the pre-aligned dataset for earnings calls, where the audio is segmented and aligned with each corresponding utterance of the transcript using the Iterative Forced Alignment (IFA) algorithm. IFA is the process of determining the time interval (in the audio file) containing the spoken text for each fragment of the transcript. Qin and Yang (2019) implemented IFA using Aeneas[3] as the fundamental forced alignment method. Formally, we represent the segmented audio clips as $(a_1, a_2, ..., a_K)$ where a_i is the i^{th} audio clip and K being the number of clips of an earning call, with each clip being represented by 26 acoustic features. Similar to the processing of verbal utterances, we employ a BiLSTM layer to sequentially encodes these features, and obtain an audio encoding A_t as:

$$\overrightarrow{A_t^{(f)}} = \text{BiLSTM}^{(f)}(a_t, A_{t-1}^{(f)}) \tag{7}$$

$$\overleftarrow{A_t^{(b)}} = \text{BiLSTM}^{(b)}(a_t, A_{t+1}^{(b)}) \tag{8}$$

$$A_t = [\overrightarrow{A_t^{(f)}}, \overleftarrow{A_{T-t}^{(b)}}] \tag{9}$$

4.3 Verbal-Vocal Attention

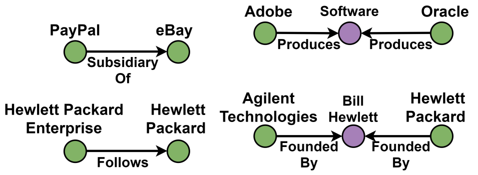
The acoustic features provide context and structure to the verbal cues. To capture the associations between verbal and vocal cues, we employ a Cross-Modal Gated Attention Fusion (CM Attn) mechanism that simultaneously learns the alignment weights between audio features and text sentence sequences. Thus, we employ this mechanism to highlight the contributing features by giving more attention to the respective utterance and neighboring utterances. Motivated by Akhtar et al. (2019); Dhingra et al. (2016), we employ the multiplicative gated attention mechanism to generate modality-specific attentive representations.

Formally, a multiplicative gating mechanism is used to attend the important components of text and audio sequences to get the final attentive feature embeddings F_t, F_a which are then combined as:

$$W_a = softmax(T \cdot A^T), W_t = softmax(A \cdot T^T) \tag{10}$$

---

[3] `https://github.com/readbeyond/aeneas`



(a) First-order relation (b) Second-order relation

Figure 2: Wiki-company based relations

$$G_a = W_a \cdot T,\ G_t = W_t \cdot A \tag{11}$$

$$H = F_a \oplus F_t = (G_a \odot A) \oplus (G_t \odot T) \tag{12}$$

$\cdot$ is the dot product, $\odot$ represents element-wise multiplication, and $\oplus$ represents concatenation. The fused verbal-vocal feature vector per earnings call is then fed to a GCN, as described next.

4.4 Graph-based Semi Supervised Learning

Mining Stock Relations First, we construct a company graph, inspired by the relations defined by Feng et al. (2019). We mine connections between companies from Wikidata (Vrandečić and Krötzsch, 2014). Wikidata represents relations in the form of statements like (subject; predicate ;object), such as (Facebook; founded by; Mark Zuckerberg).[4] We say that Company A has a first-order relation with company B if there is a statement with A as the subject and B as the object. Similarly, there exists a second-order relation between them if they are related by an intermediate entity. This Wiki-Company graph $G_{WC} = (V, E_{WC})$ is a homogeneous graph, where each node represents a company, and two nodes are connected by an edge representing either a first or second-order relation. We present examples of first and second-order relations in Figure 2. Since the companies are related and not the earnings calls, we extend the graph G_{WC} by incorporating nodes corresponding to earnings calls. Each call is connected to the company it corresponds to through an edge. This extended graph $G(V, E)$ is heterogeneous with two types of nodes (companies and earnings calls).

Graph Convolution Network We frame the task as a graph-based semi-supervised learning problem since we have labels (volatility values) available for a subset of nodes (i.e., earnings call nodes) (Kipf and Welling, 2017). Our intuition behind applying GCNs is to allow the model to distribute gradient information from the supervised loss on the labeled earnings call nodes. As shown in Figure 1, we feed the fused verbal-vocal features H as node features for each earnings call node to the GCN. As for the stock nodes, since a stock may have multiple earnings calls, we consider the mean of feature vectors of all calls pertaining to a stock as its feature vector, to incorporate features across all earnings calls corresponding to that stock. Formally, let $F \in \mathbb{R}^{n \times m}$ represent the input feature matrix comprising these feature vectors of length m for the nodes in G, and D represent the diagonal degree matrix defined as $D_{ii} = \sum_j A_{ij}$. The update rule at layer l of the GCN is then:

$$O^{(l)} = ReLU(\widetilde{A}O^{(l-1)}W^{(l)}) \tag{13}$$

where the first layer is represented as:

$$O^{(1)} = ReLU(\widetilde{A}FW^{(1)}) \tag{14}$$

We experiment with a single layer and a 2-layer GCN, and find better results with the latter. We formulate the exact computation our GCN performs to yield estimated volatility values as follows:

$$O = linear(\widetilde{A}ReLU(\widetilde{A}FW^{(1)})W^{(2)}) \tag{15}$$

Using the earnings call node labels, we train the GCN on the MSE loss using the semi-supervised learning mechanism. This mechanism generates feature representations for both the company nodes and the earnings call nodes, of which we use the latter. Subsequently, these earnings call node features, denoted by O_e are fed along with the financial features to a multimodal LSTM network in a multi-task learning setup as described next.

4.5 Multimodal LSTM for Risk Forecasting

Prior work (Figlewski, 1994) in the financial domain has shown the benefits of using past data for future volatility forecasting. However, fusing the sequential historical volatility data with non-temporal GCN embeddings poses a challenge. To overcome this disparity, we employ multimodal ”conditioned” LSTM networks (Karpathy and Fei-Fei, 2015). In our case, we add GCN node embeddings from the first layer with the ReLU nonlinearity to the hidden state of the LSTM model at the first time-step to integrate temporally diverse

---

[4] https://www.mediawiki.org/wiki/Wikibase/DataModel/JSON

modalities. Further, the past data introduces historical context in cases where calls may not have major announcements that would lead to large fluctuations in stock volatility.

Network Optimization To incorporate financial data, we extract past n-day average volatilities prior to the earning call, where $n \in [2, 30]$. Formally, training the LSTM model takes the sequence input vectors $(x_1, .., x_T)$ representing the past financial data along with the earnings call node embeddings O_e, obtained using GCN. The model computes a series of hidden states $(h_1, .., h_T)$ and a sequence of outputs $(y_1, ..y_T)$, by repeating the following recurrence relation from time $t = 1$ to T:

$$h_t = f(W_{hx}x_t + W_{hh}h_{t-1} + O_e + b_h) \quad (16)$$

$$y_t = softmax(W_{oh}h_t + b_o) \quad (17)$$

Here, $W_{hx}, W_{hh}, W_{oh}, x_i, b_h, b_o$ are learnable parameters and x_t is the average t-day past volatility. Following Karpathy and Fei-Fei (2015), we feed the GCN embeddings to the LSTM only at the first iteration. We use the output y_T from the last LSTM unit for the final multi-output prediction.

Network Optimization We finally train VolTAGE by optimizing a multi-task loss as:

$$\mathcal{L} = \frac{1}{2n}\left(\mu\sum_{i}(\hat{y_i} - y_i)^2 + (1-\mu)\sum_{j}(\hat{y_j} - y_j)^2)\right) \quad (18)$$

Here, $\hat{y_i}$, $\hat{y_j}$ are predicted volatilities and y_i , y_j are true volatilities for the main and auxiliary tasks, respectively. μ is a parameter that controls the relative weight of the loss between the two tasks.

5 Experimental Setup

5.1 Data

We used the S&P 500 2017 Earnings Conference Calls dataset (Qin and Yang, 2019).[5] The dataset consists of 559 earnings call audio recordings and their transcripts for 277 public companies in the S&P 500 index. Each call is segmented into a sequence of audio clips aligned with their corresponding text sentences, as spoken by the Chief Executive Officer (CEO) during the call. We temporally divide the data into train, validation, and test sets in a ratio of $70 : 10 : 20$ respectively to ensure future data is not used for forecasting. We extract stock prices for each company using Yahoo Finance[6] from 1 January'17 till 31 December'17. The stock data for 11 earnings calls was not available on Yahoo Finance; hence we excluded these calls from our dataset. Following Qin and Yang (2019); Yang et al. (2020), we experiment with $n \in \{3, 7, 15, 30\}$ days to analyze the performance over both short and long term periods.

5.2 Baselines

We compare VolTAGE with the following methods:

- $\mathbf{V_{past}}$: Following Qin and Yang (2019), we use V_{past}, the average log volatility of the past d days to predict the future d days' average log volatility.
- **bc-LSTM:** We also compare against bc-LSTM (Poria et al., 2017) which extracts the uni-modal features using separate contextual Bi-LSTMs and fuses them.
- **MDRM:** Qin and Yang (2019) extract pre-trained GloVe embeddings and hand-crafted acoustic features that are fed to separate BiLSTMs to get their uni-modal contextual embeddings, which are then fused and fed to a two-layer dense network.
- **HTML:** Yang et al. (2020) is the state-of-the-art model using WWM-BERT to encode text tokens. HTML makes use of the same audio features as MDRM. The unimodal features are fused and fed to a sentence-level transformer to get the multimodal representations for each call.

5.3 Training Setup

We tune the hyperparameters on the validation mean square error (MSE) to get: dropout $\delta \in [0, 0.8]$, learning rate $\lambda \in \{10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$, batch size $b \in \{8, 16, 32, 64\}$ and epochs (< 100).

We use FinBERT with default pre-training parameters, which outputs a 768-dimensional embedding for each sentence. The maximum number of audio clips in any call is 520. Hence, we zero-pad the calls that have less than 520 clips for efficient batching. The number of neurons in the time distributed dense layer following the audio and text BiLSTMs is 100. The heterogeneous graph

contains 559 nodes for earning calls connected to the 277 interrelated company nodes. The GCN is trained using Pytorch Geometric (Fey and Lenssen, 2019).[7] We use two GCN layers having 200 and 100 units respectively, inter-spaced by ReLU and followed by a single dense layer. The 200 dimensional feature vectors from the first layer of the GCN after the ReLU activation are fed to a 200-unit conditioned LSTM model for multi-task volatility prediction. We optimize VolTAGE using the Adam (Kingma and Ba, 2014) optimizer.

6 Results and Analysis

6.1 Comparative Analysis

We present the volatility prediction performance of VolTAGE and the baselines in Table 1. We report the MSE averaged across 10 different runs for all models for the main task (n-day average prediction). Our choice of using MSE as a comparative metric is motivated by prior work (Qin and Yang, 2019; Yang et al., 2020). Additionally, we also report the coefficient of determination $R^2 = 1 - \frac{MSE}{MSE_{V_{past}}}$, to illustrate the improvements with V_{past}. We observe gains across the multimodal HTML that leverages both text and audio modalities. We ascribe this improvement to the cross-modal attention fusion mechanism, which uses associations between audio and text modalities over each contextual utterance instead of concatenation used in HTML. Moreover, a key limitation of the baselines is the assumption of independence of inter-stock movements. VolTAGE captures the correlations between price movements of related stocks through the GCN, and hence, volatility, amplifying performance. Similar to prior work (Qin and Yang, 2019), Table 1 illustrates that forecasting volatility in the short-term is a more intricate task than long-term. Based on Post Earnings Announcement Drift (PEAD) (Bernard and Thomas, 1989), a documented financial phenomenon, we note that the price fluctuations around earning calls tend to stabilize over long periods. We observe that VolTAGE outperforms the baselines by a large margin in short-term prediction ($n = 3, 7$); however the margin diminishes over longer durations ($n = 30$).

6.2 Ablation Study

We observe an improvement across the text modality (T), when compared to the HTML (Text) model (Yang et al., 2020) in Table 1 and Table 2. This performance gain can be attributed to FinBERT, which is trained to handle language tasks in the financial domain, while the sentence-level transformer employed in the HTML (Text) model is a generalized implementation of BERT (Devlin et al., 2019). We also note that representations learned by FinBERT outperform both GloVe (Pennington et al., 2014) and BERT embeddings, reiterating the effectiveness of domain-specific pre-training. Further, we observe from Table 2, that the Audio+FinBERT (CM Attn) model outperform unimodal components, demonstrating the utility of multimodal verbal-vocal cues for volatility prediction. On adding the GCN, we observe a gain of 17.7%, likely due to the GCN's ability to learn correlations between price movements of related stocks that are captured by the company relations. Finally, on introducing the financial modality via

---

[7] We extract features for nodes using the last layer of verbal-vocal fusion tuned only for average n-day volatility prediction. The verbal-vocal attention fusion was not trained on multi-task loss, and VolTAGE is not trained end-to-end.

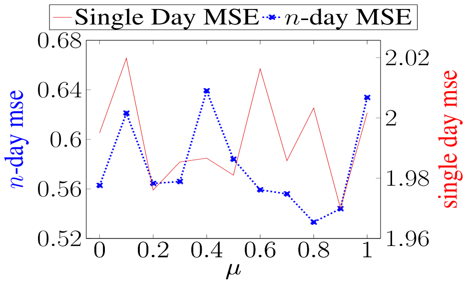

Figure 3: 3-Day Validation MSE vs μ

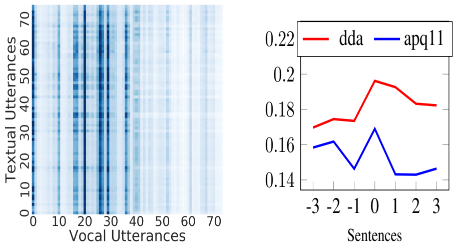
the conditioned LSTM network helps in counteracting the impact of PEAD by introducing earnings call independent information into the model; this can be observed in Table 2. We note that VolTAGE outperforms all its ablative components, demonstrating how each of its multimodal components complement each other.

6.3 On Multi-task Learning

Training a network for multiple tasks jointly has shown to improve performance on tasks that share a conceptual similarity (Caruana, 1997). In our case, we optimize VolTAGE on both n-day average and single-day volatility prediction tasks a multi-task formulation. In Figure 3, we analyze the variation of the weight parameter μ with the 3-day validation MSE of n-day average, and single-day predicted volatility. As both tasks share a weighted loss function, by tuning μ, we trade-off between the two tasks. We observe from Figure 3, that at the extreme values of the weight parameter $\mu = 0$ and $\mu = 1$, that represent single task learning on the single-day and n-day average prediction tasks respectively, VolTAGE does not obtain optimal performance. Empirically, we find the optimal $\mu = 0.8$ for 3-day volatility forecasting on the main task, thus validating our hypothesis that multi-task learning across both average and single day spans of volatility prediction improve predictive power.

7 Qualitative Analysis

We analyze the Q3-2017 earnings call for DG (Dollar General), an American variety store company. The stock's price became highly volatile for a few days following the earnings call. Figure 4a shows the audio-aware text attention heatmap for the duration of the earning call. The heatmap represents cross-modal attention weights assigned to textual utterances using corresponding vocal cues. Here each cell (i, j) represents the weight of j^{th} vocal utterance on the i^{th} textual utterance. It is observed that the highest attention is towards the middle of the call, suggesting that the verbal cues of this portion have the highest impact on the text contextual embeddings for most of the sentences in the call. Earning calls of companies are often structured such that the beginning of the call involves introductory disclaimer and greetings, while the CEO starts presenting financial results for the reporting quarter along with future goals of the company towards the middle of the call, which indicates why we see such influential utterances in this portion.



(a) Audio Aware Text Attention (b) DG: Shimmer Analysis

Figure 4: Verbal and Vocal features from the earnings call for Dollar General from Q3 2017.

Figure 4b shows the disparity between CEO's vocal and verbal cues around the utterance. While textual content seems positive, a sudden spike in shimmer features in CEO's voice while speaking this sentence suggests disharmony between verbal and vocal cues. Past research in acoustics (Li et al., 2007) suggests an elevated shimmer could be indicative of underlying stress in speech. After the earning call, it was noted that the gross margin of the company slipped by 0.4%, due to the increased transportation costs due to hurricane Irma in 2017. On analyzing the graph, we observe that DG has edge connections with WMT (Wallmart) and TGT (Target Corp.), both of which are retail variety stores, like DG. Analysts had estimated a negative impact of about $2.8 Billion on the retail sector due to the hurricane Irma. This examination is also reflected in the high volatilities recorded for WMT and TGT during the same quarter. A unimodal model may miss these subtle disparities between text and audio. Therefore, VolTAGE, by leveraging cross-modal attention fusion and correlation graphs, accurately forecasts the volatility of DG, three days post the earnings call.

8 Conclusion and Future Work

Volatility, measured as a deviation in returns, is a reliable indicator of market risk linked with a stock. A rich source of company information is earnings calls that provide high risk-reward opportunities given their uniqueness and critical information disclosure. Although evidence shows that enriching models with speech and inter-stock correlations can improve volatility forecasting, this area is underexplored. We propose VolTAGE, a neural architecture that jointly exploits coherence over speech, text, and inter-stock correlations for volatility forecasting following earnings calls. Through experiments on S&P 500 index data, we show the merit of cross-modal gated attention fusion, graph-based learning, and multi-task prediction for volatility forecasting.

There are several promising directions of future work that we wish to explore. First, we want to improve upon the audio feature extraction. To model the speech of CEOs in earnings calls, using semitones rather than raw frequency for pitch-related features. Experimenting with other sets of commonly used acoustic features such as MFCC coefficients, OpenSMILE features and auDeep features for representing audio utterances also form a future direction for audio feature extraction. Second, we want to expand the analysis presented in this paper beyond the S&P 500 index and US-based companies. Existing research (Qin and Yang, 2019; Yang et al., 2020) and this work at the intersection of natural language processing and earnings calls are limited to a small set of companies and earnings calls. Analyzing the demographic, cultural, and gender bias in research pertaining to financial disclosures, particularly earnings calls, forms a future direction of research. We would also want to work on studying a wider set of earnings calls and companies spanning multiple languages, demographics, speakers and gender.

A Appendices

A.1 Pitch Analysis

We extract the following audio features corresponding to pitch:

1. **Minimum pitch:** The minimum pitch frequency of the frames within a specified time duration.
2. **Maximum pitch:** The maximum pitch frequency of the frames within a specified time duration.
3. **meanF0:** The mean of the fundamental frequency (f0) within a specified time duration.
4. **stdevF0:** The standard deviation of the fundamental frequency (f0) within a specified time duration.
5. **Number of pulses:** The number of pulses within a given time window.
6. **Number of periods**: The number of periods/cycles within a given time window.
7. **Degree of voice breaks:** This is the total duration of the breaks between the voiced parts of the signal, divided by the total duration of the analysed part of the signal.
8. **voiced_frames:** The number of voiced frames. A frame is regarded as locally unvoiced if it has a voicing strength below the voicing threshold (whose standard value is 0.45), or a local peak below the silence threshold (whose standard value is 0.03).
9. **Voiced to total ratio:** The number of voiced frames in a window divided by the total number of frames.
10. **Voiced_to_unvoiced_ratio:** The number of voiced frames in a window divided by the number of unvoiced frames (unvoiced frames are given by total frames-voiced frames).

A.2 Voice Analysis

Under voice analysis, we extract different features quantifying *jitter* and *shimmer* in the earnings call audio. *Jitter* is the relative average vocal perturbation while *Shimmer* is the moment-to-moment amplitude variation. We now describe the various features extracted in this category:

1. **Jitter (local):**This is the fraction of average absolute difference between consecutive periods by the average period.
2. **Jitter (local, absolute):** This is the average absolute difference between consecutive periods in seconds.
3. **Jitter (RAP):** This is the Relative Average Perturbation, the average absolute difference between a period and the average of it and its two neighbours, divided by the average period.
4. **Jitter (ppq5):** This is the five-point Period Perturbation Quotient, the average absolute difference between a period and the average of it and its four closest neighbours, divided by the average period.
5. **Jitter (ddp):** This is the average absolute difference in jitter between consecutive periods divided by the average period. This is Praat's original Get jitter and is proportional to three times RAP.
6. **Shimmer (local) :** This is the average absolute difference between the amplitudes of consecutive periods, divided by the average amplitude.
7. **Shimmer (local, dB):** This is the average absolute base-10 logarithm of the difference between the amplitudes of consecutive periods, multiplied by 20.
8. **Shimmer (apq3):** This is the three-point Amplitude Perturbation Quotient, the average absolute difference between the amplitude of a period and the average of the amplitudes of its neighbours, divided by the average amplitude.
9. **Shimmer (apq5):** This is the five-point Amplitude Perturbation Quotient, the average absolute difference between the amplitude of a period and the average of the amplitudes of it and its four closest neighbours, divided by the average amplitude.
10. **Shimmer (apq11):** This is the 11-point Amplitude Perturbation Quotient, the average absolute difference between the amplitude of a period and the average of the amplitudes of it and its ten closest neighbours, divided by the average amplitude.
11. **Shimmer (ddp):** This is the average absolute difference of shimmer between the amplitudes of consecutive periods. This is Praat's original

Get shimmer and its value is proportional to three times APQ3.

A.3 Intensity Analysis

We extract the following intensity features:

1. **Mean Intensity:** The mean (in dB) of the intensity values of the frames within a specified time duration.
2. **Minimum intensity:** The minimum (in dB) of the intensity values of the frames within a specified time duration.
3. **Maximum intensity:** The maximum (in dB) of the intensity values of the frames within a specified time duration.
4. **SD_energy:** Standard deviation of energy in the frames within a specified time duration.

A.4 Harmonicity Analysis

We extract the *Harmonics-to-Noise Ratio (HNR)* of the earnings calls audio which has shown to be a measure of the ”hoarseness of a speaker”.

1. **Harmonics-to-Noise Ratio (HNR):** It represents the degree of acoustic periodicity. It is expressed in decibels. It can be used as a measure for the signal-to-noise ratio of periodic voice signals.

Effectively pretraining a speech translation decoder with Machine Translation data

Ashkan Alinejad, Anoop Sarkar
Simon Fraser University, Burnaby, BC, Canada
{aalineja,anoop}@sfu.ca

Abstract

Directly translating from speech to text using an end-to-end approach is still challenging for many language pairs due to insufficient data. Although pretraining the encoder parameters using the Automatic Speech Recognition (ASR) task improves the results in low resource settings, attempting to use pretrained parameters from the Neural Machine Translation (NMT) task has been largely unsuccessful in previous works. In this paper, we will show that by using an adversarial regularizer, we can bring the encoder representations of the ASR and NMT tasks closer even though they are in different modalities, and how this helps us effectively use a pretrained NMT decoder for speech translation.

1 Introduction

Automatic Speech Translation (AST) aims to directly translate audio signals in the source language into the text words in the target language. For many years, the pipeline of transcribing speech with ASR and then translating with the MT component was a standard method to address the speech translation problem. Having access to lots of data in many language pairs, the cascaded model for speech translation can benefit from well-trained ASR and MT components and generate high-quality translations.

In recent years, it has shown that we can remove the transcription step and build an end-to-end model that is strong enough to compete with the cascaded model (Pino et al., 2019). Such models not only have lower inference latency, but they also do not suffer from the problem of errors that propagate from one component to the next. However, the scarcity of available resources is the main challenge in this task, and a variety of methods are proposed to address this problem. One of the most effective approaches to increase the performance of AST systems is to pretrain the encoder using an ASR model (Bansal et al., 2018). While pretraining the encoder by an ASR model even in different languages shows promising results (Bansal et al., 2019), using a pretrained MT decoder is not beneficial (Berard et al., 2018; Bansal et al., 2018) or slightly improve the result (Sperber et al., 2019) and even in some cases may worsen the results (Bahar et al., 2019).

One explanation for this phenomenon is that the decoder works well only if its input comes from an encoder that it was trained with (Lample et al., 2018). To solve the problem of invariant encoder representations, we make use of an adversarial regularizer in our loss function to bring the output of the ASR encoder closer to the input of MT decoder. We show that this modification can improve the BLEU score by +2.0 BLEU points.

2 Models

2.1 End-to-End Speech Translation

Similar to conventional MT models, the speech translation task generates translated words in the target language, representing as $\hat{Y} = (\hat{y}_1, \dots, \hat{y}_m)$, given the sequence of source speech features $X = (x_1, \dots, x_n)$. The translation model then minimizes the Cross-Entropy loss $\mathrm{L}_{CE} = \Delta(\hat{Y}, Y)$, where Δ is the sum of character-level Cross-Entropy losses.

We use character-level encoding and decoding using Transformer (Vaswani et al., 2017) as the basic architecture of all our models. For the AST and ASR models, we use similar architecture to (Di Gangi et al., 2019b) with an S-Transformer (Gangi et al., 2019). The main difference between transformer and S-Transformer is the way it encodes the input features. S-Transformer encodes the audio features by passing them into two stacked layers of Convolutional Neural Nets (CNN). Then,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8014–8020,
November 16–20, 2020.

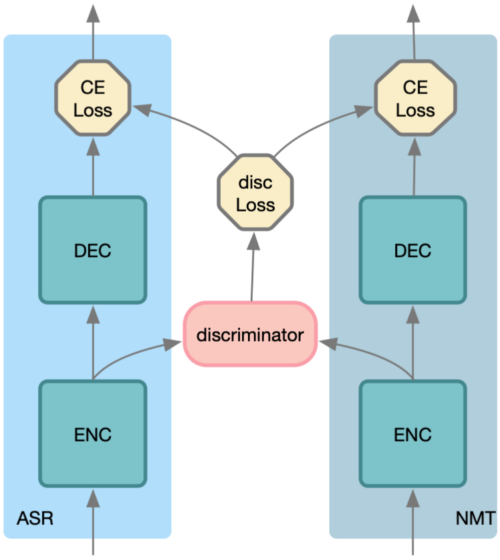

Figure 1: The proposed pretraining method using an adversarial loss.

it uses a 2D self Attention layer to compute the attention matrix using the second CNN's output. We followed the architecture of (Vaswani et al., 2017) in our MT model.

The conventional method for training an AST model is to pretrain ASR and NMT models separately and then transferring parameters of the encoder from ASR and the decoder from MT to the AST model, before starting to train via speech translation data.

2.2 Aligning encoder representations

Since we are training the encoder representations of the ASR model and the decoder parameters of the NMT system to work with their own encoder and decoder, pretraining the parameters of the AST model with a speech encoder from ASR and a text decoder from NMT is not ideal. Therefore, we propose to use adversarial training to bring NMT encoder and ASR encoder representations closer together.

An overview of our model is depicted in Figure 1. Instead of separately pretraining the ASR and NMT, we propose to update their parameters simultaneously. In order to add explicit incentives to learn multi-modal representations in the encoder, we will train our NMT and ASR models on both Cross-Entropy loss and a new regularization loss. The final training objective for each task can be formulated as:

$$\mathrm{Loss} = \mathrm{L}_{CE} + \alpha\, \mathrm{L}_{DISC}$$

where L_{CE} is the Cross-Entropy loss, L_{DISC} is the newly added regularization term, and α is the constant parameter to control the effect of our regularizer. Since L_{DISC} is a smaller number compared to L_{CE}, we set α to 5 in all our experiments to make the regularizer loss more perceptible during backward propagation. We are also sharing the parameters of the transformer layers in the encoder between AST and MT models. In the following section, we describe the regularizer.

2.3 Adversarial regularizer

Given the embeddings of inputs x_i in each modalities (speech features for ASR or character embeddings for NMT), the encoder computes the encoder representations Z_{x_i}. By passing Z_{x_i} to the discriminator, we can train its network by minimizing the loss function $Loss_D = -\mathbb{E}_{(x_i,m_i)}[\log P_D(m_i|Z_{x_i})]$, where m_i is the modality of x_i, with $m_i \in \{\mathrm{ASR}, \mathrm{NMT}\}$ and P_D is the probability of choosing the right modality given the output of encoder.

The encoder of NMT or ASR will be trained in order to deceive the discriminator by minimizing the loss:

$$\mathrm{L}_{DISC} = -\mathbb{E}_{(x_i,m_i)}[\log P_D(m_j|Z_{x_i})]$$

where $m_j = \mathrm{ASR}$ if $m_i = \mathrm{NMT}$ and vice versa. By incorporating this regularizer, we ensure that the encoder representations from different modalities (speech and text) become indistinguishable during training.

Our discriminator consists of a three-layer feed-forward network with 1024 hidden units, followed by a Leaky-ReLU activation function (Lample et al., 2018).

3 Experiments

3.1 Dataset

To evaluate our AST systems, we conducted our experiments on two datasets. For the English-German language pair, we use the MuST-C corpus (Di Gangi et al., 2019a), which consists of 408 hours of speech data aligned with 234K translated sentences. For the English-French language pair, we use the full training set of Translation

Augmented Librispeech (Libri-Trans) corpus (Kocabiyikoglu et al., 2018) with 230 hours of speech aligned with 131K french sentences.

We use LibriSpeech corpus (Panayotov et al., 2015) with 960h of English speeches in order to train our ASR system. Since the test and dev sets of Libri-Trans corpus is part of the ASR LibriSpeech dataset, we remove all utterances from ASR LibriSpeech that share the same (chapter-id, reader-id) pairs with the test and dev sets in the Libri-Trans corpus. For En-De MT training, we use the combination of TED and Opensubtitle2018 corpora [1] [2] which contains more than 18M sentences pairs after filtering noisy pairs. The MT training of the English-French language pair uses the En-Fr portion of the WMT14 competition (Bojar et al., 2014).

3.2 Preprocessing and Evaluation

For each speech utterance, we extract 40 Mel-filterbank energy features with a step size of 10 ms and a window size of 25ms. For features extracted from MuSt-C and ASR LibriSpeech, we apply mean and variance normalization for each speaker.

We keep all the texts in our experiments true-case and tokenize them using Moses tokenizer[3]. We remove the punctuation from all English texts (both from the target side of ASR and the source side of MT).

For translation tasks (AST and MT), we report BLEU score (Papineni et al., 2002) on tokenized sentences[4]. We evaluate our ASR systems using Word Error Rate (WER)[5].

3.3 Model settings

For both En-De and En-Fr tasks, we followed the architecture in (Di Gangi et al., 2019b). We use six Transformer layers of size 512 in the encoder and decoder with eight attention heads. The size of feed-forward mechanism is 1024. The embedding layer in the encoder for the AST task contains two layers of 2D CNNs (Lecun et al., 1998) followed by a ReLU activation function. Each CNN layer has 16 output channels, with a stride of (2, 2). We run all our models on two GeForce GTX 1080 GPUs with 12GB RAM each. The total number of parameters and run-time of our models in Table 1.

	En-De		En-Fr	
	#param	#hours	#param	#hours
cascaded NMT	45M	27	45M	13
cascaded ASR	31M	22.5	31M	18.2
AST	31M	34	31M	18

Table 1: The number of parameters and run-time of our models on MuSt-C dataset (En-De) and Libri-Trans dataset (En-Fr).

Task	En-De	En-Fr
cascaded	18.76	15
AST + ASR pre	18.71	14.7
AST + ASR pre + MT pre	19.05	15.3
AST + regularizer	20.24	17.01

Table 2: Results of AST models trained only with AST data. The performance is measured with BLEU score on MuST-C test set.

3.4 Training settings

In all our models, we use the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.00005. During the first 6000 warm-up updates, we increase it linearly to 0.003, then decrease it with inverse square root decay (Vaswani et al., 2017). The number of warm-up updates in our MT systems is 8000.

4 Results

In this section, we analyze the effect of our regularizer on two different settings: (A) When we only have access to AST data (section 4.1) and (B) When we can benefit from External data (section 4.2). For each setting, we run experiments on four different models:

1. The cascaded model
2. AST model with pretrained ASR encoder
3. AST model with pretrained ASR encoder and MT decoder
4. Our proposed model with adversarial loss.

Task	En-De	En-Fr
cascaded	21.06	19.21
AST + ASR pre	19.01	16.13
AST + ASR pre + MT pre	19.12	16.27
AST + regularizer	20.81	17.7

Table 3: BLEU scores of AST models, trained with both AST and external ASR and MT data.

4.1 Using only AST data

Table 2 shows the performance of AST models for En-De and En-Fr language pairs. When the cascaded model is restricted to use small AST datasets merely, the model will not be strong enough to beat an AST model with a pretrained encoder and decoder. We should also note that unlike (Bansal et al., 2019; Bahar et al., 2019), where transferring decoder parameters were not effective, in all our AST models, we could only beat the cascaded model by pretraining the decoder.

The last row in the table gives the AST model results, which uses adversarial regularizer during the pretrain step. As we can see, training the NMT and the ASR models simultaneously can help pretrained components be compatible with each other and improve the final performance by 1.2 and 1.7 BLEU scores for En-De and En-Fr language pairs respectively.

4.2 Using both AST and External data

Limiting the training data for the speech translation models to AST datasets is not a realistic assumption for many language pairs, and in practice, the cascaded model can greatly benefit from the large amounts of NMT and ASR corpora.

Table 3 summarizes the effects of adding external training data to our experiments. Adding external data can boost the performance of the cascaded model and by comparing Table 2 and 3, we can see that the additional NMT and ASR data can improve the translation quality of the cascaded model by +2 BLEU scores, while it can barely affect the AST model with pretrained encoder and the decoder. Consequently, the gap between the AST model and the cascaded system increases by around +3 BLEU scores for En-Fr and +2 BLEU scores for the En-De language pair.

As we can see in the last row of Table 3, adding our proposed pretraining step can help the model perform better during training, and compared to the conventional pretraining step, we can see an increase of more than 1 BLEU point in each language pair. Although the cascaded model by having access to all the pretrained parameters (the encoder and decoder of both NMT and ASR) still has better translation quality, we can bring the performance of an end-to-end model closer to it by adding the new regularizer. It is also important to note that since we are not changing the final structure of the AST model, most of the other techniques for further improving the translation quality, such as data augmentation, which was examined in previous studies (McCarthy et al., 2020; Park et al., 2019) can also be applied. But we won't study them in this paper.

5 Related Work

The cascaded pipeline of transcribing speech signals and then translating them using an MT component (Ney, 1999; Cho et al., 2017) was for many years the standard design of speech translation systems (Inaguma et al., 2019). The idea of having an end-to-end structure for this task showed promising results in the works of (Adams et al., 2016; Duong et al., 2016; Bérard et al., 2016; Anastasopoulos et al., 2016; Anastasopoulos and Chiang, 2017; Bansal et al., 2017). After the success of (Weiss et al., 2017) in creating a powerful model for ST systems, more recent studies focused on exploring their power, and one of the main approaches to boost the performance of such models is to make use of available data from other tasks, such as ASR and NMT. (Weiss et al., 2017; Anastasopoulos and Chiang, 2018; Sperber et al., 2019) show that multitask learning can be effective and (Jia et al., 2019; Pino et al., 2019; Park et al., 2019; McCarthy et al., 2020) investigate various data augmentation techniques. The impact of pretraining the encoder with ASR model is also studied in (Berard et al., 2018; Bansal et al., 2018, 2019). In experiments of (Bahar et al., 2019; Bansal et al., 2019) the performance gain of pretraining the decoder with an MT model was marginal.

(Kano et al., 2020) addresses the ASR encoder and MT decoder gap problem by proposing a "Transcoder" and use smooth-L1 loss to bring ASR hidden representation close to MT encoder hidden representation.

The idea of modifying loss function in AST models was also discussed in (Sperber et al., 2019). Their formulation of the additional loss is different from ours, and they use their additional loss function in a different NMT architecture from ours.

The idea of adding adversarial regularizer was discussed in other tasks such as unsupervised MT (Lample et al., 2018) or zero-shot translation (Pham et al., 2019). The closest research to our work is (Arivazhagan et al., 2019), which uses a similar adversarial network to bring encoder representations closer together. However, they apply their model to the zero-shot machine translation task, with a different architecture. They also apply their regularizer to the representations of the different languages with the same modalities.

6 Conclusion

In this paper, we study the impact of pretraining an AST decoder using an MT model and propose a method to make the pretraining step more effective. We show that we can align the latent representations of different modalities by using adversarial loss and make the ASR encoder more compatible with the MT decoder. Our experiments demonstrate that we can improve the performance by around 1.5 BLEU points on two language pairs compared to conventional pretraining methods.

Abstract

We introduce a new keyphrase generation approach using Generative Adversarial Networks (GANs). For a given document, the generator produces a sequence of keyphrases, and the discriminator distinguishes between human-curated and machine-generated keyphrases. We evaluated this approach on standard benchmark datasets. We observed that our model achieves state-of-the-art performance in the generation of abstractive keyphrases and is comparable to the best performing extractive techniques. Although we achieve promising results using GANs, they are not significantly better than the state-of-the-art generative models. To our knowledge, this is one of the first works that use GANs for keyphrase generation. We present a detailed analysis of our observations and expect that these findings would help other researchers to further study the use of GANs for the task of keyphrase generation.

1 Introduction

Keyphrases capture the most salient topics of a document and are often indexed in databases to help with search and information retrieval techniques. Researchers tag their scientific publications with high-quality keyphrases to ensure discoverability in scientific repositories. Automatic identification of keyphrases is of great interest to the scientific community as it helps to recommend relevant articles, suggest missing citations to authors, identify potential peer reviewers, and analyze research trends (Augenstein et al., 2017).

Keyphrases could either be *extractive* (part of the document) or *abstractive* (not part of the document). Some prior works have referred to them as present and absent keyphrases, respectively. Keyphrase generation is the process of predicting both extractive and abstractive keyphrases from a given document. Most of the previous works in keyphrase domain, including both supervised and unsupervised techniques, primarily focus on extractive keyphrases (Hasan and Ng, 2014; Mahata et al., 2018; Sahrawat et al., 2020). Recent studies Meng et al. (2017); Ye and Wang (2018); Chan et al. (2019) have started to develop generative approaches that produce both abstractive and extractive keyphrases from documents. Though these studies have shown some promise, the results suggest that there is great room for improvement.

Most of the supervised natural text generation approaches use Maximum Likelihood Estimation (MLE) objective (Lu et al., 2018). However, MLE techniques have often been observed not to be generating satisfactory text because of exposure bias (Lu et al., 2018). Generative approaches based on Reinforcement Learning (RL) or adversarial training have been shown to address some of the challenges of exposure bias. One such example is the success in the field of summary generation using GANs (Wang and Lee, 2018). Driven by these developments, we posit that, as with summarization, keyphrase generation can also benefit from the use of GANs. To pursue this hypothesis, in this paper, we propose a new GAN architecture for keyphrase generation where the generator produces a sequence of keyphrases from a given document, and the discriminator distinguishes between human-curated and machine-generated keyphrases (Section 2).

We introduce an adversarial training setup for the state-of-the-art generative approaches used in (Chan et al., 2019) (Section 3). We also propose a hierarchical attention-based discriminator architecture. Our empirical analysis shows that the generative models, in GAN setup, improves generation of abstractive keyphrases but do not show any significant improvements for extractive keyphrases.

As concluded by (Çano and Bojar, 2019), we

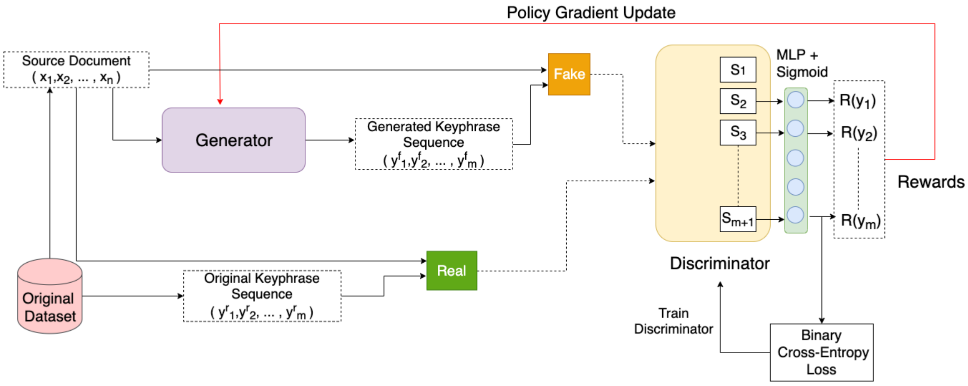

Figure 1: GAN framework for generating keyphrases.

think keyphrase generation is still a hard text summarization challenge. We share our observations as well as our implementations with the scientific community. We expect these findings would help other researchers further explore the application of GANs for keyphrase generation. Following are our main contributions:

- We propose a GAN framework using reinforcement learning for keyphrase generation with a new discriminator architecture based on hierarchical attention that allows for providing reward to partially decoded sequences.
- We evaluate our proposed method on four publicly available datasets and compare our results with five state-of-the-art deep neural generative models for keyphrase generation[1].

2 Methodology

Given a document $T = \{x_1, x_2, ..., x_n\}$, where x_i is the i^{th} token, the problem of keyphrase generation is to generate a set of keyphrases $y = \{y_1, y_2, ..., y_m\}$ that best capture the semantic meaning of T. In this paper, we approach this as a supervised problem solved specifically using GAN (Goodfellow et al., 2014). Our GAN model consists of a generator G trained to produce a sequence of keyphrases from a given document, and a discriminator D that learns to distinguish between machine-generated and human-curated keyphrases.

Adversarial learning for text is a challenging task as it is not straight-forward to back-propagate the loss of the discriminator due to the discrete nature of text data (Rajeswar et al., 2017). We use RL to address this issue, where the generator is treated as an RL agent, and its rewards are obtained from the discriminator's outputs. Fig 1, shows an overview of our framework.

2.1 Generator

- We employ CatSeq (Yuan et al., 2018) as our generator. CatSeq model uses an encoder-decoder framework where the encoder is a bidirectional Gated Recurrent Unit (bi-GRU), and the decoder a forward GRU. For a given document, the generator produces a sequence of keyphrases: $y = \{y_1, y_2, ..., y_m\}$, where each keyphrase y_i is composed of tokens $y_i^1, y_i^2, ..., y_i^{l_i}$. To incorporate out-of-vocabulary tokens, we use a copying mechanism (Gu et al., 2016). We also use an attention mechanism to help the generator identify the relevant components of the source text.

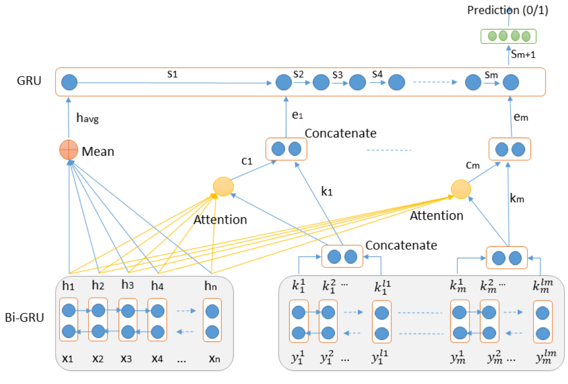

Figure 2: Schematic of Proposed Discriminator (D)

2.2 Discriminator

- The main aim of the discriminator is to distinguish between human-curated and machine-generated keyphrase sequences. To achieve this, the discriminator would also require a representation of the original document T. We proposed a new conditional hierarchical discriminator model (Fig 2) that

---

[1] Code - `https://github.com/avinsit123/keyphrase-gan`

consumes the original document T, a sequence of keyphrases y, and outputs that probability of the sequence being human-curated.

The first layer of this hierarchical model consists of $m + 1$ bi-GRUs. The first bi-GRU encodes the input document T as a sequence of vectors: $h = \{h_1, h_2, ..., h_n\}$. The other m bi-GRUs, which share the same weight parameters, encode each keyphrase y_j as a vector k_j, resulting in a sequence of vectors: $\{k_1, k_2, ..., k_m\}$. We then use an attention-based approach (Luong et al., 2015) to build context vectors c_j for each keyphrase (eq. 1), where c_j is a weighted average over h. By concatenating c_j and k_j, we get a contextualized representation $e_j = [c_j : k_j]$ of y_j.

$$c_j = \frac{\sum_{i=1}^{n} h_i \cdot e^{h_i w_s k_j}}{\sum_{i=1}^{n} e^{h_i w_s k_j}} \tag{1}$$

The second layer of the discriminator is a GRU which consumes the average of the document representations h_{avg} and all the contextualized keyphrase representations $e_1, e_2, ..., e_m$ as:

$$s_{t+1} = \begin{cases} GRU(h_{avg}, s_t), & if\ t = 0 \\ GRU(e_t, s_t), & otherwise \end{cases}. \tag{2}$$

The final state of this layer is passed through one fully connected layer (w_f) and sigmoid transformation to get the probability that a given keyphrase sequence is human-curated $P_h = \sigma(w_f s_{m+1})$.

2.3 Adversarial Training

The goal of the framework is to optimize the generator to produce keyphrase sequences that resemble human-curated keyphrase sequences. This is achieved by training the generator and discriminator in an alternating fashion. Namely, we train the first version of the generator using maximum likelihood estimation (MLE). We then use this generator to produce machine-generated keyphrases (S_f) for all documents. We combine them with the corresponding human curated keyphrases (S_r), and train the first version of the discriminator to optimize for the following loss function:

$$D_{loss} = -E_{y \in S_r}[log(D(y))] - E_{y \in S_f}[log(1 - D(y))] \tag{3}$$

To train the subsequent versions of the generator, we employ reinforcement learning, where the policy gradient is defined as:

$$\triangledown R_G = \sum_{i=1}^{m} [D(y_i) - B] \triangledown log \prod_{j=1}^{l_i} G(y_i^j | y_i^{1:j-1}, y_{1:i-1}, x) \tag{4}$$

B is a baseline obtained by greedy decoding of keyphrase sequence using self-critical sequence training (Rennie et al., 2016) method. The rewards for the generator are calculated from the outputs of the discriminator trained in the previous iteration. The resulting generator is then used to create new training samples for the discriminator. This process is continued until the generator converges.

When using RL for text generation (Li et al., 2017), it is necessary to support rewards for intermediate steps or partially decoded sequences. One of the advantages of our proposed discriminator architecture it can assign individual rewards to each generated keyphrase or one reward to the entire sequence. To support individual rewards, each state s_i of the final discriminator layer is passed through a feed-forward neural network with a sigmoid activation $R(y_i) = D(y_i) = \sigma(W_f s_{i+1})$. To obtain reward for the entire sequence, we just use the final predicted probability.

3 Experimental Work

3.1 Datasets

We trained the proposed GAN model using KP20k dataset (Meng et al., 2017) which consists of 549,818 samples (train: 509,818, test: 20,000, validation: 20,000). Each sample is a scientific article consisting of the title, abstract, and the corresponding human-assigned keyphrases. In addition to KP20k, we also evaluated the model on three other standard keyphrase datasets: Inspec (Hulth, 2003), NUS (Le et al., 2016), and Krapivin (Krapivin et al., 2009) which contain 500, 211, and 400 test samples respectively. We discarded all samples from KP20k training set that overlap with the other three test datasets.

3.2 Baselines

We compare our proposed GAN model against five state-of-the-art generative approaches: CatSeq, CatSeq-D, CatSeq-Corr, CatSeq-TG, CatSeq-RL as implemented in (Chan et al., 2019). All the baselines models were trained from scratch using MLE except for CatSeq-RL, which was trained using RL. We report the performance of our model under two different reward strategies: GAN_{MR}: one reward per keyphrase, and GAN$_{SR}$: one reward per keyphrase sequence.

Table 2: F1 scores for abstractive keyphrases on 4 datasets

3.3 Experimental Settings

For the CatSeq generator model, the word embeddings were initialized to 300 dimensions and hidden layers to 150 units. For the hierarchical discriminator model, word embeddings were initialized to 200 dimensions, and the hidden layer set to 150 units. A dropout of 0.5 is applied to both discriminator layers. We pre-trained both the generator and discriminator using Adam optimizer at a learning rate of 0.001 and batch size of 64 and 32, respectively. Whenever the loss stops converging, we apply learning rate decay. During adversarial training, we switched to Adagrad optimizer with a learning rate of 0.00005. These parameter choices were driven by tuning on the KP20k validation dataset.

The generator model was first pre-trained for 3 epochs. The entire GAN architecture was then trained for four iterations. In each iteration, the discriminator was first trained using MLE for 4 epochs, then generator using policy gradient (with rewards from discriminator) for 4 epochs. We observed that GAN model started to diverge after the fourth iteration. The target sequence consisted of a semicolon-separated list of extractive keyphrases, followed by a tag, followed by another semicolon-separated list of abstractive keyphrases. The tag was useful in distinguishing between the extractive and abstractive keyphrases during evaluation.

3.4 Evaluation Metrics

We present the model performances in terms of F1@K (Yuan et al., 2018), and F1@M (M denotes the no. of unique keyphrases). F1@K is calculated by comparing the top K items ($y_{:K}$) of the generated keyphrase sequence with the ground-truth sequence. In our experimental work, we set $K = 5$. When calculating F1@M, we consider the entire sequence of generated keyphrases. For comparison between keyphrases, we first apply Porter stemming and then use exact matching (Chan et al., 2019).

3.5 Results

Table 1 summarizes the results in terms of F1@5 and F1@M for extractive keyphrases. Table 2 presents the same for abstractive keyphrases. For extractive keyphrases, GAN$_{MR}$ model obtains the best performance on Krapivin dataset and the second best performance on the other three datasets (NUS, Inspec, and KP20K). Overall, the CatSeq-RL seems to be doing best for extractive keyprhases with the GAN$_{MR}$ model being a very close second. In the case of abstractive keyphrases, GAN$_{MR}$ obtains the best performance across all datasets, with the exception of F1@M for NUS. Also, we observed that GAN$_{MR}$ consistently outperforms the GAN$_{SR}$ model. Since GAN$_{SR}$ assigns a single reward to an entire sequence, it is possible that bad keyphrases when present in good keyphrase sequence might receive a high reward. Likewise, a

Model	Extractive		Abstractive	
	F1@5	F1@M	F1@5	F1@M
CatSeq(Pre-trained)	0.291	0.367	0.015	0.031
GAN	0.292	0.365	0.014	0.032
GAN$_{GRU}$	0.299	0.374	0.022	0.038
GAN$_{MR}$	**0.303**	**0.378**	**0.032**	**0.045**

Table 3: F1 Scores for different discriminator structures on the KP20k data

good keyphrase is present in a bad sequence might receive a low reward. This type of a reward scheme could prove detrimental to the training of the generator. On the other hand, GAN$_{MR}$ assigns reward to each keyphrase based on its quality and irrespective of the sequence.

3.6 Discriminator Structure

We conducted a small ablation study to understand how different aspects of the discriminator architecture contribute towards the performance. We compare our hierarchical discriminator against two simpler versions: GAN and GAN$_{GRU}$. In GAN, we remove the part of the architecture that conditions on the original document. In GAN$_{GRU}$, we remove the attention mechanism. Table 3 presents a comparison of these three architectures on KP20k dataset. We observe that both GAN$_{MR}$ model and GAN$_{GRU}$ outperform GAN suggesting that incorporating the original document is necessary for generation. Also, GAN$_{MR}$ outperforms GAN$_{GRU}$ showing that the attention mechanism was beneficial.

3.7 Keyphrase Diversity

We also evaluated the models in terms of α-nDCG@5 scores (Clarke et al., 2008). α-nDCG is an extension of the DCG ranking and is used to measure the diversity of content generated. It works by penalizing redundant keyphrases and rewarding new keyphrases. The results are summarized in Table 4. Our model obtains the best performance on three out of the four datasets, with the exception of CatSeq-RL performing the best on Krapivin. The GAN$_{MR}$ model shows a significant improvement in the α-nDCG@5 scores over the pre-trained CatSeq model, in case of KP20k GAN$_{MR}$ model improves by almost 6%.

4 Conclusions and Future work

In this paper, we proposed the first GAN architecture for keyphrase generation. The model consists of a generator that produces a sequence of keyphrases given a document, and a discriminator that distinguishes between human-curated and machine-generated keyphrases. The two components of the GAN model are trained in an alternating fashion: the scores from the discriminator are used in the policy update of the generator, the keyphrases produced by the generator are used in the training of the discriminator. Our results show that the proposed model obtains better performance in generating abstractive keyphrases but fails to outperform baseline model for extractive keyphrases.

Further analysis of the results (details in supplementary materials) suggest that our model is effective in removing duplicates and generating diverse keyphrases. However, we observed the recall of our model is capped by the CatSeq generator, it did not produce any new keyphrases. We also observed that that our model suffers with some of the common challenges observed in GAN training such as vanishing gradient and mode collapse. Recent works (Lu et al., 2018; d'Autume et al., 2019) have proposed some solutions to address these challenges and we plan to explore them. Future direction also include alternate architectures, reward schemes, and evaluation using human judges.

A Appendix

We further analyse the performance of the GAN model . All graphs indicate metrics for GAN models with multiple rewards trained on the KP20k train dataset, validated on KP20k validation dataset and tested on the Krapivin and Inspec dataset. The GAN$_{MR}$ model is trained for 4 *iterations* with each iteration being composed of 4 *epochs* of discriminator training followed by generator training.

A.1 Vanishing Gradients

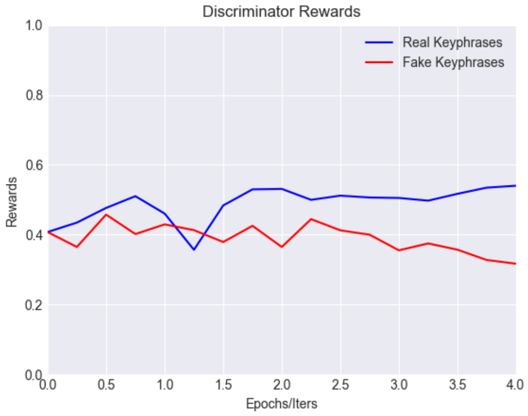

Figure 3: Discriminator Rewards while training GAN$_{MR}$ [2]

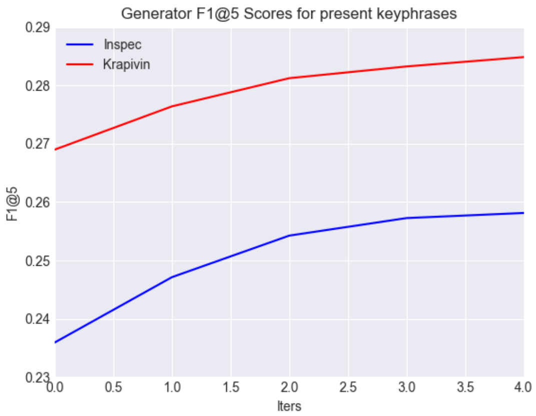

Figure 4: Generator's F1@5 Scores for present keyphrases

One problem we noticed in the GAN training process is as the discriminator performance improves, the ability of the generator to converge decreases. Fig. 3 shows after couple of iterations the discriminator becomes stronger, and assigns high rewards to all real keyphrases and low rewards to all fake keyphrases. While the magnitude of improvement in generator's F1 scores decreases for both present keyphrases (Fig 4) and absent keyphrases (Fig 5), and further training over the 4^{th} iteration causes the generator to diverge.

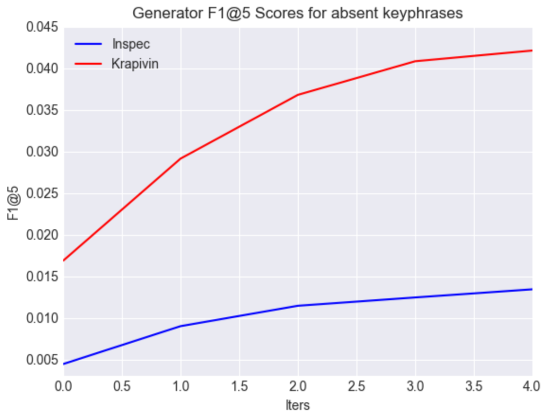

Figure 5: Generator's F1@5 Scores for absent keyphrases

This problem in GAN training is commonly known as *vanishing gradient problem* (Arjovsky and Bottou, 2017), where in the presence of stronger discriminator causes smaller gradients assigned to the generator during training. Thus, as the discriminator improves its strength throughout the iterations, it decreases the ability of the generator to converge.

A.2 Learning Rate

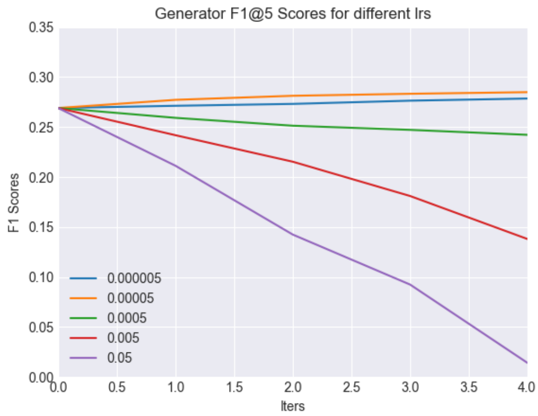

Figure 6: Changes in F1@5 scores of present keyphrases from Krapivin dataset for different learning rates

Some research shows increasing the learning rate might help the generator converge faster and overcome the gradient problem. Increase in the learning rate during GAN training, however causes the generator to enter *mode collapse*. In this case while the generator receives higher rewards from the discriminator, its performance with respect to F1 scores drastically decreases. Figure 6, shows the change in F1@5 scores for present keyphrases over the Krapivin dataset as we vary the learning rate. We observe that increasing the learning rate even by small amount leads to decrease in the F1 scores of the generator, and the decrease is more prominent as we increase the learning rate further, at learning rate 0.05, the generator starts generating gibberish text after 4 iterations.

A.3 Discriminator early stopping

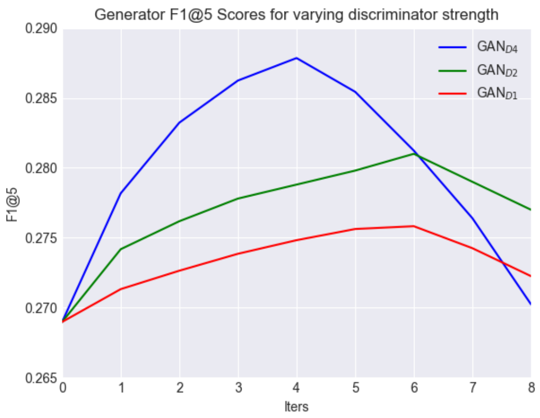

Figure 7: Change in F1@5 Scores on Krapivin dataset for varying strength of discriminator

The improvement in the strength of discriminator impedes the convergence of discriminator after each iteration of training. Thus, we experiment the effect of weaker discriminator on GAN training. The strength of the discriminator is reduced by early stopping and training it just for 1 and 2 epochs in each iteration instead of original 4 epochs . Table 5, shows performance for various generators on Krapivin dataset based on the strength of the discriminator. GAN$_{D1}$, GAN$_{D2}$ and GAN$_{D4}$ are the GAN models in which the discriminator is trained for 1, 2 and 4 epochs in each adversarial training iteration respectively. The F1 scores of these models indicate slowing down discriminator training actually end up with worse performance

Model	Present		Absent	
	F1@5	F1@M	F1@5	F1@M
CatSeq(Pre-trained)	0.269	0.360	0.017	0.032
GAN$_{D1}$	0.276	0.364	0.028	0.039
GAN$_{D2}$	0.281	0.367	0.036	0.047
GAN$_{D4}$	**0.288**	**0.369**	**0.042**	**0.057**

Table 5: Generator's F1 scores on krapivin dataset for varying strength of discriminator

Further analysis of an increase in generator's F1@5 scores on present keyphrases in fig 7 show that while training with a weak discriminator does improve the generator's convergence in later iterations as evidence by GAN$_{D1}$ and GAN$_{D2}$ improving their F1 scores till 6th iterations, this magnitude of increase in not large enough. Fig 7 shows that initial increase in F1 scores of GAN$_{D2}$ in the 1st iteration is quite large compared to GAN$_{D2}$ and GAN$_{D1}$. This small improvement can be attributed to the fact that a weak discriminator find its difficult to distinguish between false and real keyphrases, thus assigning rewards closer to the baseline which do not reflect the reality of generated keyphrases causing the generator to converge less. We further see a manifestation of *vanishing gradient problem* in all 3 GAN models - the improvement in F1 scores decreases as we move across increasing iterations thus, this initial large increase is crucial in improving GAN$_{D4}$'s scores and making it the best performing model.

A.4 Examples

Table 6 and Tabel 7 shows examples of keyphrases generated by GAN$_{MR}$ and all baselines along with the original and author assigned keyphrases. Table 6 showcases some scenarios where the GAN$_{MR}$ improves upon existing keyphrases and Table 7 highlights examples where GAN$_{MR}$ performs worse.The following observations are made with respect to these examples.

1. **GAN$_{MR}$ model improves upon existing keyphrases generated by the pre-trained CatSeq model** - As seen in both examples of Table 6 the GAN model improves upon existing keyphrases generated by the pre-trained CatSeq model. In Ex.1, CatSeq generates keyphrases *object* and *image*. These differ from the original keyphrases *object recognition* and *image registration* only by 1 word. GAN$_{MR}$ model helps in introducing these new words and improves upon CatSeq-generated keyphrases by providing them with a higher reward and encouraging the generator. Similarly, in Ex.2 GAN$_{MR}$ improves

Table 7: Negative Examples generated by GAN$_{MR}$ and other baselines

upon CatSeq-generated *Noise* by generating *Background Noise.*

2. **GAN$_{MR}$ model removes repeated and unwanted keyphrases and improves diversity**.
   All baseline models in Ex 2 of Table 6 generate keyphrase *speech* 2 times. However, GAN$_{MR}$ removes all repeating occurences of keyphrases and generates a diverse keyphrase sequence as evidenced by α-nDCG@5 metrics of diversity in Table 4.

3. **GAN$_{MR}$ model doesn't help the generator introduce new keyphrases**
   A consistent feature noticeable across all examples is that while the GAN model does improve upon generated keyphrases, it doesn't generate full new keyphrases. In none of the examples, does the GAN$_{MR}$ model introduce new keyphrases.

4. **GAN$_{MR}$ removes original keyphrases predicted by the pre-trained CatSeq model**
   Sometimes when the keyphrase is present in both the real and fake keyphrase sequence, the discriminator assigns low rewards to these keyphrases even though they might be true. These keyphrases often get discarded due to these low rewards during the GAN training process. Consider Ex.1 of Table 7, even though keyphrases *interestingness* and *data*

mining, both, are predicted by the CatSeq generator and are present in the original keyphrase sequence. However, the GAN$_{MR}$ model removes both these keyphrases generating a less original keyphrase sequence, thereby decreasing F1 score.

Thus GAN$_{MR}$ improves upon the CatSeq-generated keyphrases and removes repeated keyphrases. However, it falls short in generating new keyphrases thus not increasing the F1 score much.

A.5 Absent vs Present Keyphrases

GAN's cause an improvement in both present and absent keyphrases. While the improvement in F1 scores is more significant for present keyphrases, the marginal improvement in F1 scores of absent keyphrases is enough to make the GAN model perform better than all baselines. This improvement in F1 scores can be attributed to our reward scheme and the structure of the discriminator which gives equal priority in rewarding both absent and present keyphrases.

A.6 Conclusion

Analysis indicates that GAN training suffers from *vanishing gradient problem* preventing the generator from achieving maximum potential. Increasing the learning rate causes *mode collapse* and using a weaker discriminator does not guarantee a large increase in F1 scores. These observations indicate the inherent difficulty in training GANs on textual data especially keyphrases. The GAN model improves upon the MLE-Generated keyphrases and improves diversity by removing repeated keyphrases, however it fails to introduce new keyphrases.

TESA: A Task in Entity Semantic Aggregation for Abstractive Summarization

Abstract

Human-written texts contain frequent generalizations and semantic aggregation of content. In a document, they may refer to a pair of named entities such as 'London' and 'Paris' with different expressions: "the major cities", "the capital cities" and "two European cities". Yet generation, especially, abstractive summarization systems have so far focused heavily on paraphrasing and simplifying the source content, to the exclusion of such semantic abstraction capabilities. In this paper, we present a new dataset and task aimed at the semantic aggregation of *entities*. TESA contains a dataset of 5.3K crowd-sourced entity aggregations of PERSON, ORGANIZATION, and LOCATION named entities.[1] The aggregations are document-appropriate, meaning that they are produced by annotators to match the situational context of a given news article from the New York Times. We then build baseline models for generating aggregations given a tuple of entities and document context. We finetune on TESA an encoder-decoder language model and compare it with simpler classification methods based on linguistically informed features. Our quantitative and qualitative evaluations show reasonable performance in making a choice from a given list of expressions, but free-form expressions are understandably harder to generate and evaluate.

1 Introduction

Input Entities	François Bayrou, Nicolas Sarkozy, Ségolène Royal
Document Context	François Bayrou, Nicolas Sarkozy, and Ségolène Royal are the main contenders in the French presidential elections.
Possible Aggregations	• the French politicians • the French presidential candidates • the politicians

Table 1: An example of semantic entity aggregation. The input consists of a tuple of named entities, a situational (document) context, and background information about the entities (not shown here). The expected output is an aggregation of the tuple of entities.

Abstractly speaking, abstraction can be defined as the process of deriving general concepts from specific instances. In automatic summarization, however, "abstractive" summarization often means any type of rewriting of words in some source document into an output summary. Concretely, recent summarization datasets including XSum (Narayan et al., 2018) and NEWSROOM (Grusky et al., 2018) quantify the degree of abstractiveness of a summary in terms of its novel N-grams.

While such a surface-level definition of abstractiveness is certainly useful and convenient, it is nevertheless only a proxy for abstraction in the broader sense which concerns semantic generalization. We argue that it is important to also focus explicitly on semantic abstraction, as this capability is required for more difficult types of summarization which are out of reach of current methods. For example, generating a plot summary of a novel might require describing sequences of events using one sentence. Writing a survey of a scientific field would require categorizing papers and ideas, and being able to refer to them as a whole. Outside of domain-specific settings such as opinion summarization (Ganesan et al., 2010; Gerani et al., 2014, *inter alia*), and tasks such as sentence fusion (Barzilay and McKeown, 2005), there has been little work focusing on semantic generalization and abstraction.

---

[1] TESA's code and access to its dataset can be found at: `https://github.com/clementjumel/tesa`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8031–8050,
November 16–20, 2020.

In this paper, we start to tackle this issue by focusing on the specific task of semantic aggregation of entities; i.e., how to refer to a tuple of named entities using a noun phrase instead of enumerating them (See Table 1 for an example). We define a task to evaluate summarization models on semantic entity aggregation, which we call **TESA** (A **T**ask in **E**ntity **S**emantic **A**ggregation). In TESA, a system is presented with a list of named entities in an original textual context, and it must produce a *non-enumerating* noun phrase which refers to the designated entities. Solving this task requires finding a semantic link between all the entities in the list (e.g., London and Paris are cities of considerable sizes), then using this information to generate a noun phrase (e.g., "the major cities").

We introduce an accompanying dataset of entities in context drawn from the New York Times corpus (Sandhaus, 2008), and their aggregations which were written by crowd workers. Our dataset contains 5.3K aggregation expressions. Each example, contains a tuple of PERSON, ORGANIZATION or LOCATION named entities, a paragraph context from an NYT article discussing the entities, and background information about entities in the form of summary snippets from Wikipedia. We also introduce the first models for the TESA task which are based on an encoder-decoder system pretrained for abstractive summarization, BART (Lewis et al., 2019). We present two ways of fine-tuning BART to TESA, either in a discriminative or in a generative fashion, and compare them against simpler statistical and frequency-based methods.

The simple classifier achieves decent results on TESA. It is however outperformed by a wide margin by BART, when fine-tuned on our task in a discriminative manner. When fine-tuned as a generative model, BART yields similar performance as the simple classifier. Yet, the generative model is able to freely generate entity aggregations with diversity and quality, despite some factual inconsistencies.

2 Related work

Abstractive summarizers have gained prominence with the popularization of RNNs (Sutskever et al., 2014; Nallapati et al., 2016), and more recently Transformers (Vaswani et al., 2017) like BERT (Devlin et al., 2019). Several abstractive models have achieved state-of-the-art performances on benchmark summarization datasets in terms of ROUGE, including ProphetNet (Yan et al., 2020), PEGASUS (Zhang et al., 2019) and BART (Lewis et al., 2019). Recent work has also focused on specific issues such as preventing inappropriate repetition (Kryściński et al., 2018), word-level rewriting, and evaluating factual consistency (Kryściński et al., 2019; Maynez et al., 2020).

Abstraction is critical for certain domains and applications, but has not been thoroughly explored in many. For example, in scientific article summarization the particular structure and length of scientific articles make extractive techniques much easier to apply (Agarwal et al., 2011), therefore abstractive summarizers (Lloret et al., 2013) remain a minority. In opinion summarization, there have been abstractive systems that leverage cues specific to this task, such as redundancy in opinions (Ganesan et al., 2010) and specific discourse structures (Gerani et al., 2014). As abstractive systems have become strong in terms of generation capabilities, the time is apt to examine issues in semantic abstraction that could be useful in many summarization domains and tasks. Our work is a step in this direction.

Our proposed entity aggregation task is related to referring expression generation (REG). REG is concerned with determining the form and content that entity references should take during generation (Krahmer and van Deemter, 2012; Castro Ferreira et al., 2018; Cao and Cheung, 2019). It emphasizes finding the right distinguishing characteristics of the intended referent or referents. Our work can be seen as a specific REG task that focuses on semantically abstracting multiple named entities. Our work is also related to coreference resolution, especially those that examine multi-antecedent resolution (Burga et al., 2016; Vala et al., 2016), an inverse problem to ours. To the best of our knowledge, no previous work has directly addressed entity aggregation.

3 The TESA dataset

We used the New York Times (NYT) Annotated Corpus (Sandhaus, 2008) to extract tuples of named entities and their document context. The NYT corpus contains high-quality metadata listing the salient named entities mentioned in each article. We form our tuples from entities tagged in the metadata for the same article.

We refer to a tuple of entities and its associated information as an **aggregatable instance**. We first describe the components of an aggregatable instance in more detail. Then, we describe our data extraction and crowd-sourcing experiments.

3.1 An aggregatable instance

The starting point of an aggregatable instance is the tuple of named entities which should be aggregated and the type of its entities (e.g., PERSON). As we aim for contextual entity aggregations, an aggregatable instance also contains a document context; i.e., a passage from a document in which all the entities are mentioned. To provide additional background knowledge, we also include introductory summaries for the entities taken from Wikipedia.

An example of aggregatable instance, as presented to the annotators, is in Figure 1. For more examples, see Table 8 in the appendix.

3.2 Data extraction

While we could have gathered naturally occurring entity aggregations, work on multi-antecedent coreference resolution is still nascent, and our initial attempts to define heuristic methods to extract entity aggregations were very noisy. We instead used crowd-sourcing to gather human-generated aggregations from sets of entities.

We used the 2006 and 2007 portions of the New York Times corpus. We started with the editorial metadata which tags salient named entities in each article. These are entities we believe are likely to be included in a summary. We filtered the entity tuples to remove those that are unlikely to be naturally aggregatable using the following two constraints. First, the entities should have the same type (PERSON, LOCATION, or ORGANIZATION in this corpus). Second, the entities should be mentioned close together, within a span of consecutive sentences of the same length as the size of the tuple of entities (e.g., three consecutive sentences for three entities). We also selected those entity tuples that are mentioned together in the abstract of an article.

To extract the document context, we extracted both the title of the article and the span of sentences which mentions the entities. If the same entity tuple is mentioned in different qualifying sentence spans in the same article, they would be extracted as different aggregatable instances.

As for the background information, we extracted an excerpt of each entity's Wikipedia article, using the first paragraph of the article if it exists, up to 600 tokens. We used the entity name to identify its Wikipedia page[2], and, in case of ambiguous or incorrect linking, we corrected it manually when possible, or discarded it.

Data collected	
aggregatable instances	2100
annotators	63
annotations	6299
Preprocessed dataset	
aggregatable instances	1718
annotators	42
annotations	4675
PERSON entities tuples	941 (801)
LOCATION entities tuples	629 (412)
ORGANIZATION entities tuples	148 (123)
PERSON aggregations	2900 (951)
LOCATION aggregations	2041 (505)
ORGANIZATION aggregations	456 (239)

Table 2: Statistics on the sizes of the annotated data and of the final dataset. For entity tuples and aggregations, we indicate the total count of occurrences, and in parentheses the count of unique occurrences.

After extraction, we sampled 2,100 instances uniformly at random for annotation. A tuple contains between 2 and 6 entities, for an average of 2.4.

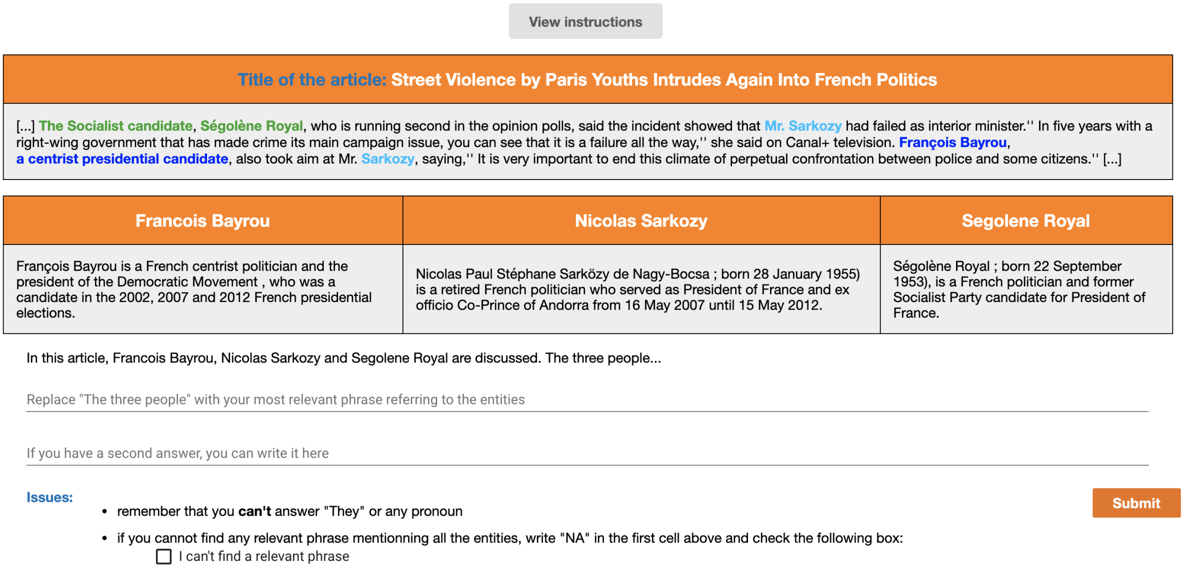
3.3 Data Annotation

We used Amazon Mechanical Turk to collect entity aggregations. Annotators were asked to generate aggregations given information about an aggregatable instance. For each instance, we showed the same information as described above, including the mentions of the entities in context, and a link to the Wikipedia pages of the entities. Some of the instructions given to the annotators and examples of the annotation layout are in Figures 1, 2. The complete instructions and examples are available in Figures 3–6 in the appendix.

The entity tuple, document context, Wikipedia background information are presented to annotators, alongside a prompt (see Figure 1). For the PERSON entities in our example, this prompt is *"In this article, François Bayrou, Nicolas Sarkozy and Ségolène Royal are discussed. The three people..."* Annotators were asked to replace the phrase "The three people" with a relevant one referring to the entities. The prompt serves to prime the annotator to produce a fluent and comprehensive aggregation

---

[2] Using `Wikipedia` python's library: `https://pypi.org/project/wikipedia/`



Title of the article: **Street Violence by Paris Youths Intrudes Again Into French Politics**

[...] **The Socialist candidate**, **Ségolène Royal**, who is running second in the opinion polls, said the incident showed that Mr. Sarkozy had failed as interior minister.'' In five years with a right-wing government that has made crime its main campaign issue, you can see that it is a failure all the way,'' she said on Canal+ television. **François Bayrou**, **a centrist presidential candidate**, also took aim at Mr. Sarkozy, saying,'' It is very important to end this climate of perpetual confrontation between police and some citizens.'' [...]

Francois Bayrou	Nicolas Sarkozy	Segolene Royal
François Bayrou is a French centrist politician and the president of the Democratic Movement , who was a candidate in the 2002, 2007 and 2012 French presidential elections.	Nicolas Paul Stéphane Sarközy de Nagy-Bocsa ; born 28 January 1955) is a retired French politician who served as President of France and ex officio Co-Prince of Andorra from 16 May 2007 until 15 May 2012.	Ségolène Royal ; born 22 September 1953), is a French politician and former Socialist Party candidate for President of France.

In this article, Francois Bayrou, Nicolas Sarkozy and Segolene Royal are discussed. The three people...

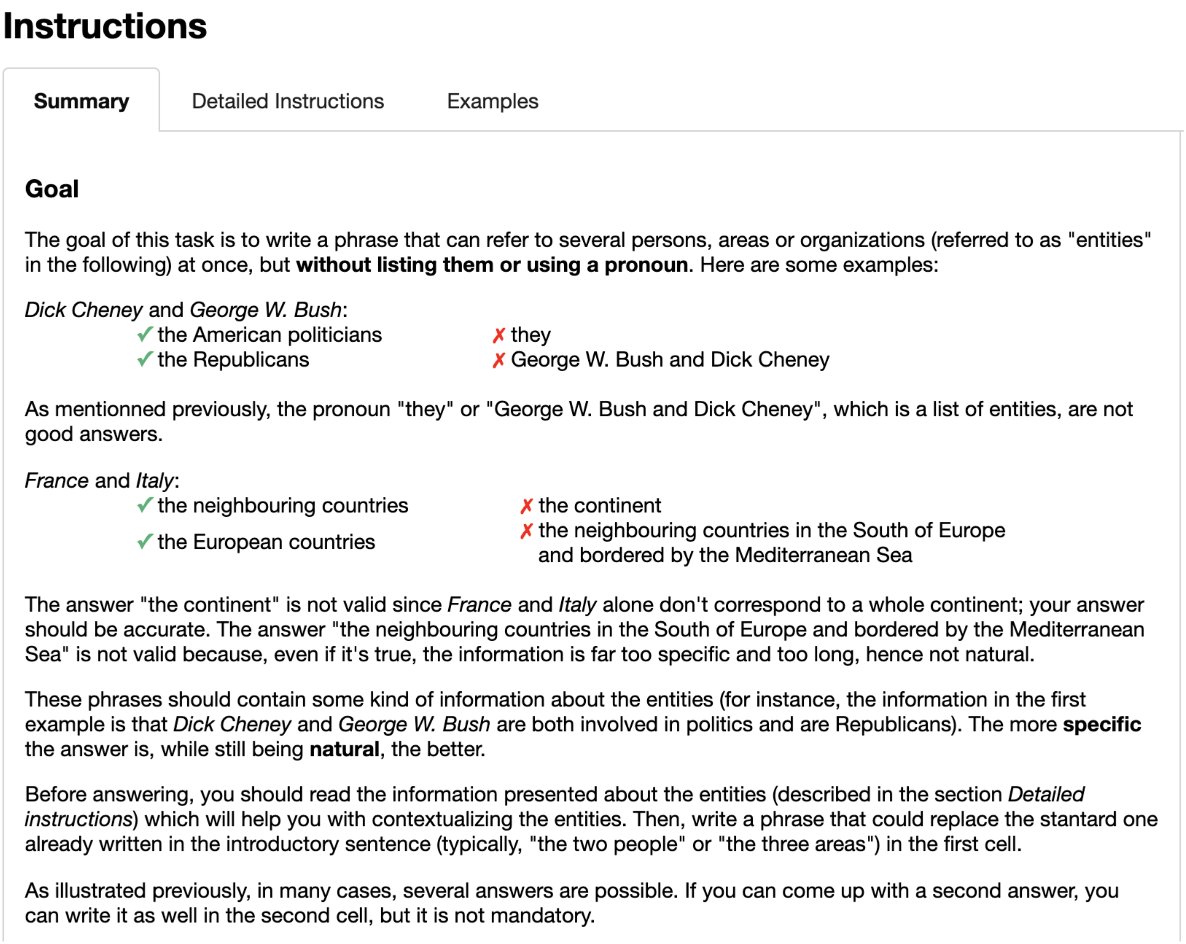
Replace "The three people" with your most relevant phrase referring to the entities

If you have a second answer, you can write it here

Issues:

- remember that you **can't** answer "They" or any pronoun
- if you cannot find any relevant phrase mentionning all the entities, write "NA" in the first cell above and check the following box:
  ☐ I can't find a relevant phrase

Figure 1: Layout of the annotation task. The mentions of the entities in the New York Times article are colored and the name of the corresponding entity is visible when an annotator clicks on a mention. The title of the Wikipedia information is an hyperlink to the corresponding web page.



Instructions

Goal

The goal of this task is to write a phrase that can refer to several persons, areas or organizations (referred to as "entities" in the following) at once, but **without listing them or using a pronoun**. Here are some examples:

Dick Cheney and *George W. Bush*:

✓ the American politicians	✗ they
✓ the Republicans	✗ George W. Bush and Dick Cheney

As mentionned previously, the pronoun "they" or "George W. Bush and Dick Cheney", which is a list of entities, are not good answers.

France and *Italy*:

✓ the neighbouring countries	✗ the continent
✓ the European countries	✗ the neighbouring countries in the South of Europe and bordered by the Mediterranean Sea

The answer "the continent" is not valid since *France* and *Italy* alone don't correspond to a whole continent; your answer should be accurate. The answer "the neighbouring countries in the South of Europe and bordered by the Mediterranean Sea" is not valid because, even if it's true, the information is far too specific and too long, hence not natural.

These phrases should contain some kind of information about the entities (for instance, the information in the first example is that *Dick Cheney* and *George W. Bush* are both involved in politics and are Republicans). The more **specific** the answer is, while still being **natural**, the better.

Before answering, you should read the information presented about the entities (described in the section *Detailed instructions*) which will help you with contextualizing the entities. Then, write a phrase that could replace the stantard one already written in the introductory sentence (typically, "the two people" or "the three areas") in the first cell.

As illustrated previously, in many cases, several answers are possible. If you can come up with a second answer, you can write it as well in the second cell, but it is not mandatory.

Figure 2: First page of the instructions provided to the annotators.

covering all the entities. For other named entity types, the prompt is changed accordingly. While simple, we found this prompt to be rather effective in the collection process.

We also presented detailed examples (see Figure 2) explaining the desired aggregations. Annotators were asked not to use generic aggregations involving only the entities' type (e.g., "the three people") and to avoid using "and", as it would often imply an enumeration.

For each of the 2,100 aggregatable instances, three different annotators were asked to provide an annotation. In each annotation, an annotator could provide between zero (meaning the instance is not aggregatable) and two aggregations.

The aggregations produced for the example of Figure 1 by the three annotators are below:

Annotator 1
- french politicians

Annotator 2
- the French politicians
- the French presidential candidates

Annotator 3
- the politicians

We discarded instances that at least two of the three annotators considered as 'not aggregatable'. In addition, we discarded those annotations that did not conform to our instructions, and annotations from workers who performed less than five annotations.

Finally, we post-processed the aggregations, removing determiners, numerical expressions and standardized the casing (e.g., "The two cities" became "cities").

Table 2 presents statistics on the size of the data collected and the final dataset.

3.4 Data Splits

We split the dataset into training, validation, and test sets using a 2:1:1 ratio, resulting in 858/430/430 aggregatable instances in each set, respectively (corresponding to 20592/10320/10320 ranking candidates, respectively).

The entities in our dataset are quite diverse. In the validation and test sets, 29% and 30% of the aggregatable instances respectively have a set of input entities which do not overlap with entities in the training set at all. On average, each aggregatable instance has 2.7 different aggregations.

4 The TESA task

4.1 Task Definition

We frame TESA as a ranking task where, given an aggregatable instance as input, models must rank a list of candidates according to their plausibility as an aggregation of the input entities (in context). We choose a discriminative approach to avoid relying on word-overlap metrics, and we opt for a ranking task set-up to avoid classification between heavily imbalanced classes, as the number of gold standards remains limited. In this set-up, generative models can also be evaluated.

In our experiments, the list of candidate aggregations contains 24 candidates in total, including the gold-standard, correct aggregations generated by the human annotators, as well as a list of negative candidates which serve as distractors. The candidates' number is chosen to yield approximately 10 times more negative candidates than gold standards. Negative candidates are sampled uniformly at random from other aggregatable instances sharing the same named entity type.

An example of TESA's tasks is available in Table 3; for more examples, see Table 9 in the appendix.

4.2 Evaluation Measures

We evaluate the models' performances using three widely used ranking performance measures. Let $\textit{rank}(i)$ be the rank of candidate i, G be the set of gold-standard candidates in a ranking and $R(n)$ be the set of candidates retrieved up to and including position n. Then, for an aggregatable instance:

Average precision.

$$AP = \frac{1}{|G|} \sum_{i \in G} \frac{|G \cap R(\textit{rank}(i))|}{|R(\textit{rank}(i))|} \tag{1}$$

Recall at 10.

$$R@10 = \frac{1}{|G|} |G \cap R(10)| \tag{2}$$

Reciprocal rank.

$$RR = \frac{1}{\min_{i \in G} \textit{rank}(i)} \tag{3}$$

We report the mean of these values across all instances in the test set (MAP, $\overline{R@10}$, MRR). We chose these measures because they provide different perspectives on the evaluation results. Recall

BART-based models' input	Candidates to rank
François Bayrou is a French centrist politician [...], who was a candidate in the 2002, 2007 and 2012 French presidential elections. Nicolas Paul Stéphane Sarkozy [...] is a retired French politician who served as President of France [...] from 16 May 2007 until 15 May 2012. Ségolène Royal [...] is a French politician and former Socialist Party candidate for President of France. Street Violence by Paris Youths Intrudes Again Into French Politics: The Socialist candidate , Ségolène Royal , who is running second in the opinion polls, said the incident showed that Mr. Sarkozy had failed as interior minister. [...] François Bayrou , a centrist presidential candidate , also took aim at Mr. Sarkozy , saying," It is very important to end this climate of perpetual confrontation between police and some citizens." Francois Bayrou, Nicolas Sarkozy, Segolene Royal	afghans, police officers, **french presidential candidates**, intelligence analysts, tv talent, american lobbyists, former presidents, defectors, former boxers, **politicians**, real estate company owners, participants in anna nicole smith case, american men, **french politicians**, new york mafiosos, people involved in the scandal, iraqi citizens, billionaire businessmen, male speed skaters, investors, men involved in professional sports, screen artists, poets, alleged criminals

Table 3: Ranking task from the running example. BART-based models' inputs are presented in the left-hand-side column. Background information is in blue, context is in violet, and entities' names are in orange. Models have to rank the 24 candidates (separated by commas) of the right-hand-side column. The gold-standard aggregations are in bold. For displaying purposes, this example has been shortened.

at 10 captures the models' ability to rank correct aggregations as promising or neutral at worst. Reciprocal rank focuses solely on the best ranked correct aggregation.

5 Models

We tested several simple baselines as well as models adapted from current work on abstractive summarization on TESA.

5.1 Simple Baselines

All the baselines and models are given as input an aggregatable instance and a list of candidates to rank with the same entity type as the aggregatable instance. The first two baselines are agnostic to the aggregatable instance:

Random. This baseline produces a random ordering of the candidate entities.

Frequency. This baseline ranks the candidates according to their frequency as a correct aggregation in the training set.

5.2 Logistic Regression

We defined a number of statistical and linguistically informed features, which we extracted from each candidate aggregation and its aggregatable instance's context and background information. These 15 features include:

- the count of the "frequency" baseline,
- the number of common tokens (with repetition) between the candidate and the union of the background information,
- the size of the word overlap between a candidate and the intersection of the entities' background information,
- the cosine similarity between the average word embeddings of the candidate and of the context.

We detail these features in Appendix C. We trained a binary logistic regression using this representation, to discriminate between the gold-standard aggregations and the negative candidates. We used the model's predictive probability for the gold-standard class to produce a ranking over the candidate list.

5.3 BART-based models

We tested BART (Lewis et al., 2019) as a representative model of recent high-performance abstractive summarization systems based on an encoder-decoder architecture with a Transformer backbone. We compared three versions of BART, which differ based on whether and how they are fine-tuned on TESA.

Pre-trained BART. We applied an existing pre-trained version of BART in a generative set-up without fine-tuning. We formatted each aggregatable instance into a single sequence of tokens by concatenating the fields of the aggregatable instances in the following order: background information, context (title of the article and excerpt), and entity names. An example of such input can be seen in Table 3.

We fed this as input to BART's encoder, and we evaluated the probability of each candidate aggregation to be generated autoregressively by the decoder. We used these probabilities to rank the candidates.

Generative BART. This version is similar to the above, but we fine-tuned BART on TESA, considering each correct aggregation as a separate target, and training the model to generate each target given the corresponding aggregatable instance. For the aggregatable instances, we used the same input format as above. We did not add any form of separation tokens, as our initial experiments showed that they slightly hurt the performance.

Discriminative BART. Finally, we fine-tuned BART discriminatively as a classifier. During fine-tuning, we consider each candidate and its aggregatable instance as a separate sample, and the model was trained on these samples to discriminate the correct aggregations from the negative candidates. At test time, we rank the candidates by their probability of being the correct aggregation according to the classifier. Again, we did not add any separation tokens, as it did not improve the performance.

The main advantage of this approach over the previous one is that it leverages the set-up of TESA as a ranking task, and the model is exposed to both correct and incorrect aggregations during training (which, on the other hand, makes it more computationally expensive). By contrast, generative BART only sees correct ones. We thus expect the discriminative model to produce higher performance. However, this comes at a cost, as this approach cannot generate freely an aggregation, but only retrieve one from a set of candidates.

For all three versions above, we built upon code that is available through fairseq (Ott et al., 2019). We use the version of BART pre-trained on the CNN/DailyMail dataset. The choice of hyperparameters is described in Appendix D.

6 Results

The results of the models on TESA's test set are presented in Table 4. We see that most models outperform the frequency baseline, except pre-trained BART. Fine-tuning BART on TESA increased its performance significantly, especially if done discriminatively. Discriminative BART achieves the best results. Its high performance can be mitigated by our choice of ranking only 24 candidates, which makes unlikely confusing negative candidates.

Method	MAP	$\overline{R@10}$	MRR
Random baseline	0.222	0.442	0.289
Frequency baseline	0.570	0.655	0.761
Logistic regression	0.700	0.863	0.840
Pre-trained BART	0.389	0.682	0.505
Generative BART	0.701	0.903	0.840
Discriminative BART	**0.895**	**0.991**	**0.954**

Table 4: Results of the different models on the TESA test set.

Method	context, entities	info., entities	entities
Generative BART (0.701)	-0.079	-0.049	-0.145
Discriminative BART (0.895)	-0.035	-0.024	-0.100

Table 5: Results of the ablation study. We report the mean average precision differences between the ablated system and the full model's performance (in parentheses) on TESA. Negative numbers mean the performance of the full model is higher.

6.1 Ablation Study

To understand the importance of the different components of the input for this task, we performed an ablation study, where we removed selected parts of the input: without the background information (context, entities), without context (info., entities) and with only the names of the entities (entities). We fine-tuned generative and discriminative BART on these modified datasets. The hyperparameters used are described in Appendix D.

We report the mean average precision results, which are representative of the other measures, in Table 5. Models perform best when all information is available, which validates our choice of input format. The background information seems to be more important than the context, as removing the context leads to the smallest drop in average precision. Interestingly, models perform quite well when given only the entities' names, though the performance gap is still quite significant.

Discriminative BART	Generative BART
Entities Francois Bayrou, Nicolas Sarkozy and Segolene Royal	
1. **politicians**	1. **politicians**
2. **french politicians**	2. **french politicians**
3. **french presidential candidates**	3. people involved in the scandal
4. former presidents	4. **french presidential candidates**
5. police officers	5. new york mafiosos
6. alleged criminals	6. american men

Table 6: Results of generative and discriminative BART on the running example. We show the input entities, and the candidates ranked from 1 to 6, as well as any other gold standard candidate, if any. Gold standards are in bold.

Aggregations generated
Entities François Bayrou, Nicolas Sarkozy and Ségolène Royal
1. **politicians [0.084]**
2. american politicians [0.060]
3. **french politicians [0.057]**
4. political figures [0.041]
5. **French politicians [0.037]**
6. political leaders [0.029]
7. politician [0.025]
8. political candidates [0.024]
9. politicans [0.023]
10. Politicians [0.008]

Table 7: Aggregations generated by generative BART on the running example. The model's encoder is fed an aggregatable instance, and the decoder generates autoregressivly the aggregations without constraint. We show the input entities, and the 10 aggregations retrieved by the beam search, ranked according to their likelihoods. If a generated aggregation matches a gold standard (except for capital letters), it is in bold; the generated examples probabilities are in brackets.

6.2 Qualitative analysis

We compare the two best-performing models: generative and discriminative BART. In Table 6, we present an example of their results on a ranking task from TESA's test set. In general, the discriminative approach performs well, is robust and the negative candidates ranked at high positions are quite coherent (e.g., "former presidents" and "police officers"). On the other hand, generative BART performs quite well on the ranking task, but is far less robust and its negative candidates ranked at high positions are more intriguing (e.g., "new york mafiosos" and "american men"), which seems to indicate a poorer understanding of the aggregatable instance.

Besides, we show some aggregations generated by the generative approach in Table 7. Qualitatively speaking, the generated samples are quite interesting as many of them are accurate and have a diverse vocabulary (e.g., "politicians", "figures", "candidates", "leader"). However, some samples are factually inconsistent (e.g., "american politicians") which seems to indicate that the model does not have a deep understanding of relevant semantic concepts (e.g., nationalities cannot be substituted for each other).

For other examples, including some specifically chosen as the models failed on them, see Tables 10–13 in the appendix.

7 Conclusion and future work

We have proposed TESA, a novel task and an accompanying dataset of crowd-sourced entity aggregations in context. TESA directly measures the ability of summarizers to abstract at a semantic level. We have compared several baseline models and models adapted from existing abstractive summarizers on TESA, and find that a discriminative fine-tuning achieves the best performance, though this model inherently cannot *generate* aggregations.

In future work, we would like to expand the domains covered by our dataset, which is biased towards topics found in the source corpus, such as politics. Another important direction is to investigate how to integrate the ability to aggregate entities derived from training on TESA into an abstractive summarizer. This would require models to tackle another challenging issue which we have not addressed: which set of entities *should* a model aggregate in the first place?

Acknowledgements

We would like to thank Ido Dagan for useful initial discussions about this work, Jingyun Liu, whose automatic preprocessing of the New York Time Corpus was a precious help, and José Ángel González Barba, who helped us with analysis and proofreading. We also wish to mention our two pilot annotators. Finally, we would like to thank our anonymous reviewers for their kind and helpful comments.

Appendix A Detailed examples

In Tables 8, 9, 10 and 11, we present several examples following the examples presented in Figure 1 and Tables 3, 6 and 7 respectively.

In Tables 12 and 13, we present two examples of aggregatable instances where BART-based models performed poorly.

Appendix B Human-sourcing set-up

To ensure maximal reproducibility, we provide here some details regarding the collection of the human annotations. For the task set-up, we used the Amazon Mechanical Turk website. We present in details the layout of the annotation process in Figure 3, and its instructions in Figures 4, 5 and 6.

Appendix C Linguistically informed features

For the representation of an aggregatable instance to train the logistic regression, we used the following features:

- count of the "frequency" baseline,
- number of common tokens (with repetition) between the candidate and the union of the entities' background information,
- size of the word overlap between a candidate and the union of the entities' background information,
- size of the word overlap between a candidate and the intersection of the entities' background information,
- number of entities whose background information words are overlapping the candidate's words,
- cosine similarity between the average token embeddings of the candidate and the union of the entities' background information,
- cosine similarity between the average word embeddings of the candidate and the intersection of the entities' background information,
- number of common tokens (with repetition) between the candidate and the context,
- size of the word overlap between a candidate and the context,
- cosine similarity between the average token embeddings of the candidate and the context,
- number of common tokens (with repetition) between the candidate and the union of the entities' background information, the context, and the names of the entities,
- size of the word overlap between a candidate and the union of the entities' background information, the context, and the names of the entities,
- size of the word overlap between a candidate and the union of the context and the intersection of the entities' background information,
- cosine similarity between the average token embeddings of the candidate and the union of the entities' background information, the context, and the names of the entities,
- cosine similarity between the average word embeddings of the candidate and the union of the context and the intersection of the entities' background information.

During the feature extraction, we removed any capitalization and any punctuation. We removed the stop-words from the candidates' tokens. We removed the stop-words and we lemmatized the tokens of the context and of the background information.

Appendix D Hyperparameters

In the following, we describe our choice of hyperparameters for each model, as well as any eventual hyperparameter search.

D.1 Logistic regression

We used a simple logistic regression for binary classification. The model has 32 parameters, and we use Adam optimizer, a learning rate of $3e-3$ and the cross entropy loss. We ran the experiment for 50 epochs, which took typically 15 minutes on a CPU, and we kept the model's parameters of the epoch maximizing the average precision of the validation set.

D.2 Pre-trained BART

To evaluate pre-trained BART, we used the following parameters to evaluate candidates' likelihood:

- `beam=10`,
- `lenpen=1.0`,
- `max_len_b=100`,
- `min_len=1`,
- `no_repeat_ngram_size=2`.

This model had 401 million parameters, none of them was trained in this approach.

D.3 Generative BART

To finetune generative BART, our choice of hyperparameter search and final hyperparameters was inspired by BART's finetuning on summarization datasets described here. We kept the model's parameters of the experiment and the epoch maximizing the average precision of the validation set. We performed a grid search on the following hyperparameters:

- `lr` in {`3e-6, 5e-6, 1e-5, 2e-5, 3e-5`},
- `max-tokens` in {`1024, 2048`}.

We used the following final hyperparameters:

- `lr=5e-06`,
- `max-tokens=1024`,
- `max-epochs=6`,
- `update-freq=1`,
- `total-num-updates=4974`,
- `warmup-updates=149`.

`total-num-updates` was determined empirically as $\frac{\texttt{max-epochs} \cdot \texttt{updates-per-epoch}}{\texttt{update-freq}}$ and `warmup-updates` was chosen as 3% of `total-num-updates`. During the hyperparameter search we used `total-num-updates=4974, 375` and `warmup-updates=149, 67` for `max-tokens=1024, 2048` respectively. To evaluate candidates' likelihood and to generate aggregations, we modified slightly the code of Ott et al. (2019) to compute all hypotheses of the beam search (not only the most probable one) and we used the same parameters as in Appendix D.2. We ran our experiments on a single V100 GPU with 32GB of memory with the `fp16` option, and an experiment took typically 1 hour. This model had 401 million parameters, all of them being trained.

For the ablation study, we used the final hyperparameters, except for `total-num-updates` and `warmup-updates` which were determined empirically as above. We added `max-sentences=16` for the "entities" ablation experiment.

D.4 Discriminative BART

For this approach, our choice of hyperparameter search and final hyperparameters was largely inspired by BART's finetuning on GLUE tasks (Wang et al., 2018) described here. We kept the model's parameters of the experiment and the epoch maximizing the average precision of the validation set. We performed a grid search on the following hyperparameters:

- `lr` in {`5e-6, 1e-5, 2e-5, 3e-5`},
- `max-sentences` in {`4, 8, 16`}.

We used the following final hyperparameters:

- `lr=2e-5`,
- `max-sentences=8`,
- `num-classes=2`,
- `max-epochs=6`,
- `total-num-updates=18180`,
- `warmup-updates=1090`.

`total-num-updates` was determined empirically as $\frac{\texttt{max-epochs} \cdot \texttt{updates-per-epoch}}{\texttt{update-freq}}$ and `warmup-updates` was chosen as 6% of `total-num-updates`. During the hyperparameter search we used `total-num-updates=30888, 18180, 16254` and `warmup-updates=1853, 1090, 975` for `max-sentences=4, 8, 16` respectively. We ran each experiment on a single V100 GPU with 32GB of memory with the `memory-efficient-fp16` option, and an experiment took typically 5 hours. This model had 401 million parameters, all of them being trained.

For the ablation study, we used the following hyperparameters, as they yielded very similar performances:

- `lr=1e-5`,
- `max-tokens=1024`,
- `max-sentences=8`,
- `update-freq=4`,
- `max-epochs=5`.

`total-num-updates` and `warmup-updates` were determined empirically as above.

Appendix E Validation results

For reproducibility purposes, we include in Table 14 the validation scores corresponding to the main results, in Table 4.

Aggregatable instance	Aggregations
Input entities Chicago and London **Entity type** location **Background information** **Chicago:** Chicago , locally also), officially the City of Chicago, is the most populous city in the U.S. state of Illinois and the third most populous city in the United States. Title of the article: **Street Violence by Paris Youths Intrudes Again Into French Politics**

[...] **The Socialist candidate**, **Ségolène Royal**, who is running second in the opinion polls, said the incident showed that Mr. Sarkozy had failed as interior minister.'' In five years with a right-wing government that has made crime its main campaign issue, you can see that it is a failure all the way,'' she said on Canal+ television. **François Bayrou**, **a centrist presidential candidate**, also took aim at Mr. Sarkozy, saying,'' It is very important to end this climate of perpetual confrontation between police and some citizens.'' [...]

Francois Bayrou	Nicolas Sarkozy	Segolene Royal
François Bayrou is a French centrist politician and the president of the Democratic Movement , who was a candidate in the 2002, 2007 and 2012 French presidential elections.	Nicolas Paul Stéphane Sarközy de Nagy-Bocsa ; born 28 January 1955) is a retired French politician who served as President of France and ex officio Co-Prince of Andorra from 16 May 2007 until 15 May 2012.	Ségolène Royal ; born 22 September 1953), is a French politician and former Socialist Party candidate for President of France.

In this article, Francois Bayrou, Nicolas Sarkozy and Segolene Royal are discussed. The three people...

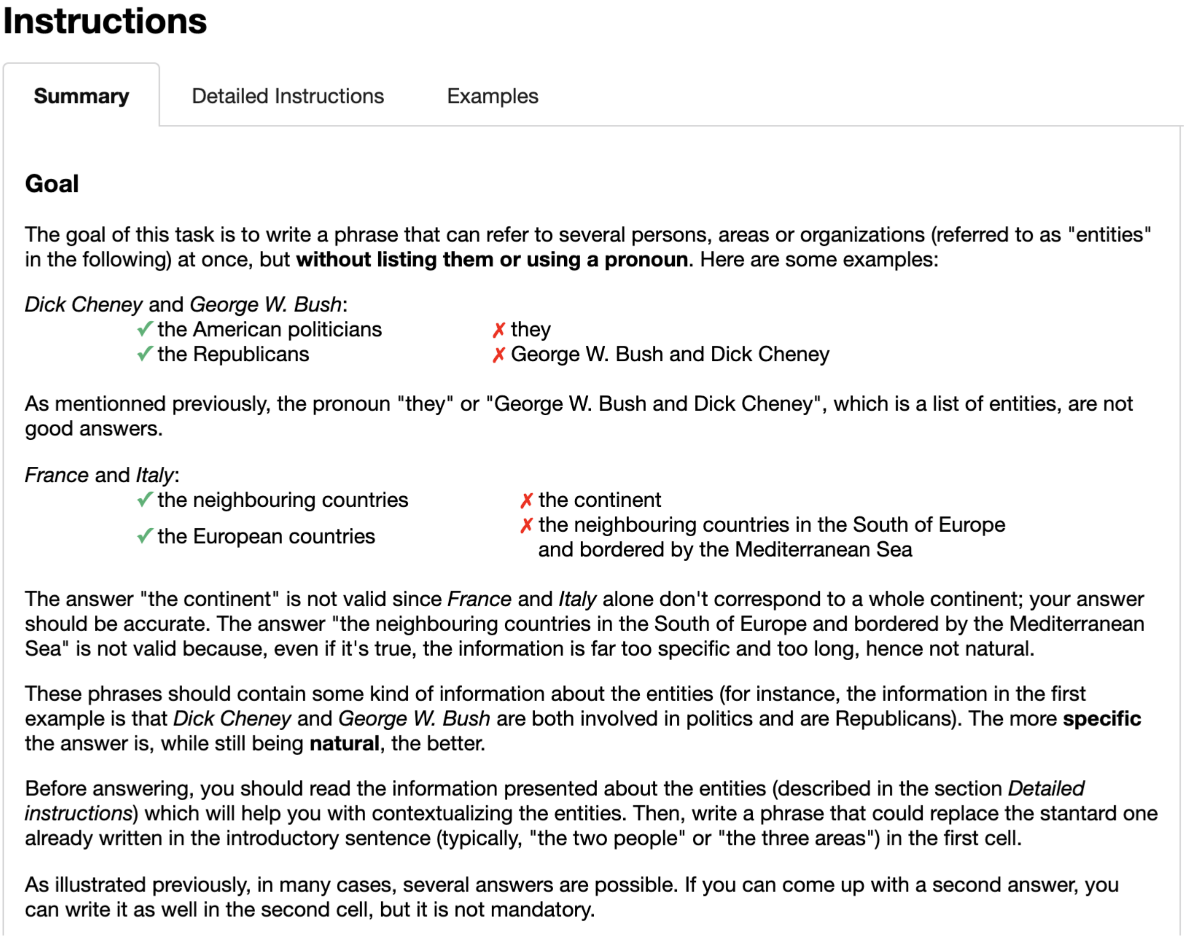
Replace "The three people" with your most relevant phrase referring to the entities

If you have a second answer, you can write it here

Issues:

- remember that you **can't** answer "They" or any pronoun
- if you cannot find any relevant phrase mentionning all the entities, write "NA" in the first cell above and check the following box:
  ☐ I can't find a relevant phrase

Figure 3: Layout of the annotation task. The mentions of the entities in the New York Times article are colored and the name of the corresponding entity is visible when an annotator clicks on a mention. The title of the Wikipedia information is an hyperlink to the corresponding web page.



Instructions

Goal

The goal of this task is to write a phrase that can refer to several persons, areas or organizations (referred to as "entities" in the following) at once, but **without listing them or using a pronoun**. Here are some examples:

Dick Cheney and *George W. Bush*:
✓ the American politicians ✗ they
✓ the Republicans ✗ George W. Bush and Dick Cheney

As mentionned previously, the pronoun "they" or "George W. Bush and Dick Cheney", which is a list of entities, are not good answers.

France and *Italy*:
✓ the neighbouring countries ✗ the continent
✗ the neighbouring countries in the South of Europe and bordered by the Mediterranean Sea
✓ the European countries

The answer "the continent" is not valid since *France* and *Italy* alone don't correspond to a whole continent; your answer should be accurate. The answer "the neighbouring countries in the South of Europe and bordered by the Mediterranean Sea" is not valid because, even if it's true, the information is far too specific and too long, hence not natural.

These phrases should contain some kind of information about the entities (for instance, the information in the first example is that *Dick Cheney* and *George W. Bush* are both involved in politics and are Republicans). The more **specific** the answer is, while still being **natural**, the better.

Before answering, you should read the information presented about the entities (described in the section *Detailed instructions*) which will help you with contextualizing the entities. Then, write a phrase that could replace the stantard one already written in the introductory sentence (typically, "the two people" or "the three areas") in the first cell.

As illustrated previously, in many cases, several answers are possible. If you can come up with a second answer, you can write it as well in the second cell, but it is not mandatory.

Figure 4: First page of the instructions provided to the annotators.

Summary | **Detailed Instructions** | Examples

Full example

Title of the article: **Iraq Findings Leaked by Aide Were Disputed**
[...] The official refused to be named because he was not authorized to discuss the issue. Why those three men were acting so quietly remains a mystery, and Mr. Bush and **Mr. Cheney** have never discussed it in public. [...]

Dick Cheney	George W. Bush
Richard Bruce Cheney is an American politician and businessman who served as the 46th vice president of the United States from 2001 to 2009. He has been cited as the most powerful vice president in American history.	George Walker Bush is an American politician and businessman who served as the 43rd president of the United States from 2001 to 2009. He had previously served as the 46th governor of Texas from 1995 to 2000.

In this article, Dick Cheney and George W. Bush are discussed. The two people...
[Replace "The two people" with another phrase referring to the entities]

✓ the politicians
✓ the Republicans
✓ the American statesmen

✗ they
✗ George W. Bush and Dick Cheney

The entities

In this task, you are presented with several entities of the same type (either people, areas, or organizations). In the example presented above, the entities are people: *Dick Cheney* and *George W. Bush*. Your task is to replace the standard phrase (here: "The two people") with another phrase that can refer to all the entities at once, and ideally which is **natural** and brings information that is **specific** to the context of the entities' mentions.

Be careful, your answer **should not be a list of the entities, nor a pronoun**.

Information available

***New York Times* excerpt**

Title of the article: **Iraq Findings Leaked by Aide Were Disputed**
[...] The official refused to be named because he was not authorized to discuss the issue. Why those three men were acting so quietly remains a mystery, and Mr. Bush and **Mr. Cheney** have never discussed it in public. [...]

As you can see above, you could think about several different phrases for the same entities, therefore having a few sentences to help you contextualize your answer can help. These sentences come from a *New York Times* article, and should be used to determine what information you wish to underline: ideally, your answer should be **specific** to the excerpt (this means that your answer could be used in the same context as the article).

In order to help you, the entities have been colored in the excerpt (you can click on a colored word to see to which entity it is referring to). However, it is an automatic process, so in some cases there might be some bugs. In that case you should try to give an answer without taking the highlighting into account.

***Wikipedia* information**

Dick Cheney	George W. Bush
Richard Bruce Cheney is an American politician and businessman who served as the 46th vice president of the United States from 2001 to 2009. He has been cited as the most powerful vice president in American history.	George Walker Bush is an American politician and businessman who served as the 43rd president of the United States from 2001 to 2009. He had previously served as the 46th governor of Texas from 1995 to 2000.

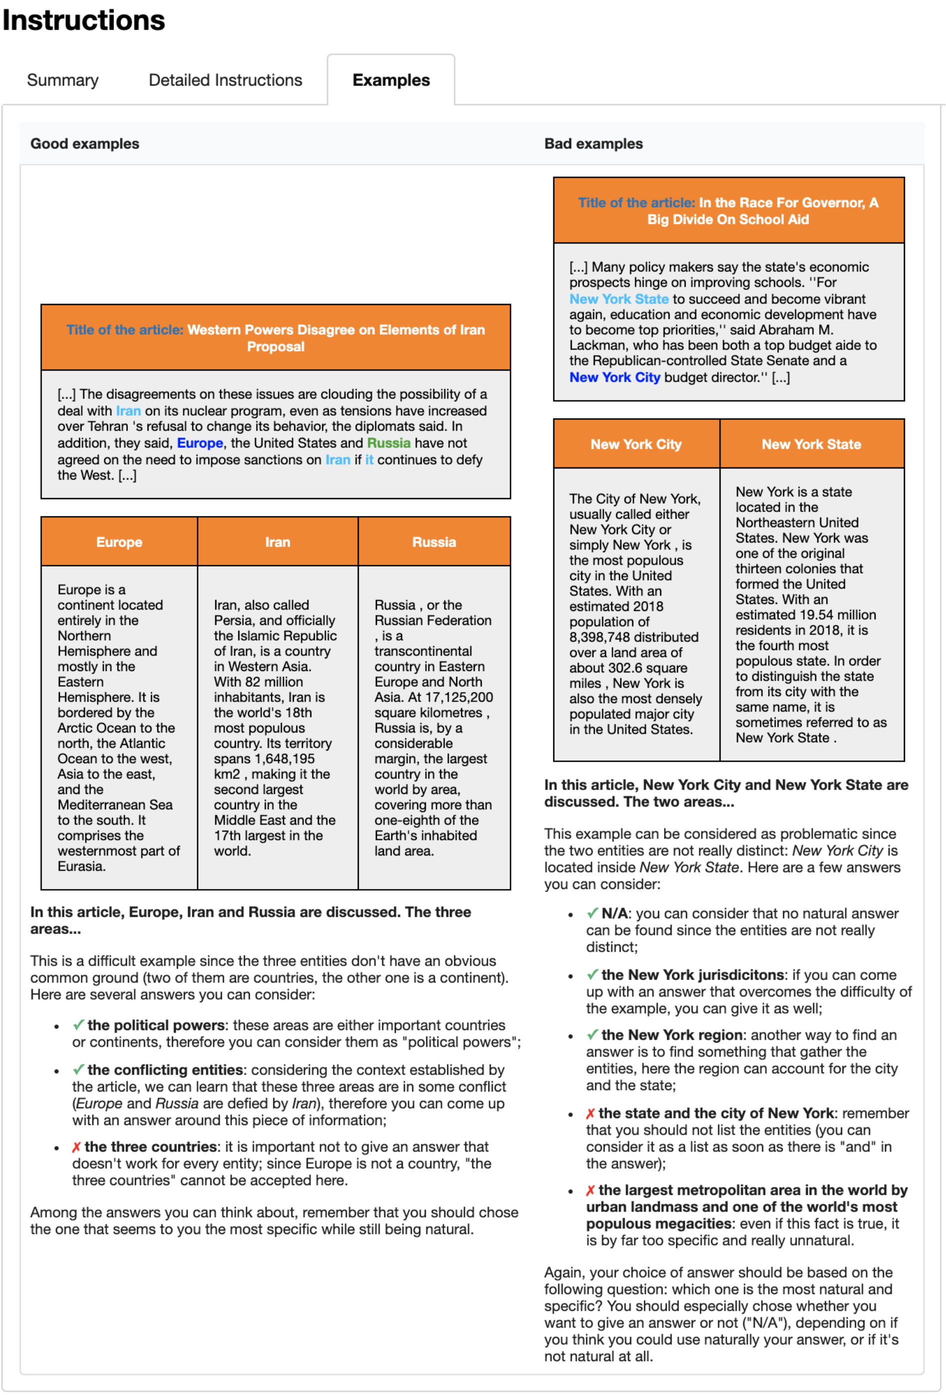
In order to write a relevant phrase, you also need to have some knowledge about the entities. In the example above, you cannot write any of the answers if you don't know that *Dick Cheney* and *George W. Bush* are politicians, Republicans, etc. You can use your own knowledge, but in case you don't know enough about the entities, we provide some information extracted from *Wikipedia*. If you need more information, the name of the entity is a link to the *Wikipedia* page.

Note that the *Wikipedia* information is just an help. Sometimes no information is found about an entity or the information retrieved is about an irrelevant article (espcially when namesakes can be found). In that case you should still try to give an answer, using only what you know or what you can infer from the example.

Issue

In some cases, it can happen that you may not be able to find an answer. Such situation can happen for several reasons: not enough information about the entities, no common ground or opposition between them, or bug in the example that you cannot overcome... In that case, you should write "N/A" (for "no answer") or in short "NA" in the first cell, and check the corresponding box.

Figure 5: Second page of the instructions provided to the annotators.



Instructions

Good examples

Title of the article: Western Powers Disagree on Elements of Iran Proposal

[...] The disagreements on these issues are clouding the possibility of a deal with Iran on its nuclear program, even as tensions have increased over Tehran 's refusal to change its behavior, the diplomats said. In addition, they said, **Europe**, the United States and **Russia** have not agreed on the need to impose sanctions on Iran if it continues to defy the West. [...]

Europe	Iran	Russia
Europe is a continent located entirely in the Northern Hemisphere and mostly in the Eastern Hemisphere. It is bordered by the Arctic Ocean to the north, the Atlantic Ocean to the west, Asia to the east, and the Mediterranean Sea to the south. It comprises the westernmost part of Eurasia.	Iran, also called Persia, and officially the Islamic Republic of Iran, is a country in Western Asia. With 82 million inhabitants, Iran is the world's 18th most populous country. Its territory spans 1,648,195 km2 , making it the second largest country in the Middle East and the 17th largest in the world.	Russia , or the Russian Federation , is a transcontinental country in Eastern Europe and North Asia. At 17,125,200 square kilometres , Russia is, by a considerable margin, the largest country in the world by area, covering more than one-eighth of the Earth's inhabited land area.

In this article, Europe, Iran and Russia are discussed. The three areas...

This is a difficult example since the three entities don't have an obvious common ground (two of them are countries, the other one is a continent). Here are several answers you can consider:

- ✓ **the political powers**: these areas are either important countries or continents, therefore you can consider them as "political powers";
- ✓ **the conflicting entities**: considering the context established by the article, we can learn that these three areas are in some conflict (*Europe* and *Russia* are defied by *Iran*), therefore you can come up with an answer around this piece of information;
- ✗ **the three countries**: it is important not to give an answer that doesn't work for every entity; since Europe is not a country, "the three countries" cannot be accepted here.

Among the answers you can think about, remember that you should chose the one that seems to you the most specific while still being natural.

Bad examples

Title of the article: In the Race For Governor, A Big Divide On School Aid

[...] Many policy makers say the state's economic prospects hinge on improving schools. ''For New York State to succeed and become vibrant again, education and economic development have to become top priorities,'' said Abraham M. Lackman, who has been both a top budget aide to the Republican-controlled State Senate and a **New York City** budget director.'' [...]

New York City	New York State
The City of New York, usually called either New York City or simply New York , is the most populous city in the United States. With an estimated 2018 population of 8,398,748 distributed over a land area of about 302.6 square miles , New York is also the most densely populated major city in the United States.	New York is a state located in the Northeastern United States. New York was one of the original thirteen colonies that formed the United States. With an estimated 19.54 million residents in 2018, it is the fourth most populous state. In order to distinguish the state from its city with the same name, it is sometimes referred to as New York State .

In this article, New York City and New York State are discussed. The two areas...

This example can be considered as problematic since the two entities are not really distinct: *New York City* is located inside *New York State*. Here are a few answers you can consider:

- ✓ **N/A**: you can consider that no natural answer can be found since the entities are not really distinct;
- ✓ **the New York jurisdicitons**: if you can come up with an answer that overcomes the difficulty of the example, you can give it as well;
- ✓ **the New York region**: another way to find an answer is to find something that gather the entities, here the region can account for the city and the state;
- ✗ **the state and the city of New York**: remember that you should not list the entities (you can consider it as a list as soon as there is "and" in the answer);
- ✗ **the largest metropolitan area in the world by urban landmass and one of the world's most populous megacities**: even if this fact is true, it is by far too specific and really unnatural.

Again, your choice of answer should be based on the following question: which one is the most natural and specific? You should especially chose whether you want to give an answer or not ("N/A"), depending on if you think you could use naturally your answer, or if it's not natural at all.

Abstract

We present MLSUM, the first large-scale MultiLingual SUMmarization dataset. Obtained from online newspapers, it contains 1.5M+ article/summary pairs in five different languages – namely, French, German, Spanish, Russian, Turkish. Together with English news articles from the popular CNN/Daily mail dataset, the collected data form a large scale multilingual dataset which can enable new research directions for the text summarization community. We report cross-lingual comparative analyses based on state-of-the-art systems. These highlight existing biases which motivate the use of a multi-lingual dataset.

1 Introduction

The document summarization task requires several complex language abilities: understanding a long document, discriminating what is relevant, and writing a short synthesis. Over the last few years, advances in deep learning applied to NLP have contributed to the rising popularity of this task among the research community (See et al., 2017; Kryściński et al., 2018; Scialom et al., 2019). As with other NLP tasks, the great majority of available datasets for summarization are in English, and thus most research efforts focus on the English language. The lack of multilingual data is partially countered by the application of transfer learning techniques enabled by the availability of pre-trained multilingual language models. This approach has recently established itself as the *de-facto* paradigm in NLP (Guzmán et al., 2019).

Under this paradigm, for encoder/decoder tasks, a language model can first be pre-trained on a large corpus of texts in multiple languages. Then, the model is fine-tuned in one or more *pivot* languages for which the task-specific data are available. At inference, it can still be applied to the different languages seen during the pre-training. Because of the dominance of English for large scale corpora, English naturally established itself as a pivot for other languages. The availability of multilingual pre-trained models, such as BERT multilingual (M-BERT), allows to build models for target languages different from training data. However, previous works reported a significant performance gap between English and the target language, e.g. for classification (Conneau et al., 2018) and Question Answering (Lewis et al., 2019) tasks. A similar approach has been recently proposed for summarization (Chi et al., 2019) obtaining, again, a lower performance than for English.

For specific NLP tasks, recent research efforts have produced evaluation datasets in several target languages, allowing to evaluate the progress of the field in zero-shot scenarios. Nonetheless, those approaches are still bound to using training data in a *pivot* language for which a large amount of annotated data is available, usually English. This prevents investigating, for instance, whether a given model is as fitted for a specific language as for any other. Answers to such research questions represent valuable information to improve model performance for low-resource languages.

In this work, we aim to fill this gap for the automatic summarization task by proposing a large-scale MultiLingual SUMmarization (MLSUM) dataset. The dataset is built from online news outlets, and contains over 1.5M article-summary pairs in 5 languages: French, German, Spanish, Russian, and Turkish, which complement an already established summarization dataset in English.

The contributions of this paper can be summarized as follows:

1. We release the first large-scale multilingual summarization dataset;
2. We provide strong baselines from multilingual abstractive text generation models;

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8051–8067,
November 16–20, 2020.

3. We report a comparative cross-lingual analysis of the results obtained by different approaches.

2 Related Work

2.1 Multilingual Text Summarization

Over the last two decades, several research works have focused on multilingual text summarization. Radev et al. (2002) developed MEAD, a multi-document summarizer that works for both English and Chinese. Litvak et al. (2010) proposed to improve multilingual summarization using a genetic algorithm. A community-driven initiative, MultiLing (Giannakopoulos et al., 2015), benchmarked summarization systems on multilingual data. While the MultiLing benchmark covers 40 languages, it provides relatively few examples (10k in the 2019 release). Most proposed approaches, so far, have used an extractive approach given the lack of a multilingual corpus to train abstractive models (Duan et al., 2019).

More recently, with the rapid progress in automatic translation and text generation, abstractive methods for multilingual summarization have been developed. Ouyang et al. (2019) proposed to learn summarization models for three low-resource languages (Somali, Swahili, and Tagalog), by using an automated translation of the New York Times dataset. Although this showed only slight improvements over a baseline which considers translated outputs of an English summarizer, results remain still far from human performance. Summarization models from translated data usually under-perform, as translation biases add to the difficulty of summarization.

Following the recent trend of using multi-lingual pre-trained models for NLP tasks, such as Multilingual BERT (M-BERT) (Pires et al., 2019)[1] or XLM (Lample and Conneau, 2019), Chi et al. (2019) proposed to fine-tune the models for summarization on English training data. The assumption is that the summarization skills learned from English data can transfer to other languages on which the model has been pre-trained. However a significant performance gap between English and the target language is observed following this process. This emphasizes the crucial need of multilingual training data for summarization.

2.2 Existing Multilingual Datasets

The research community has produced several multilingual datasets for tasks other than summarization. We report two recent efforts below, noting that both *i)* rely on human translations, and *ii)* only provide evaluation data.

The Cross-Lingual NLI Corpus The SNLI corpus (Bowman et al., 2015) is a large scale dataset for natural language inference (NLI). It is composed of a collection of 570k human-written English sentence pairs, associated with their label, entailment, contradiction, or neutral. The Multi-Genre Natural Language Inference (MultiNLI) corpus is an extension of SNLI, comparable in size, but including a more diverse range of text. Conneau et al. (2018) introduced the Cross-Lingual NLI Corpus (XNLI) to evaluate transfer learning from English to other languages: based on MultiNLI, a collection of 5,000 test and 2,500 dev pairs were translated by humans in 15 languages.

MLQA Given a paragraph and a question, the Question Answering (QA) task consists in providing the correct answer. Large scale datasets such as (Rajpurkar et al., 2016; Choi et al., 2018; Trischler et al., 2016) have driven fast progress.[2] However, these datasets are only in English. To assess how well models perform on other languages, Lewis et al. (2019) recently proposed MLQA, an evaluation dataset for cross-lingual extractive QA composed of 5K QA instances in 7 languages.

XTREME The Cross-lingual TRansfer Evaluation of Multilingual Encoders benchmark (Hu et al., 2020) covers 40 languages over 9 tasks. The summarization task is not included in the benchmark.

XGLUE To train and evaluate their performance across a diverse set of cross-lingual tasks, Liang et al. (2020) recently released XGLUE, covering both Natural Language Understanding and Generation scenarios. While no summarization task is included, it comprises a News Title Generation task: the data is crawled from a commercial news website and provided in form of article-title pairs for 5 languages (German, English, French, Spanish and Russian).

[2] For instance, see the SQuAD leaderboard: `rajpurkar.github.io/SQuAD-explorer/`

2.3 Existing Summarization datasets

We describe here the main available corpora for text summarization.

Document Understanding Conference Several small and high-quality summarization datasets in English (Harman and Over, 2004; Dang, 2006) have been produced in the context of the Document Understanding Conference (DUC).[3] They are built by associating newswire articles with corresponding human summaries. A distinctive feature of the DUC datasets is the availability of multiple reference summaries: this is a valuable characteristic since, as found by Rankel et al. (2013), the correlation between qualitative and automatic metrics, such as ROUGE (Lin, 2004), decreases significantly when only a single reference is given. However, due to the small number of training data available, DUC datasets are often used in a domain adaptation setup for models first trained on larger datasets such as Gigaword, CNN/DM (Nallapati et al., 2016; See et al., 2017) or with unsupervised methods (Dorr et al., 2003; Mihalcea and Tarau, 2004; Barrios et al., 2016a).

Gigaword Again using newswire as source data, the english Gigaword (Napoles et al., 2012; Rush et al., 2015; Chopra et al., 2016) corpus is characterized by its large size and the high diversity in terms of sources. Since the samples are not associated with human summaries, prior works on summarization have trained models to generate the headlines of an article, given its incipit, which induces various biases for learning models.

New York Times Corpus This large corpus for summarization consists of hundreds of thousand of articles from The New York Times(Sandhaus, 2008), spanning over 20 years. The articles are paired with summaries written by library scientists. Although (Grusky et al., 2018) found indications of bias towards extractive approaches, several research efforts have used this dataset for summarization (Hong and Nenkova, 2014; Durrett et al., 2016; Paulus et al., 2017).

CNN/Daily Mail One of the most commonly used dataset for summarization (Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017; Dong et al., 2019), although originally built for Question Answering tasks (Hermann et al., 2015a). It consists of English articles from the CNN and The Daily Mail associated with bullet point highlights from the article. When used for summarization, the bullet points are typically concatenated into a single summary.

NEWSROOM Composed of 1.3M articles (Grusky et al., 2018), and featuring high diversity in terms of publishers, the summaries associated with English news articles were extracted from the Web pages metadata: they were originally written to be used in search engines and social media.

BigPatent Sharma et al. (2019) collected 1.3 million U.S. patent documents, across several technological areas, using the Google Patents Public Datasets. The patents abstracts are used as target summaries.

LCSTS The Large Scale Chinese Short Text Summarization Dataset (Hu et al., 2015) is built from 2 million short texts from the Sina Weibo microblogging platform. They are paired with summaries given by the author of each text. The dataset includes 10k summaries which were manually scored by human for their relevance.

3 MLSUM

As described above, the vast majority of summarization datasets are in English. For Arabic, there exist the Essex Arabic Summaries Corpus (EASC) (El-Haj et al., 2010) and KALIMAT (El-Haj and Koulali, 2013); those comprise circa 1k and 20k samples, respectively. Pontes et al. (2018) proposed a corpus of few hundred samples for Spanish, Portuguese and French summaries. To our knowledge, the only large-scale non-English summarization dataset is the Chinese LCSTS (Hu et al., 2015). With the increasing interest for cross-lingual models, the NLP community have recently released multilingual evaluation datasets, targeting classification (XNLI) and QA (Lewis et al., 2019) tasks, as described in 2.2, though still no large-scale dataset is avaulable for document summarization.

To fill this gap we introduce MLSUM, the first large scale multilingual summarization corpus. Our corpus provides more than 1.5 millions articles in French (FR), German (DE), Spanish (ES), Turkish (TR), and Russian (RU). Being similarly built from news articles, and providing a similar amount of training samples per language (except for Russian), as the previously mentioned CNN/Daily Mail, it can effectively serve as a multilingual extension of the CNN/Daily Mail dataset.

---

3.1 Collecting the Corpus

The CNN/Daily Mail (CNN/DM) dataset (see Section 2.3) is arguably the most used large-scale dataset for summarization. Following the same methodology, we consider news articles as the text input, and their paired *highlights/description* as the summary. For each language, we selected an online newspaper which met the following requirements: (1) Being a *generalist* newspaper: ensuring that a broad range of topics is represented for each language allows to minimize the risk of training topic-specific models, a fact which would hinder comparative cross-lingual analyses of the models; (2) Having a large number of articles in their public online archive; (3) Providing human written highlights/summaries for the articles that can be extracted from the HTML code of the web page.

After a careful preliminary exploration, we selected the online version of the following newspapers: Le Monde[4] (French), Süddeutsche Zeitung[5] (German), El Pais[6] (Spanish), Moskovskij Komsomolets[7] (Russian), and Internet Haber[8] (Turkish).

For each outlet, we gathered archived articles from 2010 to 2019. We applied one simple filter: all the articles shorter than 50 words or summaries shorter than 10 words are discarded, so as to avoid articles containing mostly audiovisual content. Each article was archived on the Wayback Machine,[9] allowing interested research to fully re-build (or extend) MLSUM. We distribute the dataset as a list of immutable snapshot URLs of the articles, along with the accompanying corpus-construction code,[10] allowing to replicate the parsing and preprocessing procedures we employed. This is due to legal reasons: the content of the articles is copyrighted and redistribution might be seen as infringing of publishing rights.[11]

We provide recommended train/validation/test splits following a chronological ordering based on the articles' publication dates. In our experiments below, we train/evaluate the models on the training/test splits obtained in this manner. Specifically, we use: data from 2010 to 2018, included, for training; data from 2019 (~10% of the dataset) for validation (up to May 2019) and test (May-December 2019). While this choice is arguably more challenging, due to the possible emergence of new topics over time, we consider it as the realistic scenario a successful summarization system should be able to deal with. Incidentally, this also brings the advantage of excluding most cases of leakage across languages: it prevents a model, for instance, from seeing a training sample describing an important event in one language, and then being submitted for inference a similar article in another language, published around the same time and dealing with the same event.

3.2 Dataset Statistics

We report statistics for each language in MLSUM in Table 1, including those computed on the CNN/Daily Mail dataset (English) for quick comparison. MLSUM provides a comparable amount of data for all languages, with the exception of Russian with ten times less training samples. Important characteristics for summarization datasets are the length of articles and summaries, the vocabulary size, and a proxy for abstractiveness, namely the percentage of novel n-grams between the article and its human summary. From Table 1, we observe that Russian summaries are the shortest as well as the most abstractive. Coupled with the significantly lower amount of articles available from its online source, the task can be seen as more challenging for Russian than for the other languages in MLSUM.

4 Models

We experimented on MLSUM with the established models and baselines described below. Those include supervised and unsupervised methods, extractive and abstractive models. For all the experiments, we train models on a per-language basis. We used the recommended hyperparameters for all languages, in order to facilitate assessing the robustness of the models. We also tried to train one model with all the languages mixed together, but we did not see any significant difference of performance.

4.1 Extractive summarization models

Oracle Extracts the sentences, within the input text, that maximise a given metric (in our experiments, ROUGE-L) given the reference summary. It

[11] A similar approach has been adopted for several dataset releases in the recent past, such as Question Answering Corpus (Hermann et al., 2015b) or XSUM (Narayan et al., 2018a).

	FR	DE	ES	RU	TR	EN
Dataset size	424,763	242,982	290,645	27,063	273,617	311,971
Training set size	392,876	220,887	266,367	25,556	249,277	287,096
Mean article length	632.39	570.6	800.50	959.4	309.18	790.24
Mean summary length	29.5	30.36	20.71	14.57	22.88	55.56
Compression Ratio	21.4	18.8	38.7	65.8	13.5	14.2
Novelty (1-gram)	15.21	14.96	15.34	30.74	28.90	9.45
Total Vocabulary Size	1,245,987	1,721,322	1,257,920	649,304	1,419,228	875,572
Occurring 10+ times	233,253	240,202	229,033	115,144	248,714	184,095

Table 1: Statistics for the different languages. *EN* refers to CNN/Daily Mail and is reported for comparison purposes. Article and summary lengths are computed in words. *Compression ratio* is computed as the ratio between article and summary length. *Novelty* is the percentage of words in the summary that were not in the paired article. *Total Vocabulary Size* is the total number of different words, and *Occurring 10+ times* is the total number of words occurring at least 10 times.

is an indication of the maximum one could achieve with extractive summarization. We rely on the implementation of Narayan et al. (2018b).

Random To compare the performances of the different models across languages, it is useful to include an unbiased model as a point of reference. To that purpose, we define a simple random extractive model that randomly extracts N words from the source document, with N fixed as the average length of the summary.

Lead-3 Simply selects the three first sentences from the input text. Sharma et al. (2019), among others, showed that this is a robust baseline for several summarization datasets such as CNN/DM, NYT and BIGPATENT.

TextRank An unsupervised algorithm proposed by Mihalcea and Tarau (2004). It consists in computing the co-similarities between all the sentences in the input text. Then, the most central to the document are extracted and considered as the summary. We used the implementation provided by Barrios et al. (2016b).

4.2 Abstractive summarization models

Pointer-Generator See et al. (2017) proposed the addition of the copy mechanism (Vinyals et al., 2015) on top of a sequence to sequence LSTM model. This mechanism allows to efficiently copy out-of-vocabulary tokens, leveraging attention (Bahdanau et al., 2014) over the input.

We used the publicly available OpenNMT implementation[12] with the default hyper-parameters. However, to avoid biases, we limited the preprocessing as much as possible and did not use any sentence separators, as recommended for CNN/DM. This explains why we obtain lower ROUGE compared to when using a language-specific preprocessor.

M-BERT Encoder-decoder Transformer architectures are a very popular choice for text generation. Recent research efforts have adapted large pretrained self-attention based models for text generation (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019). In particular, Liu and Lapata (2019) added a randomly initialized decoder on top of BERT. Avoiding the use of a decoder, Dong et al. (2019) proposed to instead add a decoder-like mask during the pre-training to *unify* the language models for both encoding and generating. Both these approaches achieved SOTA results for summarization. In this paper, we only report results obtained following Dong et al. (2019), as in preliminary experiments we observed that a simple multilingual BERT (M-BERT), with no modification, obtained comparable performance on the summarization task.

5 Evaluation Metrics

ROUGE Arguably the most used set of metrics for Summarization, it is defined as the percentage of common n-grams between the evaluated summary and the human reference summary (Lin, 2004).

---

Table 2: ROUGE-L (METEOR) scores obtained by the models described in Section 4.1. *EN* refers to CNN/DM.

METEOR The Metric for Evaluation of Translation with Explicit ORdering (Banerjee and Lavie, 2005) was designed for the evaluation of machine translation output. It is based on the harmonic mean of unigram precision and recall, with recall weighted higher than precision. METEOR is often reported in summarization papers (See et al., 2017; Dong et al., 2019) in addition to ROUGE.

Novelty Because of their use of copy mechanisms, some abstractive models have been reported to rely too much on extraction (See et al., 2017; Kryściński et al., 2018). Hence, it became a common practice to report the percentage of novel n-grams produced within the generated summaries.

Note that several approaches based on neural models have been recently proposed. Recent works (Eyal et al., 2019; Scialom et al., 2019) have proposed to evaluate summaries with QA based methods: the rationale is that a good summary should answer the most relevant questions about the article. Further, Kryściński et al. (2019) proposed a discriminator trained to measure the factualness of the summary. Böhm et al. (2019) learned a metric from human annotation. All these models were only trained on English datasets, preventing us to report them in this paper. The availability of MLSUM will enable future works to build such metrics in a multilingual fashion.

6 Results and Discussion

The results we now present allow to compare the models across languages, and to investigate or hypothesize where their performance variations may come from.

To explain those, we note the following factors: *(1)* differences in the data, independently from the language, such as the structure of the article, the abstractiveness of the summaries, or the quantity; and *(2)* differences due to the language itself – either due to metric biases (e.g. sensitivity to morphology) or to biases inherent to the model. While the former have more to do with domain adaptation, the latter motivate further the development of multilingual datasets, since they are instrumental for studying such phenomena.

Turning to the observed results, we report in Table 2 the ROUGE-L and METEOR scores obtained by each model for all languages. We note that the overall order of systems (for each language) is preserved when using either metric (modulo some swaps between Lead_3 and Pointer Generator, but with relatively close scores).

Russian, the low-resource language in MLSUM For all experimental setups, the performance on Russian is comparatively low. This can be explained by at least two factors. First, the corpus is the most abstractive (see Table 1, limiting the performance obtained by extractive models (Random, LEAD-3, and Oracle). Second, one order of magnitude less training data is available for Russian than for the other MLSUM languages, a fact which can explain the impressive performance improvement (+66% in terms of ROUGE-L, see Table 2) between a *not pretrained* model (Pointer Generator) and a *pretrained* model (M-BERT).

How abstractive are the models? We report novelty in Figure 1. As previous works noted (See et al., 2017), pointer-generator networks are poorly abstractive, as they rely heavily on the copy mechanism. This is particularly true for Russian: the lack of data probably makes it easier to learn to copy than to cope with natural language generation. As expected, pretrained language models such as M-BERT are consistently and largely more abstractive, since they are exposed to other texts during pretraining.

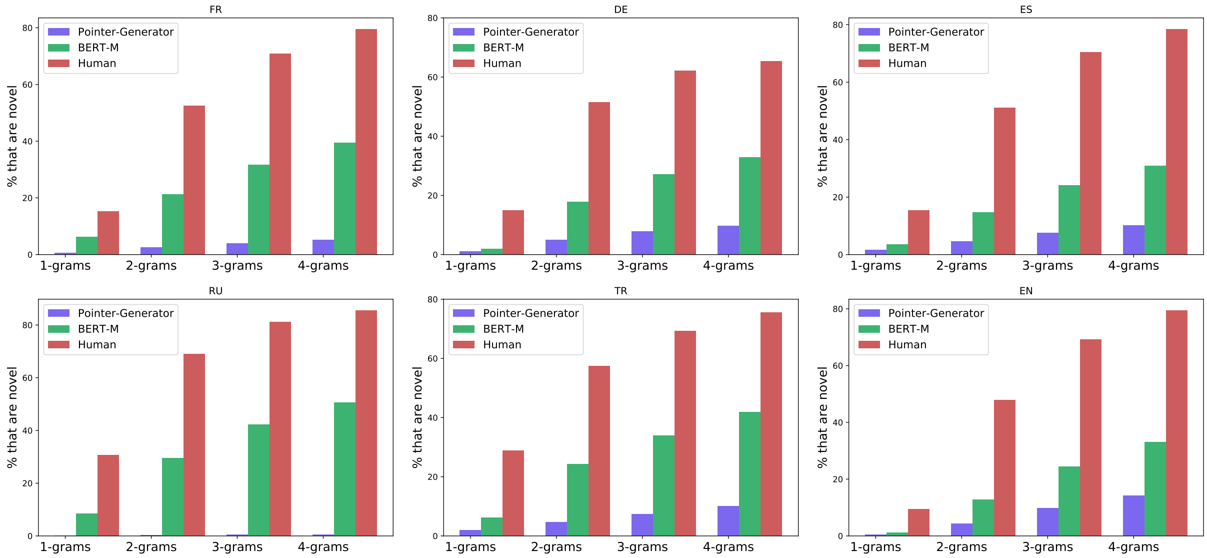

Figure 1: Percentage of novel n-grams for different abstractive models (neural and human), for the 6 datasets.

6.1 Model Biases toward Languages

Consistency among ROUGE scores The Random model obtains comparable ROUGE-L scores across all languages, except Russian. This can again be due to the Russian corpus characteristics – highest novelty, shortest summaries, and longest input documents (see Table 1). As this limits our ability to draw meaningful interpretations over Russian, compared to other languages, for the pair-wise language-based comparisons below we only focus on French, German, Spanish, and Turkish.

Abstractiveness of the datasets The Oracle performance can be considered as the upper limit for an extractive model since it extracts the sentences that provide the best ROUGE-L. We can observe that while being similar for English and German, and to some extent Turkish, the Oracle performance is lower for French or Spanish. However, as described in Figure 1, the percentage of novel words are similar for German (14.96), French (15.21) and Spanish (15.34). This may indicate that the relevant information to extract from the article is more spread among sentences for Spanish and French than for German. This is confirmed with the results of Lead-3: German and English have a much higher ROUGE-L – 35.20 and 33.09 – than French or Spanish – 19.69 and 13.70.

	T/P	B/P
FR	0.53	1.06
DE	0.37	1.20
ES	0.53	1.15
RU	0.57	1.65
TR	0.65	1.01
CNN/DM (EN)	1.10	1.06
CNN/DM (EN, full preproc)	0.85	-
DUC (EN)	1.21	-
NEWSROOM (EN)	1.10	-

Table 3: Rouge-L ratios: T/P is the ratio of TextRank to Pointer-Generator and B/P is the ratio of M-BERT to Pointer-Generator. The results for CNN/DM-full preprocessing, DUC and NEWSROOM datasets are those reported in Table 2 of Grusky et al. (2018) (Pointer-C in their paper is our Pointer-Generator).

The case of TextRank The TextRank performance varies widely across the different languages, regardless Oracle. It is particularly surprising to see the low performance on German whereas, for this language, Lead-3 has a comparatively higher performance. On the other hand, the performance on English is remarkably high: the ROUGE-L is 33% higher than for Turkish, 126% higher than for French and 200% higher than for Spanish. We suspect that the TextRank parameters might actually overfit English. This is confirmed by the results reported in Table 3, where we report the performance ratio between TextRank and Pointer Generator on our corpus, as well as on CNN/DM and two other English corpora (DUC and NewsRoom). TextRank has a performance close to the Pointer Generator on English corpora (ratio between 0.85 to 1.21) but not in other languages (ratio between 0.37 to 0.65).

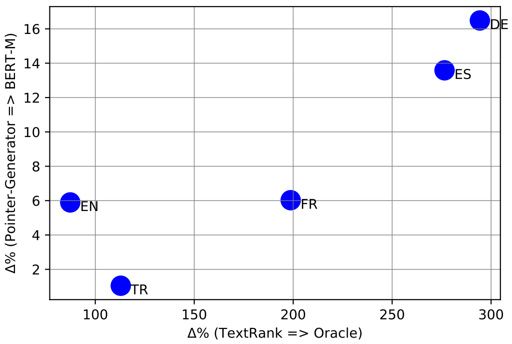

Figure 2: Improvement rates from TextRank to Oracle (in abscissa) against rates from Pointer Generator to M-BERT (in ordinate).

The benefits of pretraining We hypothesize that the closer an unsupervised model performance to its maximum limit, the less improvement would come from pretraining.

In Figure 2, we plot the improvement rate from TextRank to Oracle, against that of Pointer-Generator to M-BERT. Looking at the correlation emerging from the plot, the hypothesis appears to hold true for all languages, including Russian – not plotted for scaling reasons ($x = 808; y = 40$), with the exception of English. This is probably due to the aforementioned bias of TextRank towards the English language.

Pointer Generator and M-BERT We observe that M-BERT always outperforms the Pointer Generator. However, the ratio is not homogeneous across the different languages, see Table 3.

In particular, the improvement for German is much more important than the one for French. Interestingly, this observation is in line with the results reported for Machine Translation: the Transformer (Vaswani et al., 2017) outperforms significantly ConvS2S (Gehring et al., 2017) for English to German but obtains comparable results for English to French – see Table 2 in Vaswani et al. (2017). Neither model is pretrained, nor based on LSTM (Hochreiter and Schmidhuber, 1997), and they both use BPE tokenization (Shibata et al., 1999). Therefore, the main difference is represented by the self-attention mechanism introduced in the Transformer, while ConvS2S used only source-to-target attention.

We thus hypothesise that self-attention plays an important role for German but has a limited impact for French. This could find an explanation in the morphology of the two languages: in statistical parsing, Tsarfaty et al. (2010) considered German to be very sensitive to word order, due to its rich morphology, as opposed to French. Among other reasons, the flexibility of its syntactic ordering is mentioned. This corroborates the hypothesis that self-attention might help preserving information for languages with higher degrees of word order freedom.

6.2 Possible derivative usages of MLSUM

Multilingual Question Answering Originally, CNN/DM was a Question Answering dataset (Hermann et al., 2015a), under the assumption that the information in the summary is also contained in the pair article. Questions can thus be generated from the summary sentences by masking the Named Entities contained therein. The masked entities represent the answers, and thus a masked question should be answerable given the source article.

As no multilingual QA *training* dataset has been proposed so far, this methodology could be applied to MLSUM to obtain a large-scale multilingual Question Answering corpus. Incidentally, this would also allow progressing towards multilingual Question Generation, a crucial component of the neural summarization metrics mentioned in Section 5.

News Title Generation While the release of MLSUM hereby described covers only article-summary pairs, the archived articles also include the titles. The accompanying code for parsing the articles allows to easily retrieve the titles and thus use them for News Title Generation.

Topic detection With the exception of Turkish, a topic/category can be associated with each article/summary pair, by simply parsing the corresponding URL. A natural application of this data for summarization would be for template based summarization (Perez-Beltrachini et al., 2019), using it as additional features. However, it can also be a useful multilingual resource for topic detection.

7 Conclusion

We presented MLSUM, the first large-scale MultiLingual SUMmarization dataset, comprising over 1.5M article/summary pairs in French, German, Russian, Spanish, and Turkish. We detailed its construction, and its complementary nature to the CNN/DM English summarization dataset.

We reported extensive preliminary experiments, highlighting biases observed in existing models, and analyzed the relative performances across languages of state-of-the-art models. In future works we plan to add other languages including Arabic and Hindi, and to investigate the adaptation of neural metrics to multilingual summarization.

B Topic Shift

With the exception of Turkish, the article URLs in MLSUM allow to identify a category for a given article. In Figure 3 we show the shift over categories among time. In particular, we plot the 6 most frequent categories per language.

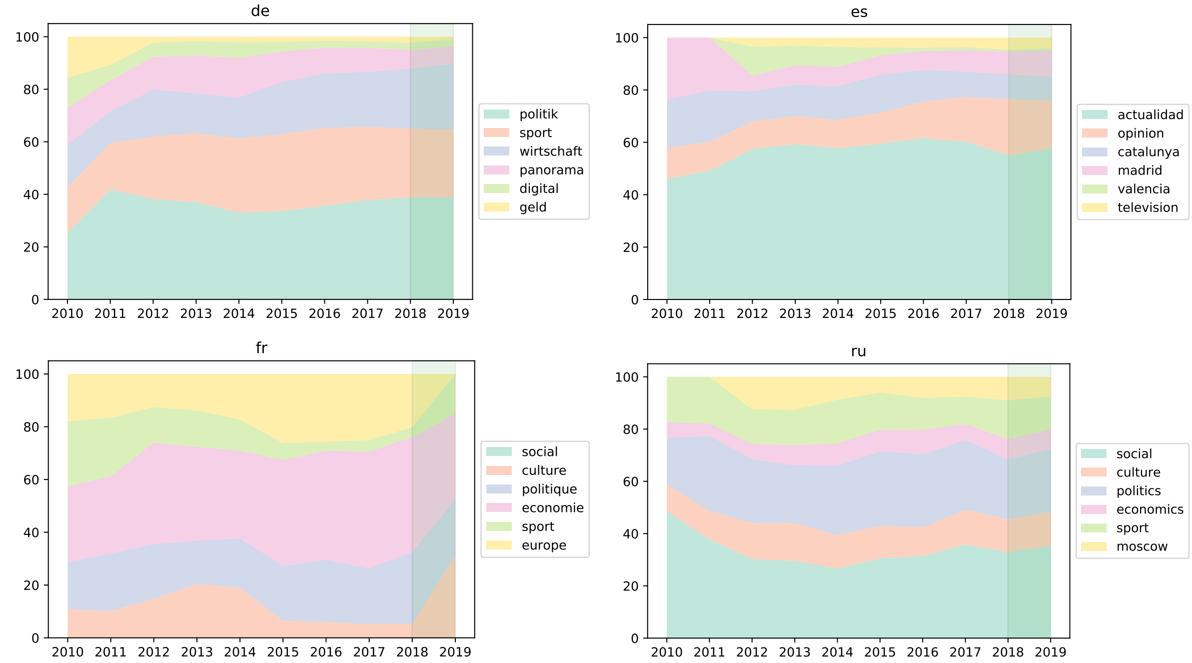

Figure 3: Distribution of topics for German (top-left), Spanish (top-right), French (bottom-left) and Russian (bottom-right), grouped per year. The shaded area for 2019 highlights validation and test data.

summary Terre d'origine du clan Karzaï, la ville méridionale de Kandahar est aussi un bastion historique des talibans, où le mollah Omar a vécu et conservé de profondes racines. C'est sur cette terre pachtoune, plus qu'à Kaboul, que l'avenir à long terme du pays pourrait se décider.

body Lorsque l'on parle de l'Afghanistan, les yeux du monde sont rivés sur sa capitale, Kaboul. C'est là que se concentrent les lieux de pouvoir et où se détermine, en principe, son avenir. C'est aussi là que sont réunis les commandements des forces civiles et militaires internationales envoyées sur le sol afghan pour lutter contre l'insurrection et aider le pays à se reconstruire. Mais, à y regarder de plus près, Kaboul n'est qu'une façade. Face à un Etat inexistant, une structure du pouvoir afghan encore clanique, des tribus restées puissantes face à une démocratie artificielle importée de l'extérieur, la vraie légitimité ne vient pas de Kaboul. La géographie du pouvoir afghan aujourd'hui oblige à dire qu'une bonne partie des clés du destin de la population afghane se trouve au sud, en terre pachtoune, dans une cité hostile aux étrangers, foyer historique des talibans, Kandahar. Kandahar est la terre d'origine du clan Karzaï et de sa tribu, les Popalzaï. Hamid Karzaï, président afghan, tient son pouvoir du poids de son clan dans la région. Mi-novembre 2009, dans la grande maison de son frère, Wali, à Kandahar, se pressaient des chefs de tribu venus de tout l'Afghanistan, les piliers de son réseau. L'objet de la rencontre : faire le bilan post-électoral après la réélection contestée de son frère à la tête du pays. Parfois décrié pour ses liens supposés avec la CIA et des trafiquants de drogue, Wali Karzaï joue un rôle politique méconnu. Il a organisé la campagne de son frère, et ce jour-là, à Kandahar, se jouait, sous sa houlette, l'avenir de ceux qui avaient soutenu ou au contraire refusé leur soutien à Hamid. Chef d'orchestre chargé du clan du président, Wali est la personnalité forte du sud du pays. Les Karzaï adossent leur influence à celle de Kandahar dans l'histoire de l'Afghanistan. Lorsque Ahmad Shah, le fondateur du pays, en 1747, conquit la ville, il en fit sa capitale. "Jusqu'en 1979, lors de l'invasion soviétique, Kandahar a incarné le mythe de la création de l'Etat afghan, les Kandaharis considèrent qu'ils ont un droit divin à diriger le pays", résume Mariam Abou Zahab, experte du monde pachtoune. "Kandahar, c'est l'Afghanistan, explique à ceux qui l'interrogent Tooryalaï Wesa, gouverneur de la province. La politique s'y fait et, encore aujourd'hui, la politique sera dictée par les événements qui s'y dérouleront." Cette emprise de Kandahar s'évalue aux places prises au sein du gouvernement par "ceux du Sud". La composition du nouveau gouvernement, le 19 décembre, n'a pas changé la donne. D'autant moins que les rivaux des Karzaï, dans le Sud ou ailleurs, n'ont pas réussi à se renforcer au cours du dernier mandat du président. L'autre terre pachtoune, le grand Paktia, dans le sud-est du pays, à la frontière avec le Pakistan, qui a fourni tant de rois, ne dispose plus de ses relais dans la capitale. Kandahar pèse aussi sur l'avenir du pays, car s'y trouve le coeur de l'insurrection qui menace le pouvoir en place. L'OTAN, défiée depuis huit ans, n'a cessé de perdre du terrain dans le Sud, où les insurgés contrôlent des zones entières. Les provinces du Helmand et de Kandahar sont les zones les plus meurtrières pour la coalition et l'OTAN semble dépourvue de stratégie cohérente. Kandahar est la terre natale des talibans. Ils sont nés dans les campagnes du Helmand et de Kandahar, et le mouvement taliban s'est constitué dans la ville de Kandahar, où vivait leur chef spirituel, le mollah Omar, et où il a conservé de profondes racines. La pression sur la vie quotidienne des Afghans est croissante. Les talibans suppléent même le gouvernement dans des domaines tels que la justice quotidienne. Ceux qui collaborent avec les étrangers sont stigmatisés, menacés, voire tués. En guise de premier avertissement, les talibans collent, la nuit, des lettres sur les portes des "collabos". "La progression talibane est un fait dans le Sud, relate Alex Strick van Linschoten, unique spécialiste occidental de la région et du mouvement taliban à vivre à Kandahar sans protection. L'insécurité, l'absence de travail poussent vers Kaboul ceux qui ont un peu d'éducation et de compétence, seuls restent les pauvres et ceux qui veulent faire de l'argent." En réaction à cette détérioration, les Américains ont décidé, sans l'assumer ouvertement, de reprendre le contrôle de situations confiées officiellement par l'OTAN aux Britanniques dans le Helmand et aux Canadiens dans la province de Kandahar. Le mouvement a été progressif, mais, depuis un an, les Etats-Unis n'ont cessé d'envoyer des renforts américains, au point d'exercer aujourd'hui de fait la direction des opérations dans cette région. Une tendance qui se renforcera encore avec l'arrivée des troupes supplémentaires promises par Barack Obama. L'histoire a montré que, pour gagner en Afghanistan, il fallait tenir les campagnes de Kandahar. Les Britanniques l'ont expérimenté de façon cuisante lors de la seconde guerre anglo-afghane à la fin du XIXe siècle et les Soviétiques n'en sont jamais venus à bout. "On sait comment cela s'est terminé pour eux, on va essayer d'éviter de faire les mêmes erreurs", observait, mi-novembre, optimiste, un officier supérieur américain.

summary Die Wurzeln des Elends liegen in der Vergangenheit. Haiti bezahlt immer noch für seine Befreiung vor 200 Jahren. Auch damals nahmen die Wichtigen der Welt den Insel-Staat nicht ernst.

body Das Portrait von 1791 zeigt Haitis Nationalhelden François-Dominique Toussaint L'Ouverture. Er war einer der Anführer der Revolution in Haiti und Autor der ersten Verfassung. Die Wurzeln des Elends liegen in der Vergangenheit. Haiti bezahlt immer noch für seine Befreiung vor 200 Jahren. Auch damals nahmen die Wichtigen der Welt den Insel-Staat nicht ernst. Am vergangenen Wochenende schickte der britische Architekt und Gründer der Organisation Architecture for Humanity eine atemlose, verzweifelte E-Mail an seine Freunde und Unterstützer. "Nicht Erdbeben, sondern Gebäude töten Menschen" schrieb er in die Betreffzeile. Damit brachte er auf den Punkt, was auch der Geologe und Autor Simon Winchester oder der Urbanist Mike Davis immer wieder geschrieben haben - es gibt keine Naturkatastrophen. Es gibt nur gewaltige Naturereignisse, die tödliche Folgen haben. Die Konsequenz aus dieser Schlussfolgerung ist die Schuldfrage. Einfach lässt sie sich beantworten: Gier und Korruption sind fast immer die Auslöser einer Katastrophe. In Haiti aber liegen die Wurzeln der Tragödie tief in der Geschichte des Landes. Diese begann nach europäischer Rechnung im Jahre 1492, als Christopher Kolumbus auf der Insel landete, die ihre Ureinwohner Aytí nannten. Kolumbus benannte die Insel in Hispaniola um und gründete mit den Trümmern der gestrandeten Santa Maria die erste spanische Kolonie in der Neuen Welt. Ende des 17. Jahrhunderts besetzten französische Siedler den Westen der Insel, den Frankreich 1691 zur französischen Kolonie Sainte Domingue erklärte. Ideale der Französischen Revolution Gut hundert Jahre währte die Herrschaft der beiden Kolonialherren über die geteilte Insel. "Saint Domingue war die reichste europäische Kolonie in den Amerikas", schrieb der Historiker Hans Schmidt. 1789 kam fast die Hälfte des weltweit produzierten Zuckers aus der französischen Kolonie, die auch in der Produktion von Kaffee, Baumwolle und Indigo Weltmarktführer war. 450000 Sklaven arbeiteten auf den Plantagen, und sie erfuhren bald vom neuen Geist ihrer Herren. Die Französische Revolution brachte die Ideale von Freiheit, Gleichheit und Brüderlichkeit in die Karibik. Im August 1791 war es so weit. Der Voodoo-Priester Dutty Boukman rief während einer Messe zum Aufstand. Einer der erfolgreichsten Kommandeure der Rebellion war der ehemalige Sklave François-Dominique Toussaint L'Ouverture, nach dem heute der Flughafen von Port-au-Prince benannt ist. 1801 gab Toussaint dem Land seine erste Verfassung, die gleichzeitig eine Unabhängigkeitserklärung war. Für Napoleon sollte Haiti eine Schmach bleiben. Daraufhin sandte Napoleon Bonaparte Kriegsschiffe und Soldaten. Toussaint wurde verhaftet und nach Frankreich gebracht, wo er im Kerker starb. Doch als Napoleon im Jahr darauf die Sklaverei wieder einführen wollte, kam es erneut zum Aufstand. Verzweifelt baten die französischen Truppen im Sommer 1803 um Verstärkung. Da aber hatte Napoleon schon das Interesse an der Neuen Welt verloren. Im April hatte er seine Kolonie Louisiana an die Nordamerikaner verkauft, ein Gebiet, das rund ein Viertel des Staatsgebietes der heutigen USA umfasste. Für Napoleon sollte Haiti eine Schmach bleiben. Am 1. Januar 1804 erklärte der Rebellenführer Jean-Jacques Dessalines, die ehemalige Kolonie heiße nun Haiti und sei eine freie Republik. Der erste und bis zur Abschaffung der Sklaverei einzige erfolgreiche Sklavenaufstand der Neuen Welt war ein Schock für die Großmächte der Kolonialära, die ihren Reichtum auf der Sklaverei gegründet hatten. Ein Handel, der die Geschichte Haitis bis heute bestimmt Die Freiheit hatte ihren Preis. Ein Großteil der Plantagen war zerstört, ein Drittel der Bevölkerung Haitis den Kämpfen zum Opfer gefallen. Vor allem aber wollte keine Kolonialmacht die junge Republik anerkennen. Im Gegenteil -die meisten Länder unterstützten das Embargo der Insel und die Forderungen französischer Sklavenherren nach Reparationszahlungen. In der Hoffnung, als freie Nation Zugang zu den Weltmärkten zu erhalten, ließ sich die neue Machtelite Haitis auf einen Handel ein, der die Geschichte der Insel bis heute bestimmt. Mehr als zwei Jahrzehnte nach dem Sieg der Rebellen entsandte König Karl X. seine Kriegsschiffe nach Haiti. Ein Emissär stellte die Regierung vor die Wahl: Haiti sollte für die Anerkennung als Staat 150 Millionen Francs bezahlen. Sonst würde man einmarschieren und die Bevölkerung erneut versklaven. Haiti nahm Schulden auf und bezahlte. Bis zum Jahre 1947 lähmte die Schuldenlast die haitianische Wirtschaft und legte den Grundstein für Armut und Korruption. 2004 ließ der damalige haitianische Präsident Jean-Bertrand Aristide errechnen, was diese "Reparationszahlungen" für Haiti bedeuteten. Rund 22 Milliarden amerikanische Dollar Rückzahlung forderten seine Anwälte damals von der französischen Regierung. Vergebens. Lesen Sie auf der nächsten Seite, wie Haiti von den Akteuren der Weltbühne geschnitten wurde.

summary El aeropuerto ha estado hasta las 15.00 con sólo dos pistas por ausencia de 5 de los 18 controladores aéreos.- Varias aerolíneas han denunciado demoras de "hasta 60 minutos con los pasajeros embarcados"

body El espacio hará un repaso cronológico de la vida de la Esteban desde el momento en el que una completa desconocida comenzó a aparecer en los medios en 1998 como la novia de Jesulín de Ubrique hasta llegar a hoy en día, convertida en la princesa del pueblo, en concreto del popular madrileño distrito de San Blas donde vive, tal y como algunos la han calificado, y protagonista de portadas de revistas, diarios y portales web y de aparecer incluso entre los personajes más populares de Google. Junto a María Teresa Campos, estarán en el plató Patricia Pérez, presentadora del programa matinal de los sábados en Telecinco Vuélveme loca, quien ha conducido las campanadas en cuatro ocasiones, y los comentaristas Maribel Escalona, Emilio Pineda y José Manuel Parada.Los vuelos han venido registrando este viernes importantes retrasos en Barajas a pesar de que desde las 15.00 el aeropuerto opera con las cuatro pistas, según han informado fuentes de AENA, mientras las compañías han denunciado demoras por parte de los controladores de hasta 60 minutos con los pasajeros embarcados. Según los datos facilitados por AENA, la ausencia por la mañana de 5 de los 18 controladores que estaban programados en el turno de la torre de control de Barajas obligó a cerrar dos de las pistas del aeropuerto, lo que generó retrasos medios de 30 minutos.

summary Ataması yapılmayan öğretmenler miting yaptı. Öğretmen adaylarına Muharrem İnce ve TEKEL işçileri de destek verdi.

body Yetersiz açılan kadrolar nedeniyle ataması yapılamayan öğretmen adayları Ankara'da miting yaptı. Tekel işçilerinin de destek verdiği öğretmen adaylarının mitinginde öğretmen kökenli CHP Milletvekili Muharrem İnce de hazır bulundu. Türkiye'nin çeşitli illerinden gelen "Ataması Yapılmayan Öğretmenler Platformu" üyesi sözleşmeli öğretmenler, öğle saatlerinde Abdi İpekçi Parkı'nda toplandı. "Milletvekilliği için KPSS getirilsin", "1 kadrolu öğretmen = 3 ücretli öğretmen" ve "Ücretli köle olmayacağız" yazılı dövizler taşıyan ve aynı içerikli sloganlar atan öğretmenlerin düzenlediği mitinge, bazı siyasi parti, sivil toplum kuruluşu temsilcileri ve TEKEL işçileri de destek verdi. CHP Yalova Milletvekili Muharrem İnce, okullarda derslerin boş geçtiğini öne sürerek, "Okullar öğretmensiz, öğretmenler ise işsiz" dedi. Hükümetin bu gençlerin sesini duyması gerektiğini belirten İnce, "Bu ülkenin 250 bin eğitim fakültesi mezunu genci iş bekliyorsa bu hükümetin ve ülkenin ayıbıdır. Eğitim sorununu çözememiş bir hükümet bu ülkenin hiçbir sorununu çözememiş demektir. Bu kadar önemli bir soruna kulaklarını tıkayamaz" diye konuştu. "Ankara'nın göbeğinde derslerin boş geçtiğini" ileri süren İnce, "Bu ülkede fizik ve matematik öğretmeni atanmıyor ama bunların 100 katı din dersi öğretmeni atanıyor" dedi. Platform adına yapılan açıklamada da Türkiye'de her yıl üniversite bitirerek diplomasını alan öğretmenlerin eğitim alanındaki yetersizlik dolayısıyla işsizler kervanına katıldığı ifade edildi. Talep edilen hakların insancıl ve makul olduğu belirtilen açıklamada, öğretmenlerin haklarını vermeyenlerin kötü niyetli olduğu öne sürüldü. Açıklamada, hükümetin eğitim politikası eleştirilerek, sözleşmeli öğretmenlerin kadrolu atamalarının yapılması, öğretmen yetiştiren fakültelere öğretmen ihtiyacı kadar öğretmen adayı alınması ve KPSS yerine daha şeffaf bir atama sistemi getirilmesi istendi. ÖLÜM ORUCU BAŞLATACAKLAR Çeşitli sivil toplum kuruluşu temsilcilerinin de konuştuğu mitingde, kadrolu atamalar yapılmadığı takdirde iş bırakma eylemi ve ölüm orucu yapılacağı duyuruldu.

summary Старший преподаватель института коммунального хозяйства и строительства был задержан на днях в Москве за растление школьника

body Сладострастник в течение трех лет преследовал подростка в надежде совратить его. Как сообщили "МК" в следственном отделе по Хорошевскому району СУ СК при Прокуратуре РФ по Москве, 26 августа 2006 года 13-летний Павел вместе с другом отдыхал на берегу Москвы–реки рядом с Крылатским мостом. Там к ребятам подошел мужчина. Новый знакомый представился Евгением и предложил вместе пообедать в ресторане быстрого питания, а потом искупаться. Именно там, на берегу, педагог начал приставать к мальчику. Школьник убежал, но педофил успел снять голого подростка на мобильный телефон. После этого жизнь мальчика превратилась в сущий ад. Евгений узнал, где живет Павел, и стал шантажировать его. Этот кошмар продолжался три года. Преподаватель угрожал показать фотографию друзьям и знакомым Павла. Негодяй исписал непотребными надписями стены подъезда, где проживали друзья школьника. В один из дней он приехал в Сергиев Посад, к бабушке мальчика, и там накинулся на школьника с ножом. Наконец, отчаявшийся подросток рассказал обо всем матери, и та обратилась в милицию. Первый раз стражи порядка упустили 43-летнего педофила (к слову, он разведен). Милиционеры нагрянули в его квартиру, а Евгений под предлогом прощания с мамой-инвалидом зашел в соседнюю комнату, выпрыгнул из окна и был таков. Задержать извращенца стражам порядка помогла случайность. Несколько дней назад мать Павла увидела Евгения на станции метро "Александровский сад". На мужчине красовался парик, но женщина узнала негодяя в толпе. Милиционеры, дежурившие на станции, по просьбе дамы задержали растлителя. В его кармане они обнаружили нож. Кстати, за несколько дней до задержания мужчина подкараулил Павла на улице и ударил его по лицу, обзывая нехорошими словами. Всех, чьи дети стали жертвами педофила, просят звонить по телефону 8-499-197-88-17 или 02.

Multi-XScience: A Large-scale Dataset for Extreme Multi-document Summarization of Scientific Articles

Abstract

Multi-document summarization is a challenging task for which there exists little large-scale datasets. We propose Multi-XScience, a large-scale multi-document summarization dataset created from scientific articles. Multi-XScience introduces a challenging multi-document summarization task: writing the related-work section of a paper based on its abstract and the articles it references. Our work is inspired by extreme summarization, a dataset construction protocol that favours abstractive modeling approaches. Descriptive statistics and empirical results—using several state-of-the-art models trained on the Multi-XScience dataset—reveal that Multi-XScience is well suited for abstractive models.[1]

1 Introduction

Single document summarization is the focus of most current summarization research thanks to the availability of large-scale single-document summarization datasets spanning multiple fields, including news (CNN/DailyMail (Hermann et al., 2015), NYT (Sandhaus, 2008), Newsroom (Grusky et al., 2018), XSum (Narayan et al., 2018a)), law (BigPatent (Sharma et al., 2019)), and even science (ArXiv and PubMed (Cohan et al., 2018)). These large-scale datasets are a necessity for modern data-hungry neural architectures (e.g. Transformers (Vaswani et al., 2017)) to shine at the summarization task. The versatility of available data has proven helpful in studying different types of summarization strategies as well as both extractive and abstractive models (Narayan et al., 2018a).

In contrast, research on the task of multi-document summarization (MDS) — a more general scenario with many downstream applications — has not progressed as much in part due to the lack of large-scale datasets. There are only two available large-scale multi-document summarization datasets: Multi-News (Fabbri et al., 2019) and WikiSum (Liu et al., 2018). While large supervised neural network models already dominate the leadboard associated with these datasets, obtaining better models requires domain-specific, high-quality, and large-scale datasets, especially ones for abstractive summarization methods.

Source 1 (Abstract of query paper)
... we present an approach based on ... lexical databases and ... Our approach makes use of WordNet synonymy information to .... Incidentally, WordNet based approach performance is comparable with the training approach one.
Source 2 (cite1 abstract)
This paper presents a method for the resolution of lexical ambiguity of nouns ... The method relies on the use of the wide-coverage noun taxonomy of WordNet and the notion of conceptual distance among concepts ...
Source 3 (cite2 abstract)
Word groupings useful for language processing tasks are increasingly available ... This paper presents a method for automatic sense disambiguation of nouns appearing within sets of related nouns ... Disambiguation is performed with respect to WordNet senses ...
Source 4 (cite3 abstract)
In ... word sense disambiguation... integrates a diverse set of knowledge sources ... including part of speech of neighboring words, morphological form ...

Summary (Related work of query paper)
Lexical databases have been employed recently in word sense disambiguation. For example, ... [cite1] make use of a semantic distance that takes into account structural factors in WordNet ... Additionally, [cite2] combines the use of WordNet and a text collection for a definition of a distance for disambiguating noun groupings. ... [cite3] make use of several sources of information ... (neighborhood, part of speech, morfological form, etc.) ...

Table 1: An example from our Multi-XScience dataset showing the input documents and the related work of the target paper. Text is colored based on semantic similarity between sources and related work.

We propose Multi-XScience, a large-scale dataset for multi-document summarization using *scientific articles*. We introduce a challenging multi-document summarization task: *write the re-*

November 16–20, 2020.

lated work section of a paper using its abstract (source 1 in Tab. 1) and reference papers (additional sources).

Multi-XScience is inspired by the XSum dataset and can be seen as a multi-document version of extreme summarization (Narayan et al., 2018b). Similar to XSum, the "extremeness" makes our dataset more amenable to abstractive summarization strategies. Moreover, Table 4 shows that Multi-XScience contains fewer positional and extractive biases than previous MDS datasets. High positional and extractive biases can undesirably enable models to achieve high summarization scores by copying sentences from certain (fixed) positions, e.g. lead sentences in news summarization (Grenander et al., 2019; Narayan et al., 2018a). Empirical results show that our dataset is challenging and requires models having high-level of text abstractiveness.

2 Multi-XScience Dataset

We now describe the Multi-XScience dataset, including the data sources, data cleaning, and the processing procedures used to construct it. We also report descriptive statistics and an initial analysis which shows it is amenable to abstractive models.

2.1 Data Source

Our dataset is created by combining information from two sources: `arXiv.org` and the Microsoft Academic Graph (MAG) (Sinha et al., 2015). We first obtain all arXiv papers, and then construct pairs of target summary and multi-reference documents using MAG.[2]

2.2 Dataset Creation

We construct the dataset with care to maximize its usefulness. The construction protocol includes: 1) cleaning the latex source of 1.3 millions arXiv papers, 2) aligning all of these papers and their references in MAG using numerous heuristics, 3) five cleaning iterations of the resulting data records interleaved with rounds of human verification.

Our dataset uses a query document's abstract Q^a and the abstracts of articles it references $R_1^a, \ldots, R_n^a$, where n is the number of reference articles cited by Q in its related-work section. The target is the query document's related-work section segmented into paragraphs $Q_1^{rw}, \ldots Q_k^{rw}$, where k is the number of paragraphs in the related-work section of Q. We discuss these choices below. Table 1 contains an example from our dataset.

Target summary: Q_i^{rw} is a paragraph in the related-work section of Q. We only keep articles with an explicit related-work section as query documents. We made the choice of using paragraphs as targets rather than the whole related-work section for the following two reasons: 1) using the whole related work as targets make the dataset difficult to work on, because current techniques struggle with extremely long input and generation targets; [3] and 2) paragraphs in the related-work section often refer to (very) different research threads that can be divided into independent topics. Segmenting paragraphs creates a dataset with reasonable input/target length suitable for most existing models and common computational resources.

Source: the source in our dataset is a tuple $(Q^a, R_1^a, \ldots, R_n^a)$. We only use the abstract of the query because the introduction section, for example, often overlaps with the related-work section. Using the introduction would then be closer to single-document-summarization. By only using the query abstract Q^a the dataset forces models to focus on leveraging the references. Furthermore, we approximate the reference documents using their abstract, as the full text of reference papers is often not available due to copyright restrictions.[4]

2.3 Dataset Statistics and Analysis

Dataset	# train/val/test	doc. len	summ. len	# refs
Multi-XScience	30,369/5,066/5,093	778.08	116.44	4.42
Multi-News	44,972/5,622/5,622	2,103.49	263.66	2.79
WikiSum	1, 5m/38k/38k	36,802.5	139.4	525

Table 2: Comparison of large-scale multi-document summarization datasets. We propose Multi-XScience. Average document length ("doc. len") is calculated by concatenating all input sources (multiple reference documents).

In Table 2 we report the descriptive statistics of current large-scale multi-document summarization (MDS) datasets, including Multi-XScience. Compared to Multi-News, Multi-XScience has 60% more references, making it a better fit for the MDS settings. Despite our dataset being smaller than WikiSum, it is better suited to abstractive summarization as its reference summaries contain more

---

[2] Our dataset is processed based on the October 2019 dump of MAG and arXiv.

[3] 10–20 references as input, 2–4 paragraphs as output

[4] Since our dataset relies on MAG for the reference paper as input, some reference papers are not available on arXiv. Our dataset contains all available paper information, including paper ids and corresponding MAG entry.

novel n-grams when compared to the source (Table 3). A dataset with a higher novel n-grams score has less extractive bias which should result in better abstraction for summarization models (Narayan et al., 2018a). Multi-XScience has one of the highest novel n-grams scores among existing large-scale datasets. This is expected since writing related works requires condensing complicated ideas into short summary paragraphs. The high level of abstractiveness makes our dataset challenging since models cannot simply copy sentences from the reference articles.

Datasets	% of novel n-grams in target summary			
	unigrams	bigrams	trigrams	4-grams
CNN-DailyMail	17.00	53.91	71.98	80.29
NY Times	22.64	55.59	71.93	80.16
XSum	35.76	83.45	95.50	98.49
WikiSum	18.20	51.88	69.82	78.16
Multi-News	17.76	57.10	75.71	82.30
Multi-XScience	**42.33**	**81.75**	**94.57**	**97.62**

Table 3: The proportion of novel n-grams in the target reference summaries across different summarization datasets. The first and second block compare single-document and multi-document summarization datasets, respectively.

Datasets	LEAD			EXT-ORACLE		
	R-1	R-2	R-L	R-1	R-2	R-L
CNN-DailyMail	39.58	17.67	36.18	54.67	30.35	50.80
NY Times	31.85	15.86	23.75	52.08	31.59	46.72
XSum	16.30	1.61	11.95	29.79	8.81	22.65
WikiSum	38.22	16.85	26.89	44.40	22.59	41.28
Multi-News	43.08	14.27	38.97	49.06	21.54	44.27
Multi-XScience	**27.46**	**4.57**	**18.82**	**38.45**	**9.93**	**27.11**

Table 4: ROUGE scores for the LEAD and EXT-ORACLE baselines for different summarization datasets.

Table 4 reports the performance of the lead baseline[5] and the extractive oracle[6] for several summarization datasets. High ROUGE scores on the lead baseline indicate datasets with strong lead bias, which is typical of news summarization (Grenander et al., 2019). The extractive oracle performance indicates the level of "extractiveness" of each dataset. Highly-extractive datasets force abstractive models to copy input sentences to obtain a high summarization performance. Compared to the existing summarization datasets, Multi-XScience imposes much less position bias and requires a higher level of abstractiveness from models. Both results consolidate that Multi-XScience requires summarization models to "understand" source text (models cannot obtain a high score by learning positional cues) and is suitable for abstractive models (models cannot obtain a high score by copying sentences).

2.4 Human Evaluation on Dataset Quality

Two human judges evaluated the overlap between the sources and the target on 25 pairs randomly selected from the test set.[7] They scored each pair using the scale shown in Table 5.

Score	Criteria
4	75% - 100% facts (perfect coverage)
3	50% -75% facts (major coverage)
2	25% - 50% facts (partial coverage)
1	less than 25% facts (poor coverage)

Table 5: Dataset quality evaluation criteria

The average human-evaluated quality score of Multi-XScience is 2.82±0.4 (95% C.I.). There is a large overlap between the reference abstracts and the targets' related work based on this score [8] which highlights that the major facts are covered despite using only the abstract.

3 Experiments & Results

We study the performance of multiple state-of-the-art models using the Multi-XScience dataset. Detailed analyses of the generation quality are also provided, including quantitative and qualitative analysis in addition to the abstractiveness study.

3.1 Models

In addition to the *lead baseline* and *extractive oracle*, we also include two commonly used unsupervised extractive summarization models, *LexRank* (Erkan and Radev, 2004) and *TextRank* (Mihalcea and Tarau, 2004), as baselines.

For supervised abstractive models, we test state-of-the-art multi-document summarization models *HiMAP* (Fabbri et al., 2019) and *HierSumm* (Liu and Lapata, 2019a). Both deal with multi-documents using a *fusion* mechanism, which performs the transformation of the documents in the vector space. HiMAP adapts a pointer-generator

---

[5] The lead baseline selects the first-K sentences from the source document as summary.

[6] The EXT-oracle summarizes by greedily selecting the sentences that maximize the ROUGE-L F1 scores as described in Nallapati et al. (2017).

[7] We invited two PhD students who have extensive research experiences to conduct the dataset quality assessment on our scientific related-work summarization dataset.

[8] This is expected, as it is standard to discuss the key contribution(s) of a paper in its abstract.

model (See et al., 2017) with maximal marginal relevance (MMR) (Carbonell and Goldstein, 1998; Lebanoff et al., 2018) to compute weights over multi-document inputs. HierSumm (Liu and Lapata, 2019a) uses a passage ranker that selects the most important document as the input to the hierarchical transformer-based generation model.

In addition, we apply existing state-of-the-art single-document summarization models, including *Pointer-Generator* (See et al., 2017), *BART* (Lewis et al., 2019) and *BertABS* (Liu and Lapata, 2019b), for the task of multi-document summarization by simply concatenating the input references. Pointer-Generator incorporates attention over source texts as a copy mechanism to aid the generation. BART is a sequence-to-sequence model with an encoder that is pre-trained with the denosing auto-encoder objective. BertABS uses a pretrained BERT (Devlin et al., 2019) as the encoder and trains a randomly initialized transformer decoder for abstractive summarization. We also report the performance of BertABS with an encoder (SciBert) pretrained on scientific articles (Beltagy et al., 2019).

3.2 Implementation Details

All the models used in our paper are based on open-source code released by their authors. For all models, we use the default configuration (model size, optimizer learning rate, etc.) from the original implementation. During the decoding process, we use beam search (beam size=4) and tri-gram blocking as is standard for sequence-to-sequence models. We set the minimal generation length to 110 tokens given the dataset statistics. Similar to the CNN/Dailymail dataset, we adopt the anonymized setting of citation symbols for the evaluation. In our dataset, the target related work contains citation reference to specific papers with special symbols (e.g. cite_2). We replace all of these symbols by a standard symbol (e.g. cite) for evaluation.

3.3 Result Analysis

Automatic Evaluation We report ROUGE Scores[9] and percentage of novel n-grams for different models on the Multi-XScience dataset in Tables 6 and 7. When comparing abstractive models to extractive ones, we first observe that almost all abstractive models outperform the unsupervised extractive models—TextRank and LexRank—by wide margins. In addition, almost all the abstractive models significantly outperform the extractive oracle in terms of R-L. This further shows the suitability of Multi-XScience for abstractive summarization.

To our surprise, Pointer-Generator outperforms self-pretrained abstractive summarization models, such as BART and BertABS. Our analyses (Table 7) reveal that this model performs highly abstractive summaries on our dataset, indicating that the model chooses to generate rather than copy. BART is highly extractive with the lowest novel n-gram among all approaches. This result may be due to the domain shift of the self pre-training datasets (Wikipedia and BookCorpus) since the performance of SciBertAbs is much higher in terms of ROUGE-L. In addition, the large number of parameters in the transformer-based decoders require massive supervised domain-specific training data.

Models	ROUGE-1	ROUGE-2	ROUGE-L
Multi-doc Extractive			
LEAD	27.46	4.57	18.82
LEXRANK	30.19	5.53	26.19
TEXTRANK	31.51	5.83	26.58
EXT-ORACLE	38.45	9.93	27.11
Multi-doc Abstractive (Fusion)			
HIERSUMM(MULTI)	30.02	5.04	27.60
HIMAP(MULTI)	31.66	5.91	28.43
Multi-doc Abstractive (Concat)			
BERTABS	31.56	5.02	28.05
BART	32.83	6.36	26.61
SCIBERTABS	32.12	5.59	29.01
POINTER-GENERATOR	**34.11**	**6.76**	**30.63**

Table 6: ROUGE results on Multi-XScience test set.

Models	% of novel n-grams in generated summary			
	unigrams	bigrams	trigrams	4-grams
PG (CNNDM)	0.07	2.24	6.03	9.72
PG (XSUM)	27.40	73.33	90.43	96.04
PG	18.82	57.54	80.22	89.32
HIERSUMM	27.52	77.16	**95.03**	**98.51**
HIMAP	23.13	63.58	86.50	94.15
BART	8.15	30.13	44.53	51.75
BERTABS	**34.18**	**81.99**	95.70	98.64
SCIBERTABS	46.57	89.05	97.92	99.31

Table 7: The proportion of novel n-grams in generated summary. PG (CNNDM) and PG (XSUM) denotes the pointer-generator model performance reported by papers (See et al., 2017; Narayan et al., 2018b) trained on different datasets. All the remaining results are trained on Multi-XScience dataset.

Human Evaluation We conduct human evaluation on ext-oracle, HiMAP, and Pointer-Generator, since each outperforms others in their respective

Table 8: Generation example of extractive oracle (EXT-ORACLE), HiMAP and Pointer-Generator (PG).

section of Table 6. For evaluation, we randomly select 25 samples and present the system outputs in randomized order to the human judges. Two human judges are asked to rank system outputs from 1 (worst) to 3 (best). Higher rank score means better generation quality. The average score is 1.54, 2.28 and 2.18 for ext-oracle, HiMAP, and Pointer-Generator, respectively. According to the feedback of human evaluators, the overall writing style of abstractive models are much better than extractive models, which provides further evidence of the abstractive nature of Multi-XScience.

In addition, we show some generation examples in Table 8. Since the extractive oracle is copied from the source text, the writing style fails to resemble the related work despite capturing the correct content. In contrast, all generation models can adhere to the related-work writing style and their summaries also the correct content.

4 Related Work

Scientific document summarization is a challenging task. Multiple models trained on small datasets exist for this task (Hu and Wan, 2014; Jaidka et al., 2013; Hoang and Kan, 2010), as there are no available large-scale datasets (before this paper). Attempts at creating scientific summarization datasets have been emerging, but not to the scale required for training neural-based models. For example, CL-Scisumm (Jaidka et al., 2016) created datasets from the ACL Anthology with 30–50 articles; Yasunaga et al. and AbuRa'ed et al.[10] proposed human-annotated datasets with at most 1,000 article and summary pairs. We believe that the lack of large-scale datasets slowed down development of multi-document summarization methods, and we hope that our proposed dataset will change that.

5 Extensions of Multi-XScience

We focus on summarization from the text of multiple documents, but our dataset could also be used for other tasks including:

- Graph-based summarization: Since our dataset is aligned with MAG, we could use its graph information (e.g., the citation graph) in addition to the plain text as input.
- Unsupervised in-domain corpus: Scientific-document understanding may benefit from using using related work (in addition to other sources such as non-directly related reference manuals). It is worth exploring how to use unsupervised in-domain corpus (e.g., all papers from N-hop subgraph of MAG) for better performance on downstream tasks.

6 Conclusion

The lack of large-scale dataset has slowed the progress of multi-document summarization (MDS) research. We introduce Multi-XScience, a large-scale dataset for MDS using scientific articles. Multi-XScience is better suited to abstractive summarization than previous MDS datasets, since it requires summarization models to exhibit high text understanding and abstraction capabilities. Experimental results show that our dataset is amenable to abstractive summarization models and is challenging for current models.

Intrinsic Evaluation of Summarization Datasets

cardie@cs.cornell.edu

Abstract

High quality data forms the bedrock for building meaningful statistical models in NLP. Consequently, data quality must be evaluated either during dataset construction or *post hoc*. Almost all popular summarization datasets are drawn from natural sources and do not come with inherent quality assurance guarantees. In spite of this, data quality has gone largely unquestioned for many recent summarization datasets. We perform the first large-scale evaluation of summarization datasets by introducing 5 intrinsic metrics and applying them to 10 popular datasets. We find that data usage in recent summarization research is sometimes inconsistent with the underlying properties of the datasets employed. Further, we discover that our metrics can serve the additional purpose of being inexpensive heuristics for detecting generically low quality examples.

1 Introduction

Data understanding is fundamentally important in natural language processing (NLP); for data-driven learning-based methods (e.g. neural networks), the quality of the training data bounds the quality of models learned using it. Therefore, understanding this data is necessary in order to ensure that models learn to perform a given task correctly.

Understanding data is a multidimensional problem. One line of inquiry has demonstrated why prominent datasets are insufficiently challenging: many data examples can be solved by alternative heuristics that do not encode an approach that is faithful to the task (McCoy et al., 2019). From the perspective of datasets, several works have shown that standard datasets in areas such as visual question answering (Zhang et al., 2016; Kafle and Kanan, 2017), natural language inference (Gururangan et al., 2018; Poliak et al., 2018), and reading comprehension (Kaushik and Lipton, 2018) contain annotation artifacts that often give rise to these spurious correlations or reasoning shortcuts. Data understanding can also inform scientific and ethical decision-making (Bender and Friedman, 2018; Gebru et al., 2018; Mitchell et al., 2019) with recent work studying how social biases encoded in training data propagate to learned models (Zhao et al., 2019; Tan and Celis, 2019).

In this work, we extend these efforts towards the setting of summarization. We find this to be particularly timely since several summarization datasets have been released in recent years with little discussion of data quality. While prior work on evaluating NLP datasets has focused on their difficulty, transparency, or bias, we consider broadly the overall quality of the dataset — in our case, for the task of summarization.[1] Our central insight is that desirable properties of a summary can be readily estimated by adapting and applying existing NLP methods. With this in mind, we present a multi-aspect large-scale study of summarization datasets that dissects summarization into 5 properties that are evaluated across 10 datasets spanning multiple summarization domains. Our analysis reveals that our metrics can serve as lightweight detectors of generically low quality examples. Most strikingly, we show that quantifiable aspects of summarization datasets are inconsistent with their use by the NLP community in several instances.

2 Motivation

Quality assurance for data. Nuanced understanding of data is requisite for drawing sound scientific conclusions. In particular, without evaluating for the quality and accuracy of data used to test models, it is impossible to be certain that progress is being made and that successive iterations of models truly

---

[1] Concurrent to our work, Kathy McKeown, during her keynote address at ACL 2020, also called for the renewed study of datasets being used in the summarization community (McKeown, 2020).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8075–8096,
November 16–20, 2020.

make progress on the underlying task or linguistic phenomena of interest.

Within NLP, iconic datasets such as the Penn Treebank (Marcus et al., 1993) have sustained subareas such as language modelling, part-of-speech tagging, and syntactic parsing for years due to the painstaking annotation efforts put into making these high-fidelity resources. And in the context of summarization, initial datasets, such as those produced during the Document Understanding Conference (DUC) and Text Analysis Conference (TAC) evaluations, implemented fine-grained verification of data quality.[2]

In part due to the emergence of data-hungry modelling techniques, the demands for larger datasets often render quality assurance procedures of this standard to be impractical and infeasible. Nonetheless, several recent natural language understanding datasets (Bowman et al., 2015; Rajpurkar et al., 2016; Suhr et al., 2017) institute explicit quality-control procedures in crowd-sourcing dataset construction (Zaidan and Callison-Burch, 2011; Yan et al., 2014; Callison-Burch et al., 2015), such as using additional annotators to validate annotations (c.f. Geva et al., 2019). In the sibling subfield of machine translation, which often shares similar modelling challenges and evaluation regimes as summarization due to the shared nature of being sequence-to-sequence natural language generation tasks, the annual WMT conference[3] consistently furnishes high quality data. In summary, ensuring data quality is both crucial and challenging. And in comparison with other subareas of NLP, we argue that summarization has lagged behind in rigorously ensuring the quality of widely-used datasets.

Relating data quality and model quality. The correctness and quality of data inherently bounds what can be learned from the data about the task of interest. From an information-theoretic perspective, this can be made fully formal as follows:[4]

$$\underbrace{I(S;M)}_{\text{learned model}} \leq \underbrace{I(S;T)}_{\text{training data}} + \underbrace{I(S;P)}_{\text{pretraining}} + \underbrace{I(S;A)}_{\text{inductive bias}}$$

Here, I denotes the mutual information, S denotes understanding of the underlying summarization task and M denotes a model learned using summarization training data T, additional pretraining data P, and the model's architecture A. For fully learning-based methods, especially those with weak/minimal inductive biases such as neural networks, $I(S;A)$ is approximately zero. While $I(S;P)$ may be greater than zero (e.g. language modelling pretraining provides statistical information that may facilitate a model to avoid *a priori* unlikely summaries), standard pretraining regimes such as large-scale language modelling over generic text corpora (Devlin et al., 2019; Raffel et al., 2019) are likely insufficient to meaningfully learn to summarize. Under these assumptions, the mutual information between S and M is critically upper-bounded in terms of $I\left(S;T\right)$. We hypothesize that the quality of the training dataset T is highly correlated with its mutual information with respect to the summarization task S, $I(S;T)$.

One size does not fit all. Spärck Jones (1999) famously argued that summarization systems should be understood conditional on the context in which they will be used. In recent years, the field has significantly departed from this perspective and primarily studied "general-purpose summarization" (Kryscinski et al., 2019), which she denounced as *ignis fatuus*. With our work, we adopt the perspective that for all datasets it is strictly preferable to have all properties quantified; it is the responsibility of practitioners building summarization systems to accurately weight different metrics based on their ultimate goals and use cases. As such, we refrain from providing prescriptive domain-agnostic or context-agnostic notions of summarization.

3 Metrics

In this work, we evaluate the quality of a dataset by aggregating scores for each example in the dataset. We conjecture that for many NLP tasks, estimating the quality of a particular data example is of similar complexity as correctly performing the task on the example.[5] Nevertheless, for summarization, our insight is that various aspects of a summarization example (a document-summary pair) can be reliably estimated by re-purposing existing NLP methods. We are guided by pioneering work (Luhn, 1958; Edmundson, 1969; Mani, 1999) that defined core properties of summarization systems and influential sub-

[4] Proof deferred to Appendix D.

[5] Research in algorithms provides a natural parallel: many computationally hard optimization problems remain intractable when relaxed to their decision problem version. For example, the travelling salesman problem of finding the least costly Hamiltonian cycle remains NP-hard even if we just ask *"Does there exist a Hamiltonian cycle of cost $\leq L$?"*

sequent work (Radev et al., 2002; Nenkova, 2006; Nenkova and McKeown, 2012; Peyrard, 2019a) that refined and extended these properties. From this literature, we specifically study *compression*, *topic similarity*, *abstractivity*, *redundancy*, and *semantic coherence* as these properties are of recurring and sustained interest.[6]

For each abstract property, numerous concrete methods can be proposed to quantify it. In Appendix A, we describe alternatives we considered and detail how we decided which methods performed best. We restrict discussion to the best-performing approaches in the main paper.

Notation. Our metrics will assume indexed sets $\mathcal{D}$, $\mathcal{S}$ such that summary $S_i \in \mathcal{S}$ summarizes document $D_i \in \mathcal{D}$. The length in words of a sequence s is $|s|$ and the length in sentences is $||s||$. Each metric assigns a value $x \in [0,1]$ to every (D_i, S_i) where 1 is the maximal score and example-level scores are averaged to yield a dataset-level score.

Compression. We quantify compression at the word (w) and sentence (s) levels:

$$\mathbf{CMP}_w(D_i, S_i) = 1 - \frac{|S_i|}{|D_i|} \qquad (1)$$

$$\mathbf{CMP}_s(D_i, S_i) = 1 - \frac{||S_i||}{||D_i||} \qquad (2)$$

Topic Similarity. We learn a topic model $\mathcal{M}$ on training corpus $\mathcal{T}$ with k topics using LDA (Blei et al., 2003) and quantify topic similarity by comparing the inferred topic distributions $\theta_{D_i|\mathcal{M}}, \theta_{S_i|\mathcal{M}}$ for a given summary and document:

$$\mathbf{TS}(D_i, S_i) = 1 - \mathrm{JS}(\theta_{D_i|\mathcal{M}}, \theta_{S_i|\mathcal{M}}) \qquad (3)$$

where JS is the Jensen-Shannon distance. We set $k = 20$ and $\mathcal{T} = \mathcal{D}$.

Abstractivity. Grusky et al. (2018) introduced *fragments* $\mathcal{F}(D_i, S_i)$, which are greedily-matched spans shared between D_i and S_i. We quantify abstractivity as a normalized function of the aggregate fragment length; our definition generalizes the definition of Grusky et al. (2018). We set $p = 1$.

$$\mathbf{ABS}_p(D_i, S_i) = 1 - \frac{\sum\limits_{f \in \mathcal{F}(D_i, S_i)} |f|^p}{|S_i|^p} \qquad (4)$$

Redundancy. ROUGE (Lin, 2004) implicitly penalizes redundancy but underestimates its detrimental impacts (Chaganty et al., 2018). However, we find that ROUGE is effective for identifying redundancy given the definitional focus on overlapping spans. We quantify redundancy as the average ROUGE-L F-score for all pairs of distinct sentences in the summary.

$$\mathbf{RED}(S_i) = \underset{(x,y) \in S_i \times S_i, x \neq y}{\mathrm{mean}} \mathrm{ROUGE}(x, y) \qquad (5)$$

Semantic Coherence. We evaluate the semantic coherence of multi-sentence summaries by predicting the probability of each successive sentence conditioned on the previous one using a powerful language model, BERT (Devlin et al., 2019), pretrained with precisely this objective.

$$\mathbf{SC}(S_i) = \frac{\sum\limits_{j=2}^{||S||} \mathbb{1}_{\mathrm{BERT}(S_i^j \mid S_i^{j-1})}}{||S_i|| - 1} \qquad (6)$$

4 Data

We study the following 10 summarization datasets that have been frequently used in recent years.[7] Table 1 contains standard dataset statistics in the upper half and our aspect-level scores in the lower half; datasets are grouped by domain.

CNN-DM (Hermann et al., 2015; Nallapati et al., 2016) is a dataset composed of CNN and Daily Mail news articles with summaries that are a concatenated list of highlight bullet points.

NYT (Sandhaus, 2008) is a dataset of curated New York Times articles paired with abstracts written by library scientists.

NWS (Grusky et al., 2018) is the Newsroom dataset of news articles drawn from 38 top English publishers paired with multi-sentence summaries written by the original authors and editors.

GW (Graff and Cieri, 2003) is the Gigaword *headline generation* dataset that some refer to as a summarization dataset (Rush et al., 2015; Chopra et al., 2016). Examples in the dataset are drawn from seven news sources and are the article prefix paired with its headline.

XSum (Narayan et al., 2018) is an *extreme summarization* dataset where BBC articles are paired with single-sentence summaries written generally by the author of the article that tries to motivate the BBC audience to read the article by answering "What is the article about?".

PeerRead (Kang et al., 2018) is a dataset of paper drafts from top-tier computer science venues as well as arXiv.[8] Consistent with its use in the summarization community, we consider the full introduction to be the source document and the ab-

---

[6] Different names and interpretations have been given for these properties in the literature. We revisit this in Appendix A in discussing alternate metrics.

[7] Several of these datasets are catalogued in the repository of Dernoncourt et al. (2018).

[8] Some papers also have peer reviews which we ignore.

stract to be the target summary.

PubMed (Cohan et al., 2018) is a dataset of papers drawn from the biomedical and life sciences. Unlike **PeerRead**, the full paper is taken as the document but the summary is still specified as the abstract.

TL;DR (Völske et al., 2017) is a dataset of user-written articles from the social media platform Reddit along with the author-provided courtesy summaries that tend to be multi-sentence. Völske et al. (2017) applied a series of preprocessing procedures to filter out bot-generated content.

AMI (Carletta et al., 2005) is a dataset of transcribed meetings, some which are naturally occurring and the rest of which are elicited, with hand-annotated summaries. The transcription process has multiple steps that are described extensively by Carletta et al. (2005). Various additional data provided within the **AMI** dataset is neglected in this work.

MovieScript (Gorinski and Lapata, 2015) is a dataset of movie scripts drawn from the ScriptBase corpus that are aligned with user-written summaries sourced either from Wikipedia or IMDB. Various additional data provided within the **MovieScript** dataset is neglected in this work.

5 Results and Analysis

Compression scores quantitatively disambiguate summarization tasks.

Concretely, we observe **GW** has the lowest compression scores and while **GW** is sometimes described as a summarization dataset (Rush et al., 2015; Chopra et al., 2016), it is better seen as a *headline generation* dataset that is more in the style of *sentence compression* (as is suggested by $\|S_i\| = \|D_i\| = 1$). Conversely, **AMI** and **MovieScript** achieve the highest scores by a substantial margin and are *long-document summarization* datasets. Classifying new summarization datasets accurately may prove useful given that successful methods from one domain often do not extend to another and this shortcoming in generalization can be attributed to the differences in compression requirements (Cohan et al., 2018).

Given the goals stated in the XSum dataset paper, TL;DR may be a better choice than XSum.
In particular, Narayan et al. (2018) introduce **XSum** as a large dataset that legitimately requires abstraction. While **XSum** is more abstractive than other News datasets (barring **GW**) and is relatively large, **TL;DR** displays greater abstractivity, similar length summaries, and is 15 times larger. That said, Narayan et al. (2018) explore topic-oriented strategies in their work and such methods may be better suited to **XSum** given the **TS** scores.

CNN-DM and NYT are suboptimal for studying abstractive/extractive systems respectively.
Several recent works (See et al., 2017; Paulus et al., 2018; Li et al., 2018) have used **CNN-DM** to build and evaluate abstractive systems. Conversely, **NYT** has been used to build extractive systems (Hong and Nenkova, 2014; Li et al., 2016). Given our findings, we find both of these trends to be inconsistent with dataset properties and suboptimal given other preferable datasets for these purposes: **CNN-DM** is one of the least abstractive datasets and there are larger and more extractive alternatives to **NYT** such as **NWS**. Especially in the case of **CNN-DM**, we note that training learning-based systems (e.g. neural methods) using data with limited abstractivity implies the resulting summarizers will be limited in their ability to generate genuinely abstractive text. This is validated by empirical findings as both See et al. (2017) and Zhang et al. (2018) observe limited abstractivity in abstractive systems trained on **CNN-DM**. In light of this, we argue systems should be characterized as abstractive or not based on their empirical behavior rather than their theoretical capability.[9]

CNN-DM is not a representative benchmark for summarization as a whole.
Recent work (Kryscinski et al., 2019; Raffel et al., 2019) has explicitly portrayed **CNN-DM** as the benchmark dataset for summarization; the field has implicitly done this for several years (Kryscinski et al., 2019). While there is clear value in evaluating pretrained representations on summarization datasets, we caution against using **CNN-DM** as a stand-in for the entire summarization subfield. Instead, we suggest using a diverse group of datasets and not reducing a highly heterogeneous subfield to a single dataset. While this adds additional overhead, this cost is necessary to draw meaningful conclusions about the impact of advances on summarization broadly given the pronounced diversity in summarization datasets (Table 1).

Post-processing methods for mitigating redundancy may be needed for practical systems.
While evaluation on standard datasets using ROUGE

Table 1: **Upper half**: Standard dataset statistics. **Lower half**: Aspect-level scores for each dataset (0 is minimal value, 1 is maximal value). Corresponding standard deviations appear in Table 9. Redundancy and semantic coherence are not reported for datasets with $> 95\%$ single-sentence summaries.

may not penalize for this, redundancy is clearly undesirable (Carbonell and Goldstein, 1998; Peyrard, 2019a) and existing datasets (and thereby systems learned using that data) display significant amounts of redundancy in their gold-standard summaries (exceptions are datasets with short summaries where cross-sentence redundancy is constrained to be low). Specifically, Nenkova (2006) argues that redundancy is a clear inhibitor for practical application of summarization systems. Consequently, *post hoc* methods that reduce redundancy after initial evaluation may be useful in generating summaries that are suitable for human users.

Semantic coherence captures observable variation in summary coherence.
We observe that the Scientific summaries (which are abstracts of published papers) are clearly more coherent than the author-generated summaries in **TL;DR**, the fragmented summaries in **AMI**, and the concatenated bullet-point summaries in **CNN-DM**. We find that this distinction is captured by the **SC** measure using BERT. Quantifying semantic coherence is especially important given that the coherence of reference summaries will inform the coherence of system summaries, especially for learning-based approaches. Akin to what we discuss for abstractivity, See et al. (2017) and Paulus et al. (2018) both demonstrate that neural summarizers generate incoherent summaries despite achieving high ROUGE scores.

5.1 Pairwise Correlations

While the properties we evaluate for do not exhaust all aspects of summarization that may be of interest, it is unclear to what extent different measures overlap in judgments. To quantify this, in Table 2 we report pairwise correlations for every pair of metrics. In each case, the value reported is the Spearman rank correlation coefficient ρ computed between the length 10 vectors containing the scores for each dataset.[10] $\rho = 1$ indicates perfect positive correlation (which is why we see this for all diagonal entries) and $\rho < 0$ indicates the metrics are anti-correlated.

	CMP$_w$	**CMP$_s$**	**TS**	**ABS$_1$**	**RED**	**SC**
CMP$_w$	1	0.733	-0.188	-0.406	-0.179	-0.321

SC	-0.321	0.0	0.643	-0.214	0.321	1

Table 2: Pairwise correlations measured using Spearman ρ coefficient between metrics studied in this work.

Unsurprisingly, the compression metrics are strongly correlated with each other. We further observe that redundancy and topic similarity are correlated whereas abstractivity is anti-correlated with both. In particular, when summaries are considerably redundant, we qualitatively observe that the repeated content in the summary was both important and repeated in the context of the reference document. As a result, this may explain why redundancy and abstractivity are anti-correlated as this would suggest that highly redundant summaries are highly extractive. Additionally, since we measure topic similarity using LDA and unigram count statistics, it is not surprising that extractions may correlate with high topic similarity. In part, this may suggest a deficiency of our measure of topic

---

[10] We omit scores for datasets that do not have scores for a given metric.

similarity to accurately consider references to the same topic using substantially different words.

We also observe that semantic coherence patterns similarly to redundancy. In particular, while we find the semantic coherence scores are appropriate for most examples we manually inspected, this suggests that BERT relies upon word-level overlaps in making next-sentence judgments (similar to behaviors seen in other sentence-pair tasks such as natural language inference, c.f Gururangan et al., 2018)

6 Detecting Low Quality Examples

To complement our quantitative dataset-level analysis, we conduct a qualitative study of individual examples by examining outliers. For each (dataset, metric) pair, we sample 10 examples from both the top and bottom 10% of examples for that metric and in that dataset.

Since manually considering all of the 1080 examples was not feasible, we began by examining the sampled examples for topic similarity, redundancy, and semantic coherence. Our hypothesis was that example quality would positively correlate with coherence and topic similarity and negatively correlate with redundancy. We found this hypothesis to be validated by our observations as we found that examples with low coherence, low topic similarity, or high redundancy scores were generally low quality examples. Every example which we judged to be low quality demonstrated at least one of the following defects:

- The summary contains critical disfluencies that severely hinder accurate processing.[11]
- The summary excludes unambiguously critical information from the reference document.
- Crucial information in the summary does not appear in the reference document and is not general knowledge.
- Substantial fractions of the summary involve entities, relations, or events that are ambiguous and that we could not resolve from the summary alone. In particular, accurate interpretation of the summary would require also reading the reference document to resolve various coreferring expressions; the summary is not self-contained.[12]
- The summary is entirely inappropriate as a summary of the reference document. For example, the summary only discusses an event with no obvious relationship to the contents of the reference document.
- The summary includes an entire sentence or long phrase describing something that appears in the main document but that is clearly an auxiliary detail. We flagged examples as low quality due to this condition quite conservatively, only using it when we could come to no basis for why the sentence/phrase should appear in the summary.

On the other hand, we did not find any systematic defects in examples with high coherence, high topic similarity, or low redundancy scores. Instead, almost all of these examples were satisfactory.

For the remaining two properties (compression measured by $\mathbf{CMP}_w$, abstractivity measured by $\mathbf{ABS}_1$), we analyzed all of the associated 400 examples. What we observed is that many of these examples tended to be generically low quality and we quantify this in Table 3. Since this analysis may be difficult to replicate and involves subjective decisions about example quality, we comprehensively enumerate all example IDs we use in Table 8.

Table 4 shows a representative subset of the low quality examples we found in our analysis. We provide further examples in Appendix C and Figures 1–9.

Compression. Minimally compressed summaries in **NYT**, **NWS**, **TL;DR**, and **PubMed** often are supplementary information to the document rather than a summary of it; in some cases, we believe this is due to errors in alignment in dataset construction/release. On the other hand, heavily compressed summaries in **NWS** and **XSum** often are just category labels (e.g. *Sports*), in **TL;DR** are

---

[11] We invoked this condition fairly judiciously as we observed that the domain of summaries also could influence the fluency of summaries in terms of grammaticality. In particular, we unsurprisingly found that academic papers in the Science domain generally have highly grammatical summaries whereas the bullet-point summaries in **CNN-DM** and the author-written summaries in **TL;DR** often were ungrammatical but still sufficiently clear to be interpreted correctly.

[12] Many summaries drawn from the News domain have references that could be resolved by world knowledge or that could be reasonably understood using common sense knowledge. In these cases, while the summary is not fully self-contained, we did not judge them to be low quality. However, we expect that systems trained using these datasets would require knowledge beyond what is afforded by the reference document to accurately generate summaries of this type.

usually attention-grabbers, and in **NYT** are near-exact duplicates of reference documents, which themselves are letters to the editor.

Abstractivity. Manual inspection reveals highly abstractive summaries in **NYT** and **NWS** generally are exceedingly vague or are entirely unrelated to the original document. Highly abstractive summaries in **PeerRead** are often translated to English from the reference document's language and discuss results that do not appear in the introduction but likely appear later in the paper. Conversely, extremely extractive summaries in **NWS** and **NYT** often are just the lede and cannot be understood without the reference document. However, in most other instances, the lede is an effective summary for examples drawn from the News domain.

Within the context of our sample of examples, we find that eight of the ten summarization datasets (all but **AMI**, **MovieScript**) contain at least 8% low quality examples, the majority contain at least **14**% low quality examples, and that these low quality examples can be detected using our *compression* and *abstractivity* metrics. For the worst-offending **TL;DR** dataset, we conservatively estimate at least **20**% of examples are of substantially subpar quality. In general, we find that the low quality **TL;DR** "summaries" we detect often serve a different rhetorical purpose than summarization (e.g. attention grabbing, responding to a previous post that is not available in the dataset, sarcasm/humor).

7 Related Work

Dataset Analysis. As an alternative to automated evaluation, Chen et al. (2016) and Yatskar (2019) conduct human evaluations of standard datasets in reading comprehension and question answering. In some cases, dataset creators perform manual analyses of the data they introduce (e.g. Sandhaus (2008) and Grusky et al. (2018) for the **NYT** and **Newsroom** corpora, respectively). Automated and human evaluation provide complementary benefits with respect to their scalability and reliability. Even in the context of human evaluations, we advocate that automatic metrics can be useful in guiding the exploration of data and informing subsampling procedures that provide fine-grained insights.

Quality Estimation. Our work bears resemblance both in name and structure to work on quality estimation. Quality estimation, often centered on natural language generation, is the task of measuring system-generated output quality (Paetzold and Specia, 2016; Yuan and Sharoff, 2020). It is closely related to work on unsupervised or reference-free evaluation (Napoles et al., 2016; Ethayarajh and Sadigh, 2020). Within the context of summarization, the special case of quality estimation regarding factual consistency/faithfulness has been of recent interest (Wang et al., 2020; Maynez et al., 2020; Durmus et al., 2020) since neural abstractive summarizers have been shown to hallucinate/misrepresent facts (See et al., 2017). In comparison to these settings, our metrics make no use of labelled data (even in training) and are entirely intrinsic/unsupervised.

Summarization Practices. Several analyses and critiques exist for different aspects of the summarization pipeline. From a modelling perspective, Zhang et al. (2018) assess whether abstractive systems are truly abstractive, Kedzie et al. (2018) evaluate content selection policies in a variety of methods, and Mao et al. (2020) assess the facet-level performance of extractive summarizers. From an evaluation perspective, several works have discussed the shortcomings of ROUGE/automated evaluation (Liu and Liu, 2008; Chaganty et al., 2018; Hashimoto et al., 2019; Peyrard, 2019b) as well proposed alternative metrics for summarization or natural language generation more broadly (Clark et al., 2019; Zhang et al., 2020; Sellam et al., 2020).

Two recent works are highly related to our own. Kryscinski et al. (2019) provide a critical reevaluation of summarization research. Most relevant to our work, they show that web-scraped datasets, specifically **CNN-DM** and **NWS**, contain a nontrivial fraction of examples (approx. 3.5%) with HTML artifacts (which can be easily detected/removed). Jung et al. (2019) provide an aspect-level evaluation of both summarization datasets and systems. In their work, the dataset analyses center on biases in the data (e.g. positional biases, which are often seen in news summarization), which is reminiscent of the annotation artifacts seen in other NLP tasks (Gururangan et al., 2018; Niven and Kao, 2019).

8 Discussion

Open Problems and Future Directions. Our results demonstrate that a sizeable fraction of examples in most summarization datasets are low quality. However, it remains open whether modellers should simply prune these examples, manually/automatically attempt to correct them, or model them without change. We do note that research in the machine learning and learning theory communities shows that models both theoretically and empirically do substantially worse when trained using low quality examples, even when the examples are not strictly adversarially chosen (Klivans et al., 2009; Biggio et al., 2012; Koh et al., 2018). These concerns are further compounded by the evidence of Belinkov and Bisk (2018) that neural models for natural language generation are not robust to naturally noisy data.

Our metrics may be repurposed to rank examples in designing curricula for curriculum learning approaches (Bengio et al., 2009). Alternatively, they can serve as additional metrics for the (possibly unsupervised) evaluation of summarization systems, potentially mitigating deficiencies in standard metrics, such as ROUGE, by directly penalizing redundancy and semantic incoherence.

Limitations. In this work, we restrict ourselves to single-document single-reference English language summarization datasets. While the datasets we study constitute a considerable fraction of dataset usage in the summarization community, several multi-document summarization datasets have been introduced (e.g. Fabbri et al., 2019; Antognini and Faltings, 2020) and multi-reference summarization datasets have often been argued to be desirable due to under-constrained nature of the summarization task (Kryscinski et al., 2019) and the ideal evaluation paradigm for ROUGE (Lin, 2004). Beyond English, both large summarization datasets (Nguyen and Daumé III, 2019; Varab and Schluter, 2020) and more general language resources/technologies (Joshi et al., 2020) are less available, which may heighten the need for data quality assurance.

More broadly, the measures that we introduce are automated, and therefore non-human, judgments of the quality of summarization data. Therefore, we only envision these measures to be useful as inexpensive first-order approximations of aspect-level summary quality rather than bona fide replacements for human evaluation. Additionally, since we principally envision applying these metrics to datasets, we make no efforts to make these metrics robust to adversarially-crafted data and they are likely quite susceptible to adversarial attack.

9 Conclusion

In this work, we demonstrate that various aspects of summarization datasets can be intrinsically evaluated for. We specifically show this for 5 properties across 10 popular datasets, uncovering that dataset use is sometimes incongruous with the attributes of the underlying data. We also find that some aspect-level estimators may be surprisingly effective at detecting low quality dataset examples. Our findings suggest that more intentional and deliberate decisions should be made in selecting summarization datasets for downstream modelling research and that further scrutiny should be placed upon summarization datasets released in the future.

10 Reproducibility

All code is made publicly available.[13] Exhaustive reproducibility details, including how to access all datasets, are provided in Appendix B. We fully adhere to the EMNLP 2020 Reproducibility guidelines, addressing all relevant checklist items.

Acknowledgments

We thank Anna Huang for her help with analyzing the data. We thank Ge Gao, Esin Durmus, and members of the Cornell and Stanford NLP groups for their valuable advice. We especially thank the reviewers and area chairs for their articulate and constructive feedback.

A Alternative Metrics

A.1 Compression

For compression, we found sentence-level compression to be a naturally motivated metric given that many extractive systems are constrained to extract sentence-length sequence. We also considered byte-level compression as an alternative to word-level compression (as computational length constraints have sometimes been used in evaluation instead of word length constraints). We found the results to be highly correlated with word-level compression and to not be further revealing (and bytes may be inherently less interpretable for NLP when compared with words). We also considered only considering content words, motivated by literature in topic modelling (Schofield et al., 2017) that has considered removing stopwords and other such lexical categories. These results were also highly correlated with the original word-level compression results and we did not find any discerning trends in looking at individual examples.

A.2 Topic Similarity

In the main paper, we compute topic similarity using the Jensen-Shannon distance. We initially considered the Kullback-Leibler (KL) divergence. While the JS distance and/or divergence has been more frequently used in the context of similarity in topic modelling, the KL divergence is also frequently considered. Intuitively and under some interpretations, the asymmetry of the KL divergence may be desirable as the extent to which a summary is topically similar to a document may not be the same as the extent to which a document is topically similar to a summary. In spite of this, in viewing the results using KL, we found that the measure lacked discriminative power in disambiguating examples we believed were more topically similar than others. We qualitatively found the judgments via the JS distance to be accurate. That said, the judgments between the measures tended to be highly correlated as the Spearman rank correlation coefficient was $\rho \geq 0.7$ for all topic modelling settings and in most cases exceeded 0.8.

We also considered a topic model learned using both the documents and summaries $\mathcal{D} \cup \mathcal{S}$ and just the documents $\mathcal{D}$. Both are natural choices, with using the documents being more general in some sense as the topic similarity of a summary should be able to be assigned without requiring the summary collection. We further considered several choices for the number of topics as well. In Table 5, we report the full results for all pairs of (training corpus $\mathcal{T}$, # topics k) for all

$$(\mathcal{T}, k) \in \{\mathcal{D} \cup \mathcal{S}, \mathcal{D}\} \times \{10, 20, 50, 100\}.$$

In all cases, the number of training examples is truncated to 20000 (hence 10000 summaries and 10000 documents when using the training corpus of $\mathcal{D} \cup \mathcal{S}$). We fix the number of training documents across datasets to attempt to control for the confound of larger datasets inducing higher quality topic models. We did not observe significant changes in the result by relaxing this (i.e. using the full datasets instead of just 20000 examples).

We find that there is significant variation in cross-dataset rankings with respect to these two parameters. We chose to report the results corresponding to $k = 20, \mathcal{T} = \mathcal{D}$. We chose the value for k based on qualitative judgments about topic quality for **CNN-DM**, **PeerRead**, and **AMI**, as we considered these to be a diverse subset of all 10 datasets. The topics we observed were highly disjoint and reasonably aligned with our intuitions about what sensible topics should be. We chose the value for $\mathcal{T}$ based on the generality referenced previously. While the results are substantially different for $\mathcal{D}$ versus $\mathcal{D} \cup \mathcal{S}$, we did not find any consistent and interpretable discriminative properties between the two.

A.3 Abstractivity

Our general framework for quantifying abstractivity is derived from Grusky et al. (2018). We considered $p \in \{1, 2, 3, 4\}$ initially and found $p = 1$ to be the most informative regarding abstractivity. In particular, we find that for increasing p, useful conclusions about abstractivity are inherently masked by the dominance of the $|S_i|^p$ denominator in the definition. We report the scores for $\mathbf{ABS}_2$ in Table 6.

We also considered the natural extensions to $\mathbf{ABS}_3$ and $\mathbf{ABS}_4$ but we found that the normalization dominates any deviation in the scores and all datasets essentially receive a score of 1. We also considered other forms of normalization (i.e. normalizing $\mathbf{ABS}_2$ in the style of the L_2 norm/the style of generalized p-norms) in initial experiments but found no substantial differences.

A.4 Redundancy

In the main paper, we compute redundancy scores for each distinct sentence pair using ROUGE-L F-measure and then average these individual values to get a score for the entire summary. Alternatively, we considered other ROUGE scores (specifically ROUGE-1 and ROUGE-2) as well as max pooling the sentence pair scores. We report these results below in Table 7.

We do not observe significant changes with the specific ROUGE metric considered (i.e. a Spearman ρ of 1.0 which indicates a perfect correlation in the case of max pooling across the ROUGE variants). We do see substantial differences between averaging and max pooling; we find that max pooling turns out to precisely correlate ($\rho = 1.0$) with the average summary length. This is somewhat expected, given that the max-pooled redundancy estimates doesn't inherently control for summary length. We therefore chose to report redundancy scores using averaging as we also qualitatively found them to be more useful and characteristic, especially for datasets such as **AMI** and the Scientific datasets as max pooling was overly aggressive. While the nuances of the specific ROUGE variant did not significantly impact trends in redundancy scores, we chose to report the ROUGE-L scores in the main paper as we (highly subjectively) found the values to be most interpretable/consistent with values we would have assigned.

A.5 Semantic Coherence

We evaluate for semantic coherence between successive pairs of sentences, exploiting the auxiliary training objective of BERT beyond its masked language modeling objective. In particular, we were especially interested in this given that many systems are designed with explicit handling of sentence boundaries (e.g. more extractive systems first rank extractive sentences and then order a thresholded subset) and datasets such as **CNN-DM**, which are artificially concatenated, may not be inherently coherent across sentence-boundaries.

Table 6: Alternative methods for estimating abstractivity. Results in the main paper are for $\mathbf{ABS}_1$.

Our observations regarding the measure of coherence provided by BERT's next-sentence predictions seem to contradict existing findings. In particular, Liu et al. (2019) introduce RoBERTa as a direct followup study to BERT and find that the next-sentence prediction objective is not an effective pretraining objective for improving representations for natural language understanding; Yang et al. (2019) also provide similar evidence. However, our findings do not contest these conclusions but instead suggest that, nonetheless, BERT is a strong next-sentence predictor and that these predictions are still useful for measuring coherence across sentences. While we considered word or subword measures of coherence, we did not consider alternative pretrained models that are pretrained on other objectives related to inter-sentence coherence such as ALBERT (Lan et al., 2020). Given the findings of Lan et al. (2020, §4.6), it seems likely that the sentence order prediction task they use may be more effective for measuring semantic coherence. Concurrent work by Prabhumoye et al. (2020) also substantiates the usefulness of BERT-based next-sentence prediction for measuring coherence and ranking sentences orders.

That said, semantic coherence could also be evaluated using (neural) language models, especially in light of results suggest they may be consistent with human judgments regarding grammaticality and acceptability (Chowdhury and Zamparelli, 2018; Warstadt et al., 2019). We did consider this and found language modeling scores (e.g. surprisal) assigned via a pretrained high-quality causal language model (GPT-2) to be inconsistent with our human judgments. We believe language modeling scores in this sense are likely highly sensitive to the domain (and even within-domain effects, e.g. lexical variation for **XSum** which is fairly limited given all articles are sourced from the BBC whereas for **Newsroom** the variation is greater given the heterogeneous group of publishers with more diversified writing styles).

B Reproducibility Details

We provide precise and comprehensive details discussing all data, preprocessing and modelling decisions. All code will be made publicly available as noted in the main paper.

B.1 Dataset Sources

We use the versions of **GW** and **CNN-DM** dataset released by Gehrmann et al. (2018).[14] Sentence boundary tokens inserted by Gehrmann et al. (2018) to improve summarization quality were removed to ensure fair comparison in our work. An important distinction in the use of the **CNN-DM** dataset for modeling is whether the entity-anonymized or non-anonymized version was used. This copy is non-anonymized and it is important to consider the stability of our metrics under this anonymization. We used the released version of the **NYT** dataset directly as it was released via LDC.[15]

Table 7: Alternative methods for estimating redundancy. Results in main paper are equivalent to those in the row corresponding to mean and ROUGE-L.

We use the released version of the **TL;DR** dataset provided by the authors of Völske et al. (2017).[16]
We use a version of the **NWS** dataset that was released via private communication with the authors of Grusky et al. (2018). We have verified with the authors that the data can be requested with the platform they released in their original work.[17]
For all remaining datasets, we use the version released by Jung et al. (2019).[18] All of our conventions in using these five datasets follow their work.

B.2 Data Preprocessing

All datasets were first filtered to remove examples where either the document or summary was empty. We found only examples in **CNN-DM** failed this criterion and this constituted less than $0.1\% \left(\frac{114}{287227}\right)$ of the dataset.

All results were reported then on the standard training set if we were aware of a standard split used consistently in the summarization system literature. Splits in the case of datasets sourced from the work of Jung et al. (2019) followed their work. In all cases, the training set was at least 80% of the full data collection, so we expect results to generalize to the portions of the collection that were not considered assuming splits were constructed by sampling uniformly at random (we did not verify this).

Sentence-level tokenization was performed using `NLTK` (Loper and Bird, 2002). Word-level tokenization was performed using `SpaCy` (Honnibal and Montani, 2017).

B.3 Topic Similarity

We lowercase all terms, remove stopwords using the list specified in `NLTK` (Loper and Bird, 2002), and lemmatize using `SpaCy` (Honnibal and Montani, 2017). We only retain words tagged with a POS category in {*NOUN, ADJ, VERB, ADV*} by the `SpaCy` POS tagger. We use LDA (Blei et al., 2003) to learn all topic models and rely on the implementation in `Gensim` (Řehůřek and Sojka, 2010) based on specification of Hoffman et al. (2010). All hyperparameters are set as default and we discussed the number of topics k and training corpus $\mathcal{T}$ in §A.2 with the results in the main paper using $k = 20$ and $\mathcal{T} = \mathcal{D}$ where $\mathcal{T}$ is truncated to be at most 20000 documents. We compute the Jensen-Shannon distance using `SciPy` (Virtanen et al., 2020).

B.4 Abstractivity

Fragments (Grusky et al., 2018) were computed using the scripts released in that work for the purposes of estimating abstractivity. In the case of the **NWS** dataset, the authors already provide fragment-related scores which we use without recomputing these values.

B.5 Redundancy

We make use of the native Python reimplementation of ROUGE (Lin, 2004), `easy-rouge`.[19] All scores reported in the main paper use ROUGE-L and use the computed F-measure score.

B.6 Semantic Coherence

We compute semantic coherence by predicting the probability of a sentence conditional on the preceding sentence using BERT. BERT was pretrained with exactly this objective (beyond its masked language modeling objective) and we use the released model as-is with no further fine-tuning. We use the `bert-base-uncased` model along with the associated tokenizer that was implemented in `PyTorch` (Paszke et al., 2017) by HuggingFace in the `transformers` repository.[20]

B.7 Efficiency

All metrics reported in the main paper can be computed over all datasets in less than 10 ten hours on a single CPU. The only model with a nontrivial number of parameters used in this work is the `bert-base-uncased` models we use in measuring semantic coherence. We refer readers to Devlin et al. (2019) for more details and to the HuggingFace implementation we reference previously.

C Detecting Low-Quality Examples

In the main paper, we briefly discuss how we discovered that several of our metrics can serve the dual purpose of detecting generally low quality examples for example that achieve extreme scores. Figures 1 through 9 are several examples we found to be representative of the general structure of low quality examples for a given metric. In some cases, the trends are highly dataset-specific whereas in others they are more general. To facilitate reproducibility efforts, we provide all examples IDs we studied for each (dataset, metric) in Table 8.

Original Text (truncated): Let us, in the beginning, give a word of cordial praise to the American publishers of these splendid volumes. The undertaking, in the first place, was an intellectual compliment to the country. It was based on the faith that there is in this country enough of philosophy and scholarship to justify a new and complete edition of . . .

Summary: Let us, in the beginning, give a word of cordial praise to the American publishers of these splendid volumes. The undertaking, in the first place, was an intellectual compliment to the country.

Detector: Extremely Low Abstraction

Figure 1: **Dataset: NWS**. This summary simply is the lede and we do not find it to be a useful summary for readers not familiar with the full context of the article. We hypothesize that such a summary may have been useful for members of a newsroom communicating information about the article to the other (given their intimate familiarity with the article) but this likely is inappropriate as a summary in most settings.

D Mutual Information Bounds

The *entropy* of a random variable X is defined as:

$$H(X) \triangleq -\sum_{x} p(x) \log_2 p(x)$$

Original Text (truncated): A FULL-SERVICE hotel and conference center is to go up in the Lafayette Yard area of Trenton, giving the city a hotel for the first time since the 1980's and bringing to an end its unenviable distinction as the only state capital without lodging for visitors . . .

Summary: Acquest

Detector: Extremely Low Abstraction

Figure 2: **Dataset: NYT**. This summary simply conveys no useful information to someone who has not also read the reference document and simply is a word copied from the source document. It appears to be a label rather than a summary.

Original Text (truncated): a lógica é o estudo dos princípios e critéiros de inferências e demonstrações válidas. um sistema lógico é composto por três partes: a sintaxe (ou notação), . . .

Summary (truncated): logic is the science of correct inferences and a logical system is a tool to prove assertions in a certain logic in a correct way . . .

Detector: Extremely High Abstraction

Figure 3: **Dataset: PeerRead**. This summary simply is not in the same language and hence achieves a very high abstractivity.

Table 8: Exhaustive list of example IDs we studied in the evaluation described in Section 6 of the main paper. $\uparrow$ indicates the examples are sampled from the top 10% for a given metric, $\downarrow$ indicates the examples are sampled from the bottom 10% for a given metric. Since **AMI** has 97 summaries (which is less than 100), it is impossible to select 10 unique examples from either the top or bottom 10% for a given metric. Therefore, we simply consider the 9 examples within the top or bottom 10%.

Summary: David Moyes has returned to former club Manchester United to strengthen his Sunderland squad after agreeing a fee for Paddy McNair and Donald Love.

Detector: Extremely Low Compression

Figure 6: **Dataset: NWS**. This summary has a negative compression score and, in this case, this seems to indicate the summaries and documents were extracted inaccurately using the scraper of Grusky et al. (2018).

Original Text: An article yesterday about plans by members of the House Intelligence Committee to visit Libya misidentified the member of Congress who headed a delegation to that country last month. He was Curt Weldon, Republican of Pennsylvania, not Tom Lantos, Democrat of California.

Summary: Six members of House Intelligence Committee are scheduled to meet in Libya with Col Muammar el-Qaddafi and other top Libyan officials, in second meeting between American Congressional delegation and Qaddafi since Libya agreed to dismantle its chemical and biological weapons program; members of House panel hope to use meeting to gauge accuracy of earlier American intelligence about Libya (M)

Detector: Extremely Low Compression

Figure 7: **Dataset: NYT**. Similar to the previous example, this summary has a negative compression score and, in this case, this seems to indicate the summaries and documents were created/aligned incorrectly in Sandhaus (2008).

Original Text (truncated): Brodie (the dog) was neglected, and ended up with serious anger and health issues concerning his skin and allergies. My boyfriend adopted him …

Summary: Onions.

Detector: Extremely High Compression

Figure 8: **Dataset: TL;DR**. We observe this trend quite frequently in **TL;DR**. Specifically, since authors on the social discussion platform Reddit choose to provide these summaries at their discretion, we often find the “summaries” are attention-grabbing and serve a starkly different rhetorical purpose from how summaries are generally conceived.

Original Text (truncated): these are external links and will open in a new window1908 - king carlos and eldest son assassinated in lisbon. second son manuel becomes king. 1910 - king manuel ii abdicates amid revolution …

Summary: a chronology of key events :

Detector: Extremely High Compression

Figure 9: **Dataset: XSum**. We observe this trend quite frequently in **XSum**. For articles that are essentially timelines or other types of chronologies discussing historic events diachronically (which forms a small but distinctive section of the writing style of BBC from our analysis), the summary extracted to accompany it is generally this string or a slightly altered version. We argue this summary is fairly unhelpful (and is likely fairly uninteresting to test models on; simple rule-based filtering made be preferable to avoid overestimating performance on this dataset because of these examples).

The *mutual information* between random variables X and Y is defined as:

$$I(X;Y) \triangleq H(X) - H(X \mid Y)$$

The entropy measures the uncertainty in the probability mass/density function of a random variable. As such, the mutual information measures how much the entropy of X is reduced by (on average) due to the observation of Y.

In the main paper, we state the following inequality:

$$\underbrace{I(S;M)}_{\text{learned model}} \leq \underbrace{I(S;T)}_{\text{training data}} + \underbrace{I(S;P)}_{\text{pretraining}} + \underbrace{I(S;A)}_{\text{inductive bias}},$$

where I denotes the mutual information, S denotes understanding of the underlying summarization task and M denotes a model learned using summarization training data T, additional pretraining data P, and the model’s architecture A.

Intuitively, the claim is that the uncertainty about the summarization task that is reduced by the model (which is uniquely determined by its training data, pretraining data, and architecture) is at most what can be cumulatively reduced by the training data, pretraining data, and inductive biases encoded in the model’s architecture.

Our hypothesis is that $I(S;A)$ is small for learning-based models with minimal inductive biases, such as neural networks. Further, we hypothesize that while $I(S;P)$ is likely nontrivial for popular pretraining regimes, the dominant term on the right-hand side is likely $I(S;T)$. We do note that this second hypothesis may be false given the partial evidence of GPT-3 (Brown et al., 2020) and the successes it enjoys in few-shot learning due to pretraining at unprecedented scale. However, no evaluation is conducted on summarization data in that work.

Proof.

Abstract

Diverse data is crucial for training robust models, but crowdsourced text often lacks diversity as workers tend to write simple variations from prompts. We propose a general approach for guiding workers to write more diverse text by iteratively constraining their writing. We show how prior workflows are special cases of our approach, and present a way to apply the approach to dialog tasks such as intent classification and slot-filling. Using our method, we create more challenging versions of test sets from prior dialog datasets and find dramatic performance drops for standard models. Finally, we show that our approach is complementary to recent work on improving data diversity, and training on data collected with our approach leads to more robust models.

1 Introduction

Crowdsourcing is widely used to collect data, including cases where workers are writing new text, such as questions (Rajpurkar et al., 2016), dialog (Budzianowski et al., 2018), and captions (Russakovsky et al., 2015). To avoid repetition of short labels for images, von Ahn and Dabbish (2004) proposed using a taboo list, preventing workers from writing labels that previous workers had written. This idea has since been applied to emotion annotation (Pearl and Steyvers, 2010) and word association (Vickrey et al., 2008; Lafourcade and Joubert, 2012). However, in all of these cases the constraint is that there cannot be an exact match with another label. This limits the approach to tasks where workers write a single word or a short phrase. Meanwhile, recent work on dialog has found that crowdsourced data can have limited diversity (Jiang et al., 2017; Kang et al., 2018; Larson et al., 2019a). This limited diversity has dramatic consequences, as models trained on such data may not generalize well to unseen or uncommon inputs.

We present a generalization of the taboo list idea that can be applied to longer text like sentences. First, rather than features in the taboo list being complete labels, we allow them to be anything, e.g., for intent classification, each feature in the list is a single word that the worker cannot use in their new utterance. To create the taboo list, we propose using a simple model to find over-represented features in the data collected so far. Second, rather than having a 1-1 mapping of taboo lists to examples we allow any mapping, e.g., for intent classification we have a taboo list for each intent. To show how this idea improves diversity for longer text, we apply it to crowdsourcing paraphrases for two standard dialog tasks: intent classification and slot-filling.

We evaluate our approach in two ways. First, we generate new test sets for several standard intent classification and slot-filling dialog datasets. We find that results on our new test sets are dramatically lower than on the standard test sets, indicating these standard datasets do not provide data of sufficient diversity to train robust models. Second, we compare our approach to another recent effort to improve diversity in dialog data (Larson et al., 2019a). We collect data with both approaches, a baseline, and a mixture of all three, then evaluate models on all combinations of training and test sets. The mixed approach performs best, indicating that the two approaches complement each other by encouraging different types of diversity.

Simply collecting enormous datasets may be a way to develop robust models, but it is certainly not sample efficient. Without any guidance, workers will mainly write examples that are in the head of the distribution of expressions, only slowly filling in the long tail (if at all). This work provides a method to encourage crowd workers to cover the long tail by using constraints to promote diversity. Our results show that by collecting more diverse data, we can produce more robust and therefore useful models.

2 Related Work

Crowdsourcing Dialog Data: Data for most recent task-oriented dialog datasets (Coucke et al., 2018; Gupta et al., 2018; Liu et al., 2019; Larson et al., 2019b), and custom dialog agents (Han et al., 2013; Iyer et al., 2017; Campagna et al., 2017; Ravichander et al., 2017; Shah et al., 2018) has been written by crowd workers via paraphrasing. Recent work has shown that diverse training data is important for robust dialog systems (Kang et al., 2018) and that a range of factors impact the diversity of utterances (Wang et al., 2012; Jiang et al., 2017). There has been some work on improving diversity using outlier detection (Larson et al., 2019a), and our idea is orthogonal to this approach.

Taboo Lists: von Ahn and Dabbish (2004)'s ESP game introduced the taboo list idea that we extend. In their game, a pair of players label an image with a single word up to 13 characters long. If they write the same label, it becomes a label for the image and is added to a taboo list for future players looking at that image. Of the papers in the ACL Anthology that cite their work, 38 cite the general idea of a game-with-a-purpose, but do not use the taboo idea; 25 cite the dataset released with the paper; two have the paper in the references but not in the main text; three use the taboo idea in new games. Two of the new games use static taboo lists defined by the researchers (Pearl and Steyvers, 2010; Vickrey et al., 2008), while the third uses the ESP game approach, but applies it to a new task (Lafourcade and Joubert, 2012). Being based on exact matching limits the range of tasks the taboo idea can apply to. Our work overcomes this limitation. Concurrent work by Yaghoub-Zadeh-Fard et al. (2020) also uses taboo lists to encourage diversity in paraphrases, but they use simple frequency-based taboo word selection, and do not apply their approach to intent classification and slot-filling data.

Adversarial Methods: Our work is related to generation of adversarial examples. Recent work has shown that inserting text can confuse question answering models (Jia and Liang, 2017; Wallace et al., 2019), as can one-word changes to sentences that require world knowledge (Glockner et al., 2018), and changing syntax can confuse pretrained models (Iyyer et al., 2018). The methodology of our first experiment is similar to this work, as we show that models trained on existing crowdsourced datasets perform poorly on the more diverse test sets that we collect.

3 Taboo Data Collection

We propose a general iterative algorithm for data collection that encourages diversity. By introducing constraints, we can force writers to go beyond the most obvious response to a prompt. This increases the diversity of data, which is crucial for the creation of robust models. The general idea works as follows:

- Start with a set of prompts and an empty list of taboo features for each prompt.
- Collect new crowdsourced responses for each prompt while telling workers not to use features from the taboo list for that prompt.
- Identify new taboo features for each prompt.
- Stop or return to the second step above.

This algorithm can be varied in four key ways:

1. The type of prompt.
2. The type of features we make taboo.
3. The method of mining taboo features.
4. The mapping from taboo features to prompts.

Within this framework, the ESP game involves (1) prompts that are images, (2) taboo features that are complete labels assigned to images, (3) making all labels assigned to a prompt taboo features, and (4) having a separate taboo list for each prompt. However, our algorithm is more general than this, enabling use across a range of other tasks with suitable choices of these four properties. For example: the prompts could be text, tables, or audio; the features could be words, longer n-grams, parse structures, or named entity types; the mining method could be a statistical model, rules, or done by other workers; and the mapping of features to prompts could be many-to-one, one-to-many, or many-to-many.

3.1 Application to Dialog Tasks

We consider two dialog tasks: intent classification and slot-filling. In both cases, we have (1) either example utterances or scenarios as prompts, (2) words as taboo features, (3) taboo words identified using a model, and (4) a set of taboo words for each dialog intent or slot type. For intent classification, (3) is achieved by training a linear SVM with a bag-of-words representation on all of the data. For each intent label we take the highest weighted words over a certain frequency (5 in our experiments) in the SVM model and make them taboo words. The intuition for this approach is that the SVM identifies tokens that are over-represented within a label set and so may lead models to learn

Taboo	Paraphrases of *What is the capital of Florida?*
—	*what city is the state capital of florida* *what is florida's capital*
florida	*what is the capital of FL* *what is the capital of the sunshine state*
capital	*what is florida's statehouse city* *where is the seat of government in florida*
what	*i would like to know the capital of florida* *tell me the name of florida's capital*

Table 1: Crowdsourced paraphrases with variation in the taboo features workers could not use.

only surface cues. Similarly, for slot-filling, (3) is achieved by training a CRF with token features on all of the data. For each slot we use tokens with high weights that are from the context (not the slot itself) as taboo words. In the slot-filling case, we restrict to context words because slot diversity can be introduced by substituting values from a list.

As a motivating example of how this can encourage diversity, consider the crowdsourced paraphrases in Table 1. In all cases, workers received the same prompt, but in the first section they had no constraints and in the other three sections they were not permitted to use a particular taboo word. All of the paraphrases are accurate, but the type of changes depends heavily on the taboo word. Without a taboo word, paraphrases are very similar to the prompt. For "florida", crowd workers used real-world knowledge of nicknames and acronyms to refer to the state, but kept the rest of the sentence the same. For "capital", they again used world knowledge, but also started modifying the rest of the sentence. For "what", they were forced to make substantial changes to the sentence. More examples can be found in Appendix A.

4 Experiments

To demonstrate our approach we consider two experiments. First, we show that existing datasets from prior work are brittle, with training sets that are not sufficiently diverse to train robust models. Second, we show how our approach can be used to collect more robust training data from scratch.

4.1 Challenge Test Versions of Current Datasets

As discussed in Section 2, most existing datasets were crowdsourced with a fixed set of prompts and no taboo constraints, which leads to limited diversity in the data. As a result, models trained on the data may be brittle, failing when tested on new data in the same domain. To test this, we use our taboo approach to create new test sets. If the original training set is diverse then models will achieve high performance on the new test set. We also measure the vocabulary size of each new test set, hypothesizing that as the number of taboo words increases, so does the vocabulary size.

It would be very expensive to collect new versions of every intent and slot type in every dataset, so we randomly sample a subset for our experiments. We crowdsourced the paraphrases using Amazon Mechanical Turk. Paraphrases were checked by hand to ensure they were semantically valid. We collected 3 paraphrases per prompt. We consider ATIS (Hemphill et al., 1990), NewTable (Jaech et al., 2016), Snips (Coucke et al., 2018), Facebook (Gupta et al., 2018), Liu et al. (2019), and Larson et al. (2019b). These cover restaurant and flight booking, home media control, navigation, and general knowledge queries. All datasets are in the English language. More details can be found in Appendices B and C.

4.2 Robust Data Collection for New Datasets

Our second experiment involves bootstrapping datasets from scratch. We compare four data collection approaches:

1) **`same`**: static prompts, the standard approach.
2) **`unique`**: Larson et al. (2019a)'s approach. They collect data in several rounds, with new prompts chosen using outlier detection to get samples from underrepresented regions in the space of utterances.
3) **`taboo`**: our proposed approach from Section 3.
4) **`mixed`**: a random sample from each approach, with the same amount of total data.

For intent classification, we use the data from Larson et al. (2019a) for `same` and `unique`. For slot-filling we considered three domains, flight booking, money transfer, and restaurant booking, but display results for the first two in Appendix F due to lack of space (the trends for all three were very similar).

We conducted three rounds of data collection using each method on each dataset. The first round was shared across all three methods. The second and third rounds were collected using either the same prompt (`same`) or new prompts (`unique` and `taboo`). Crowd workers were asked to write five paraphrases for each prompt in intent classification and three for each prompt in slot-filling.

Following Larson et al. (2019a) and advice in Gorman and Bedrick (2019), we average results

Dataset	Original Test Example	Taboo Words	Paraphrase Written with Taboo Constraints
Facebook	*where is the closest back road exit* *how long will i'll be in traffic* *did black bear wash flood last night?*	station, where long, time icy, flooding	*find me the closest back road exit* *what is the period i'll be in traffic for* *did black bear wash overflow with water last night?*
Larson	*how much in taxes will i owe* *this charge is bs* *when should my tires be changed*	taxes, tax fraud, fraudulent tires, change	*how much do i owe uncle sam?* *this charge is a mistake.* *when do i need new shoes on my car?*
Snips	*play a sixties soundtrack* *weather in kaneville maryland* *play all things must pass.*	hear, play forecast, weather hear, play	*put on a sixties soundtrack* *atmospheric conditions showing for kaneville maryland* *i want to listen to all things must pass*

Table 2: Examples where BERT gets the original utterance right, but our paraphrase wrong. The paraphrases were crowdsourced using our *taboo* method, which requires crowd workers to avoid using certain words in their paraphrases. Note that taboo words are defined for each intent and so do not always occur in the prompt sentence.

# Taboo	ATIS	Snips	Larson	FB	Liu
0	88.2	96.9	93.7	77.4	93.4

6	283	299	352	281

(b) Slot-Filling Dataset Vocabulary Size

Table 4: Vocabulary sizes (number of token types) in each paraphrased dataset for a given number of taboo words. In almost all cases, the vocabulary size increases with the number of taboo words.

across 10 runs with different random train/test splits. In each case, the test data is drawn only from the second and third rounds of data collection to ensure there is no train-test data overlap across methods (since the first round data is shared).

4.3 Models

In both experiments, we use standard models: BERT (Devlin et al., 2019) for intent classification, and a Bi-LSTM for slot-filling. The Appendices show results using an SVM and FastText for intent classification, which showed the same trends as BERT, though more severe. More model details can be found in Appendix D.

5 Results

5.1 Challenge Versions of Current Test Sets

Tables 3a and 3b show the impact of collecting more diverse test cases using our approach. Performance consistently decreases as the number of taboo words increases from 0 to 4. Even with just two taboo words, the median performance drop for BERT is 9 points. In the worst case, ATIS, it drops 33.2 points. The shift is even more severe for FastText (results in Appendix E). Table 4 shows that the vocabulary size tends to increase as the number of taboo words increases. For instance, it increases from 946 to 1345 with 6 on the Larson data, further indicating that crowd workers generate more diverse text using our approach.

Table 2 shows examples where BERT was right on the original test set but wrong on our paraphrase. The new versions generally do not appear significantly different. There are a few exceptions, for instance: “uncle sam” is a more creative though still reasonable phrase that we would want our systems to handle; and “shoes” instead of “tires”, which seems unlikely to occur naturally. These stranger cases are relatively rare, but may be worth filtering out with a checking process in future work.

In general, these results indicate that current intent classification and slot-filling evaluation datasets are less than ideal insofar as they do not supply the diversity needed to train robust models. We posit that such datasets are also *too easy*

	Round 2		**Round 3**

due to this lack of diversity, and do not sufficiently test a model's ability to generalize. These observations are complementary to recent work (Béchet and Raymond, 2018; Niu and Penn, 2019; Larson et al., 2020) that found the ATIS dataset in particular to lack sufficient diversity to evaluate modern slot-filling models.

5.2 Robust Data Collection

Table 6 presents accuracy (top) and F_1 (bottom) for models trained and tested with different data collection methods. As expected, `mixed` is consistently the best approach. Ignoring `mixed`, the highest scores are on the diagonals: classifiers trained and tested on data collected using the same method perform the strongest. Looking at the off-diagonals, it seems that `taboo` and `unique` are introducing different types of diversity. Both methods see a drop in performance on data collected the other way, and both do well on `same`'s data. However, the drop tends to be larger for models trained on the `unique` data. This was particularly true for FastText (results in Appendix F), which lacks BERT's large-scale pretraining on external data.

Looking at the data, there are shifts similar to those visible in the examples in Table 1. As shown in Table 5, these included vocabulary changes such as (1) "dial" and "ring" replacing "call", (2) "cheques" replacing "checks" (a spelling substitution), and (3) "digit" instead of "number". They also included use of real-world and domain-specific knowledge, replacing a bank account's "routing number" with "aba digits", "rtn", and "the first set of numbers on the bottom of [a] check". While some of these substitutions might be uncommon in a deployed environment, we should nevertheless expect an intelligent system to be able to understand them. We also looked at the examples in the taboo set broken down by the number of taboo words. We find that the examples sometimes became more unusual as the number of taboo words increased, suggesting two might be enough to introduce diversity without becoming too odd. Finally, we observe that models trained on `taboo` data are robust to new test sets gathered using `taboo`, while `unique` is much less robust (see Appendix F).

6 Conclusion

This paper presents a novel way of guiding data collection away from over-represented areas in the sample space. We show how the approach is a generalization of prior work in crowdsourcing and present a new form of it for dialog data. In experiments on a range of datasets, we show that prior data collection approaches fail to capture diverse examples, leading to brittle models. Finally, we show our approach is complementary to other efforts to increase data diversity, producing higher quality datasets. Collecting data by combining the standard approach, outlier-based collection, and our taboo-based approach produces better training data that in turn leads to more robust models.

A More examples for Section 3

Table 7 displays more examples relevant to the Table 1 discussed in Section 3 of the main paper.

B Data Collection

All data was collected using crowdsourcing. We used the Amazon Mechanical Turk crowdsouring platform. Workers were presented with a prompt which asked them to paraphrase a question or a statement n times (n was 3 in all experiments except the "Robust Data Collection" for intent classification data, where n was 5). An example of a question in a prompt could be "what is my balance?", while a statement could be "tell me how much money I have". Workers were paid \$0.05 per paraphrase. We used prompts similar to those shown in Figure 1. For the data collected in the "Challenge Versions of Current Datasets" experiments, we sampled test samples from each dataset's test set, and asked crowd workers to paraphrase these samples. Taboo words were presented as comma-separated lists in prompts. We used a regular expression to prohibit workers from submitting paraphrases that contained taboo words. In the "Challenge Datasets"

Rephrase an original question or statement

Suppose you have an intelligent device such as Amazon Alexa, Apple Siri, or Google Assistant.

Given an original phrase, provide 5 different ways of saying the same phrase.

Original phrase: "how's the weather"

Scenario:

Determine the type of aircraft used on a flight from Cleveland to Dallas that leaves before noon.

Rephrase an original question or statement

Suppose you have an intelligent device such as Amazon Alexa, Apple Siri, or Google Assistant.

Given an original phrase, provide 5 different ways of saying the same phrase.

Original phrase: "what is my routing number"

Don't use the words "routing" or "number" in your responses.

Figure 1: Examples of data collection prompts for rephrase (top, from Larson et al. (2019b)) and scenario (middle, from ATIS) tasks. An example of a rephrase prompt used in the present work with taboo words is shown at bottom.

Taboo	Paraphrases of *What is the capital of Florida?*
-	*- what city is the state capital of florida* *- what is florida's capital* *- florida's capital is what* *- can you name the capital of florida*
florida	*- what is the capital of FL* *- what is the capital of the state that is located directly south of georgia* *- what is the capital of the state where miami is located* *- what is the capital of the sunshine state*
capital	*- what is florida's statehouse city* *- where is the state government of florida headquartered* *- where is the seat of government in florida* *- what city does the governor of florida live in*
what	*- i would like to know the capital of florida* *- can you tell me florida's capital* *- provide the name of the capital of florida* *- tell me the name of florida's capital*

Table 7: Crowdsourced paraphrases with variation in the taboo features workers could not use.

experiments, each round of data collection introduced 2 new taboo words (except the initial round). In the "Robust Data Collection" experiments, each round of data collection introduced 3 new taboo words for the intent classification experiments (except the initial round), and 2 taboo words for each slot (except the initial round) for the slot-filling experiments.

B.1 Preprocessing

All crowdsourced paraphrases were checked by hand to ensure they were semantically valid. Queries were tokenized on white space. For the slot-filling "Robust Data" experiments, crowd workers were asked to use default slot values in their paraphrases. We used large lists of replacement slot values to replace the default values, so that the slot-filling models would not memorize the default values.

C Datasets used in "Challenge Versions" experiments

This section provides more detail on the datasets investigated in the "Challenge Versions of Current Datasets" experiments.

Newtable: A slot-filling dataset from Jaech et al. (2016) meant for booking restaurants using a virtual assistant. For the "Challenge Versions" experiment, we sampled two slots (`people` and `place`) for the slot filling experiment. We sampled 50 queries to be used as seeds to be paraphrased by crowd workers. All sampled queries contained at least one slot (`people` or `place`).

Facebook: An intent classification and slot-filling dataset from Gupta et al. (2018), with intents related to interacting with a task-driven virtual assistant. For the "Challenge Versions" experiment, we sampled 10 intents for the intent classification experiment and two slots (`source` and `destination`) for the slot filling experiment. We sampled 30 queries from each sampled intent to be seeds for the intent classification experiment. We sampled 50 queries containing both `source` and `destination` slots to be seeds for the slot filling experiment.

Snips: An intent classification and slot-filling benchmark from Coucke et al. (2018). For the "Challenge Versions" experiment, we sampled all (seven) intents for the intent classification experiment and two slots (`entity` and `playlist`) from the dataset's `AddToPlaylist` intent. We sampled 50 queries from each intent to be used as crowdsourcing seed, and sampled 50 queries from the `AddToPlaylist` intent for the slot filling experiment (all these sampled contained at least one slot (either `entity` or `playlist`).

Larson: An intent classification benchmark with a wide variety of topic domains and a larg number of intents with limited training data per intent class

	Larson		Snips		ATIS		Facebook		Liu	
# Taboo	**FastText**	**BERT**	**FastText**	**BERT**	**FastText**	**BERT**	**FastText**	**BERT**	**FastText**	**BERT**
0	83.3	93.7	94.6	96.9	83.7	88.2	72.7	77.4	78.2	93.4
2	59.6	80.4	90.4	94.9	45.2	55.0	62.6	72.6	65.3	84.5
4	42.1	73.8	84.1	93.3	43.3	56.7	51.6	65.6	54.7	85.7
6	29.0	74.5	83.0	93.2	36.1	51.0	46.2	64.9	44.6	76.5

Table 8: Results of testing on paraphrased test sets using taboo paraphrases for the classifier datasets using FastText and BERT. Across almost all datasets and models there is a substantial drop in performance as the number of restricted words increases.

(Larson et al., 2019b). For the "Challenge Versions" experiment, we sampled 40 intents for the intent classification experiment. From each sampled intent, we sampled 10 queries to be used as seeds for crowdsourcing paraphrases.

ATIS: The ATIS corpus (Hemphill et al., 1990) has long been a benchmark for evaluating both slot-filling and intent classification models. We use the dataset split as used by Tur et al. (2010). Intents in ATIS are related to interacting with a flight booking virtual assistant. For the "Challenge Versions" experiment, we sampled six intents for the intent classification experiment and two slots (`to-city` and `from-city`) for the slot filling experiment. For the intent classification experiment, we sampled between 8 and 50 queries to serve as seeds to crowdsourcing paraphrase tasks for the intent classification experiment. For the slot filling experiment, we sampled 50 queries containing both `to-city` and `from-city` to serve as seed phrases for the crowdsourcing paraphrase task.

Liu: We use the dataset from (Liu et al., 2019) as an intent classification benchmark. Intents from this dataset are similar to the Facebook and Snips datasets. For the "Challenge Versions" experiment, we sampled 10 intents for the intent classification experiment. From each intent, we sampled 10 queries to be seeds for crowdsourcing paraphrase tasks.

C.1 A note on ATIS

The ATIS corpus has long been a benchmark for evaluating both slot-filling and intent classification models. While the ATIS dataset was generated in the early 1990s, and hence did not use any modern crowdsourcing platform like Amazon Mechanical Turk to generate data, the corpus was nonetheless collected using a *scenario*-driven data collection scheme using non-expert workers. The ATIS corpus saw human "subjects" recruited to generate natural language queries targeting an automated flight booking system. Subjects were given scenarios with goals (e.g. booking a flight with time or fare constraints). This is essentially the same as the methods used in crowdsourcing today, but with a small set of participants rather than the crowd. An example of such a scenario prompt from the ATIS data collection procedure is shown in Figure 1 (bottom).

C.2 Train-Test Splits for "Challenge Versions of Current Datasets"

For each dataset described above, we generate new test phrases with our taboo paraphrasing method using samples from each dataset's published test set as seed phrases to the crowdsourcing prompts. With the exception of the Liu dataset, all datasets have standard train-test splits: we randomly created an 85-15 train-test split for the Liu dataset.

D Computing and Model Details

The main contribution of our paper is not in model development, but in data collection. However, we discuss the relevant aspects of the models used in the experiments here. We used off-the-shelf BERT, SVM, and FastText models for the intent classification experiments. For BERT, we used the BERT large (uncased) model from `https://github.com/google-research/bert`; when using this model we fine tuned the model to each dataset. We used the sklearn's SVC classifier as our SVM; with the SVM we used bag-of-words feature representations. We used the version of FastText found here: `https://github.com/facebookresearch/fastText`. The slot-filling experiments used a bi-directional LSTM for the evaluation experiments, and a CRF (using token features) for the model to identify taboo words. The LSTM model was adapted from (Finegan-Dollak et al., 2018) and uses pre-trained GloVe word embeddings. The CRF was adapted from `https://sklearn-crfsuite.readthedocs.io/`. All model experiments were run on an Nvidia GPU (in the case

Model	Training	Test Set `same`	 `unique`	 `taboo`	 `mixed`
SVM Accuracy	`same`	98.3	77.4	58.9	77.9
	`unique`	97.8	**97.9**	58.5	85.0
	`taboo`	97.5	84.1	**94.9**	92.4
	`mixed`	**98.6**	97.8	94.8	**97.1**
FastText Accuracy	`same`	98.4	76.8	62.7	78.6
	`unique`	97.8	**98.1**	62.2	85.9
	`taboo`	97.6	81.6	94.3	90.8
	`mixed`	**98.6**	**98.1**	**94.8**	**97.2**
BERT Accuracy	`same`	**99.3**	83.2	83.6	88.6
	`unique`	98.7	98.4	80.9	92.7
	`taboo`	99.0	89.7	**97.6**	95.4
	`mixed`	99.0	**98.8**	**97.6**	**98.5**

Table 9: Classifier model accuracy when training and testing on data collected by each data collection method. Models not trained on the `taboo` data perform poorly on the `taboo` data, indicating that data collected by `taboo` is challenging.

of BERT and the bi-LSTM) or using in Intel i7 CPU (all other models).

As our paper does not introduce a new model, we do not compare average runtimes for each approach, nor do we compare number of parameters in each model, as each of the models we use in our experiments are well-established.

E FastText Results for "Challenge Versions" Experiments

Table 8 shows side-by-side comparison of FastText and BERT for the "Challenge Versions of Current Datasets" intent classification experiments. The performance drop for FastText is much more severe than BERT, falling to as low as 29.0 accuracy on the Larson dataset.

F Additional "Robust Data Collection" Results

Tables 9 and 10 show additional results (SVM and FastText) for the intent classification experiment and on additional datasets for the slot-filling experiment. Table 11 shows the performance of a BERT classifier when trained and tested on data collected using the same method. This experiment mimics the setup of the "Challenge Version" experiment. When trained and tested on data collected using the `taboo` method, BERT stays robust even when the number of taboo words for the test set is increased. However the performance of the classifier trained and tested on the data collected using the `same` and `unique` methods suffers when the number of taboo words for the test set is increased.

Domain	Training	Test Set `same`	 `unique`	 `taboo`	 `mixed`
flights F_1	`same`	96.4	83.3	67.4	83.2
	`unique`	94.7	92.2	68.4	86.0
	`taboo`	94.7	86.1	82.7	88.2
	`mixed`	**98.0**	**94.1**	**85.7**	**93.0**
transfer F_1	`same`	97.9	91.8	70.8	87.8
	`unique`	97.7	95.7	70.2	88.9
	`taboo`	96.0	90.2	83.4	90.2
	`mixed`	**98.6**	**96.6**	**84.8**	**93.8**
restaurant F_1	`same`	90.9	75.8	77.0	81.0
	`unique`	90.1	80.4	75.0	81.7
	`taboo`	90.1	77.2	84.9	84.0
	`mixed`	**95.8**	**90.9**	**90.6**	**92.3**

Table 10: Slot-filling F_1 performance on various slot-filling datasets. The performance of models trained on data collected using the `same` and `unique` methods drop substantially when tested on data collected using the `taboo` method. Models trained on the `mixed` datasets produce the best performance overall.

# Taboo	`same`	`unique`	`taboo`
0	98.1	98.6	97.6
2	79.0	82.1	97.3
4	80.1	80.5	96.4
6	78.5	76.7	96.1

Table 11: Classifier model accuracy when the training and testing data are collected using the same method, keeping seed prompts constant, but with a varying number of taboo words used for the testing set. The classifier used here is BERT. We observe that `taboo` yields a model that is robust to the taboo data collection method that was able to "break" the models trained on the published datasets in the "Challenge Versions" experiments in Section 5.1. The `unique` and `same` approaches are much less robust.

F.1 Dataset Statistics for "Robust Data Collection" Experiments

The sizes of the datasets used in the "Robust Data Collection" Experiments are presented here. For intent classification, `same` had 6091 samples, `unique` had 5999 samples, and `taboo` had 6097 samples. For the slot filling experiments, `flights-same` had 639 samples, `flights-unique` had 648 samples, and `flights-taboo` had 586 samples. The `transfer-same` had 601, `transfer-unique` had 618, and `transfer-taboo` had 529 samples. The `restaurant-same` had 632, `restaurant-unique` had 629, and `restaurant-taboo` had 649 samples.

Conversational Semantic Parsing for Dialog State Tracking

Abstract

We consider a new perspective on dialog state tracking (DST), the task of estimating a user's goal through the course of a dialog. By formulating DST as a semantic parsing task over hierarchical representations, we can incorporate semantic compositionality, cross-domain knowledge sharing and co-reference. We present TreeDST, a dataset of 27k conversations annotated with tree-structured dialog states and system acts.[1] We describe an encoder-decoder framework for DST with hierarchical representations, which leads to 20% improvement over state-of-the-art DST approaches that operate on a flat meaning space of slot-value pairs.

1 Introduction

Task-based dialog systems, for example digital personal assistants, provide a linguistic user interface for all kinds of applications: from searching a database, booking a hotel, checking the weather to sending a text message. In order to understand the user, the system must be able to both parse the meaning of an utterance and relate it to the context of the conversation so far. While lacking the richness of a conversation between two humans, the dynamics of human-machine interaction can still be complex: the user may change their mind, correct a misunderstanding or refer back to previously-mentioned information.

Language understanding for task-based dialog is often termed "dialog state tracking" (DST) (Williams et al., 2016), the mental model being that the intent of the user is a partially-observed state that must be re-estimated at every turn given new information. The dialog state is typically modelled as a set of independent slots, and a standard DST system will maintain a distribution over values for each slot. In contrast, language understanding for other NLP applications is often formulated as semantic parsing, which is the task of converting a single-turn utterance to a graph-structured meaning representation. Such meaning representations include logical forms, database queries and other programming languages.

These two perspectives on language understanding—DST and semantic parsing—have complementary strengths and weaknesses. DST targets a fuller range of conversational dynamics but typically uses a simple and limiting meaning representation. Semantic parsing embraces a *compositional* view of meaning. By basing meaning on a space of combinable, reusable parts, compositionality can make the NLU problem space more tractable (repeated concepts must only be learned once) and more expressive (it becomes possible to represent nested intents). At the same time, most semantic parsing research treats a sentence as an isolated observation, detached from conversational context.

This work unifies the two perspectives by reformulating DST as *conversational semantic parsing*. As in DST, the task is to track a user's goal as it accumulates over the course of a conversation. The goal is represented using a structured formalism like those used in semantic parsing. Specifically, we adopt a hierarchical representation which captures domains, verbs, operators and slots within a rooted graph grounded to an ontology. The structured dialog state is capable of tracking nested intents and representing compositions in a single graph (Turn 5 Table 1). The formalism also naturally supports cross-domain slot sharing and cross-turn co-reference through incorporating the shared slots or the references as sub-graphs in the representation (Turn 3 Table 1).

Using a reverse annotation approach inspired

Table 1: An example conversation in TreeDST with annotations. User and system utterances are marked in red and blue respectively. We use *dot* to represent tree edges and increased indentation levels to reveal multiple children attached to the same parent node. A side-by-side comparison between a dotted tree and its full drawing can be found in Appendix A.

by Shah et al. (2018) and Rastogi et al. (2019), we have collected a large dataset of task-oriented dialogs annotated with hierarchical meaning representations. Each dialog was generated through a two-step process. First, a generative dialog simulator produces a meaningful conversational flow and a template-based utterance for each turn in the conversation. Then the utterances are paraphrased by human annotators to render more realistic and natural conversations. The resulting dataset, which we call TreeDST, covers 27k conversations across 10 domains. Conversations in TreeDST are non-linear: they contain glitches which represent system failures and uncooperative user behaviors such as under- and over-specifying slot information. There are also use cases not addressed in existing slot-filling datasets, including compositional intents and multi-intent utterances.

The second contribution of this work is a conversational semantic parser that tackles DST as a graph generation problem. At each turn, the model encodes the current user utterance and representations of dialog history, based upon which the decoder generates the updated dialog state with a mixture of generation and copy mechanism. In order to track practical conversations with intent switching and resumption (Lee and Stent, 2016; El Asri et al., 2017), we adopt a stack (Rudnicky and Xu, 1999) to represent multiple tasks in the dialog history, and a parent-pointer decoder to speed up decoding. We conducted controlled experiments to factor out the impact of hierarchical representations from model architectures. Overall our approach leads to 20% improvement over state-of-the-art DST approaches that operate on a flat meaning space.

2 Related Work

Modeling Traditional DST models apply discriminative classifiers over the space of slot-value combinations (Crook and Lemon, 2010; Henderson et al., 2014b; Williams et al., 2016). These models require feature extraction from user utterances based on manually constructed semantic dictionaries, making them vulnerable to language variations. Neural classification models (Mrkšić et al., 2017; Mrkšić and Vulić, 2018) alleviate the problem by learning distributed representations of user utterances. However, they still lack scalability to large unbounded output space (Xu and Hu, 2018; Lee et al., 2019) and structured representations. To address the limitations, some recent work treats slot filling as a sequence generation task (Ren et al., 2019; Wu et al., 2019).

On the other hand, single-turn semantic parsers have long used structured meaning representations to address compositionality (Liang et al., 2013; Banarescu et al., 2013; Kollar et al., 2018; Yu et al., 2018; Gupta et al., 2018). Solutions range from chart-based constituency parsers (Berant et al., 2013) to more recent neural sequence-to-sequence models (Jia and Liang, 2016). The general challenge of scaling semantic parsing to DST is that dialog state, as an accumulation of conversation history, requires expensive context-dependent annotation. It is also unclear how utterance semantics can be aggregated and maintained in a structured way. In this work we provide a solution to unify DST with semantic parsing.

Data Collection The most straightforward approach to building datasets for task-oriented dialog is to directly annotate human-system conversations (Williams et al., 2016). A limitation is that the approach requires a working system at hand, which causes a classic chicken-and-egg problem for improving user experience. The issue can be avoided with Wizard-of-Oz (WoZ) experiments to collect human-human conversations (El Asri et al., 2017; Budzianowski et al., 2018; Peskov et al., 2019; Byrne et al., 2019; Radlinski et al., 2019). However, dialog state annotation remains challenging and costly in WoZ, and the resulting distribution could be different from that of human-machine conversations (Budzianowski et al., 2018). One approach that avoids direct meaning annotation is to use a dialog simulator (Schatzmann et al., 2007; Li et al., 2016). Recently, Shah et al. (2018) and Rastogi et al. (2019) generate synthetic conversations which are subsequently paraphrased by crowdsourcing. This approach has been proven to provide a better coverage while reducing the error and cost of dialog state annotation (Rastogi et al., 2019). We adopt a similar approach in our work, but focusing on a structured meaning space.

3 Setup

3.1 Problem Statement

We use the following notions throughout the paper. A conversation X has representation Y grounded to an ontology $\mathcal{K}$: at turn t, every user utterance x_t^u is annotated with a *user dialog state* y_t^u, which represents an accumulated user goal up to the time step t. Meanwhile, every system utterance x_t^s is annotated with a *system dialog act* y_t^s, which represents the system action in response to y_t^u. Both y_t^u and y_t^s adopt the same structured semantic formalism to encourage knowledge sharing between the user and the system. From the perspective of the system, y_t^s is observed (the system knows what it has just said) and y_t^u must be inferred from the user's utterance. For the continuation of an existing goal, the old dialog state will keep being updated; however, when the user proposes a completely new goal during the conversation, a new dialog state will overwrite the old one. To track goal switching and resumption, a stack is used to store non-accumulable dialog states in the entire conversation history (in both data simulation and dialog state tracking).

There are two missions of this work: 1) building a conversational dataset with structured annotations that can effectively represent the joint distribution $P(X, Y)$; and 2) building a dialog state tracker which estimates the conditional distribution of every dialog state given the current user input and dialog history $P(y_t^u | x_t^u, X_{<t}, Y_{<t})$.

3.2 Representation

We adopt a hierarchical and recursive semantic representation for user dialog states and system dialog acts. Every meaning is rooted at either a `user` or `system` node to distinguish between the two classes. Non-terminals of the representation include `domains`, user `verbs`, system `actions`, `slots`, and `operators`. A `domain` is a group of activities such as creation and deletion of calendar events. A user `verb` represents the predicate of the user intent sharable across domains, such as `create`, `delete`, `update`, and `find`. A system `action` represents a type of system dialog act in response to a user intent. For example, the system could `prompt` for a slot value; `inform` the user about the information they asked for; and `confirm` if an intent or slot is interpreted correctly. Nested properties (e.g., time range) are represented as a hierarchy of `slot-operator-argument` triples, where the `argument` can be either a sub-slot, a terminal `value` node or a special `reference` node. The `value` node accepts either a categorical label (e.g., day of week) or an open value (e.g., content of text message). The `reference` node allows a whole intent to be attached as a slot value, enabling the construction of cross-domain use cases (e.g., Turn 5 of Table 1). Meanwhile, co-reference to single slots is directly achieved by subtree copying (e.g., Turn 3 of Table 1). Finally, conjunction is implicitly supported by allowing a set of arguments to be attached to the same slot. Overall, the representation presented above focuses on ungrounded utterance semantics to decouple understanding from execution. By incorporating domain-specific logic, the representation can be mapped to executable programs at a later stage.

4 Data Elicitation

4.1 Overview

We sidestep the need for collecting real human-system conversations and annotating them with complex semantics by adopting a reverse data elicitation approach (Shah et al., 2018; Rastogi et al., 2019). We model the generative process $P(X, Y) = P(Y)P(X|Y)$, where representations of conversation flows (Y) are firstly rendered by a dialog simulator, and then realised into natural dialog (X) by annotators. Two central aspects which directly impact the quality of the resulting data are: (1) the dialog simulator which controls the coverage and naturalness of the conversations; (2) the annotation instructions and quality control mechanism that ensures X and Y are semantically aligned after annotation.

4.2 Simulator

The most common approach of simulating a conversation flow is agenda-based (Schatzmann et al., 2007; Li et al., 2016; Shah et al., 2018; Rastogi et al., 2019). At the beginning of this approach, a new goal is defined in the form of slot-value pairs describing user's requests and constraints; and an agenda is constructed by decomposing the user goal into a sequence of user actions. Although the approach ensures the user behaves in a goal-oriented manner, it constrains the output space with *pre-defined* agendas, which is hard to craft for complex user goals (Shi et al., 2019).

Arguably, a more natural solution to dialog simulation for complex output space is a fully generative method. It complies with the behavior that a real user may only have an initial goal at the start of conversation, while the final dialog state cannot be foreseen in advance. The whole conversation can be defined generatively as follows:

$$P(Y) = P(y_0^u)\sum_{t=0}^{n} P(y_t^s|y_t^u)\sum_{t=1}^{n} P(y_t^u|y_{<t}^s, y_{<t}^u) \tag{1}$$

where Y is the conversation flow, y_t^u is the user dialog state at turn t and y_t^s the system dialog act. The decomposed probability of $P(Y)$ captures the functional space of dialog state transitions with three components: 1) a module generating the initial user goal $P(y_0^u)$, 2) a module generating system act $P(y_t^s|y_t^u)$, and 3) a module for user state update based on the dialog history $P(y_t^u|y_{<t}^s, y_{<t}^u)$. The conversation terminates at time step n which must be a finishing state (system success or failure).

Initial intent module $P(y_0^u)$ The dialog state y_0^u representing the initial user goal is generated with a probabilistic tree substitution grammar (Cohn et al., 2010, PTSG) based on our semantic formalism. Non-terminal symbols in the PTSG can rewrite entire tree fragments to encode non-local context such as hierarchical and co-occurring slot combinations. As explained in the example below, the algorithm generates dialog states from top down by recursively substituting non-terminals (marked in green) with subtrees.

```
$createEvent  →user.calendarEvent.create
                        .$newEvent
```

```
$newEvent  →object.equals
                  .$attendees
                  .$location
```

This example generates a calendar event creation intent that contains two slots of attendees and location. In a statistical approach, the sampling probability of each production rule could be learned from dialog data. For the purpose of bootstrapping a new model, any prior distribution can be applied.

Response module $P(y_t^s|y_t^u)$ At turn t, the system act y_t^s is generated based on the current user dialog state y_t^u and domain-specific logic. We represent the probability $P(y_t^s|y_t^u)$ with a probabilistic tree transformation grammar, which captures how an output tree (y_t^s) is generated from the input (y_t^u) through a mixture of generation and a copy mechanism. As shown in the example below, every production rule in the grammar is in the form $A \rightarrow B$, where A is an input *pattern* that could contain both observed nodes and unobserved nodes (marked in red), and B is an output *pattern* to generate.

```
          user.calendarEvent.create
               .object.equals
                    .-dateTimeRange
                          ↓
        system.prompt.calendarEvent
             .create.object.equals
                     .dateTimeRange
```

Given a user dialog state, the simulator *looks up* production rules which result in a match of pattern A, and then derives a system act based on the pattern B. Like in PTSG, probabilities of transformations can be either learned from data or specified a priori.

State update module $P(y^u_t | y^s_{<t}, y^u_{<t})$ The generation of the updated dialog state is dependent on the dialog history. While the full space of y^u_t is unbounded, we focus on simulating three common types of updates, where a user introduces a new goal, continues with the previous goal y^u_{t-1}, or resumes an earlier unfinished goal (see Turn 2-4 of Table 1 for examples, respectively). To model dialog history, we introduce an *empty* stack when the conversation starts. A dialog state and the rendered system act are pushed onto the stack upon generation, dynamically updated during the conversation, and popped from the stack upon task completion. Therefore, the top of the stack always represents the most recent unfinished task $y^{top,u}_{t-1}$ and the corresponding system act $y^{top,s}_{t-1}$.

We consider the top elements of the stack as the effective dialog history and use it to generate the next dialog state y^u_t. The generation interface is modeled with a similar tree transformation grammar, but every production rule has two inputs in the form $A, B \rightarrow C$:

```
user.calendarEvent.create  system.prompt.calendarEvent
  .object.equals               .create.object.equals
    .-dateTimeRange              .dateTimeRange
                     ↓

         user.calendarEvent.create
             .object.equals
                    .$dateTimeRange
```

where A specifies a matching pattern of the user goal $y^{top,u}_{t-1}$, B is a matching pattern of the system act $y^{top,s}_{t-1}$, and C is an output pattern that represents how the updated dialog state is obtained through a mixture of grammar expansion (marked in green) and copy mechanism from either of the two sources (marked in yellow).

4.3 Annotation

Following Shah et al. (2018); Rastogi et al. (2019), every grammar production in the simulator is paired with a template whose slots are synchronously expanded. As a result, each dialog state or system act is associated with a template utterance. The purpose is to offer minimum understandability to each conversation flow, based on which annotators will generate natural conversations.

Instructions Annotators generate a conversation based on the given templated utterances. The task proceeds turn by turn. For each turn, we instruct annotators to convey exactly the same intents and slots in each user or system utterance, in order to make sure the obtained utterance agrees with the programmatically generated semantic annotation. The set of open values (specially marked in brackets, such as event titles and text messages) must be preserved too. Besides the above restrictions, we give annotators the freedom to generate an utterance with paraphrasing, compression and expansion in the given dialog context, to make conversations as natural as possible. While system utterances are guided to be expressed in a professional tone, we encourage annotators to introduce adequate syntactic variations and chit-chats in user utterances as long as they do not change the intent to be delivered.

Quality control We enforce two quality control mechanisms before and after the dialog rendering task. Before the task, we ask annotators to provide a binary label to each conversation flow. The label indicates if the conversation contains any non-realistic interactions. We can therefore filter out low-quality data outputted by the simulator. After the task, we ask a different batch of annotators to evaluate if each human-generated utterance preserves the meaning of the templated utterance; any conversation that fails this check is removed.

4.4 Statistics

The resulting TreeDST dataset consists of 10 domains: *flight*, *train*, *hotel*, *restaurant*, *taxi*, *calendar*, *message*, *reminder*, *navigation*, and *phone*, exhibiting nested properties for *people*, *time*, and *location* that are shared across domains. Table 2 shows a comparison of TreeDST with the following pertinent datasets, **DSTC2** (Henderson

	DSTC2	WOZ2.0	FRAMES	M2M	MultiWOZ	SGD	TreeDST
Representation	Flat						Hierarchical
#Dialogs	1,612	600	1,369	1,500	8,438	16,142	27,280
Total #turns	23,354	4,472	19,986	14,796	113,556	329,964	167,507
Avg. #turns/dialog	14.5	7.45	14.60	9.86	13.46	20.44	7.14
Avg. #tokens/utterance	8.54	11.24	11.24	8.24	13.13	9.75	7.59
#slots	8	4	61	13	24	214	287

#multi-domain dialog	-	-	-	-	7,032	16,142	14,999
#compositional utterance	-	-	-	-	-	-	10,133
#cross-turn co-reference	-	-	-	-	-	-	9,609

Table 2: Comparison of TreeDST with pertinent datasets for task-oriented dialogue.

et al., 2014a), **WOZ2.0** (Wen et al., 2017), **FRAMES** (El Asri et al., 2017), **M2M** (Shah et al., 2018), **MultiWOZ** (Budzianowski et al., 2018) and **SGD** (Rastogi et al., 2019). Similar to our work, both **M2M** and **SGD** use a simulator to generate conversation flows; and both **MultiWOZ** and **SGD** contain multi-domain conversations. The difference is that all the previous work represents dialog states as flat slot-value pairs, which are not able to capture complex relations such as compositional intents.

5 Dialog State Tracking

The objective in the conversational semantic parsing task is to predict the updated dialog state at each turn given the current user input and dialog history $P(y_t^u|x_t^u, X_{<t}, Y_{<t})$. We tackle the problem with an encoder-decoder model: at turn t, the model encodes the current user utterance x_t^u and dialog history, conditioned on which the decoder predicts the target dialog state y_t^u. We call this model the Tree Encoder-Decoder, or TED.

Dialog history When a dialog session involves task switching, there will be multiple, non-accumulable dialog states in the conversation history. Since it is expensive to encode the entire history $X_{<t}, Y_{<t}$ whose size grows with the conversation, we compute a fixed-size history representation derived from the previous conversation flow ($Y_{<t}$). Specifically, we reuse the notation of a stack to store past dialog states, and the top of the stack $y_{t-1}^{top,u}$ tracks the most recent uncompleted task. The dialog history is then represented with the previous dialog state y_{t-1}^u, the dialog state on top of the stack $y_{t-1}^{top,u}$, and the previous system dialog act y_{t-1}^s. We merge the two dialog states y_{t-1}^u and $y_{t-1}^{top,u}$ into a single tree Y_{t-1}^u for featurization.

Encoding We adopt three encoders for utterance x_t^u, system act y_{t-1}^s and dialog state Y_{t-1}^u respectively. For the user utterance x_t^u, a bidirectional LSTM encoder is used to convert the word sequence into an embedding list $\mathbf{H_x} = [\mathbf{h_1^x}, \mathbf{h_2^x}, \cdots, \mathbf{h_n^x}]$, where n is the length of the word sequence. For both the previous system act y_{t-1}^s and user state Y_{t-1}^u, we linearize them into strings through depth-first traversal (see Figure 1). Then the linearized y_{t-1}^s and Y_{t-1}^u are encoded with two separate bidirectional LSTMs. The outputs are two embedding lists: $\mathbf{H_s} = [\mathbf{h_1^s}, \mathbf{h_2^s}, \cdots, \mathbf{h_m^s}]$ where m is the length of the linearized system act sequence, and $\mathbf{H_u} = [\mathbf{h_1^u}, \mathbf{h_2^u}, \cdots, \mathbf{h_l^u}]$ where l is the length of the linearized dialog state sequence. The final outputs of encoding are $\mathbf{H_x}$, $\mathbf{H_s}$ and $\mathbf{H_u}$.

Decoding After encoding, the next dialog state y_t^u is generated with an LSTM decoder as a linearized string which captures the depth-first traversal of the target graph (see Figure 1).

At decoding step i, the decoder feeds the embedding of the previously generated token $y_{t,i-1}^u$ and updates the decoder LSTM state to $\mathbf{g_i}$:

$$\mathbf{g_i} = \mathrm{LSTM}(\mathbf{g_{i-1}}, \mathbf{y^u_{t,i-1}}) \tag{2}$$

An attention vector is computed between the state $\mathbf{g_i}$ and each of the three encoder outputs $\mathbf{H^x}$, $\mathbf{H^s}$ and $\mathbf{H^u}$. For each of the encoder memory $\mathbf{H}$, the computation is defined as follows:

$$\begin{aligned} \mathbf{a_{i,j}} &= \mathit{attn}(\mathbf{g_i}, \mathbf{H}) \\ \mathbf{w_{i,j}} &= \mathit{softmax}(\mathbf{a_{i,j}}) \\ \bar{\mathbf{h}}_\mathbf{i} &= \sum_{j=1}^{n} \mathbf{w_{i,j}} \mathbf{h_j} \end{aligned} \tag{3}$$

where *attn* represents the feed-forward attention defined in Bahdanau et al. (2015) and the *softmax* is taken over index j. By applying the attention mechanism to all three sources, we get three

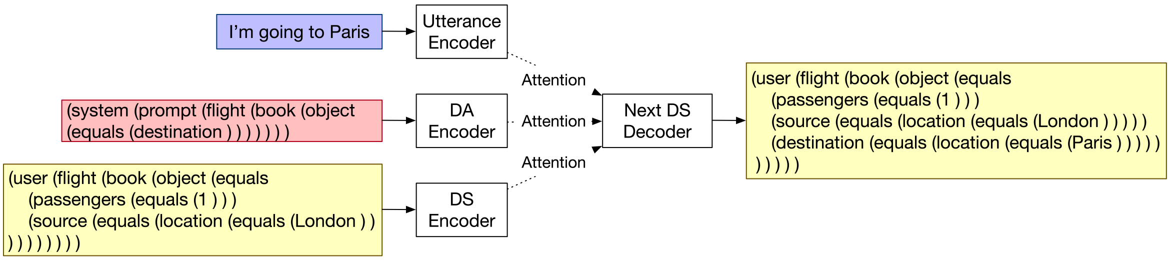

Figure 1: An overview of the TED encoder-decoder architecture.

attention vectors $\bar{\mathbf{h}}_\mathbf{i}^\mathbf{x}$, $\bar{\mathbf{h}}_\mathbf{i}^\mathbf{s}$, and $\bar{\mathbf{h}}_\mathbf{i}^\mathbf{u}$. The vectors are concatenated together with the state $\mathbf{g_i}$ to form a feature vector $\mathbf{f_i}$, which is used to compute the probability of the next token though a mixture of generation and copy mechanism (Gu et al., 2016):

$$\begin{aligned} \lambda &= \sigma(\mathbf{W_i f_i} + \mathbf{b_i}) \\ P_{gen} &= \mathit{softmax}(\mathbf{W_v f_i} + \mathbf{b_v}) \\ P_{copy} &= \mathit{softmax}(\mathbf{a_i}, \mathbf{c_i}, \mathbf{e_i}) \\ P(y_{t,i}^u) &= \lambda P_{gen} + (1-\lambda) P_{copy} \end{aligned} \tag{4}$$

where $\mathbf{W}$ and $\mathbf{b}$ are all model parameters. λ is a soft gate controlling the proportion of generation and copy. P_{gen} is computed with a softmax over the generation vocabulary. $\mathbf{a}$, $\mathbf{c}$ and $\mathbf{e}$ denote attention logits computed for the three encoders. Since there are three input sources, we concatenate all logits and normalize them to compute the copy distribution P_{copy}. The model is optimised on the log-likelihood of output distribution $P(y_{t,i}^u)$. An overview of the model is shown in Figure 1.

5.1 Parent Pointer: a Faster Graph Decoder

One observation about the standard decoder is that it has to predict long strings with closing brackets to represent a tree structure in the linearization. Therefore the total number of decoding LSTM recursions is the number of tree nodes plus the number of non-terminals. We propose a modified *parent pointer* (PP) decoder which reduces the number of autoregressions to the number of tree nodes. This optimisation is not applicable only to our DST model, but to any decoder that treats tree decoding as sequence prediction in the spirit of Vinyals et al. (2015).

The central idea of the PP decoder is that at each decoding step, two predictions will be made: one generates the next tree node, and the other selects its parent from the existing tree nodes. Eventually y_t^u can be constructed from a list of tree nodes n_t^u and a list of parent relations r_t^u. More specifically, at time step i, the decoder takes in the embeddings of the previous node $n_{t,i-1}^u$ and its parent $r_{t,i-1}^u$ to generate the hidden state g_i.

$$\mathbf{g_i} = \mathrm{LSTM}(\mathbf{g_{i-1}}, \mathbf{n_{t,i-1}^u}, \mathbf{r_{t,i-1}^u}) \tag{5}$$

This state is then used as as the input for two prediction layers. The first layer predicts the next node probability $P(n_{t,i}^u)$ with Equation 3 to 4, and the second layer selects the parent of the node by attending $\mathbf{g_i}$ to the previously generated nodes, which are represented with the decoder memory $\mathbf{G_{i-1}} = [\mathbf{g_1}, \cdots, \mathbf{g_{i-1}}]$:

$$\begin{aligned} \mathbf{f_{i,j}} &= \mathit{attn}(\mathbf{g_i}, \mathbf{G_{i-1}}) \\ P(r_{t,i}^u) &= \mathit{softmax}(\mathbf{f_{i,j}}) \end{aligned} \tag{6}$$

The model is optimised on the average negative log-likelihood of distributions $P(n_{t,i}^u)$ and $P(r_{t,i}^u)$.

6 Experiments

Setup We split the TreeDST data into train (19,808), test (3,739) and development (3,733) sets. For evaluation, we measure turn-level dialog state exact match accuracy averaged over all turns in the test set. We evaluate the proposed model with its "vanilla" decoder (TED-VANILLA) and its parent-pointer variant (TED-PP). In both cases, the utterance encoder has 2 layers of 500 dimensions; the system act encoder and dialog state encoder have 2 layers of 200 dimensions; and the decoder has 2 LSTM layers of 500 dimensions. Dimensions of word and tree node embeddings are 200 and 50 respectively. Training uses a batch size of 50 and Adam optimizer (Kingma and Ba, 2015). Validation is performed every 2 epochs and the training stops when the validation error does not decrease in four consecutive evaluations. The hyper-parameters were selected empirically based on an additional dataset that does not overlap with TreeDST.

Baselines In order to factor out the contribution of meaning representations from model changes in

Decoders	Accuracy
TED-VANILLA	0.622
TED-PP	0.622
TED-FLAT	0.535
COMER (Ren et al., 2019)	0.509
TRADE (Wu et al., 2019)	0.513

Table 3: Results on the TreeDST test set

Pattern	Accuracy
All turns	0.647
Turns with intent change	0.552
Turns with compositional utterances	0.602
Turns with multi-intent utterances	0.478

Table 4: Results on the TreeDST development set, broken down by dialog phenomena

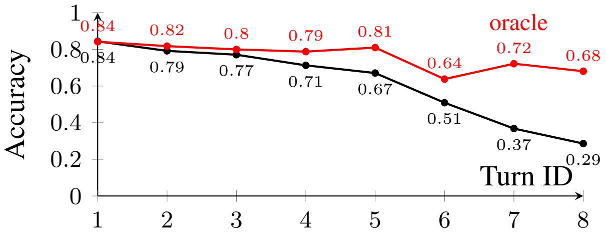

Figure 2: Validation exact match accuracy by turn ID

experiments, we additionally derive a version of our dataset where all meaning representations are flattened into slot-value pairs (details are described in the next paragraph). We then introduce a baseline TED-FLAT by training the same model (as TED-VANILLA) on the flattened dataset.

We also introduce as baselines two state-of-the-art slot-filling DST models based on encoder-decoders: they include COMER (Ren et al., 2019) which encodes the previous system response transcription and the previous user dialog state and decodes slot values; and TRADE (Wu et al., 2019) which encodes all utterances in the history. Since both TED-FLAT and the two baselines are trained with flattened slot-value representations, we can compare various models in this setup.

TreeDST flattening To flatten TreeDST we collapse each path from the `domain` to leaf nodes into a single slot. `Verb` nodes in the path are excluded to avoid slot explosion. Take the following tree as an example:

```
user.flight.book.object.equals
  .source.equals.location.equals.London
  .departureDateTime.equals
    .date.equals.definedValue.equals
      .Tomorrow
    .time.equals.hour.equals.5
```

Three slot-value pairs can be extracted:

```
(flight+object+source+location, London)
(flight+object+departureDateTime+date
+definedValue, Tomorrow)
(flight+object+departureDateTime+time
+hour, 5)
```

The operator `equals` is not shown in the slot names to make the names more concise.

Results The results are shown in Table 3. Overall, both TED-VANILLA and TED-PP models bring 20% relative improvement over existing slot-filling-based DST models. By further factoring out the impact of representation and model differences, we see that representation plays a more important role: the TED-FLAT variant, which differs only that it was trained on flattened parses, is clearly outperformed by TED-VANILLA and TED-PP. We conclude that even if dialog states can be flattened into slot-value pairs, it is still more favorable to use a compact, hierarchical meaning representation. The advantage of the representation is that it improves knowledge sharing across different domains (e.g., `message` and `phone`), verbs (e.g., `create` and `update`), and dialog participators (`user` and `system`). The second set of comparison is among different modeling approaches using the same flat meaning representation. TED-FLAT slightly outperforms COMER and TRADE. The major difference is that our model encodes both past user and system representations; while the other models used past transcriptions. We believe the gain of encoding representations is that they are unambiguous; and the encoding helps knowledge sharing between the user and the system.

The vanilla and PP decoders achieve the same exact match accuracy. The average training time per epoch for PP is 1,794 seconds compared to 2,021 for vanilla, i.e. PP leads to 10% reduction in decoding time without any effect on accuracy. We believe that the efficiency of PP can be further optimized by parallellizing the two prediction layers of nodes and parents.

Analysis First, Table 4 shows a breakdown of the TED-PP model performance by dialog behavior on the development set. While the model does fairly well on compositional utterances, states with intent switching and multiple intents are harder to predict. We believe the reason is that the prediction of intent switching requires task reference resolution within the model; while multi-intent utterances tend to have more complex trees.

Second, Figure 2 shows the vanilla model results by turn index on the development set (black curve). This shows the impact of error propagation as the model predicts the target dialog state based on past representations. To better understand the issue, we compare to an oracle model which always uses the gold previous dialog state for encoding (red curve). Vanilla model accuracy decreases with turn index, resulting in a gap with the oracle model. The error propagation problem can be alleviated by providing more complete dialog history to the encoder for error recovery (Henderson et al., 2014b), which we consider as future work.

Finally, we would like to point out a limitation of our approach in tracking dialog history with a stack-based memory. While the stack is capable of memorizing and returning to a previously unfinished task, there are patterns which cannot be represented such as switching between two ongoing tasks. We aim to explore a richer data structure for dialog history in the future.

7 Conclusion

This work reformulates dialog state tracking as a conversational semantic parsing task to overcome the limitations of slot filling. Dialog states are represented as rooted relational graphs to encode compositionality, and encourage knowledge sharing across different domains, verbs, slot types and dialog participators. We demonstrated how a dialog dataset with structured labels for both user and system utterances can be collected with the aid of a generative dialog simulator. We then proposed a conversational semantic parser that performs DST with an encoder-decoder model and a stack-based memory. A parent-pointer decoder is further proposed to speed up tree prediction. Experimental results show that our DST solution outperforms slot-filling-based trackers by a large margin.

Abstract

We introduce **doc2dial**, a new dataset of goal-oriented dialogues that are grounded in the associated documents. Inspired by how the authors compose documents for guiding end users, we first construct dialogue flows based on the content elements that corresponds to higher-level relations across text sections as well as lower-level relations between discourse units within a section. Then we present these dialogue flows to crowd contributors to create conversational utterances. The dataset includes over 4500 annotated conversations with an average of 14 turns that are grounded in over 450 documents from four domains. Compared to the prior document-grounded dialogue datasets, this dataset covers a variety of dialogue scenes in information-seeking conversations. For evaluating the versatility of the dataset, we introduce multiple dialogue modeling tasks and present baseline approaches.

1 Introduction

The task of reading documents and responding to queries has been the trigger of many recent research advances. On top of the development of contextual question answering QuAC (Choi et al., 2018) and CoQA (Reddy et al., 2019), more recent work MANtIS (Penha et al., 2019) and DoQA (Campos et al., 2020) included more kinds of user intents for querying over documents; while ShARC (Saeidi et al., 2018) added follow-up questions from agents and binary answers from users for the inference over documents. These exciting works confirm the importance of modeling document-grounded dialogue. Yet, it involves more complex scenes in practice, which requires better understanding of the inter-relations between conversations and documents. Thus, we aim to investigate how to create the training instances to further approach real-world applications of document-grounded dialogue for information seeking tasks.

In this work, we propose a new dataset of goal-oriented document-grounded dialogue. Figure 1 shows sample utterances from dialogues `D1`, `D2` and `D3` between an assisting agent and a user, and an example document in the middle. `D1` and `D2` are grounded in the given document, while `D3` is irrelevant to the document. It illustrates two different types of contexts that we aim to capture: (1) *dialogue*-based context, where a query could be formed by a single or multiple turns, and (2) *document*-based context, which corresponds to varied forms of knowledge represented in the document. More specifically, *dialogue*-based context of a query could be initiated by a user (e.g., U1 in `D1`) or an agent (e.g., A3 in `D1`), and carried out through multiple turns by both roles (e.g., all turns in `D2`). *Document*-based context could involve structural elements in documents, such as the headers `T1` and `T2` or list items of `m1` and `m2`, as well as textual discourse units, such as clauses (e.g, "If your clothing has been damaged").

For creating such dataset, we consider the document contents for social welfare websites,such as `ssa.gov` and `va.gov`, which guide users to access various forms of information. We develop a pipeline approach for dialogue data construction. Inspired by how human authors compose user-facing web content, we utilize both the high-level hierarchical relations between document components, as well as the low-level semantic relations between discourse units (Stede et al., 2019) to dynamically create outlines of dialogues, or we call dialogue flows. A ***dialogue flow*** is a sequence of interactions between an assisting agent and a user. Each turn contains a ***dialogue scene*** that is defined by a dialogue act, a role (user or agent) and a piece of grounding content from a document. Then we present these dialogue flows to crowd contributors to create conversational utterances. Such approach helps to avoid additional noise from the post-hoc

VA clothing allowance

SP1 If your clothing has been damaged, SP2 you may be able to get money each year to help you buy new clothes. This is a disability compensation …clothing allowance.

About your eligibility

Both of these must be true:

- m1 , and
- m2

About the disability benefits

- A one-time payment, or
- A yearly payment

The current clothing allowance rate is $830.56.

How to get these benefits

You'll need to file a claim for disability compensation.

...

A9: Would you like to find out whether you are eligible?

U10: *That's exactly why I contact again!*

A11: Were there any damages to your clothes that were caused by prosthetic or orthopedic device or your skin medicine?

U12: *The latter happened.*

A13: Sorry to hear that. And Is it true that you need this device or skin medicine because of an injury or illness related to your military service?

U14 : *True.*

A15: You have met the requirements.

...

...

U16: *Will it affect me applying for loads for education?*

A17: No relevant info is found unfortunately.

...

Figure 1: Sample segments of conversations (`D1`, `D2` and `D3`) with various dialogue scenes that are grounded in a webpage (middle) from `va.gov`. The relevant content elements, such as hierarchical headers, list-items and spans, are highlighted. `A` / `U` indicates Agent / User role.

human annotations of dialogue data, which is a known challenge (Geertzen and Bunt, 2009).

The dataset contains about 4500 annotated conversations with an average of 14 turns per dialogue. The utterances are grounded in over 450 documents from four domains. Unlike the previous work on document-grounded question answering or dialogues (Choi et al., 2018; Reddy et al., 2019; Saeidi et al., 2018) that are based on a short text snippet, our dialogues are grounded in a much wider span of context in the associated documents.

For evaluation, we propose three tasks that are related to identifying and generating responses with grounding content in documents: (1) user utterance understanding; (2) agent response generation; and (3) relevant document identification. For each task, we present baseline approaches and evaluation results. Our goal is to elicit further research efforts on building document-grounded dialogue models that can incorporate deeper contexts for tackling goal-oriented information-seeking tasks. We summarize our main contributions as follows:

- We introduce a novel dataset for modeling dialogues that are grounded in documents from multiple domains. The dataset is available at `http://doc2dial.github.io/`.
- We develop a pipeline approach for dialogue data collection, which has been adapted and evaluated for varied domains.
- We propose multiple dialogue modeling tasks that are supported by our dataset, and present the baseline approaches.

2 Doc2Dial

We introduce **`doc2dial`**, a new dataset that includes (1) a set of documents; and (2) conversations between an assisting agent and an end user, which are grounded in the associated documents. Figure 1 presents sample utterances from different dialogues along with a sample document from `va.gov` in the middle. It illustrates some prominent features in our dataset, such as the cases where a conversation involves multiple interconnected sub-tasks under a general inquiry (e.g., `D1`); or the cases where a conversation involves multiple interactions to verify the conditional contexts for one query (e.g., `D2`).

Recent work, such as Saeidi et al. (2018), has started to address the challenge of modeling complex contexts by allowing follow-up questions from agents based on natural language inference rules extracted from the relevant documents. However, it also simplified the task by using only restricted forms of questions and binary answers. In our work, we not only encourage free-form utterances, but also aim to include various dialogue scenes that provoke inquires with different *document*-based and *dialog*-based contexts. A user query can be formed in single-turn or multiple-turn manners: (1) the user explicitly states a context that is associated with a text-span that contains a solution to the query, e.g., U5 on T4; (2) the user describes an implicitly stated context associated with a solution, e.g., U7; (3) the user accepts or rejects a piece of agent-stated context that is associated with a solution, e.g., U4 (rejection), and U12 & U14 (acceptance). An agent response, on the other hand, either

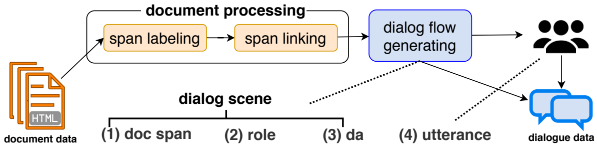

Figure 2: The overview of the process for constructing and annotating `doc2dial` dataset.

provides a solution or poses a query depending on the context of a given user query: (1) whether the query is irrelevant to the grounding document, e.g., A17; (2) whether the query is under-specified, if so, the agent will suggest associated context, e.g., A11 and A13; (3) whether a relevant answer is identified in the grounding document, e.g, A6, A8 and A15.

2.1 Data Collection

For collecting document-grounded dialogue data, we propose a pipeline approach derived from the framework proposed by Feng et al. (2020). As shown in Figure 2, it includes the components for: (1) processing the document contents; (2) generating dynamic dialogue flows; (3) crowdsourcing the dialogue utterances.

2.1.1 Data Construction Approach

Processing document contents We first select documents that contain the context-indicative elements, such as hierarchical headers and explicit discourse relations (Prasad et al., 2008, 2019), since those document contents could provoke more diversified dialogue flows. Then we extract text-spans to create a graph with the spans as nodes and semantic relations as edges. Some spans in the graph correspond to a piece of information for solving user problems, while some correspond to the conditional context of those solutions, such as `SP2` and `SP1` in Figure 1 respectively. The semantic relations are largely determined by the heuristics derived from the document structures (Mukherjee et al., 2003) and semantic connectives (Das et al., 2018) between discourse units or clauses. Both spans and semantic relations are labeled automatically via our tool. The labels can be reviewed and annotated via crowdsourcing platforms, which is also supported by our tool.

Generating dynamic dialogue flows Each flow consists of a sequence of dialogue scenes. A ***dialogue scene*** is described with (1) role, either a user or an agent; (2) a selected span as the grounding content from the given document; (3) a dialogue act that determines how to describe the selected span in the given role. Thus, each turn is inherently annotated with the dialogue act and a reference to the document contents. The dynamics of the dialogue flows are introduced by varying the three factors that are constrained by the relations from the semantic graph and dialogue history. In principle, we randomly select content from a candidate pool of spans of conditional contexts and solutions. The pool is updated after every turn is generated based on the status of the previously selected span. The general rule for updating the candidate pool is to avoid re-selecting any spans with an established status. In addition, the dialogue flow is principally aligned with common practice of dialogue management, for instance, after an agent asks a user a question, we expect the next turn would be the user answering the question.

Collecting human utterances Finally, we present the sequences of dialogue scenes to crowdsourced contributors to convert them into conversational utterances.

2.1.2 Crowdsourcing Setup

Our data collection task asks the crowd contributors to focus on one turn at a time so that they can carefully review the given dialogue scene and the dialogue history. Since the crowd generally prefers to work on tasks in batches, we try different settings to combine the tasks: (1) each writer plays the same role but for different dialogues per batch; or (2) each writer plays both agent and user role and completes entire dialogue in order, as inspired by Byrne et al. (2019). We also find that the conversations by the second setting tend to be more coherent and less time consuming. Many writers would make efforts to differentiate their writing styles for different roles. Therefore, our tasks were completed based on the second setting by about 70 qualified contributors from `appen.com`. We pay $1.5-$2 per conversation.

2.2 Document Data

For document contents, we consider the public government service websites that are designated to provide information to a vast group of users. We collect web contents from four domains and select about 450 documents for creating dialogue flows as shown in Table 1. Our dataset provides document contents in plain text and HTML, along with the meta information of titles and URLs. Each docu-

Domain	#Dials	#Docs	# per doc			
			tk	sp	p	sec
`ssa.gov`	860	86	758	66	16	5
`va.gov`	1340	138	823	70	20	9
`dmv.gov`	1420	149	955	77	18	10
`cdc.gov`	850	85	1251	94	16	9
`all`	4470	458	947	77	18	8

Table 1: The breakdown count of the dialogues, documents and average number of content elements per document by domain.

Role	DA	#Turns	#Tokens/Turn
user	request/query	25719	13
agent	request/query	8574	13
user	respond/yesOrNo	9254	7
agent	respond/reply	26273	24
total	all	69820	14

Table 2: The total # of turns and the average # of tokens per turn, aggregated on dialogue act category.

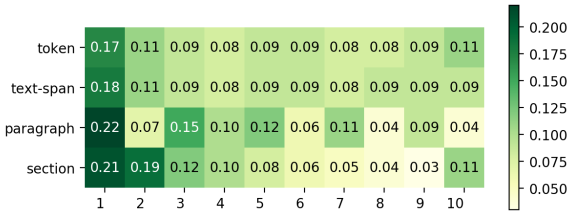

Figure 3: An illustration of the indexes of the relevant grounding contents in the documents.

ment is also represented as a sequence of spans, for which we provide indexes to the plain text and the HTML respectively.

Content elements To characterize the document contents, we examine the HTML source to extract the content elements with different scopes such as, tokens (**tk**), spans (**sp**), paragraphs (**p**) and titled sections (**sec**). Some of the spans within one sentence, such as `SP1` and `SP2` in Figure 1, are extracted via constituency parsers (Joshi et al., 2018). The paragraphs and sections are determined using HTML markups. The average counts of these elements per document in Table 1 show the rich structures that are employed across domains. While this work starts to explore the simpler semi-structured information such as D2 in Figure 1; we are yet to explore various semantics from complex list structures, tables and other multi-modal contents in the webpages for future work.

2.3 Dialogue Data

Given a grounding document, we create about 10 unique dialogue flows with an average of 14 turns for this dataset. All dialogues are created based on a unique dialogue flow. In total, there are about 4500 conversations with close to 70,000 turns from four domains as shown in Table 1. Each dialogue utterance is annotated with a dialogue scene, i.e., role, dialogue act and the grounding span. As it is a known challenge to annotate conversation turns for the dialogue scenes (Geertzen and Bunt, 2009), our pipeline approach for data collection helps avoid the cost and the noise from the additional human annotations. Next we further describe it from different perspectives regarding the dialogue scene.

Dialogue acts We adopt the hierarchical dialogue act scheme by Pareti and Lando (2018) with a focus on the ones most essential to the information-seeking tasks. We describe those dialogue acts to the crowdsourced contributors pertaining to the selected grounding content and the assigned role (detailed descriptions in Appendix A). For future work, we plan to extend current dialogue scenes with other actions such as elucidations (Azzopardi et al., 2018) and social acts (Klüwer, 2011). To examine the dialogue distributions, we aggregate the hierarchical dialogue acts and list the total of turns, and the average length per turn under each category in Table 2. For example, "agent — request/query" corresponds to the queries based on document-guided dialogue management turns via an agent role; "user — respond/yesOrNo" corresponds to the scene where a user responds to an agent's query. Since we encourage the crowd to express "yes" or "no" in natural and creative writings, such as U10 in D2 in Figure 1, the average length of "respond/yesOrNo" is 7 tokens.

Grounding content We aim to include the contents that are associated with varied conditional contexts based on the aforementioned span graph without introducing strong bias on certain index position in the document as discussed in Geva and Berant (2018). Therefore, we examine the coverage of the document contents from the generated dialogue flows. As illustrated in Figure 3, we create index of all the selected grounding contents to different document segments such as tokens, spans, paragraphs and titled sections (y-axis). The x-axis (numbered 1-10) indicates the position where 1 is closest to the beginning and 10 is closest to the end of a document. The numbers in the cells indicate the percentage distribution among all the ground-

feedback on rejected dialogue scene	%

ing contents. The heatmap shows some degree of coverage on all parts of the documents, with a higher density at the beginning as we do include the scenarios of under-specified queries that typically correspond to the intro of a document.

Dialogue flows For assessing the quality of the dialogue flows, we also ask the contributors to reject a dialogue turn when it is considered as infeasible to write a coherent utterance. We also solicit feedback via multiple choices on the reason as shown in Table 3. Out of 700 sampled dialogue flows, annotators reject about 4% of the turns. Among the rejected turns, 70% is due to not being able to interpret the selected span as applicable conditional context for user requests. In this dataset, we exclude the (sub)dialogues with rejected turns accordingly. However, we also observe certain "false positive" cases, where the crowd would rather try to adjust their writing for a less desirable dialogue scene rather than rejecting the turn, for which they get paid the same either way.

2.4 Data Recomposition

One benefit of constructing the dialogue data via our pipeline approach is that it provides a convenient and cost-effective way to reshape the existing dialogue data based on their dialogue flows. For instance, to ensure the quality, we can recollect or remove certain turns from the dialogues if they are rejected by the crowd contributors or affected by the changes in the grounding documents. In addition, for obtaining the training instances to identify the irrelevant queries, we modify an existing dialogue by inserting sub-dialogues created for another document or domain, for instance, adding `D3` to `D1` as *irrelevant* for `va.org` in Figure 1. Similarly, for creating dialogues that are grounded in multiple documents, we select sub-dialogues based on different documents and combine them into one.

3 Tasks and Baselines

For evaluation, we propose three tasks related to identifying the grounding content for a given dialogue: (1) user utterance understanding; (2) agent response prediction; (3) relevant document identification. In our tasks, we also aim to detect the cases that are irrelevant to the associated documents, for which we modify dialogues to include *irrelevant* (`Irr`) queries via data re-composition as described in Section 2.4. We split the dialogues into train/dev/test sets as 70%, 15%, 15% with half of the dev/test set grounded in "unseen" documents (not in training set). Experiment results are on test set unless otherwise stated. Numbers in the form of "mean ± stdev" are computed out of 3 random seeds.

3.1 User Utterance Understanding

One of our main goals for creating this dataset is to broaden the coverage of different user queries for various task goals. Thus, our first task is interpreting a user utterance based on the dialogue history and the grounding document content. It aims to identify the associated dialogue scene, i.e., (1) grounding span in the document and (2) dialogue act, as described in the following two sections respectively.

3.1.1 User Utterance Grounding

In our dataset, all turns are associated with a dialogue scene that includes the grounding span. Interpreting the user utterance could be quite challenging, because in some cases, it would completely depend on the dialogue history such as U12 and U14; while some cases, such as U1 and U16, depend more on the user utterance itself. For the input of this task, it takes a user utterance along with (1) the dialogue history and 2) the document content with simplified document structure. The output is a span in the document as the text reference of the given user utterance. Each grounded user turn is considered a training instance, so a dialogue with n grounded user turns is considered as n instances, with overlapping dialogue context.

Baseline Approach We formulate the problem as span selection, inspired by extractive question answering tasks such as SQuAD task (Rajpurkar et al., 2016, 2018). As a baseline, we adopt the extractive question answering model with transformers encoder by (Devlin et al., 2019). More specifically, we follow the QA example from Hugging-

Face Transformers (Wolf et al., 2019). Pretrained bert-large-uncased-whole-word-masking model is used as encoder, and is fine-tuned during training.

The document content serves as the context input of the model. The query input is the dialogue context, for which we experiment different settings of utilizing the dialogue history: (1) “last two turns”, i.e., the input user utterance for which we want to identify the dialogue scene, and the agent utterance before the given user utterance; (2) “all prev”, i.e., the input user utterance and all the utterances before it; (3) “all prev w/DA”, i.e., context in (2) along with the corresponding dialogue acts. The dialogue context is concatenated in reversed time order where the latest user utterance appears first.

Often the grounding document is longer than the maximum sequence length of transformers. In such cases, we truncate the documents in sliding windows with a stride. The dialogue context and each document trunk form one instance to be fed in batch into the encoder. The sequence of the encoded embeddings is then sent to a linear layer, which maps each embedding in the sequence into two logits, representing the probability of the corresponding position being the start and end position of the span. During training, we apply the Cross Entropy loss function to compute the loss. If the ground truth span does not fall in the document trunk, the start and end positions are both considered to be the beginning of the sequence. During decoding, the start-position and end-position logits from all document trunks are considered together to find the span most favored by the model.

Evaluation Metrics For evaluation we use Exact Match score and token-level F1 score, as in the evaluation script 2.0 of SQuAD . In addition, since our data comes with predefined spans in each document, we map predicted span to the closest predefined span start index and span end index, and evaluate the mapped span with Exact Match score, as “ts EM” in Table 4 and Table 7.

Experiment Results The experiment results are summarized in Table 4. Generally, the model performance improves with more information added to the dialogue context. It indicates that the queries in our datasets are highly conversational contextual and our dataset could serve as a valuable source for evaluating dialogue models’ capability of learning from deeper context. We also conduct an experiment using the `w/Irr` data with the “all prev” dialogue context. Table 5 summarizes the results in comparison with `wo/Irr` data. `Irr` turns impose noise in understanding the context, reduce the model accuracy from 54.3 to 53.3 on the original turns that are grounded to the document. However, the `Irr` turns themselves are easy to identify and achieve a high score of 99.1. As a result, the overall score including the `Irr` turns is increased to 62.7.

dial-ctxt	**text EM**	**text F1**	**ts EM**
last two turns	52.6 ± 0.3	64.3 ± 0.3	52.5 ± 0.4
all prev	54.3 ± 0.5	66.2 ± 0.3	54.4 ± 0.2
all prev w/ DA	55.1 ± 0.4	66.3 ± 0.3	55.2 ± 0.4

Table 4: Results for user utterance grounding.

all prev	**text EM**	**text F1**
`wo/Irr`	54.3 ± 0.5	66.2 ± 0.3
`w/Irr`	62.7 ± 0.4	70.1 ± 0.6
`has_ans` turns	53.3 ± 0.4	62.7 ± 0.8
`Irr` turns	99.1 ± 0.3	99.1 ± 0.3

Table 5: Comparison of `w/Irr` and `wo/Irr` settings for user utterance grounding.

3.1.2 User Dialogue Act Identification

Dialogue act prediction using dialogue context as input is an important task in dialogue systems modeling (Liu et al., 2017; Tran et al., 2017). We indentify the dialogue act of each user turn considering three different cases of dialogue context as input: (1) U: only the input user utterance, (2) U + A: the input user utterance and previous agent utterance, and (3) U+A(w. da): inputs in (2) along with agent turn’s dialogue act. We use the hidden state of the tokens as the representation of the dialogue context, and further process it by a linear layer to identify the probability distribution over the total number of user dialogue acts. There are 7 dialogue acts for `w/Irr`, 6 dialogue acts for `wo/Irr`. We use the common metrics of accuracy (Acc), recall (R) and precision (P) for evaluation.

Baselines and Experiment Results As a baseline we adopted BertForSequenceClassification model, a multi-class sequence classifier popular for GLUE tasks (Wang et al., 2018). We use pretrained bert-base-uncased model as the encoder and fine-tune during training.

The results in Table 6 indicate much room for improvement, e.g., by adding document context, or building a joint model with the user utterance grounding task. The macro-averaged P and R are much lower than the micro-averaged Acc because

dial-ctxt	`w/Irr`			`wo/Irr`		
	Acc.	**R.**	**P.**	**Acc.**	**R.**	**P.**
U	60.2	34.5	35.6	77.2	45.2	47.2
U+A	72.7	51.8	53.7	79.3	50.8	48.6
U+A(w. da)	76.4	53.8	55.7	80.6	50.9	55.2
-	53.3	14.3	7.6	67.4	16.7	11.2

Table 6: Results for user dialogue act identification by BERT. The last row is by majority vote. Acc. is micro-averaged, while R. and P. are macro-averaged.

of the imbalanced DA distribution as shown in Table 2. The results also reflect the challenges effectively posed by the introduction of `Irr` turns, which was intended by our task design.

3.2 Agent Response Prediction

For this task, we aim at predicting the next agent turn with a focus on identifying the reference to the grounding document for the response. Such task can be a very important step towards building explainable conversational systems with practicality.

3.2.1 Agent Response Grounding Prediction

This task takes as input 1) the dialogue context; and 2) the document content with simplified document structure, and predicts a span in the document that grounds the next agent response. This task looks very similar to the user-turn grounding text prediction task in Section 3.1.1 in that they both take dialogue context and document context as input and perform a span selection inside the document. However, they are essentially different: the user-turn grounding text prediction is to understand what the user has already said, whereas this task is to predict what the agent would want to respond.

Baseline Approach and Evaluation Metrics As opposed to investigating this task from the aspect of dialogue management and planning, as a first attempt, we continue with our focus on identifying the associated grounding content in the document. Thus, we treat this as a span selection task, and adopt the same evaluation metrics and baseline approach as in Section 3.1.1. Note that with the same input dialogue context and text context, the model output in Section 3.1.1 is the dialogue scene corresponding to the given user utterance, while the model output of this task is the dialogue scene predicted for the next agent response.

Experiment Results The experiment results are summarized in Table 7. The scores are much lower than the ones from our previous task in Table 4 due to the challenging nature of the task. However, we do see a significant improvement after including dialogue act information, which directs our further work on dialogue management to further improve the performance. Table 8 compares the experiment result in the `w/Irr` and `wo/Irr` settings, where we see a similar trend as in Table 5 unsurprisingly.

dial-ctxt	**text EM**	**text F1**	**ts EM**
last two turns	33.4 ± 0.4	49.6 ± 0.8	34.7 ± 0.5
all prev	34.3 ± 0.2	50.0 ± 0.8	35.9 ± 0.2
all prev w/ DA	36.2 ± 0.4	52.6 ± 1.0	37.6 ± 0.7

all prev	**text EM**	**text F1**
`wo/Irr`	34.3 ± 0.2	50.0 ± 0.8
`w/Irr`	47.3 ± 0.2	57.6 ± 0.6
`has_ans` turns	33.8 ± 0.3	46.7 ± 0.7
`Irr` turns	98.8 ± 0.3	98.8 ± 0.3

Table 8: Comparison of `w/Irr` and `wo/Irr` settings for agent response grounding prediction.

3.2.2 Agent Response Generation

Next we evaluate the dataset via the task of generating agent response. One primary goal of our task is to enable document-guided agent response, which overlaps with the primary goal of ShARC (Saeidi et al., 2018). However, our dataset includes more types of dialogue scenes and sets no restriction on the natural language forms of queries and responses. Thus, we investigate how one of the best performing end-to-end approaches to-date for ShARC works on our dataset. Compared to ShARC, our user queries do not come with the scenario description but are annotated with the grounding span, and the grounding documents is much longer. Therefore, we truncate the document into sub-documents with a size of 200 tokens. We try different ways to truncate the text: (1) only at the end of a span (ts); (2) only at the end of a paragraph (p).

Baseline Approach and Experiment Results We adopt the model from Zhong and Zettlemoyer (2019). The input is the user query with dialogue history of up to last 4 turns as well as their grounding spans and the document content; the output is the agent utterance. The model learns to extract the relevant spans implicitly that are entailed by the dialogue-based and document-based contexts, and then edit them to generate the agent response.

The BLEU scores are reported in Table 9. We ob-

doc-ctxt	**BLEU-1**	**BLEU-2**	**BLEU-3**	**BLEU-4**
ours (ts)	40.45	34.65	31.84	29.98
ours (p)	58.12	54.26	52.53	51.51
(ShARC)	(67.14)	(60.59)	(56.46)	(53.67)

Table 9: Results for agent turn generation (dev set).

serve better results with the preprocessing method that maintains the original document structure at larger scale. Compared to the results by the same model reported on ShARC dev dataset, our BLEU scores are significantly lower. This is related to the more dynamic forms of agent responses in our dataset; another factor is the length of relevant document context, even when truncated, ours is 4 times longer.

3.3 Relevant Document Identification

Given that the goal-oriented dialogues could correspond to different tasks from a same document or multiple documents, in order to facilitate the understanding of such challenge, we experiment with two settings for the task on retrieving the grounding document(s): (1) the dialogues that are grounded in a single document; (2) the dialogues that are grounded in multiple documents.

3.3.1 Single-Document Retrieval

This task is to identify the relevant grounding document given limited dialogue history information. Thus, the input is certain dialogue context and a pool of 594 documents from all four domains.

Baselines and Experiment Results We consider two different baselines for this task: (1) BM25 (Robertson and Zaragoza, 2009) based Information Retrieval method, and (2) A multi-class sequence classifier based on BertForMultipleChoice, using pretrained bert-base-uncased model as the encoder (Zellers et al., 2018).

BM-25 method takes the full document into account to create the index and match them against the provided dialogue contexts. BERT model takes the dialogue context d and a document y together as a sequence. We use 512 tokens and feed BERT with the 256 tokens each from d and y. For each dialogue context, we create a set of triples: one triple containing the correct document (labeled with 1), and m triples containing incorrect documents sampled randomly from the set of all documents (labeled with 0). Table 10 corresponds to the setting $m = 4$. During evaluation, we evaluate a given dialogue context against the set of all documents. The task is evaluated with the commonly used recall ($R@k$) metric in retrieval tasks, which measures the fraction of times the correct document is found in the top-k predictions.

n	**BM-25**			**BERT**		
	R@1	**R@5**	**R@10**	**R@1**	**R@5**	**R@10**
1	26.1	44.8	53.5	32.4	59.6	67.3
2	49.3	74.2	78.8	50.5	77.8	85.1
3	49.4	73.9	79.0	51.7	83.7	88.8
4	56.0	80.4	84.9	57.6	84.3	89.4
5	59.3	80.7	86.0	60.2	85.6	90.7

Table 10: Results for single-document retrieval with n previous turns as input.

Domain	**R@1**	**R@5**	**R@10**
`va.org`	52.3	78.3	86.4
`dmv.org`	50.5	76.4	86.4
`ssa.org`	33.6	74.2	86.1
`cdc.org`	46.8	74.1	83.2
Weighted Average	47.5	76.1	85.9

Table 11: Results for multi-document retrieval in single domain.

As shown in Table 10, DL-based approach shows better performance consistently. From the perspective of examining the quality of our dataset, we also see the numbers confirms that as more turns are included, the better the dialogue is grounded to the relevant document.

3.3.2 Multi-Document Retrieval

We construct the dialogues that are grounded in multiple documents as described in Section 2.4. To make the tasks more challenging and closer to real-life applications, the segments of a dialogue are all grounded in the documents from the same domain. This dataset contains 2051 conversations, out of which 1640, 206 and 205 conversations were used in the train, dev and test sets respectively.

Baselines and Experiment Results A baseline similar to Section 3.3.1 was constructed for this task using BertForMultipleChoice. At each user turn, we predict which document it should be grounded to, given the user utterance, previous agent utterance and the domain.

This task is essentially related to conversational search task Penha et al. (2019), which predicts a link to the relevant document given a dialogue. Even though our document pool is not large compared to IR tasks, each document is quite long. The results in Table 11 show much room for improvement, and our dataset could be valuable resource for further deep document modeling.

4 Related Work

Our work is mainly focused on modeling dialogues that are grounded in documents. It is generally inspired by the recent substantial interests on the challenges of machine reading comprehension and conversational QA, such as CoQA (Reddy et al., 2019), QuAC (Choi et al., 2018) and DoQA (Campos et al., 2020). Those tasks aim to support conversational question answering, which involves understanding a text passage and answering a series of interconnected questions that appear in a conversation. These tasks add the complexity of coreference resolution and contextual reasoning to the reading comprehension challenges such as SQuAD (Rajpurkar et al., 2016, 2018), yet aim at identifying a solution from a given list of candidates by reasoning over spans from a document. Our task shares those challenges and additionally introduces the dialogue scenes where the agent asks questions when the user query is identified as under-specified or additional verification required for a resolute solution.

Another recent work Kim et al. (2020) extends MultiWOZ (Budzianowski et al., 2018) by adding turns that are grounded in the FAQ knowledge for certain entity and domain. The document-based knowledge used in our work is beyond FAQs with entity as context but whole documents with more complex contexts. In addition, ours is also largely related to conversational search tasks, such as MANtIS (Penha et al., 2019). Similarly, it also provides multi-turn conversations with varied user intents that are grounded in documents from Stack Exchange website. In addition to the domain difference, one major distinction is that the grounding in MANtIS is determined by the hyperlinks to a document. Our grounding is defined at at a much finer level in addition to the link to a document.

To the best of our knowledge, the closest related work to ours is ShARC (Saeidi et al., 2018) with dialogues that are grounded to a span of a given text snippet. It also proposes to address under-specified questions by requiring follow-up questions that are answerable with yes/no answers in similar domains. Our dataset goes beyond ShARC in several aspects nonetheless: we exploit not only paragraph-level structure but also higher-level document structure, we create conversations over much longer span of document content, where utterances are free-formed, as opposed to yes/no answers.

5 Conclusion

We have introduced **`doc2dial`**, a new dialogue dataset for goal-oriented tasks that are grounded in documents from multiple domains. Compared to previous work, our dialogues cover a greater variety of dialogue scenes that correspond to a much wider span of document content. For evaluation, we investigated three types of dialogue tasks and proposed baseline approaches. We hope this work will inspire and assist both dialogue and document modeling for tackling more real-life dialogue tasks.

Acknowledgments

We thank the anonymous reviewers for their insightful comments. We thank Vera Liao and Kshitij Fadnis for their advice during the early stage of this project. We also thank crowd contributors for their valuable inputs for building our tool and dataset.

Abstract

In this work, we perform the first large-scale analysis of discourse in media dialog and its impact on generative modeling of dialog turns, with a focus on interrogative patterns and use of external knowledge. Discourse analysis can help us understand modes of persuasion, entertainment, and information elicitation in such settings, but has been limited to manual review of small corpora. We introduce INTERVIEW—a large-scale (105K conversations) media dialog dataset collected from news interview transcripts—which allows us to investigate such patterns at scale. We present a dialog model that leverages external knowledge as well as dialog acts via auxiliary losses and demonstrate that our model quantitatively and qualitatively outperforms strong discourse-agnostic baselines for dialog modeling—generating more specific and topical responses in interview-style conversations.

1 Introduction

Much of the news, information, and punditry the general public listens to and reads consists of *media dialog*—a category of open-domain conversations between an interviewer and interviewee centered on world events and situational context. A system for modeling media dialog from the perspective of one of these roles can help us better understand how media persuades and informs the public (Southwell et al., 2018). Thus, while recent work in dialog modeling has focused on goal-oriented (Bordes et al., 2017), spontaneous (Shao et al., 2017), or synthetic open-domain chit-chat (Li et al., 2017; Dinan et al., 2019; Gopalakrishnan et al., 2019), we aim to analyze discourse patterns in media dialog and their impact on dialog modeling.

Media dialog differs linguistically and in purpose from unstructured, spontaneous conversation such as open-domain chitchat, and both the topical content and interlocutor intent are heavily influenced by the social, cultural, and temporal setting (Weizman, 2008). The study of media dialog has traditionally focused on individual and manual review of small-scale (<200K word) news corpora (Bednarek, 2006; van Dijk, 2011), and we see an opportunity to scale some forms of discourse analysis to tens of thousands of such documents. In this work, we perform the first large-scale automatic analysis of structural components (response-type patterns) and question type categorization on media dialog, specifically for English news interviews. We show that predicting discourse features can improve generative dialog modeling performance, demonstrating the degree to which discourse structure impacts an interviewer's choice of response type and content. News interviews are also heavily situation-grounded and contextualized by past events and world knowledge. We explore methods to associate each conversation with a selection of world facts, and show that by modeling interviewers as *knowledge-grounded* speakers mediating a conversation we are able to generate relevant and specific utterances fitting their role.

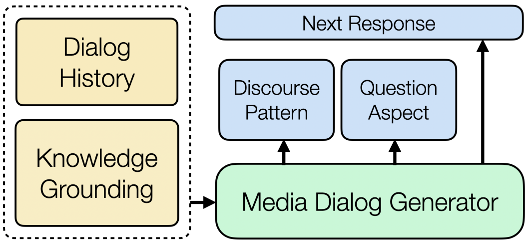

Figure 1: Our dialog model incorporates grounding documents alongside dialog history. We also leverage the dialog patterns and interrogative positioning by the host via auxiliary losses.

Our main contributions in this work are:

1. We collect a dataset of 105K media dialogs

November 16–20, 2020.

(23K two-party dialogs)[1] encompassing two decades of National Public Radio (NPR) radio programs, on which we conduct extensive experiments;

2. We present a probabilistic framework to link a dialog with facts from a large corpus of grounding documents and show that it improves downstream dialog modeling performance compared to a strong TF-IDF baseline;

3. We introduce two auxiliary losses to guide utterance generation in a media dialog setting: look-ahead dialog structure prediction and question-attribute prediction[2]. We show that these losses significantly improve generation quality via automatic and human metrics.

2 Related Work

Media dialog—specifically, the news interview—has seen study primarily in the field of speech transcription, diarization, and speaker role modeling (Chen et al.; Laurent et al., 2014). These works have typically focused on techniques to annotate broadcast audio transcripts (Hutchinson et al., 2010) in order to cluster different news stories from a continuous broadcast stream (Huang et al., 1999). While Barzilay et al. (2000) and Liu (2006) note that transition points between speaker roles (e.g. anchor and guest) can determine the high-level topical flow of a news conversation, we investigate the impact of discourse patterns on the semantics of specific utterances.

Such research is currently limited by a lack of accessible corpora for the study of media dialog at scale. The Defense Advanced Research Projects Agency has undertaken efforts to collect and transcribe broadcast conversations (Strassel, 2004; Cohen, 2007). However, it proves difficult to adopt these datasets as widely available benchmarks on dialog modeling tasks, as they come with a substantial cost ($100-$1000 per annum per dataset). More recent efforts to amass such data have either focused on collecting large volumes of conversation fragments with noisy transcripts (Beeferman et al., 2019) or human transcripts for a smaller set of long-form open-domain radio programs (Mao et al., 2020). We contribute an open-access large-scale corpus of broadcast media dialog annotated with response types, demonstrating that these are useful for modeling interviewer utterances.

We explore the application of discourse analysis (Fairclough and Wodak, 1997) on this large media dialog corpus in order to discover, confirm, and leverage *discourse patterns* regarding interrogative forms, speaker agency, and references to external knowledge. As noted by Weizman (2008) in their deep study of Israeli news television, structure in media dialog (in contrast to spontaneous natural conversation) is uniquely determined by its speaker role dynamics. Wang et al. (2011) investigate the detection of one such dynamic: agreement/disagreement between speakers. Ma et al. (2019) classify discourse relations (e.g. comparative, temporal) between two turns of dialog, but do not study discourse structure. In this work we extend our analysis to other properties of interviewer utterances (e.g. subjectivity, polarity, dialog act patterns) (Heritage, 1985) in the context of generative dialog modeling. Structured approaches for dialog modeling employ a simple concatenation of dialog history in a transformer-based architecture (Zhang et al., 2019). We draw inspiration from Luan et al. (2017) who demonstrate the usefulness of a multi-task framework for speaker-conditioned dialog modeling. Guu et al. (2020) propose a framework for jointly learning document retrieval and language modeling, and we propose a similar model to learn task-specific annotation of grounding documents.

3 INTERVIEW : A Media Dialog Corpus

We collect a new dataset of 105K multi-party interview transcripts for 7 programs on National Public Radio (NPR)[3] over 20 years (1999–2019). These transcripts contain in total 3M turns comprising 7.5M sentences (127M words) from 184K speakers, of which 287 are interviewers. To investigate host-mediated media dialog, we curate a subset, **INTERVIEW 2P**, with **two roles**: an *interviewer* and a *guest*, comprising 23K two-party conversations encompassing 455K turns, with 1.24M sentences and 21.7M words. In these two-party conversations, each speaker takes an average of nine turns per dialog. Guests tend to speak longer on their turns, with 1.6x as many sentences spoken and 2x as many words per turn. Meanwhile, hosts ask five times as many questions as guests, with 40% of their dialog turns containing questions. When ask-

Host (Question): Steve Bannon is quoted as saying [...] the president has lost it. Now, are you supporting a president who is incapable of being entrusted with [...] nuclear weapons?

Guest (Answer): Well - one thing I haven't heard yet is Steve Bannon interviewed […] so look, I think the president of the United States has shown he's very, very capable […]

Host (Question): Should he be taunting a dictator with nuclear weapons about the size of his nuclear button?
[Question types: Polar, Subjective, Combative]

Guest (Answer): Well, I - you know […] the president has a record on Twitter […] I think he makes points […] he's doing a great job from where I sit for the country.

Host (Question): Quickly, he says he's a genius. Do you agree?

Figure 2: Example conversation from Interview with annotated discourse analysis. Text highlighted in blue indicates the question of interest, uttered by the host. The dialog triplet is marked in red.

Dataset	Structured	# Dialogs	# Turns	# Words
RadioTalk (2019)	✗	5.98 M*	116 M	2.9 B
TAL (2020)	✓	663	163,808	7.4 M
Interview 2P	✓	23,714	454,739	21.7 M
Interview	✓	105,848	3,199,856	126.7 M

Table 1: Comparative media dialog dataset statistics. *RadioTalk does not contain full conversations

ing questions, hosts and guests use interrogative forms (See et al., 2019) at the same rate (65%).

3.1 Comparison with Other Datasets

Open-domain dialog datasets have traditionally focused on either spontaneous (e.g. telephone calls) or goal-oriented conversation, and there is a paucity of English-language *media dialog* datasets—that is, dialog corpora comprising semi-structured conversations for the purpose of information elicitation and presentation. The closest such datasets are This American Life (Mao et al., 2020), a dataset of several hundred long-form expository podcast episodes, and RadioTalk (Beeferman et al., 2019), which comprises over one million ten-minute snippets of talk radio transcripts. While these corpora are derived from broadcast media, episodes of the former contain a broad range of expository speakers who are not professional journalists, while the latter dataset is constructed via an automated transcription system with a 13%+ word error rate and does not contain full conversations (segments from radio conversations are transcribed). We compare Interview statistics to other English media dialog datasets in Table 7.

Traditional media dialogs (e.g. news interviews) comprise a significant body of media consumed by the general public and we believe there is value in the large-scale study of such media. Efforts to collect and transcribe broadcast news span the world, from the French EPAC corpus (Estève et al., 2010) to Arabic and Chinese news manually transcribed via the GALE program (Cohen, 2007). To our knowledge, no attempt has yet been made to analyze the discourse patterns or trends in such data—these datasets have primarily been used to support the development of automatic speech recognition, transcription, and machine translation systems. Early efforts to collect English-language broadcast conversation transcripts (Placeway et al., 1997) similarly aimed to build smaller, high-quality parallel corpora for speech transcription. The large-scale study of discourse in media dialog is not supported in such corpora, and the Interview corpus enables such analysis at scale for English-language media.

4 Interview Discourse Analysis

We tackle three aspects of discourse analysis that can be scaled to Interview: 1) Dialog patterns that emerge through new interviews; 2) Large scale annotation of interviewer question types (dialog acts); and 3) Obtaining grounding documents that provide situational context for a news interview. We study these discourse features in context of English broadcast news interviews.

4.1 Dialog Patterns

The news interview setting revolves around sets of questions and answers—naively, one may assume the interviewer to be the sole questioner. However, media dialog has steadily deviated from this rigid structure, tending toward the broadly conversational (Fairclough, 1988). Each participant may be at turns jovial, inquisitive, and critical, and this is reflected in question-answer patterning. Heritage (1985) frames the analysis of media discourse in terms of the *third-turn receipt*, where 1) they ask a question; 2) the interviewee responds; and 3) the interviewer chooses how to proceed. We are motivated by this, as well as studies of *question-response-confirmation* patterns in spontaneous dialog (Van Hekken and Roelofsen, 1982). We focus on discourse patterns in **response type triplets** beginning with an interviewer (host) question.

We define a triplet as $\{r_1, r_2, r_3\}$ where the response type at utterance i is a question or an answer: $r_i \in \{\mathrm{Q}, \mathrm{A}\}$. By imposing a binary label on each utterance, we are able to efficiently mine all occurrences of each of eight possible host-guest-host patterns across our 23K dialogs. We find that a structured interrogative Q-A-Q pattern comprises 27% of all cases, while 20% of the time the host poses a non-interrogative third response (Q-A-A). Guests respond to questions with questions of their own only 7% of the time, supporting the theory that interviewers serve as the primary *mediators* in such conversations (Weizman, 2008). Manual inspection evinces recurring action patterns corresponding to interviewer stance-taking and agendas ranging from cooperative to confrontational. For example, the conversation segment in Figure 2 is comprised entirely of Q-A-Q patterns, with the host prompting (Heritage, 1985) the guest, re-contextualizing and refocusing the guest's stance for the benefit of the audience. To leverage the inter-dependence of action choice (question or answer) and stance-taking (implicitly or explicitly via utterance content) (Haddington, 2004), we propose to predict the subsequent response type triplet while modeling an interviewer utterance. We thus explore how utterance phrasing and structure may depend on projected or desired conversation directions.

4.2 Question Types as Dialog Acts

In their role as a mediator, interviewers can shape the narrative by posing different *types* of questions to guests. Weizman (2008) posits that this choice of question type is influenced by dialog context and conversation flow. We examine ways to structurally bias our model to take advantage of conversational context in order to ask appropriate interviewer questions. Based on common interviewing guides[4] and linguistic analysis of open-ended questions in a conversational setting (Karttunen, 1977), we define three interrogative aspects (attributes): 1) **Polarity**: determining if the question is yes/no (polar) or open-ended; 2) **Subjectivity**: determining if it demands a factual answer or invites a subjective opinion; and 3) **Combativeness**: whether the question is confrontational or clarifying. Our mode of categorization resembles that of Gnisci and Bonaiuto (2003), who add additional categories that are more relevant to the study of equivocation in confrontational interviews. While previous works have primarily used question polarity and interrogative forms to improve diversity in spontaneous dialog generation (Zhao et al., 2017), we explore how a news interviewer constructs question contents given desired interrogative aspects.

History	Model	Polarity	Combativeness	Subjectivity
No	MLP	55.61	48.91	50.87
	CNN	68.20	57.19	53.91
	LSTM	66.87	49.70	51.96
	BERT	75.31	58.10	66.92
Yes	MLP	68.71	60.81	61.21
	CNN	74.71	65.87	67.98
	LSTM	70.49	60.54	63.09
	BERT	**80.20**	**70.14**	**76.92**

Table 2: F1 Performance of question-type classifier models on the test set.

We hired two expert annotators to assess a question based on these three aspects. We provided interviewer questions alongside corresponding dialog histories, and annotators marked the binary presence/absence of each aspect for each question. The first host question from Figure 2 would be marked as polar, subjective, and combative, as it asks the guest whether (polar) they endorse (subjective) an intentionally ridiculous statement (combative). We collected 1,000 questions in this manner, each labeled by both annotators. The inter-annotator agreement (Cohen's kappa (Cohen, 1960)) for each of the binary labeling tasks—polar vs. open-ended, subjective vs. objective, combative vs. clarifying—was 0.8 for polarity, 0.72 for subjectivity and 0.7 for combativeness. We observed questions in this sample to be 60.2% polar, 38.7% subjective, and 29.5% combative.

Automatic Classification We label the remainder of INTERVIEW by training a multi-label classifier, fine-tuning BERT (Devlin et al., 2019) to predict the presence of each attribute in our human-annotated set of questions. We concatenate dialog

(a) (b)

Figure 3: (a) Bar plot depicts test perplexity for linking algorithms: None (no grounding), TF-IDF, and PL/PL3 which indicate probabilistic linking with re-assignment at every 1/3 epochs respectively. Plotting validation perplexity by epoch shows that PL3 converges faster and to a better optimal (b).

history and the interviewer question separated by a `[SEP]` token and prepend a `[CLS]` token. We calculate binary cross entropy loss over a linear projection of the final hidden state of the `[CLS]` token. BERT achieves 80.20, 70.14, and 76.92 F1 scores for polarity, combativeness and subjectivity respectively on the test set in four epochs.

We consider multiple baselines: 1) an MLP model using Bag-of-Words input features; 2) a CNN (Fukushima, 1988) with 2 convolution layers; and 3) a Bi-LSTM (Graves et al., 2005) network with max-pooling of final hidden layers. We initialize all embeddings with BERT embedding vectors. As shown in Table 2, BERT achieves the highest F1-score. Including dialog history improves classification performance, confirming that the type of question asked depends on conversational context. This suggests that we may also be able to better predict question content through jointly leveraging the dialog history and question type. Both human annotators and our model find predicting polarity the easiest, and combativeness the most difficult.

4.3 Knowledge Grounding

Media dialog is frequently characterized by references to world knowledge, current events, and factual information. This can be learned to some extent in large language models pre-trained on diverse text corpora (Petroni et al., 2019), and such models can act as knowledge stores (Chen et al., 2019). However, for tasks involving complex reasoning and induction it remains beneficial to provide models with externally linked knowledge (Mitra et al., 2019; Fan et al., 2019). Specifically for dialog modeling, the Wizard of Wikipedia (Dinan et al., 2019) and Topical Chat (Gopalakrishnan et al., 2019) corpora consist of grounding documents linked with open-domain chit-chat. As such, we explore methods to link *grounding knowledge documents* for each conversation in Interview, drawn from NPR news articles from the past two decades. We aim to link documents that can best inform conversation content and structure as measured by downstream dialog modeling performance.

TF-IDF Linking We assess a strong retrieval baseline for grounding document linking, using TF-IDF (Salton and Buckley, 1988) to find relevant documents for each conversation. To support large-scale TF-IDF similarity computation, we use the Lucene-based ElasticSearch (Gormley and Tong, 2015) engine[5] to calculate TF-IDF similarity between full interview texts and the concatenation of the document headline and body, returning the 50 most similar grounding documents for each Interview conversation. We aim to link documents that would be reasonably relied on by the speakers at the time of the interview, and as such for each interview exclude articles that were published after the interview itself.

Probabilistic Linking While TF-IDF based document linking provides a co-occurence-based similarity measure between documents and conversations, there is no guarantee such linking will improve dialog modeling performance. Thus, we aim to train a linking model such that conditioning on linked documents has a positive effect on dialog modeling performance. We use a two-phase coordinate ascent framework as described in Algorithm 1. In the *Learning* phase, a dialog model is trained based on the available assignments, and its weights are fixed (frozen). Then, in the *Assignment* phase, we compute a re-assignment that maximizes dialog model performance under different possible assignments. Searching over the complete document set is computationally infeasible, so we perform an approximate greedy search over possible documents ordered by their TF-IDF prior score.

We compare the performance of a Transformer (Vaswani et al., 2017) language model provided with grounding documents assigned by different algorithms in Figure 3a. A model without grounding scores by far the worst in terms of perplexity, which indicates that knowledge grounding is important for modeling media dialog. While TF-IDF assignments significantly improve performance compared

Grounding: How The NFL's New Rule On Protesting Is Being Perceived By Players

Host: How are the players that you're talking to reacting to the stand that the NFL's taken?

Guest: Well, I think they've taken the position that the NFL has decided to fully engage with this culture war initiated by the president [...] I think this has really reignited some really bad blood between the players and the owners.

Host (Gold): And how is that manifesting itself? I mean, what conversations are the players having, and what can they actually do?

Host (Generated): So how are you responding to this ever-evolving scenario? What are the key steps are you planning to take to gauge players' sentiment?

Figure 4: Knowledge grounded generator model with two discourse-specific auxiliary tasks for media dialog

Algorithm 1 Pseudocode for probabilistic linking

```
Initialize document assignments from TF-IDF priors
while average validation perplexity decreases do
    Learning: Update the model with current assignments for $N$ epochs
    for each $d$ in Dialogs do
        Sample $K$ documents from top 50 TF-IDF priors
        for each $k$ in $K$ do
            Condition each response in the dialog with $k$, and calculate perplexity, aggregate at the dialog level
        end for
        Choose $k$ that yields the lowest perplexity
    end for
    Assignment: Gather all $k$'s for each dialog to update current assignments
end while
```

to no grounding, probabilistic grounding models achieved the best performance. The sudden drops in perplexity values at every third epoch in Figure 3b indicates that the model was well-trained based on current assignments before a new assignments were obtained.

While our articles and conversations come from the same broadcasting source, the NPR interview transcripts generally do not contain links or metadata connecting them with specific grounding documents, and thus there are no ground truth labels available to us. To ascertain that the grounding is relevant, we enlisted two native English speakers who regularly listened to broadcast radio to perform a qualitative evaluation of 100 randomly sampled interview and article pairs. We found that 87% of these pairings are highly relevant, 5% are somewhat relevant and the rest are irrelevant. The inter-annotator agreement measured by Cohen's Kappa was 0.79. The lack of ground truth is something we would argue is not a limitation, rather our probabilistic linking step avoids the dependency on data that is not likely to be available in practice.

5 Modeling Media Dialog

A model's ability to learn underlying discourse dynamics is reflected in its performance on downstream tasks. Here, we assess how well our model learns from dialog structure and question-pattern metadata using utterance generation—a simple predictive task that relies on a holistic understanding of grounding knowledge and a dialog history. This serves as an initial measure of understanding of discourse patterns and grounding even if the exact dialog produced can vary.

We treat knowledge-grounded response generation in the media dialog setting as a language modeling task: given a dialog history H and a grounding knowledge document K, we seek to predict the next utterance x by maximizing the likelihood $p(x|H, K)$. The dialog history is composed of turns spoken by both the interviewer and interviewee where each utterance is provided with the role annotation. We only model interviewer (*host*) responses, which aim to moderate the conversation via questions, follow-ups, and acknowledgements. To understand the effect of dialog structure and question types in response modeling, we introduce two *auxiliary losses* to influence generation—a multi-task setup that has seen success in goal-oriented dialog generation (Luan et al., 2017).

5.1 Knowledge Grounded Generator

We use a common decoder-only model for knowledge-grounded dialog generation (Gopalakrishnan et al., 2019): GPT2 (Radford et al., 2019), a pre-trained Transformer decoder. As model input, we concatenate tokenized grounding documents, dialog history, and the target response. To distinguish each section, we add jointly-learned segment embeddings—{`Grounding`, `Host`, `Guest`}—

Model	Dialog Pattern Pred. Accuracy	Question Type Pred. F1
KGG + Prob. Ground.	38.5	68.8
+ Dialog Pattern	86.3	76.2
+ Question types	**87.9**	**90.5**

Table 3: Performance on auxiliary tasks: Dialog Pattern prediction and Question Type prediction

to each input token. We demonstrate in Section 5.3 that such segment embeddings are essential for this kind of dialog modeling. We only consider target tokens for cross-entropy loss calculation with the conditional likelihood $p(x|H, K)$.

5.2 Predicting Look-ahead Dialog Patterns

Following Section 4.1, we use a generative model to explore the role of response type triplets in structuring media dialog (stemming from an interviewer utterance (Heritage, 1985)). Following response type triplets defined in Section 4.1, we predict the pattern of the dialog triplet beginning with the generated host question as an auxiliary predictive task alongside host utterance generation.

We treat this as a sequence transduction task, employing an LSTM (Hochreiter and Schmidhuber, 1997) decoder with an initial hidden state computed by mean-pooling GPT2 final layer hidden states. Consider $\mathbf{s}_i$ the i-th hidden state from the GPT2 decoder for a length L sequence; now for each hidden state $\mathbf{l}_i$ in the LSTM decoder, we also calculate attention over the GPT2 hidden states, where $\{\mathbf{s}_i\}$ are the keys and values, and $\mathbf{l}_i$ is the query, resulting in an attended vector. We concatenate this attended vector with the LSTM hidden state $\mathbf{l}_i$ and then project it to predict the dialog triplet sequence, maximizing the log-likelihood.

5.3 Predicting Question types

We further explore the impact of question types (dialog acts) via another auxiliary task: multi-label classification for host utterance question types (McLeod et al., 2019). We surmise that accurately predicting question types will help infer question framing and wording, improving generation fidelity. Much like dialog pattern prediction, we use a pooled representation of GPT2 hidden states. We produce a score for each of three question attributes—polarity, combativeness, and subjectivity—via a linear projection and optimize via binary cross-entropy loss.

6 Experiments

In our experiments, we seek to answering the following: 1) Does knowledge grounding help generate more topical host responses? 2) Do our two auxiliary discourse losses improve dialog generation performance? 3) Do human raters find responses generated by our model coherent and fluent? Hyperparameter details are in Appendix §A.

Metrics To measure the fidelity of generated responses, we compute BPE perplexity and BLEU (Papineni et al., 2002) between generated and gold utterances. To assess topical accuracy, we calculate the overlap between noun-phrases and named entities in the generated and gold responses. We are also interested in measuring coherence with respect to the context (i.e., grounding documents and dialog history), calculated via the noun-phrase and named entity overlap between generated responses and context. Furthermore, as news interviews are intended to inform audiences, interviewers must ask questions using specific vocabulary and construction. To assess this, we adopt the Normalized Inverse Document Frequency (See et al., 2019) to measure vocabulary specificity via word rarity. Finally since we focus on generating interrogative host responses, we also calculate the percentage of questions asked in the generated responses as a measure of model inquisitiveness.

6.1 Effect of Knowledge Grounding

To assess the usefulness of explicit grounding documents, we first compare dialog models that use and do not use such documents in Section 5.3. Using segment embeddings to mark utterance bounds improves all measures of fidelity, signifying that this is a useful way to leverage speaker role information in dialog modeling using GPT2. Models that use external grounding knowledge outperform non-grounded models by 1-8 points on almost all metrics, suggesting that such grounding is an important component of host response generation models. To assess the impact of our knowledge grounded generator (KGG) architecture, we compare performance against a strong Memory Network (MemNet) baseline for knowledge grounded dialog generation (Dinan et al., 2019). We confirm our choice of a GPT2-based KGG, as it outperforms Memory Networks in all quality metrics.

Next, we compare the impact of document assignments made via TF-IDF and our probabilistic linking (PL) method. We once again see im-

Model	PPL	BLEU	QR	NPOG	NPOC	NEOG	NEOC	NIDF
No Grounding								
Finetuned (FT) GPT2	28.6	15.4	34.2	0.67	0.57	0.92	0.98	0.105

Grounding (PL)	How The NFL's New Rule On Protesting Is Being Perceived By Players
Context	**HOST**: Host: How are the players that you're talking to reacting to the stand that the NFL's taken? **GUEST**: Well, I think they've taken the position that the NFL has decided to fully engage with this culture war initiated by the president [. . .] I think this has really reignited some really bad blood between the players and the owners. **HOST**:
Gold	And how is that manifesting itself? I mean, what conversations are the players having, and what can they actually do?
KGG (TF-IDF)	Can you tell me more about NFL's new rules?
KGG (Probabilistic Linking)	This are some significant changes in NFL's rules. I think the most effect will be on the players.
+ Dialog Pattern	Okay so let's talk about NFL players. What is your gameplan?
+ Question Types	So how are you responding to this ever-evolving scenario? What are the key steps are you planning to take to gauge players' sentiment?

Table 6: Sample generated response on NFL's new rule. When we add discourse specific losses, the models generate questions that bears more coherence to the context as well as ask clarifying questions.

proved fidelity, mirroring our observations from Section 4.3. Models trained using PL document assignments generate utterances with 19-20% higher noun-phrase and named entity overlap with the gold utterance and context, indicating that PL assignments allow the KGG to more strongly condition on the provided context.

6.2 Effect of Auxiliary Tasks

In this experiment, we investigate how predicting dialog patterns and question types impacts the specificity and fidelity of generated host responses. Each auxiliary loss contributes a significant improvement (1-2 points) in perplexity but affects fidelity and topicality in different ways.

With dialog pattern prediction, we observe that generated responses are more coherent with respect to conversational context, seeing 8% and 48% improvements in noun phrase and named entity overlap with dialog history, respectively. This supports the sociolinguistic observation that the interviewer's choice of utterance (i.e., whether to ask a question, and response content) depends on the discourse structure toward which they aim to guide the conversation (Heritage, 1985). Our results suggest that biasing a dialog model to predict future discourse structure can encourage it to more effectively leverage the past dialog structure (from the conversation history). We confirm in Table 3 that this model can predict look-ahead dialog patterns with 86.3% test-set accuracy. In light of findings that vanilla dialog models may not condition well on conversation context (Sankar et al., 2019), our results suggest one possible direction toward improving contextual language modeling for dialog with inherent structure, such as media dialog.

When we add question-type-prediction loss, we see a significant drop in perplexity and improved fidelity. As expected, by inducing our model to predict the question attributes for the target utterance, our model achieves the highest inquisitiveness (58% question rate). It can also accurately predict question types, with 90.5% macro-averaged test set F1 score. Our results suggest that as the model learns to categorize the interviewer response via specific attributes, it simultaneously learns to generate responses with more specific wording. Table 6 contains representative generations from our best model as well as other baselines, showing that when we add additional discourse specific losses, our model appropriately captures the interviewer's clarifying intent and conversation direction. More generation examples are in Appendix §C.

6.3 Human Evaluation

Automatic evaluation of dialog generation quality is still unreliable (Liu et al., 2016; Novikova et al., 2017), and thus we provide evaluation by human users. We perform pairwise comparisons between responses generated by our best system and those generated by four strong baselines: the best model with no grounding, KGG with TF-IDF, KGG with PL, and KGG with dialog pattern prediction. We also compare against the gold response. Our human evaluation study (details in Appendix §B) measures three aspects of response quality on 100 test examples: 1) How relevant the response is with respect to **dialog history**; 2) How relevant the response is with respect to **grounding documents**; and 3) Whether the generated response is **fluent** English.

We observe in Table 5 that human judges prefer responses generated by our best model (with both discourse analysis auxiliary tasks) to baselines by statistically significant margins in almost every case. This indicates that dialog structure and question types are highly useful for generative modeling in a media dialog setting—specifically news interviews. Human raters also found that despite a significant drop in perplexity when adding the question-type prediction loss, the two versions of discourse-conditioned models had similar fluency, indicating similar language modeling performance. We observe an inter-annotator agreement (Cohen's kappa) of 0.79, 0.92, and 0.73 for relevance to dialog history, grounding documents, and fluency, respectively.

7 Conclusion

In this work, we perform the first large-scale analysis of discourse patterns in media dialog, using a new dataset of 23K annotated news interview transcripts: INTERVIEW. Our results mirror findings from linguistic studies of news interviews (Weizman, 2008; Heritage, 1985). We demonstrate that adding auxiliary tasks for discourse pattern and interrogative type prediction helps model such media dialog. We observe that responses depend heavily on external knowledge, and present a probabilistic framework for linking factual documents with a conversation. While we focus on discourse *pattern* analysis, INTERVIEW also supports analysis of temporal patterns in interviewing, argumentation, and knowledge grounding in long conversations.

Acknowledgments

We thank Sudha Rao, Sujoy Paul, Digbalay Bose, and anonymous reviewers for providing valuable feedback on this work. This work is partly supported by NSF Award #1750063. Findings and observations are of the authors only, and do not necessarily reflect the views of the funding agency.

A Implementation Details

Dataset Table 7 provides the statistics for train-dev-test splits on INTERVIEW. We avoid modeling salutations and sign-offs (which tend to be formulaic, and specific to the radio station) by restricting the target turns to those with at least three prior turns and two following turns of conversation, resulting in a target training set of 87K host-only turns and 11K host-only turns for dev and test. We perform BPE tokenization with the GPT2Tokenizer[6].

Network architectures For probabilistic linking, we use a 6-layer encoder-decoder Transformer model (Vaswani et al., 2017). The input to the model consists of grounding document followed by dialog history. The output is the next response in the dialog. To speed up the learning phase, we use ReZero initialization (Bachlechner et al., 2020) that do not require learning weight warm-up schedule. We also observe that performing reassigning at every epoch results in noisy update in assignments and weaker local optima is achieved at the end. When we switch the reassignment phase for every third epoch, the learning stabilizes mirroring a line search (Wright, 2015) from coordinate descent optimization.

For the media dialog generation model, we use GPT2 (Transformer with 12 layers, 768 hidden size, 12 heads, and 117M parameters—`gpt2-small`[7]) as the base architecture. Our best model KGG with two discourse-specific auxiliary losses has 124M parameters.

Hyperparameters We use history size 5 and number of grounding documents as 5. We use the RAdam optimizer (Liu et al., 2019) and the learning rate was set at $6.25e-5$ with a linear decay of step size 10^{-1} per epoch. The loss coefficients in the multi-task loss function for dialog modeling loss, dialog pattern prediction loss and question type prediction loss were 2.0, 1.0, and 1.0 respectively.

Training Each model converged in 3 epochs on an average with batch size 4 in a TITAN X (Pascal) GPU that took 6 hours in total. While training, we only observe perplexity on the validation set to employ an early-stopping criteria.

Split	# Episodes	# Turns	# Sentences	# Words
Train	18,971	364,461	994,163	17.4 M
Dev	2,371	45,502	123,861	2.2 M
Test	2,372	44,776	122,088	2.1 M
2P	**23,714**	**454,739**	**1,240,112**	**21.7 M**
Full	**105,848**	**3,199,856**	**7,455,662**	**126.7 M**

Table 7: Statistics from two-party (2P) and multi-agent (Full) INTERVIEW dataset

B Evaluation

B.1 Human Evaluation

For human evaluation, we hired two Anglophone (Lifetime HIT acceptance % $>$ 80) annotators for every human-evaluated test generation. Figure 5 shows a sample question for a human judge for the pairwise comparison of a response generated by our best model (KGG with two discourse-specific auxiliary losses) and a response generated by a baseline for three aspects—coherence to dialog history, coherence to grounding, and English language fluency.

C Generation Examples

See Table 8 for a sample dialog history and generated host responses from each of our baseline and our best model—KGG with two auxiliary losses.

Instructions (Click to collapse)

This task requires basic English language understanding.

For each instance, you will have to read the dialog history between two people **A** and **B**, and the background knowledge provided. And then observe the two alternative responses **R1** and **R2**. We expect you to compare the two alternatives on:

1) Which response do you think is more relevant with the background knowledge?

2) Which response do you think is more relevant with the dialog history?

3) Which response is more fluent in English?

1.
Background Knowledge:
Document: How The NFL's New Rule On Protesting Is Being Perceived By Players

2.
Dialog History:
A's turn: How are the players that you're talking to reacting to the stand that the NFL's taken?
B's turn: Well, I think they've taken the position that the NFL has decided to fully engage with this culture war initiated by the president [...] I think this has really reignited some really bad blood between the players and the owners.

Alternatives for A's next turn:
Response R1: So how are you responding to this ever-evolving scenario? What are the key steps are you planning to take to gauge players' sentiment?
Response R2: And how is that manifesting itself? I mean, what conversations are the players having, and what can they actually do?

1.1 Considering English language fluency only, compare R1 and R2:
○ **R1 is better** ○ **Both have similar fluency** ○ **R1 is worse**

1.2 Which response do you think is more engaging/interesting?
○ **R1 is more engaging** ○ **Both have similar engagement level** ○ **R1 is less engaging**

1.3 Which response do you think is better in terms of relevance to the history?
○ **R1 is better** ○ **Both have similar fluency** ○ **R1 is worse**

Figure 5: Human evaluation for pairwise comparison between our best model and another baseline.

Grounding (PL)	Trump's Week Of 'Fire And Fury'
Context	**GUEST**: Steve Bannon is quoted as saying [. . .] the president has lost it. Now, are you supporting a president who is incapable of being entrusted with [. . .] nuclear weapons? **GUEST**: Well - one thing I haven't heard yet is Steve Bannon interviewed [. . .] so look, I think the president of the United States has shown he's very, very capable [. . .]. **HOST**:
Gold	Should he be taunting a dictator with nuclear weapons about the size of his nuclear button?
KGG (TF-IDF)	Well, that's what you've been talking about, right?
KGG (Probabilistic Linking)	What do you see as a future?
+ Dialog Pattern	I am worried about his political position now.
+ Question Types	Do you think it's a good idea to confront a nuclear war?

Table 8: Sample generated response on nuclear threat. KGG with discourse specific losses generate more specific and on-topic responses.

INSPIRED: Toward Sociable Recommendation Dialog Systems

Abstract

In recommendation dialogs, humans commonly disclose their preference and make recommendations in a friendly manner. However, this is a challenge in developing a sociable recommendation dialog system, due to the lack of dialog dataset annotated with such sociable strategies. Therefore, we present INSPIRED, a new dataset of 1,001 human-human dialogs for movie recommendation with measures for successful recommendations. To better understand how humans make recommendations in communication, we design an annotation scheme related to recommendation strategies based on social science theories and annotate these dialogs. Our analysis shows that sociable recommendation strategies, such as sharing personal opinions or communicating with encouragement, more frequently lead to successful recommendations. Based on our dataset, we train end-to-end recommendation dialog systems with and without our strategy labels. In both automatic and human evaluation, our model with strategy incorporation outperforms the baseline model. This work is a first step for building sociable recommendation dialog systems with a basis of social science theories[1].

1 Introduction

Sociable conversational agents build rapport with users, in order to gain trust and favor from them. Social science researchers believe that the rapport influence a more persuasive recommendation to successfully suggest an item that satisfies user needs (Yoo et al., 2012; Gkika and Lekakos; Pecune et al., 2019; Gretzel and Fesenmaier, 2006).

However, existing works on recommendation dialog systems lack a study about communication strategies used by human speakers for making successful and persuasive recommendations. They collect the dataset in scenario-based settings or convert product review datasets into question-answering conversations (Reschke et al., 2013; Yan et al., 2017; Sun and Zhang, 2018; Kang et al., 2019; Li et al., 2018). Common issues with these types of datasets are: (1) homologous utterances, (2) mostly question-answering pairs, and (3) lack of user engagement.

REC: Hi! Happy Thanksgiving! I'm here to help you find a trailer!
SEEK: Happy Thanksgiving! My favorite movie is finding Nemo I really like it

REC: Awesome! So do you like Disney movies in general?
SEEK: Yup they are so colorful and full of life!

REC: Yeah, I love Disney too! I have Disney + and watch it everyday haha. Have you seen the new Lady and the Tramp? I find it relatable to my dog!
SEEK: Lol that's good enough! Never heard of that one! what is it about?

REC: It's about a dog named Lady who runs away with a stray named Tramp out of jealousy . . What do you think?
SEEK: Woo sounds good! I definitely want to see this. Thank you!

REC: No problem! Hope you enjoy it as I did!

Figure 1: An example snippet of human-human recommendation dialog in INSPIRED. REC refers a person who recommends a movie and SEEK refers a person who looks for a recommendation. Above each recommender's utterance is the recommendation strategy annotated by human workers. Best seen in colors.

In this work, we aim to validate whether sociable recommendation strategies are effective for making a successful recommendation in a dialog. To do so,

Dataset	INSPIRED	CONVREC (Sun and Zhang, 2018)	GORECDIAL (Kang et al., 2019)	REDIAL (Li et al., 2018)
Naturalness	✓	✗	✗	✓
Sociable Strategies	✓	✗	✗	✗
Movie Information	✓	✗	✓	✗
Conversation Types	Mixed	QA	Mixed	Mixed
#Dialogs	1,001	385	9,125	10,006
#Utterances	35,811	-	160,904	182,150

Table 1: Comparison of related recommendation dialog datasets. "QA" refers to question-answer pairs. "Mixed" indicates that the conversations contain both statements and question-answer pairs. CONVREC collected 385 human-curated dialogs, but only released 875,721 simulated dialogs.

we propose INSPIRED, a recommendation dialog dataset of two-paired crowd-workers in a natural setting, with additional annotations for sociable recommendation strategies. The dataset consists of 1,001 dialogs, and each utterance is manually annotated with the sociable strategies based on social science theory. To encourage more natural dialog flow, we do not set any restrictions on the number of movies or the type of movies to recommend. Figure 1 shows an example of annotated dialog. More examples are in Table 11 and 12 in the Appendix.

Our analyses show that sociable recommendation strategies are correlated with successful recommendation in dialogs. These insights motivate us to build a more sociable recommendation dialog system to achieve better persuasion outcomes.

For extrinsic evaluation, we build two end-to-end dialog systems trained on the INSPIRED dataset: one is encoded with recommendation strategies and the other is not. We find that the model encoded with our strategy annotations performs better in both automatic and human evaluation.

We believe that enriching the intersection between social science and computational linguistics in INSPIRED opens plenty of rooms for future studies on sociable recommendation dialog.

2 Related Work

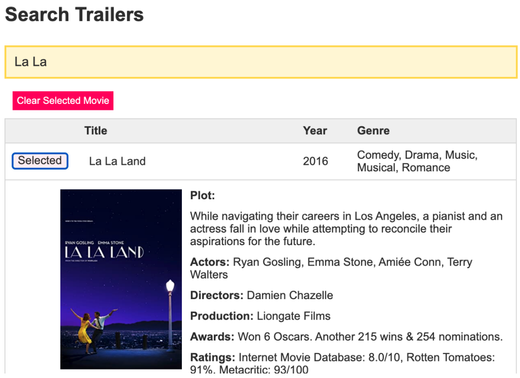
Social science theories on recommendation. Psychological researchers believe that interactions with recommendation systems should not only be seen from a technical perspective but should also be examined from a social and emotional perspective (Zanker et al., 2006). Yoo et al. (2012) propose that credibility, likeability, friendliness, humor, and other language styles are significant factors for persuasive recommendations. Pecune et al. (2019) has studied modeling social explanation for movie recommendation, such as personal opinion and personal experience. Häubl and Murray (2003) find that more information on recommendation may help consumers make better purchase decisions, but leave them overwhelmed with the abundant information. Inspired by these theories, we borrow such principles in the design of our sociable recommendation strategies.

Conversational recommendation systems. While studies on conversational recommendation systems have been done, none of them focus on the sociable recommendation strategies for persuasive outcome. This is is due to the lack of existing datasets for studying effective strategies in recommendation dialog. Table 1 compares different factors across the recommendation dialog datasets including INSPIRED.

Prior works on recommendation dialogs collect data based on template-based question-answering pairs from user reviews (Thompson et al., 2004; Reschke et al., 2013; Sun and Zhang, 2018; Zhang et al., 2018b). These datasets contain structured utterances where the recommender continuously asks for the seeker's product preference.

Kang et al. (2019) collected goal-driven recommendation dialogs (GORECDIAL) in a gamified setting where both speakers are given a small set of movies with descriptions to find the best recommendation. This role-play game setting may not effectively reflect the real-world situation since the seeker pretends that they like the given movies.

The most similar work to ours is Li et al. (2018)'s REDIAL dataset which consists of chit-chats for movie recommendation. However, the recommendations are conditioned on the movies mentioned in the dialog, and not directly on the language usage. Also, they tend to mention only movie names rather than an in-depth discussion on the movie



La La

	Title	Year	Genre
Selected	La La Land	2016	Comedy, Drama, Music, Musical, Romance

Plot:

While navigating their careers in Los Angeles, a pianist and an actress fall in love while attempting to reconcile their aspirations for the future.

Actors: Ryan Gosling, Emma Stone, Amiée Conn, Terry Walters

Directors: Damien Chazelle

Production: Liongate Films

Awards: Won 6 Oscars. Another 215 wins & 254 nominations.

Ratings: Internet Movie Database: 8.0/10, Rotten Tomatoes: 91%. Metacritic: 93/100

Figure 2: Movie search interface for recommenders.

preference.

Our work is also closely related to Radlinski et al. (2019) on movie preference elicitation and Fabian Galetzka1 (2020) on movie discussion in the dialog setting. Preference elicitation is an important step for the human recommender to comprehend seeker's taste before recommendation, but these datasets are not recommendation conversations.

Meanwhile, dialogs in INSPIRED have both stages: preference elicitation and recommendation. INSPIRED also captures sociable recommendation strategies in conversations and measures recommendation with ratings.

Sociability in dialog systems. In human-human conversations, people engage in a talk that does not only contain task-oriented topics (Bickmore and Cassell, 2005). Thus, sociability has raised more attention in dialog systems as they become more sociable, engaging, and user-adaptive (Zhang et al., 2018a; Shi and Yu, 2018; Göker and Thompson, 2000).

Zhang et al. (2018a) proposed a chit-chat dataset and presented the task of more personalized dialogs system conditioned on user profile information. Sociability leads to a more persuasive conversation (Yoo et al., 2012), so social skills are essential for dialog systems to make successful recommendations.

Communication strategies on specific tasks, such as donation and product price negotiation, have been found useful for task completion (Wang et al., 2019; Zhou et al., 2019). In this work, we connect different sociable strategies with recommendation in dialog settings and show that sociable strategies have a positive impact on recommendation success.

3 Recommendation Dialog Collection

3.1 Movie Database Creation

To ensure that the recommended movie has trailers and metadata information, we curate a database with all movie trailers from Movieclips Trailer[2] released between 2008 and 2020, and movies from MovieLens dataset (Harper and Konstan, 2015). In total, we have 17,869 movies with trailers and metadata information. We design a simple movie search interface (Figure 2) to assist recommenders in searching for a movie.

3.2 Recommendation Task

We recruit crowd-workers from Amazon Mechanical Turk. In each conversation, two workers are randomly paired and assigned different roles: one as a recommender and another as a seeker. Our collection set-up is more realistic compared to prior works as (1) recommenders have no limitations of the number of movies to recommend, (2) seekers accept or reject a movie following their true preference, and (3) we record if seekers actually watch the video trailer or not.

Recommender. Recommenders' task is to recommend a movie successfully to the seeker. Before chatting, we show them tips for sociable recommendation strategies with example utterances. Then they chat with the seekers in two phases: user information gathering and movie recommendation. In the user information gathering phase, recommenders are asked to understand the seekers' movie tastes. In the recommendation phase, the recommenders can still request seekers' preference while browsing movies to recommend. We encourage the recommenders to continue the conversation until seekers accept a movie.

Seeker. Seekers are asked to talk about movie recommendations without any strategy support. After they complete the conversation, seekers can opt to accept or reject the provided movie recommendations. If the seekers accept the recommendation, they can watch the entire recommended movie trailer or part of it, or simply skip it after the conversation. We record how long seekers watched the recommended movie trailer and ask them to rate the trailer on 5-Likert scale in the post-task survey.

# Utterances	17,472
Average tokens per turn	12.12
# Unique tokens	10,097

Table 2: INSPIRED's statistics. # denotes the number.

3.3 Dialog Data Collection Details

We use ParlAI platform (Miller et al., 2017) and hire 1,594 US crowd-workers from Amazon Mechanical Turk with a minimum of 90% task acceptance rate. The dialog collection process lasted from November 2019 to March 2020.

Workers first fill out questionnaires related to their personality traits and values before their conversations. The questionnaire consists of three personality trait models: the Big Five personality traits (15 questions) (Goldberg, 1993), the Schwartz Portrait Value (10 questions) (Schwartz, 2003), and the Decision Making Style (2 questions) (Hamilton et al., 2016)[3]. Then, recommenders start the conversation and both workers should chat for a minimum of 10 turns or until a recommendation is made. After the conversation ends, both workers will answer a post-task survey of demographic questions such as age, and gender. Seekers are asked to rate the trailer with a high score (4 or 5 stars) on a 5-Likert scale and provide the reason of why they reject or do not finish watching the video. Both workers receive a bonus up to $2 if they complete the entire process in addition to the base pay of $0.5.

Table 2 presents statistics of the collected dataset[4]. Even though our dataset has relatively small number of samples compared to REDIAL or GORECDIAL, it has human annotations on each sociable strategy. Moreover, our dataset can be used in combination with other datasets in a semi-supervised setting, as shown in our implementation of recommendation dialog systems in §6.

Cases	**#Dialogs**	
Accept (Rating 4-5)	532	(53.1%)
Accept (Rating 3 or lower)	45	(4.5%)
Accept (Other Reasons)	289	(28.9%)
Accept Uninterested	123	(12.3%)
Reject	12	(1.2%)

Table 3: Statistics of dialogs when the seekers accept or reject the final recommended movie. "Accept (Rating 4-5)" means that the seekers accept the recommendation and give rating 4 or 5, and the same is for "Accept (Rating 3 or lower)". "Accept (Other Reasons)" suggests that the seeker gives other reasons for not finishing the video. "Accept Uninterested" indicates that the seekers accept the recommendation, do not finish watching the video, and explains in the post-task survey that they are not interested in the recommended video.

The statistics of accept and reject cases are shown in Table 3. We have higher number of successful cases (79.7%) compared to failure cases. This shows that people tend to accept recommendations, and it is not surprising since watching a video trailer is an entertaining, low-risk activity. For training the dialog model, we use every dialog from all cases so that the dialog system will be able to respond to diverse responses.

4 Recommendation Strategy Annotation

4.1 Strategy Definition

After conversations are collected, two experts, trained with linguistics background, develop an annotation scheme using content analysis method (Krippendorff, 2004) and from past study on human behavior in making recommendations. Similar approaches have been done in prior studies on work for persuasion task (Wang et al., 2019) or negotiation task (Zhou et al., 2019). We divide the recommendation strategies into two categories: sociable strategies and preference elicitation strategies. Sociable strategies are also derived from our literature study on the social science theories.

Sociable strategies contain eight strategies related to the recommendation task. These strategies relate to the recommenders trying to build rapport with the seekers.

- **Personal opinion** refers to a condition when recommenders express their subjective opinion

---

[3] We also release this personality information in our dataset for future work

[4] Dialog collection interfaces are in appendix H in Appendix

Category	Example
PERSONAL OPINION	“I really like Disney’s more recent princesses”
PERSONAL EXPERIENCE	“I have Disney+ and watched it everyday!”
SIMILARITY	“Oh, I love Disney as well.”
ENCOURAGEMENT	“You should definitely watch it!”
OFFERING HELP	“I’m here to help you find a trailer!”
PREFERENCE CONFIRMATION	“So do you like Disney movies in general?”
CREDIBILITY	“It’s about a dog named Lady who runs away with a stray named Tramp”
SELF-MODELING	“We are planning to go see Maleficent, we heard it was a very good movie.”
EXPERIENCE INQUIRY	“Have you seen the new Lady and the Tramp?”
OPINION INQUIRY	“What do you like about the Avengers: End-game?”
RECOMMENDATION	“You should check out Shazam!”

Table 4: Example utterances for each strategy.

about a movie, including its plot, actors, or other movie attributes.

- **Personal experience** refers to the use of sharing personal experience related to a movie. For example, recommenders may say that they watch the movie several times to convince the seekers that the movie is good. Both personal opinion and personal experience are part of self-disclosure that leads to establishing rapport with the seekers (Altman, 1973).

- **Similarity** refers to a condition when the recommenders are empathizing and being like-minded toward seekers about their movie preference to produce similarity among them. Similarity is believed to influence the seekers’ liking for the source that leads to trust the recommenders’ judgment more (O’Keefe, 2004), following Lazarsfeld and Merton (1964)’s homophily theory that states humans like other people who are similar to them.

- **Encouragement** is the use of praise of the seekers’ movie taste and encouragement to watch a recommended movie to build rapport and promote the recommended movie.

- **Offering help** is a strategy when the recommenders disclose explicit intention to help the seeker or being transparent. It is a part of “transparency” strategy from Gretzel and Fesenmaier (2006).

- **Preference confirmation** is a strategy when the recommenders ask or rephrase the seeker’s preference. This strategy is also a part of “transparency” strategy which states that the recommenders disclose their thinking process of understanding the seekers’ preference.

- **Self-modeling** is a strategy when the recommender becomes a role model to do something first so that the Seeker would follow (Dowrick, 1999).

- **Credibility** happens when the recommender shows expertise and trustworthiness in providing information to persuade the seeker (Fogg, 2002; O’Keefe, 2004; Rhoads and Cialdini, 2002). In our study, a recommender is doing credibility appeal when they provide factual information about movie attributes, such as the plot, actors, or awards that the movie has.

Preference elicitation inquiries include the following inquiries that are asked by the recommenders to know the seekers’ movie tastes.

- **Experience inquiry** asks for seeker’s experience on movie watching, such as whether a seeker has watched a certain movie or not.

- **Opinion inquiry** asks for seeker’s opinion on movie-related attributes. Example answers for this inquiry is the seeker’s explanation on what they like about the plot or if they admire the actors’ acting skill.

Other kinds of utterances, such as greetings or thanks, fall into non-strategy category. We also label sentences which are recommendation. Recommendation is defined as when the recommender

suggests a new movie title for the first time for the seeker. 30% of the recommendation sentences are "experience inquiries", 27% are "encouragement", and 14% are "personal opinion". Example annotated utterances are displayed in Table 4. Meanwhile, Table 5 shows the number of annotated utterances in INSPIRED.

4.2 Annotation Quality

To ensure annotation quality, we separate our annotation study in two steps. First, we hire two experts with linguistics training to perform annotation, in order to test the validity of the scheme. The two experts annotated 30 randomly selected conversations and reached a Kappa agreement of 0.77, suggesting that our scheme is possible to replicate.

Our dataset contains more than 18k utterances, so it's too costly to hire experts to annotate all of them. In the second step, We hire US-based crowd-workers (95% task acceptance) from Amazon Mechanical Turk for the annotation tasks. In each task, a worker was given a tutorial of the annotation and then they were given 10 dialogs to annotate. One of the dialogs was labeled by experts to calibrate the quality of the worker's annotation, called as evaluation dialog. Five workers work on the same task. We filter out workers whose score is below the threshold 0.60 on the evaluation dialog. To set this threshold in a reasonable value, we conducted the following study. This time we ran onetask in which all the dialogs are already labeled with the experts including the evaluation dialogs. We found that if the workers' score on the evaluation dialog is above 0.60, their agreement score with the expert's annotation on the rest of the dialogs in this task is 0.77.

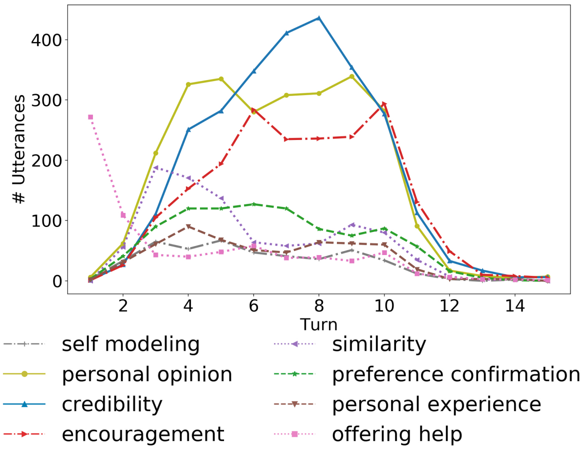

Figure 3: Distribution of sociable strategies over the dialog turns. Best viewed in color.

These selected high quality crowd-workers annotate the rest of the dialogs. We still have five workers annotate the same dialog. If more than one worker disagrees on a utterance's annotation, the experts are then involved to annotate them as quality control. The inter-annotator majority agreement among all workers is 0.78 over all dialogs. The annotation scheme for the crowd-workers are provided in Figure 12 in the Appendix.

5 Strategy Analyses

5.1 Distribution of Strategies over Dialog

As shown in Figure 3, we observe that different sociable strategies are unequally distributed across conversation turns. Most notably, "offering help" and "similarity" often happen at the beginning, indicating that recommenders strategically attempt to build rapport with seekers at the early stages. Then, "credibility" and "personal opinion" frequently appear in the conversations, as recommenders seek to persuade. Moreover, "encouragement" mostly appears in the middle and at the end of conversations.

5.2 What Strategies Contribute to Successful Recommendations?

We study the association of sociable strategies and successful recommendations. A recommendation is considered successful if seekers finish watching a substantial portion of the recommended movie trailer and rate the trailer with a high score (4 or 5 stars). We set a threshold that seekers need to watch at least more than 50% of the video duration since some videos have advertisements at the end, etc. On the other hand, a recommendation is considered unsuccessful if the seekers reject the recommendation ("Reject") or skip watching the trailer ("Accept Uninterested"). Thus, for our analysis, we use 532 successful dialogs and 135 unsuccessful dialogs for our analysis on association of strategies in successful recommendations.

To analyze the effect of our sociable recommendation strategies on success of recommendation, we run a logistic regression model to predict the success of recommendation (1 = successful, 0 = unsuccessful). We use frequency of the strategy in a dialog as the feature value.

Table 6 shows the coefficients of each strategy with respect to the recommendation. We observe that "personal opinion", "similarity", "encouragement", and "credibility" strategies have a significant positive effect on successful recommendations. This confirms with the previous studies that more sociable recommenders are more likely to be successful in the recommendation.

"Similarity" strategy has the highest coefficient value which suggests that if the recommender is conforming to the seeker's preference, the seeker is more likely to favor the recommendation. This also supports the theory in O'Keefe (2004) that likeability helps in recommendation. We also observe that all the preference elicitation inquiries are not significantly contributing to the successful recommendation. From this result, we are not saying that recommenders need not to query seekers' preferences since it is crucial to understand their tastes. However, a more sociable approach is necessary for a more successful recommendation.

Category	**Coefficient**
Sociable Strategies	
Personal Opinion	0.12*
Personal Experience	0.05
Similarity	**0.23***
Encouragement	0.20**
Offering Help	0.03

Self-Modeling	0.02
Credibility	0.09*
Preference Elicitation	
Experience Inquiry	−0.01
Opinion Inquiry	0.06

Table 6: Associations between different strategies and successful recommendation. *$p < 0.05$, **$p < 0.01$

5.3 Are Sociable Strategies Still Significant with the Presence of Movie Attributes?

In a recommendation task, a natural question to ask is how big a role the recommended product plays in the acceptance of recommendation. If the quality of the product matters more than how you recommend, it makes more sense to improve the products rather than the recommendation skills. Therefore, we also analyze if adding movie attributes, such as the genre, recent release date, and the number of likes of the movie trailer have an impact on successful recommendation along with the eight sociable strategies and two preference elicitation inquiries.

For the popularity, we categorize the top 10% movies in terms of the number of likes to be popular and the rest to be non-popular in our database. A movie is said to be recent if it is released in 2019 or 2020. For the genre, we select the top five most popular genres in the movie database. When we check with the recommended movies in INSPIRED, 96% of recommended movies are covered by the top five genres.

Results of the analysis between the strategies and movie attributes are shown in Table 8 in the Appendix. Sociable strategies remain significantly correlated with successful recommendations. Recommenders who perform "similarity" strategy, express "personal opinion", and show "encouragement" are more likely to successfully recommend a movie ($p < 0.05$). Surprisingly, none of the movie attributes has significant effect on successful recommendations. A possible reason is that the seekers' movie tastes are so diverse that movie attributes such as genre do not have a significant impact on the recommendation success.

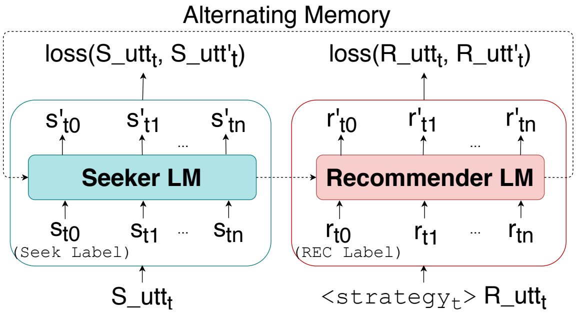

Figure 4: The Seeker's language model (Seeker LM) and the Recommender's language model (Recommender LM) are separate memory. The Seeker LM input at turn t is the seeker's utterance S_utt_t consisting of a sequence of tokens $s_{t0}, s_{t1}, ...s_{tn}$. The Recommender LM input at turn t is the recommender's utterance R_utt_t consisting of a sequence of tokens $r_{t0}, r_{t1}, ..., r_{tn}$. The `<strategy`$_t$`>` prepended as a special token. For the baseline, the recommender's input does not contain the strategies.

6 Recommendation Dialog Systems

To evaluate how the strategies in INSPIRED are useful in creating a more engaging and persuasive recommendation dialog, we develop a generative dialog model as our baseline to compare against our strategy-incorporated dialog system. We split the dialogs into 801/100/100 for train/validation/test split. We use external recommendation system from TMDB[5] with heuristics to select the movies. More details for heuristics and training set-up are in the Appendix.

6.1 Baseline Model

The baseline dialog model uses two separate Transformer-based pretrained language models (Vaswani et al., 2017; Radford et al., 2019; Wu et al., 2019) to learn the recommender's and seeker's language models separately in alternating order. Both language models are trained to maximize the likelihood of generating ground truth utterance on the alternating memory as shown in Figure 4. The model is pretrained on non-task related corpus, WebText, and task-related corpus: recommendation dataset from REDIAL (Li et al., 2018) and movie preference elicitation dataset (Radlinski et al., 2019). Then, we fine-tune the model with INSPIRED.

We replace movie attributes such as titles, actors, and genres with indexed placeholders. It is because in a single conversation, multiple attributes may be mentioned several times. The replacement with placeholders improves factual correctness as we replace them back with the original movie attributes later. At the end of the sentence, we append the attribute information as below:

Original: "If you like La La Land, you should also see Amazing Spiderman with Emma Stone"

With placeholder: "If you like `[MOVIE_TITLE_0]`, you should also see `[MOVIE_TITLE_1]` with `[MOVIE_P_ACTOR_0]`; movies: La La Land (2016), The Amazing Spider-Man (2012); people: Emma Stone"

6.2 Strategy-incorporated Model

We prepend the strategy as a special token to the input utterance so that the model does not only generate sentences but also strategies. Similar method was used to control text generation style (Rashkin et al., 2019) as a simple and effective way to incorporate the strategies. The input to the encoder is as follows:

Prepend: "`encouragement` If you like `[MOVIE_TITLE_0]`, you should also see `[MOVIE_TITLE_1]` with `[MOVIE_P_ACTOR_0]`; title: La La Land (2016), The Amazing Spider-Man (2012); people: Emma Stone"

The model first generates five candidate sentences. Then, it randomly selects a generated candidate that either contains "encouragement" strategy or has the greatest sentence length. In our experiment, we have tried various combinations of the top three strategies (e.g., "encouragement" only, "encouragement" and "similarity"), and it turns out that "encouragement" only model gave the best result. Moreover, the sentence length selection is based on our intuition when chatting with the system. This aligns from our findings, "encouragement" is the second most frequently used strategy when humans make recommendations (§4.1), and "recommendation" is associated positively with successful recommendation (Table 8)[6].

To decide if a sentence is a recommendation or not, we train a BERT-based recommendation classifier that receives an input of recommender's current utterance and seeker's utterances from previous turn with 95.4% accuracy and 91.2 % F1-score. While the index in the placeholder may become a

[6] We tried multi-task learning for utterance generation and strategy prediction, and the automatic metric result is comparable with the prepend method.

Model	PPL↓	BLEU-4↑
Baseline	9.28	5.11
Strategy	8.93	6.63

Table 7: Results for automatic metrics.

proxy to decide whether the system needs to recommend a movie or not, it is not strictly supervised. Thus, if a generated sentence is labeled as "recommendation", we enforce our dialog system to recommend a new movie.

6.3 Results

We compare the baseline dialog model without strategy supervision against our dialog model with strategy supervision. We use both automatic metrics and human evaluation.

For automatic metrics, we compute perplexity and BLEU scores (Papineni et al., 2002), suggesting that prepending strategies improves the model performance as shown in Table 7. For human evaluation, twenty-eight participants chat with both models for 2-3 times for a more reliable judgment. We randomize which model they will chat first, in order to avoid exposure bias. After chatting, they are asked to decide which model is better in these five aspects: fluency, consistency, naturalness, persuasiveness, and engagingness. If they are unable to distinguish the dialog systems, they are allowed to choose "can't tell" option.

Results in Figure 5 suggest that human users prefer the model with strategy over the baseline in all aspects[7]. It is interesting to see that although the strategy model is preferred on all metrics, people find the two model differs the most in engagingness, followed by naturalness. This supports our hypothesis that human users will find the conversations more engaging and more natural with sociable strategies incorporated in recommendation dialog systems.

7 Conclusion and Future Work

In this work, we have introduced INSPIRED, a new recommendation dialog dataset collected in natural setting and annotated with sociable recommendation strategies. We analyze the connection between different strategies and the recommendation results. Our findings show that sociable strategies do have a positive impact on the acceptance of recommendation and dialog quality. This work opens up several directions for future studies in building sociable and personalized recommendation dialog systems as follows:

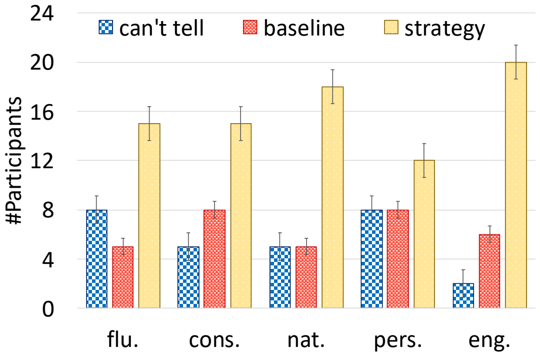

Figure 5: Human evaluation result. "Flu." stands for fluency, "cons.": consistency, "nat.": naturalness, "pers.": persuasiveness, and "eng.": engagingness.

First, we will explore more ways of utilizing the strategies, including dynamic strategy selection after decoding. Then, we plan to investigate the strategy patterns for people with different personalities and movie preferences to make dialog system more personalized. Finally, another interesting exploration is to extend the model with a jointly trainable movie recommendation and movie information modules.

Acknowledgments

We would like to thank members of the NLP lab at UC Davis for discussion and participation in the pilot study. We are also grateful for human evaluation participants and Mechanical Turk workers on contributions of building this dataset.

Abstract

Open-ended human learning and information-seeking are increasingly mediated by digital assistants. However, such systems often ignore the user's pre-existing knowledge. Assuming a correlation between engagement and user responses such as "liking" messages or asking followup questions, we design a Wizard-of-Oz dialog task that tests the hypothesis that engagement increases when users are presented with facts related to what they know. Through crowd-sourcing of this experiment, we collect and release 14K dialogs (181K utterances) where users and assistants converse about geographic topics like geopolitical entities and locations. This dataset is annotated with pre-existing user knowledge, message-level dialog acts, grounding to Wikipedia, and user reactions to messages. Responses using a user's prior knowledge increase engagement. We incorporate this knowledge into a multi-task model that reproduces human assistant policies and improves over a BERT content model by 13 mean reciprocal rank points.

1 Introduction

Conversational agents such as Alexa, Siri, and Google Assistant should help users discover, learn, and retain novel factual information. More generally, systems for conversational information-seeking should help users develop their information need, be mixed-initiative, incorporate user memory, and reason about the utility of retrieved information as a combined set (Radlinski and Craswell, 2017). We focus on a curiosity-driven, information-seeking scenario where a user starts a conversation with an assistant by asking an open-ended question and then drills down into interest areas (Figure 1).

In this setting, what policies should assistants pursue to maintain the user's interest in the topic?

U: <assistant wake-word>, tell me about Tahiti.
A: It's the largest island in French Polynesia, near the center of the Pacific
U: What is its history with France?

Figure 1: An example of information-seeking dialog that the Curiosity dataset aims to support. Assistants should answer user questions *and* convey information that inspires meaningful followup questions.

Theories of human learning, such as Vygotsky's zone of proximal development, propose that learning novel information should be rooted in pre-existing knowledge and skills of the learner (Chaiklin, 2003). Considering this, a good policy may give general information about Tahiti; a better policy would select information related to the user's knowledge (e.g., familiarity with France). We hypothesize that engagement is correlated with policies that integrate a user's pre-existing knowledge, and test this through a large-scale, Wizard-of-Oz (WoZ) style collection (Kelley, 1984; Wen et al., 2017) that captures assistant policies, user reactions, and topically relevant entities that the user knows about. The Curiosity dataset has 14,048 English dialogs annotated with sentence-level knowledge grounding, the user's prior knowledge, dialog acts per message, and binary ratings per message.[1]

In our dialog task (Figure 2), one worker takes the role of a curious user learning about a geographic entity and the other of a digital assistant with access to Wikipedia facts (Section 2). At the start of each dialog, the user is assigned an entity as their topic (e.g., Puerto Rico) along with two *aspects* (e.g., *history* and *demographics*) to investigate. Beforehand, we show the user a list of entities related to the topic, and they mark which they know; these entities are a sample of their pre-

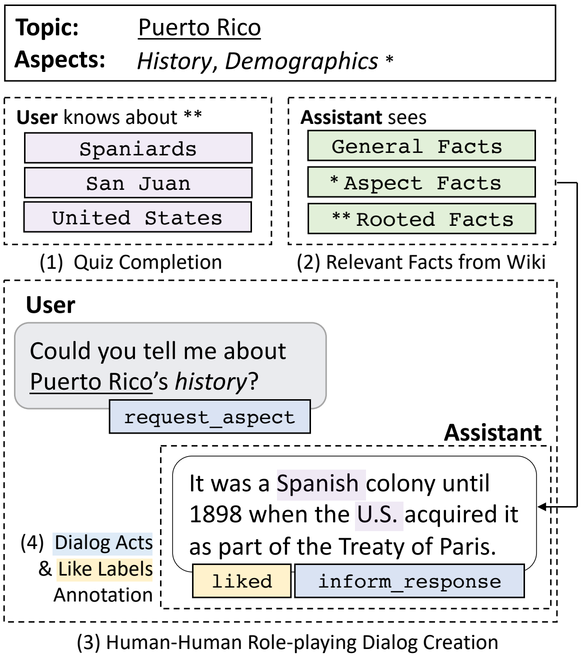

Figure 2: We sample pre-existing knowledge by asking users to indicate which topically related entities they already *know*. The assistant paraphrases facts related to either known entities (rooted facts), an aspect (aspect facts), or the topic generally (general facts). The user expresses engagement through a like button. Dialog acts are annotated in a separate crowd-source task.

existing knowledge. The user engages in open-ended discovery while the assistant simultaneously answers the user's questions and proactively introducing facts likely to prompt followup questions.

Section 3 uses dialog act annotations combined with explicit and implicit user feedback to compare assistants' content selection and presentation policies. For example, in interactions where the user asks a question and the assistant paraphrases a fact, how often does the user ask a followup question versus trail off in disinterest? Most datasets (Section 6) do not have enough annotations to answer these questions: it requires message-level dialog act annotations and feedback signals. We compare three assistant policies: using a fact with a rooted entity, a fact from the user's aspect, or a generic fact about the topic. The policies are compared through user "likes" of assistant messages and by the dialog act of their subsequent message (e.g., did they ask a specific followup or change topic).

In Section 4, we design models that predict the policies used by the assistant: what type of message to send and which fact to use (if any). All models are trained jointly with a multi-task objective function. We compare an end-to-end BERT (Devlin et al., 2018) model to our task-specific Hierarchical Recurrent Encoder model (Serban et al., 2015) and show that our model improves over the baseline.

In summary, we make three main contributions: (1) we design an experiment to test the efficacy of personalizing conversational information systems through a user's prior knowledge, (2) introduce the Curiosity dataset—the first dialog dataset combining sentence-level knowledge groundings, per message ratings, *and* per message dialog act annotations, allowing for robust and fine-grained structural learning of dialog policies for similar applications, and (3) design a multi-task model that incorporates the user's prior knowledge and improves over a natural BERT baseline.

2 Building the Curiosity Dataset

This section describes the construction of the Curiosity dataset. Dialog topics consist of prominent world geographic entities. The *worldwide* spread of entities makes each novel to most users, the consistent topic type makes starting dialogs easier, and their rich histories, demographics, and economics add topical diversity. For example, most people are only vaguely familiar with the history of Puerto Rico, but most know about related concepts such as the United States or Hurricane Maria. Section 2.1 describes how we select geographic topics, aspects, and derive a set of facts to ground against. We collected the dataset in two steps: (1) collecting dialogs with a custom interface (Section 2.2) and (2) after-the-fact dialog act annotation (Section 2.3). Sample dialogs from Curiosity are in Appendix C.

2.1 Geographic Topics, Aspects, and Facts

We select 361 geographic pages from Wikipedia that have separate geography and history pages (e.g., Puerto Rico, Geography of Puerto Rico, and History of Puerto Rico).[2] We use sentences from each page to build a set of 93,845 facts. We run an entity linker over the content (Gupta et al., 2017) and index each fact by its source page (topic), source section (*aspect*), and mentioned entities. Finally, we fit a TF-IDF text matcher (Rajaraman and Ullman, 2011) with Scikit-Learn (Pedregosa et al., 2011). While conversing, assistants are shown facts filtered by topic, aspect, or mentioned entities, that are ranked by textual similarity to the dialog.

---

[2] The existence of these pages implies that the topic has ample historical and geographical knowledge to draw from.

2.2 User and Assistant Dialog Interfaces

To collect dialogs, we build user and assistant interfaces for annotators. The user's interface samples their prior knowledge of a topic, captures which assistant messages interest them, and manages the dialog context. The assistant's interface provides contextually relevant facts. Appendix A has screenshots and details of each interface component.

Sampling User's Prior Knowledge When deployed, digital assistants can draw from prior interactions (Ram et al., 2018) to estimate what a user knows. However, since we do not have these prior interactions, we collect information about what users know. Instead of exhaustively asking about every entity related to the topic, we sample this knowledge. Before the dialog begins, we show the user fifteen related entities that range from commonplace to obscure (United States versus Taíno). Users mark the entities they could (1) locate on a map or (2) summarize succinctly in one sentence.

Like Button for User Interest As part of our collection, we aimed to determine what fact-grounded utterances users found interesting. Users "liked" the assistant's message if they found it "interesting, informative, and relevant to their topic."

Assistant's Topic Summary and Fact Bank The worldwide spread of Curiosity's entities makes them unfamiliar to most crowd-workers, including the assistants. So that the assistant can still engage the user, the assistant interface provides contextually relevant information. First, the interface shows a topic summary from Wikipedia. Second, the assistant paraphrases facts from a contextually updated fact bank (box 2 in Figure 2). To reduce information overload, we use simplified topic descriptions from SimpleWikipedia and show a maximum of nine facts at a time.[3] We encourage assistants to "stimulate user interest and relate information to things they already know or have expressed interest in." Assistants are instructed to select relevant facts, click the "use" button, and paraphrase the content into their next utterance.

Like Dinan et al. (2019), the fact bank shows facts to the assistant using TF-IDF textual similarity to recent dialog turns but differs by incorporating the user's prior knowledge. We show the assistant nine facts: three facts that mention an entity familiar to the user (rooted facts), three facts from their assigned aspects (aspect facts), and three from anywhere on the page (general facts). By construction, rooted facts overlap with the exclusive categories of aspect and general facts. For each category, we find the nine highest TF-IDF scoring facts and then randomize their order. To avoid biasing the assistant, we do not inform them about the user's known entities or distinguish between types of facts.

2.3 Dialog Act Annotation

Inducing structure on conversations through dialog acts is helpful for analysis and downstream models (Tanaka et al., 2019). We introduce structure—beyond knowledge groundings—into Curiosity by annotating dialog acts for each message.

In a separate collection, we annotate all utterances with dialogs acts using a custom interface (Appendix B). The annotation schema is based on ISO 24617-2 (Bunt et al., 2010, 2012) with customized sub-categories for our scenario. Table 1 shows our schema, descriptions, and examples.

2.4 Data Quality

We crowd-sourced conversations in two phases using ParlAI (Miller et al., 2017). In the first, pilot studies collect feedback from individual workers. Based on feedback, we create task guidelines, sample dialogs, a FAQ, tutorial videos, and qualification tests. These materials were used to train and qualify crowd-workers for the second phase. During the second, we monitor the interface usage and removed workers that ignored instructions.

Using Krippendorff's α (Krippendorff, 2004), we validate the quality of dialog act annotations. Dialog acts are multi-class and multi-label: a message can have none, one, or multiple dialog acts (e.g., positive feedback and followup). However, Krippendorff's α is computed for single-label tasks from a table where rows represent examples, columns represent annotators, and cells indicate the singular class label. We convert our multi-label problem to a single label problem by making each combination of example and label class a row in the table (Table 2). Since there are few dialog acts per utterance, most annotations agree; however, since Krippendorff's α focuses on disagreement, it is appropriate for this scenario. Using a separate annotation interface (Appendix B), we doubly annotate 4,408 dialogs and the agreement score 0.834 is higher than the 0.8 threshold recommended by Krippendorff (2004). Next, we analyze the annotated dialogs and introduce our model.

---

[3] If a description exists in simple.wikipedia.org, we use that; otherwise, we use the description from en.wikipedia.org.

Dialog Act	Count	Description	Example
request topic	10,789	A request primarily about the topic.	I'd like to know about Puerto Rico.
request aspect	41,701	A request primarily about an aspect.	Could you tell me about its *history*?
request followup	4,463	A request about mentioned concept.	Do you know more about the Taínos?
request other	10,077	Requests on unmentioned concepts.	What is there to know about cuisine?
inform response	59,269	Directly answer an info request.	Taínos were caribbean indigenous.
inform related	6,981	Not a direct answer, but related info.	I do not know, but...
inform unrelated	557	Does not answer question, not related.	Politics is tiring!
feedback positive	26,946	Provide positive feedback	Thats quite interesting!
feedback negative	176	Provide negative feedback	Thats pretty boring.
feedback ask	36	Ask for feedback	Do you find < info > interesting?
offer topic	91	Offer to discuss topic	Want to learn about Puerto Rico?
offer aspect	1,440	Offer to discuss aspect	How about more on its *demographics*?
offer followup	63	Offer to discuss mentioned concept.	I could say more about the Spanish.
offer other	1,619	Offer to discuss unmentioned concept.	How about I tell you about its exports.
offer accept	1,727	Accept offer of information.	I'd love to learn about its history.
offer decline	405	Decline offer of information	Sorry, I'm not interested in that.

Table 1: Counts, abbreviated descriptions and examples of the dataset's dialog acts.

	Annotator 1	Annotator 2
Utterance 1, Label A	Yes	No
Utterance 1, Label B	Yes	No
Utterance 2, Label A	Yes	Yes
Utterance 2, Label B	Yes	Yes

Table 2: Consider a task where each utterance has labels A and B. In the single-label version, each utterance is labeled as either A or B. The table shows the outcome of converting the multi-label version to single-label by creating a row for each example–label combination. Cell values are binary indicators.

Metric (# of)	Total	Train	Val	Test	Zero
Dialogues	14,048	10,287	1,287	1,287	1,187
Utterances	181,068	131,394	17,186	17,187	15,301
Likes	57,607	41,015	5,928	5,846	4,818
Topics	361	331	318	316	30
Facts Total	93,845	NA	NA	NA	NA
Facts Shown	76,120	66,913	29,785	30,162	6,043
Facts Used	27,486	21,669	4,950	4,952	2,290

Table 3: Curiosity has 14,048 dialogs. On average, dialogs have 12.9 utterances. 60% of the assistants' 90,534 utterances were liked.

3 Dataset Analysis

This section shows statistics of the Curiosity dataset and that users prefer aspect-specific, rooted facts.

3.1 Dataset Statistics

Table 3 shows the basic statistics of the Curiosity dataset. In total, our dataset contains 14,048 dialogs with 181,068 utterances. The fact database contains 93,845 facts; of those, 76,120 (81%) were shown to the assistants and 27,486 (29%) were used in at least one message. We randomly split dialogs into training, validation, and testing folds.

3.2 What Facts do User Prefer?

In Section 1, we hypothesized that when assistants use facts that mention previously known entities (rooted facts), users will be more likely to engage. In our data collection, we incorporate two mechanisms to test this hypothesis. The first mechanism is explicit: we directly ask users—through a like button—to indicate what messages they preferred. The second mechanism is implicit and derived by mining dialogs for specific sequences of dialog acts that suggest engagement with the content. For each of these mechanisms, we compute the likelihood $P(\text{Prefer} \mid \text{Fact Source})$ of a user preferring utterances grounded to each fact source (Rooted, Aspect, or General). Figure 3 shows this likelihood and indicates that users prefer: (1) facts relevant to aspects versus general ones and (2) rooted facts in three of four scenarios.

3.2.1 Likes for Explicit Preference Elicitation

Explicit preference is computed directly from like button usage and shown on the right panel of Figure 3. Overall, users liked 60% of messages, and they prefer on-aspect, rooted facts.

3.2.2 Mining Acts for Implicit Preferences

When users ask specific followup questions—as opposed to generic ones—about an assistant's fact, it shows that the user implicitly prefers these kinds of messages. For example, asking about an entity like the Taínos is more specific than asking about history and therefore indicates engagement. We

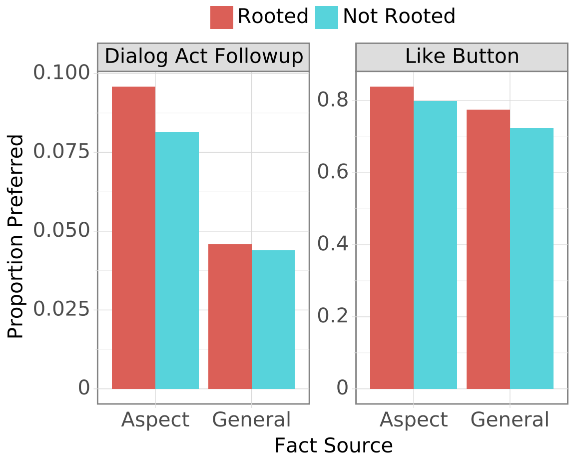

Figure 3: User engagement is measured by dialog act followups (left) and like button usage (right). We compare reactions to messages that use a fact mentioning an entity the user knew about (rooted) and whether the fact is general or aspect-specific. Pairwise differences are statistically significant (99%+) with a two proportion z-test *except* for dialog act followups between rooted and non-rooted general facts. Overall, users prefer on-aspect, rooted facts.

identify these interactions by mining for pairs of assistant-user messages where the assistant uses a fact and their message is labeled with an "inform" dialog act. With these, we compute the likelihood

$$P(\text{Outcome} = \text{request followup} \mid \text{Fact Source})$$

that the user's message has the "request followup" dialog act given the source. Similarly to likes, users engage more with aspect-oriented and rooted facts.

3.2.3 Paraphrase Analysis

Although our work does not include a paraphrase model, we manually analyze a random sample of two hundred and fifty assistant messages where facts were used. Of these messages, 51% were acceptable paraphrases, 27% were verbatim copies, 12% were contextualizations of near copies, and the remainder were errors such as incorrect paraphrases or did not incorporate the fact. Appendix D shows descriptions, counts, and random examples of each category. This analysis estimates that about half of grounded messages have non-trivial signal for future paraphrase models to use.

4 Models

We design a machine learning model that predicts assistant and user actions. We introduce a multitask architecture for **C**uriosity that **Hi**er**ar**chically **M**odels (CHARM, Figure 4) dialogs to: (1) predict the dialog acts of the user message (utterance act prediction), (2) select the best fact (fact prediction), (3) choose the best set of dialog acts for the next message (policy act prediction), and (4) predict if the assistant message will be liked (like prediction).

4.1 Text Representation

CHARM jointly encodes the text of utterances and facts with one encoder. E is a bi-directional LSTM (Sutskever et al., 2014) over GLoVE (Pennington et al., 2014) word embeddings and Wikipedia2Vec (Yamada et al., 2020) entity embeddings.[4] The text t_i^u of utterance u_i in dialog D is represented as $E(t_i^u)$. Similarly, fact f_j on turn i is represented as $E(t_{i,j}^f)$ where j indexes facts shown on that turn.

4.2 Dialog Representation

In our models, we use a hierarchical recurrent encoder (HRE) architecture (Sordoni et al., 2015; Serban et al., 2015) where a forward LSTM contextualizes each utterance to the full dialog. We modify the HRE model by adding additional inputs beyond the utterance's textual representation. First, we represent user's known entities

$$\boldsymbol{k} = \text{avg}(E_{\text{entity}}(e_1), \ldots, E_{\text{entity}}(e_k))) \tag{1}$$

as the average of entity embeddings. An entity embedding also represents the topic

$$\boldsymbol{t} = E_{\text{entity}}(\text{topic}) \tag{2}$$

of the dialog. Next, we create trained speaker embedding $\boldsymbol{v}_s$ for the user and $\boldsymbol{v}_t$ for the assistant. Given the set of all dialog acts $\mathcal{A}$, each utterance has a set of dialog acts $\mathcal{A}_u \in \mathcal{P}(\mathcal{A})$ where $\mathcal{P}(\mathcal{X})$ denotes the set of all subsets of $\mathcal{X}$. Finally, we use an act embedder A to compute an act representation

$$\boldsymbol{a}^i = \frac{1}{|\mathcal{A}_u|} \sum_{a_k \in \mathcal{A}_u} A(a_k) \tag{3}$$

by averaging embeddings at each turn. The input at each step is the concatenation

$$\boldsymbol{c}^i = [E(t_i^u); \boldsymbol{a}^i; \boldsymbol{t}; \boldsymbol{k}; \boldsymbol{v}] \tag{4}$$

of the representations for text, speaker, topic, known entities, and utterance dialog acts.[5] With this joint representation, the contextualized dialog representation

$$\boldsymbol{h}^{i-1} = \text{LSTM}(\boldsymbol{c}^1, \ldots, \boldsymbol{c}^{i-1}) \tag{5}$$

---

[4] In CHARM, BERT was not as effective an encoder.

[5] The speaker embedding $\boldsymbol{v}$ alternates between $\boldsymbol{v}_s$ and $\boldsymbol{v}_t$.

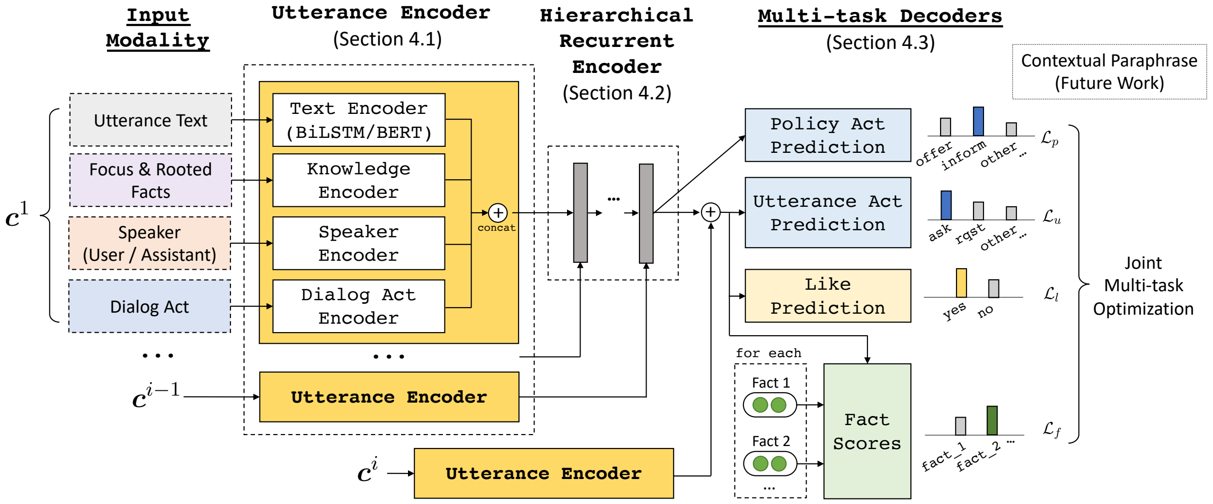

Figure 4: **Architecture**: CHARM builds a dialog context up to $t = i - 1$ to predict the current message's dialog acts (policy prediction) and the best facts to use. The model uses this combined with the current utterance to classify it's dialog acts and if it will be liked.

is the final LSTM state and includes time step $t = i - 1$. The dialog up to and including time i is

$$\boldsymbol{d}^i = [\boldsymbol{h}^{i-1}; \boldsymbol{c}^i] \tag{6}$$

which emphasizes the current utterance and makes multi-task training straightforward to implement.

4.3 Tasks and Loss Functions

In our model, we jointly learn to predict fact usage, user likes, utterance acts, and policy acts.

Fact Prediction For every assistant turn, the model predicts which fact(s) from

$$\{f_1, \ldots, f_k\} \in \mathcal{F}^{(i)}, \mathcal{F}^{(i)} \in \mathcal{P}(\mathcal{F})$$

the assistant marked as "used" where $\mathcal{F}$ is the set of all facts. We frame this task as pointwise learning to rank (Li et al., 2008). A fact prediction network

$$\boldsymbol{s}_j^{f,(i)} = \text{GELU}\left(\left[\boldsymbol{W}^f \cdot \boldsymbol{h}^{(i-1)} + \boldsymbol{b}^f; E(t_j^f)\right]\right) \tag{7}$$

with parameters $\boldsymbol{W}^f$ and $\boldsymbol{b}^f$ using a Gaussian Error Linear Unit (Hendrycks and Gimpel, 2017) outputs salience scores for each fact. The network does not use utterance u_i since it contains signal from the choice of fact. The predictions

$$\hat{\boldsymbol{y}}_j^{f,(i)} = \text{softmax}(\boldsymbol{s}_j^{f,(i)}) \tag{8}$$

are converted to probabilities by the softmax

$$\text{softmax}(\boldsymbol{q}) = \frac{exp(\boldsymbol{q})}{\sum_{j=1}^{k} exp(\boldsymbol{q}_j)} \tag{9}$$

over k labels. Using this, we compute the fact loss

$$\mathcal{L}_f = \frac{1}{|\mathcal{F}^{(i)}|} \sum_{i,j} \ell_{ce}(\hat{\boldsymbol{y}}_{i,j}^f, \boldsymbol{y}_{i,j}) \tag{10}$$

where labels $\boldsymbol{y}_j^{f,(i)}$ indicate if fact from utterance i in position j was used and

$$\ell_{ce}(\hat{\boldsymbol{y}}, \boldsymbol{y}) = \sum_{p=1}^{k} \boldsymbol{y}_p \log(\hat{\boldsymbol{y}}_p). \tag{11}$$

is the cross entropy loss. To mitigate class imbalance, we also scale positive classes by nine (Japkowicz and Stephen, 2002).

Policy Act and Utterance Act Prediction Each utterance may have multiple dialog acts so we treat policy and utterance act prediction as a multi-label task. The goal of policy prediction is to choose the best act for the next utterance; the utterance act classifies the last message's acts. To predict these acts, we create a policy act network

$$\boldsymbol{s}^{p,(i)} = \text{GELU}(\boldsymbol{W}^p \cdot \boldsymbol{h}^{i-1} + \boldsymbol{b}^p) \tag{12}$$

and an utterance act network

$$\boldsymbol{s}^{u,(i)} = \text{GELU}(\boldsymbol{W}^u \cdot \boldsymbol{d}^i + \boldsymbol{b}^u) \tag{13}$$

where the probability of act a_k is $p_k^{*,i} = exp(\boldsymbol{s}_k^{*,(i)})$. From these, we derive the policy act loss

$$\mathcal{L}_p = \sum_{k}^{|\mathcal{A}|} y_{i,k}^a \log p_k^{p,i} + (1 - y_{i,k}^a) \log(1 - p_k^{p,i}) \tag{14}$$

and utterance act loss

$$\mathcal{L}_u = \sum_{k}^{|\mathcal{A}|} y_{i,k}^a \log p_k^{u,i} + (1 - y_{i,k}^a) \log(1 - p_k^{u,i}) \tag{15}$$

for an utterance at $t = i$ with act labels $y_{i,k}^a$.

	Fact Rank (MRR)		Utt. Act (F_1)		Policy Act (F_1)		Like (Accuracy)	
Model	Val	Test	Val	Test	Val	Test	Val	Test
Majority Class	N/A	N/A	0.602	0.604	0.491	0.494	0.690	0.681
E2E BERT	0.420	0.418	0.794	0.795	0.635	0.631	0.829	**0.822**
CHARM	0.546	**0.546**	0.845	**0.847**	0.682	**0.682**	0.826	0.815
− context	0.516	0.506	0.838	0.842	0.664	0.664	0.824	0.820

Table 4: The CHARM model outperforms end-to-end BERT on most tasks. We compare fact selection with MRR, dialog act prediction with micro-averaged F_1, and like prediction with accuracy. Ablating dialog history degrades context-dependent tasks (fact selection and policy act prediction), but not tasks more dependent on one message.

Like Prediction For every assistant message, the model predicts the likelihood of the user "liking" the message. We treat this as binary classification, predict the "like" likelihood

$$\hat{y}_i^l = \text{softmax}(\text{GELU}(\boldsymbol{W}^l \cdot \boldsymbol{h}^i + \boldsymbol{b}^l)), \qquad (16)$$

and use it to compute the like loss

$$\mathcal{L}_l = \ell_{ce}(\hat{y}_i^l, y_i^l) \qquad (17)$$

where y_i^l indicates if the message was liked. We train the model jointly and optimize the loss

$$\mathcal{L} = \mathcal{L}_f + \mathcal{L}_l + \mathcal{L}_p + \mathcal{L}_u. \qquad (18)$$

See Appendix F for training details.

5 Modeling Experiments

CHARM improves over a BERT model in most tasks.

5.1 Evaluation

We evaluate each sub-task with separate metrics. Fact selection is evaluated with mean reciprocal rank (MRR). For utterances with at least one selected fact, we compute the MRR using the selected facts as relevant documents. We compare like prediction with binary classification accuracy. For utterance and policy act prediction, we compare models with micro-averaged F_1 scores so that frequent classes are weighted more heavily. For each metric, we report validation and test set scores.

5.2 Baselines

BERT (Devlin et al., 2018) is a standard baseline for many NLP tasks. We use a multi-task extension of an uncased BERT model as our primary baseline and fine-tune it for our unique set of tasks (E2E BERT). Specifically, we use the CLS representation of each utterance to replace the HRE representation as a time-distributed input to the same multi-task decoders (Section 4.3). The context-less CHARM ablation replaces the dialog contextualizer LSTM with a per-timestep projection layer. Lastly, we report majority class accuracy for classification tasks.

5.3 Discussion

The proposed CHARM model for conversational curiosity is more effective than E2E BERT for most of the tasks in Curiosity (Table 4). Specifically, CHARM improves significantly in fact prediction (13 MRR points) and both dialog act prediction tasks (5 F_1 points), demonstrating the efficacy of the structural encoding of the various input modalities. Generally, models accurately predict utterance acts and likes, but their MRR and F_1 scores on fact selection and policy act prediction is comparatively worse. To a degree, this is expected since there is not always one best fact or one best action to take as the assistant; there may be various reasonable choices, which is common in information retrieval tasks. Nonetheless, models that specifically reason about the relationship between prior knowledge and entities would likely yield improvement. For example, Liu et al. (2018) predict the most relevant unmentioned entity while Lian et al. (2019) model a posterior distribution over knowledge. We leave these improvements to future work.

6 Related Work

Our work builds on knowledge-grounded conversational datasets and modeling.

Datasets Although there are numerous grounded datasets, we did not find one for conversational information seeking that contained fine-grained knowledge groundings, message-level feedback from the user, and dialog acts. Table 5 compares the Curiosity dataset to several others according to six factors: (1) is the goal of the task information seeking, (2) is the dataset collected from natural dialog with one participant always taking the role of an assistant, (3) are dialog responses constrained, (4) are document groundings annotated—as opposed to distantly supervised—and fine-grained, (5) is there message level feedback for the assistant, and (6) is the dataset annotated with dialog acts.

Dataset	Info Seeking	Dialog w/Assistant	Free Response	Annotated Grounding	Message Feedback	Dialog Acts
Curiosity (ours)	✔	✔	✔	✔	✔	✔
Topical Chat (Gopalakrishnan et al., 2019)	✔	⚠	✔	✔	✔	⚠
Search as a Conversation (Ren et al., 2020)	✔	✔	✔	✔	✗	✗
Wizard of Wikipedia (Dinan et al., 2019)	✔	✔	✔	✔	✗	✗
QuAC (Choi et al., 2018)	✔	✔	✗	✔	✗	⚠
CMU DOG (Zhou et al., 2018b)	✔	✔	✔	⚠	✗	✗
MS Marco Conv. (Nguyen et al., 2016)	✔	✗	N/A	N/A	N/A	N/A
OpenDialKG (Moon et al., 2019)	✗	✔	✔	✔	✗	✗
CoQa (Reddy et al., 2019)	✗	✔	⚠	✔	✗	✗
Holl-E (Moghe et al., 2018)	✗	⚠	✔	✔	✗	✗
Commonsense (Zhou et al., 2018a)	✗	✗	✔	✗	✗	✗
Reddit+Wiki (Qin et al., 2019)	✗	✗	✔	✗	✗	✗

Table 5: ✔ indicates a dataset has the feature, ⚠ that it does with a caveat, and ✗ that it does not. Conversational MS MARCO is a search dataset but has inquiry chains we want assistants to induce (exemplar in Appendix G). Topical Chat and Search as a Conversation are motivationally similar. While our dataset's combination of (human) annotation is unique, all three datasets are steps forward in resources for conversational information-seeking.

Our dataset is most similar to those for information-seeking such as QuAC (Choi et al., 2018), Wizard of Wikipedia (Dinan et al., 2019, WoW), CMU DOG (Zhou et al., 2018b), MS MARCO (Nguyen et al., 2016), Topical Chat (Gopalakrishnan et al., 2019), the TREC Conversational Assistance track (Dalton et al., 2019, CAsT), and Search as a Conversation (Ren et al., 2020, SaaC). QuAC constrains assistant responses to spans from Wikipedia, which makes it better for conversational *question answering*, but prevents more sophisticated assistant policies. QuAC also provides dialog acts, but they exist so that the assistant can inform the user of valid actions; we annotate dialog acts after-the-fact so that we can compare *freely chosen* user responses. Like QuAC, Topical Chat, SaaC, and WoW have annotated knowledge-groundings for each message, but responses are free-form. SaaC is a contemporaneous, CAsT-based dataset that shares our motivation to make conversation a medium for information-seeking. Topical Chat includes user feedback, but instead of explicitly defined roles, workers implicitly take dual and alternating roles as the user and assistant through knowledge asymmetry; followup work added automatically annotated dialog acts to Topical Chat (Hedayatnia et al., 2020).

Many tasks instruct annotators to take on a specific role in the dialog. For example, in Wizard of Wikipedia, annotators assume an assigned persona (Zhang et al., 2018) in addition to being the user or assistant. Consequently, many dialogs revolve around personal discussions instead of teaching about a topic. Additionally, annotators may not have the background to play their role. In contrast, we ask annotators to take roles that—as humans—they already know how to do: read about and convey interesting information on a topic (assistant) and engage in inquiry about a novel topic (user).

Our work is one of many in knowledge-grounded conversational datasets. For example, Moghe et al. (2018) have workers discuss movies and ground messages to plot descriptions, reviews, comments, and factoids; however, one worker plays both roles. In OpenDialKG (Moon et al., 2019), annotators ground messages by path-finding through Freebase (Bast et al., 2014) while discussing and recommending movies, books, sports, and music. Qin et al. (2019) use Reddit discussion threads as conversations and ground to web pages. Similarly, Ghazvininejad et al. (2018) collect Twitter three-turn threads and ground to Foursquare restaurant reviews. Our work adds to this dataset compendium.

External Knowledge in Models Our model is related to those that incorporate external information like facts in question answering (Weston et al., 2015; Sukhbaatar et al., 2015; Miller et al., 2016), knowledge base triples in dialog models (Han et al., 2015; He et al., 2017; Parthasarathi and Pineau, 2018), common sense (Young et al., 2018; Zhou et al., 2018a), or task-specific knowledge (Eric and Manning, 2017). Similarly to Kalchbrenner and Blunsom (2013); Khanpour et al. (2016), CHARM predicts the act of the current message, but also next message's act like Tanaka et al. (2019) do.

7 Future Work and Conclusion

We see two immediate directions for future work. The first is to augment our CHARM model with a text generation module to make a digital version of our human assistants. This involves contextualizing and paraphrasing facts which our dataset supports. Second, dialog act sequences could identify additional data-driven policies that could be used to define rewards or losses. By conditioning on dialog acts or sequences of dialog acts, textual outputs could be better-controlled (Sankar and Ravi, 2019; See et al., 2019) and combined with knowledge grounding (Hedayatnia et al., 2020). However, text is not the native modality of digital assistants.

We envision digital assistants participating in information-seeking, which means handling speech input. Consequently, automatic speech recognition (ASR) introduces transcription errors which are especially prevalent in knowledge-oriented text like question answering (Peskov et al., 2019). Gopalakrishnan et al. (2020) show this is also problematic in information-seeking dialog by comparing models on textual and ASR versions of Topical Chat. To close the loop in conversational information-seeking, models need to account for the speech-based environment of digital assistants.

In summary, this work introduces Curiosity: a large-scale conversational information seeking dataset. With Curiosity's unique set of annotations, we design CHARM which jointly learns to choose facts, predict a policy for the next message, classify dialog acts of messages, and predict if a message will be liked. We hope that our dataset will encourage further interest in curiosity-driven dialog.

Acknowledgments

We thank Rajen Subba, Stephen Roller, Alborz Geramifard, and Scott Yih for insightful discussions. Thanks to Becka Silvert for improving the task guidelines and Victor Ling for building the dialog act annotation tool's backend. Thanks to Sara LaRocca and Hal Daumé III for advice on adapting Krippendorff's α. We thank our anonymous ACL and EMNLP reviewers as well as Shi Feng, Jordan Boyd-Graber, Joe Barrow, Karthik Gopalakrishnan, and UMD CLIP members for feedback on the paper. Rodriguez's contributions to this work while at UMD were supported by NSF Grant IIS-1822494. A Components of Dialog Interfaces

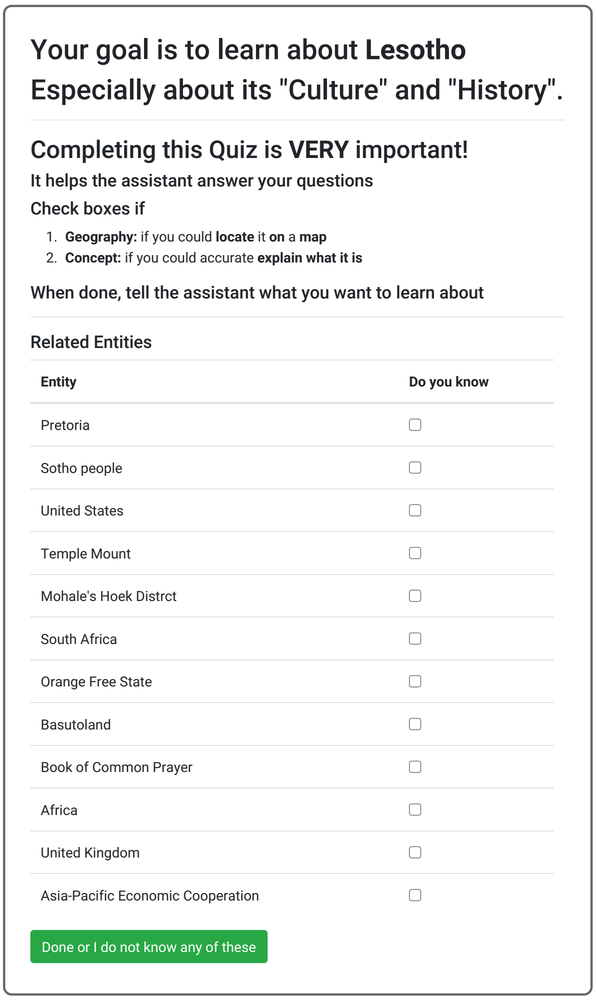
In this section, we provide short descriptions and screenshots of every component of the user and assistant dialog interfaces.

A.1 User's Interface

Figure 5 shows the interface that we use to sample the user's prior knowledge of entities related to the topic. To derive a diverse sample, we use Wikipedia page views as a proxy for how well known the entity is. All experiments use the English Wikipedia dump generated on July 23, 2019. We divide entity mentions into ten buckets based on the frequency of page views, and round-robin sample fifteen entities from those buckets. The interface is shown before the user starts chatting with the assistant.



Your goal is to learn about **Lesotho**
Especially about its "Culture" and "History".

Completing this Quiz is **VERY** important!
It helps the assistant answer your questions
Check boxes if

1. **Geography:** if you could **locate** it **on** a **map**
2. **Concept:** if you could accurate **explain what it is**

When done, tell the assistant what you want to learn about

Related Entities

Entity	Do you know
Pretoria	☐
Sotho people	☐
United States	☐
Temple Mount	☐
Mohale's Hoek Distrct	☐
South Africa	☐
Orange Free State	☐
Basutoland	☐
Book of Common Prayer	☐
Africa	☐
United Kingdom	☐
Asia-Pacific Economic Cooperation	☐

Figure 5: In this example, the user is assigned to learn about Lesotho, specifically its *culture* and *history*. In addition to their training with guidelines and videos, we repeat the instructions here. The related entities span relatively common ones like the United States or Africa to less known ones such as Basutoland.

We elicit how "interesting" a user finds each of the assistant's messages through the like button in Figure 6. Only users can "like" a message; the assistant cannot "like" user messages. Users are instructed to "like" messages if they are "interesting, informative and/or entertaining" and "relevant to their topic and/or aspects." They are specifically instructed not to "like" messages that are devoid of factual content, only express feelings, or only contain greetings or farewells.

Switching Aspect Users are randomly assigned two aspects for each dialog and told to spend time discussing each. The guidelines instruct them to spend at least two turns per topic, but we do not specify any further time requirements. When the user changes aspects, we instruct them to click a button (Figure 7) to indicate when and which aspect they are switching to. Additionally, this event triggers a reset in the context we use to rank the assistant's facts.

A.2 Assistant Interface

By design, we intend for most workers to not be familiar in depth with most of the geographic topics. Thus, the most important responsibility of the assistant interface is to provide enough information—without overwhelming them—to be engaging conversational partners. The first interface shown is a short description of the topic from either Simple Wikipedia or the English Wikipedia. This component helps the assistant reach a general understanding of the topic so that they can choose better facts.

The most important component of the assistant interface is their list of available facts. These facts have high textual similarity with the most recent three turns and are broken into three categories: facts related to entities the user knows about (rooted facts), facts related to an aspect (aspect facts), and facts from anywhere on the page (general facts). Feedback from pilot collections showed that six facts was too few which caused a lack of relevant facts, but twelve facts overwhelmed annotators. Thus, we use nine facts so that we can also balance equally across each type of fact. When composing their reply, the assistant can use any number of facts as in Figure 9. To discourage verbatim copying, we disable the paste feature in javascript. We also drop repeatedly unused facts.

Important Like Button Instructions!

Like a Message ONLY if:

- It is interesting, informative, and/or entertaining
- It is relevant to your the topic and/or aspects

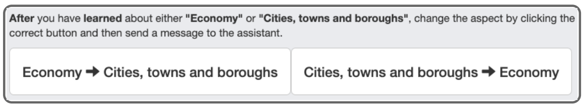
Do NOT Like a message if:

- It is empty of factual content
- Only expresses feelings
- Only says hi or bye

YOU: I'd like to know about Alaska

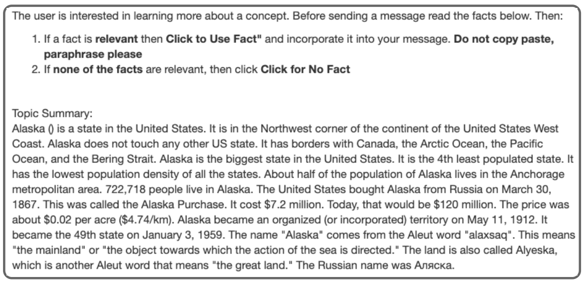
THEM: Sure, Alaska is largest state in the US and has an abundance of seafood from the North Pacific.

Figure 6: The user expresses the "interestingness" of the assistant's messages through a "like" button (right of message). The instructions are shown prominently in the full interface and repeated in training material.



After you have **learned** about either **"Economy"** or **"Cities, towns and boroughs"**, change the aspect by clicking the correct button and then send a message to the assistant.

Figure 7: The user is assigned two aspects about their topic. After they are satisfied with what they have learned about the first aspect, they click a button and switch to the next aspect. While the button click is not communicated to the assistant (the user must send a corresponding message), it resets the fact contextualizer; we observe that without this, too many facts were related to the previous aspect.



The user is interested in learning more about a concept. Before sending a message read the facts below. Then:

1. If a fact is **relevant** then **Click to Use Fact"** and incorporate it into your message. **Do not copy paste, paraphrase please**
2. If **none of the facts** are relevant, then click **Click for No Fact**

Topic Summary:
Alaska () is a state in the United States. It is in the Northwest corner of the continent of the United States West Coast. Alaska does not touch any other US state. It has borders with Canada, the Arctic Ocean, the Pacific Ocean, and the Bering Strait. Alaska is the biggest state in the United States. It is the 4th least populated state. It has the lowest population density of all the states. About half of the population of Alaska lives in the Anchorage metropolitan area. 722,718 people live in Alaska. The United States bought Alaska from Russia on March 30, 1867. This was called the Alaska Purchase. It cost $7.2 million. Today, that would be $120 million. The price was about $0.02 per acre ($4.74/km). Alaska became an organized (or incorporated) territory on May 11, 1912. It became the 49th state on January 3, 1959. The name "Alaska" comes from the Aleut word "alaxsaq". This means "the mainland" or "the object towards which the action of the sea is directed." The land is also called Alyeska, which is another Aleut word that means "the great land." The Russian name was Аляска.

Figure 8: A short topic description is always visible to the assistant. The goal is to ensure the assistant always has a general understanding of the dialog topic.

B Dialog Act Annotation

To annotate dialog acts, we create a separate annotation interface (Figure 10). The interface shows one dialog at a time, and the same annotator annotates all the utterances. In addition to the utterances, the interface shows the topic, aspects, and sender of each message. Lastly, we incorporate a "Report Dialog" feature to help identify and remove inappropriate dialogs.

C Sample Dialogs

Tables 6 and 7 show Curiosity dialogs and highlight the dataset's features. Typos and grammatical errors made by annotators are left unaltered.

D Paraphrase Analysis and Samples

In Section 3.2.3, we describe the results of a manual analysis on two hundred and fifty assistant paraphrases. Annotations were completed by the authors and shown in Table 8. We break messages into four categories: paraphrases, copies, errors, and unrelated. Paraphrases include messages that incorporate the selected fact and possibly additional information. Copies include verbatim copying, cherry-picked phrases, and trivial contextualizations like replacing an entity with a pronoun. Table 9 shows ten randomly selected paraphrases from the two hundred and fifty manual annotations.

E Like Prediction Comparison

Like prediction is the one task where CHARM was not the best model. To better understand the differences between the CHARM and BERT model, we randomly sample thirty dialogs in the test set and find assistant messages where the model predictions disagree. Of the 202 assistant messages in the thirty dialogs, the BERT like prediction is correct 174 times (86.1%) and CHARM 170 times (84.2%). The models disagree on eight predictions (3.96%); BERT is correct on six of these and CHARM on the other two. Table 10 shows the messages, predictions, and labels. Although we might guess at why the predictions differ (e.g., perhaps something in the Florida dialog confused BERT), without further analysis we cannot establish causality.

F Model Training, Implementation, and Computation

We implement all models with PyTorch (Paszke et al., 2019) and AllenNLP (Gardner et al., 2018). The learning rates for models is set using the built-in learning rate finder in AllenNLP. Model losses were optimized with Adam (Kingma and Ba, 2015);

	Topic:	Djibouti
	Aspects:	*Economy*, *Politics*
	Known Entities:	France, Africa
	Dialog Acts	Messages
U	`request topic`	Hi can you tell me about Djibouti?
A	`inform response`	The country of Djibouti is officially called the Republic of Djibouti is located in the horn of Africa. It was created out of French Somaliland. It is also recorded the country was colonized by France in1800s and later gained its independence on June 27, 1977.
U	`request aspect`	Can you tell me about their Politics
A	`inform response`	After its independence, The country had two regiments commanded by the French officers. The country also maintains its close ties with Somalia, Ethiopia, France and the United States.
U	`request aspect`	Any other information about the French and their impact of the politics?
A	`inform response`	There are no direct information on its effect on the country's politics but even though the country is already independent. The 13th Demi-brigade of the French Foreign Legion is still stationed in this country. It is also the largest french military presence abroad. commanded by a 3-star general.
U	`request aspect`	Heavy French infeleunce. what other interesting inofrmation on politics do you have?
A	`inform response`	In recent years, the country has improved its training techniques, military command, and information structure. They also became more self-reliant in supplying their military and assist in peacekeeping missions and provide military assistance to countries that officially ask them for help.
U	`request aspect,` `feedback positive`	Wow Interesting, Can you now tell me about the economy they have?
A	`offer aspect`	Sorry, I do not have that information. But I can tell you more about Politics.
U	`offer accept`	Sure
A	`inform response`	Camp Lemonnier is rented by the United State as a Naval Expeditionary Based for $63 Million a year. While Japan and France each pays $30 million a year and China pays $20 Million a year.
U	`request other`	Lastly, any any fun facts?
A	`inform response`	I am not sure if this is a fun fact, but the country's gross domestic product expanded by more than 6%. From $341 Million to 1.5 Billion
U		That's a huge increase. thank you for all your help
A		You are welcome

Table 6: Example dialog #1 from Curiosity. (U: User, A: Assistant)

the BERT model uses a learning rate of .0001 and CHARM a learning rate of .001 with otherwise default parameters. We train for a maximum of forty epochs and early stop based on the sum of validation losses. The CHARM model uses batch size 64 and the BERT model batch size 4. Our best model (CHARM), has 26, 970, 475 parameters, takes two hours and eighteen minutes to train, and early stops on epoch fifteen. In our models, text encoders for utterances and facts share parameters.

Models were developed on a single machine with eighty Intel 2.0GHz CPUs, 256GB RAM, and eight Tesla V100 graphics cards. Each model was trained and evaluated on a single graphics cards with hyper-parameter sweeps parallelized across the eight cards.

AllenNLP configuration files and software dependencies (including version) are included in our code at github.com/facebookresearch/curiosity.

G MS Marco Conversational Sample Queries

Conversational MS MARCO is a search dataset that partially inspired this work. Assistant messages should prompt followup queries like in Table 11.

	Topic:	British Columbia
	Aspects:	*Government and politics*, *Culture*
	Known Entities:	Canada, Seattle
	Dialog Acts	Messages
U	`request topic`	Hi! Can you help me learn some basic information about British Columbia? I don't know much except that it's located in Canada.
A	`inform response`	Yes, British Columbia is the westernmost province of Canada and is located between the Rocky Mountains and the Pacific Ocean.
U	`request aspect,` `feedback positive`	I didn't know it was on the coast! What can you tell me about government and politics there?
A	`inform response`	One interesting fact about the government is that the Green Part plays a larger role in this province than it does in other provinces of Canada.
U	`request followup,` `feedback positive`	Interesting. What can else you tell me about the Green Party?
A	`inform response`	The New Democratic Party and the Green Party caucuses together control 44 seats. Which seems like a lot but the British Columbia Green Party only takes up 3 of those 44 seats.
U	`request aspect`	That's a pretty small influence. Can you tell me some fun culture facts about British Columbia?
A		I am sorry I do not have any information on their culture right now.
U	`request topic`	That's okay. What other fun facts can you share?
A	`inform response`	Interestingly, Queen Victoria chose British Columbia to distinguish what was the British sector of the Columbia District from the United States which became the Oregon Territory on August 8, 1848.
U	`request aspect`	So that's why it has "British" specifically as part of it's name! Makes sense. Are there any sports or outdoor activities that are popular in British Columbia?
A	`inform response`	Horseback riding is enjoyed by many British Columbians.
U		Thanks for your help today. Now I know more than I did before.
A		No problem, it was a pleasure.

Table 7: Example dialog #2 from Curiosity. (U: User, A: Assistant). After mentioning the Green Party, the user asks a specific followup question; we use these interactions to estimate implicit preference.

Category	Label	Count	Percent
Copy	verbatim	68	27.2%
Copy	cherry-pick	6	2.40%
Copy	context	30	12.0%
Copy	Total	104	41.6%
Paraphrase	paraphrase-correct	111	44.4%
Paraphrase	paraphrase-multiple	17	6.80%
Paraphrase	Total	128	51.2%
Error	paraphrase-error	5	2.00%
Unrelated	unrelated	13	5.20%
Total		250	100%

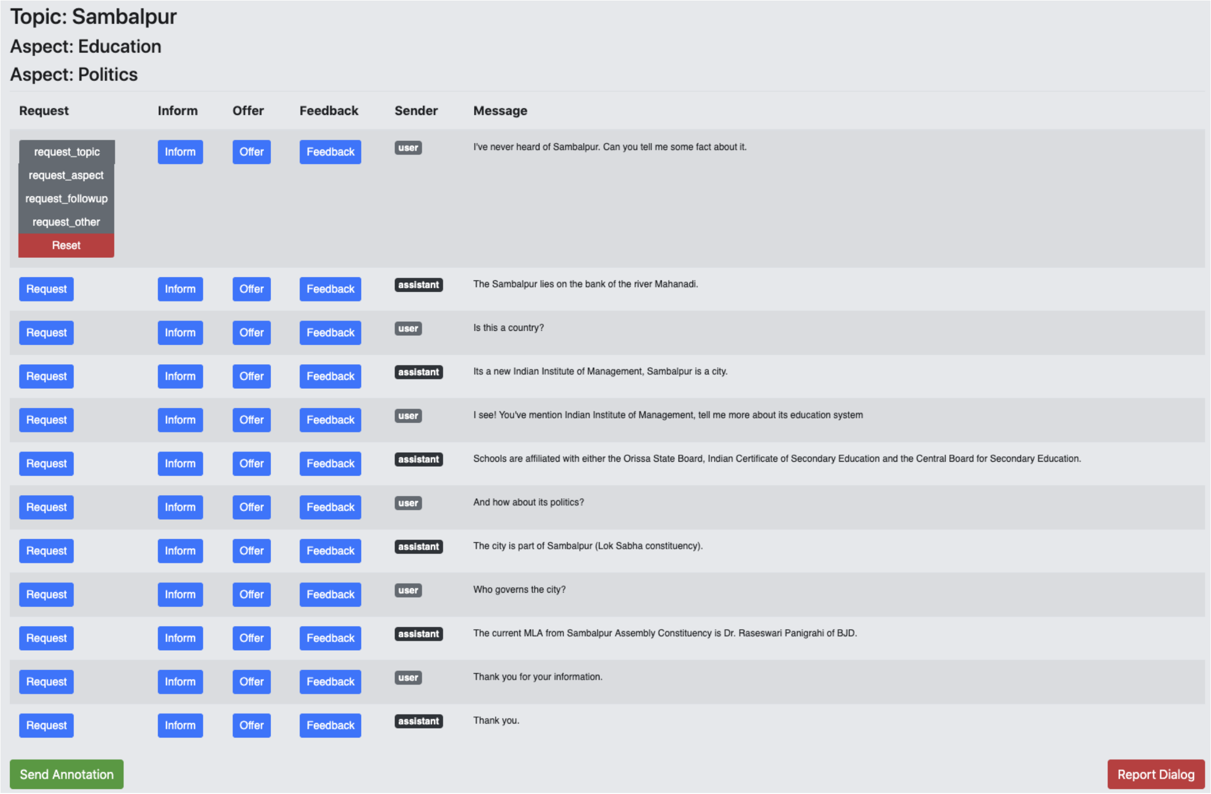
Table 8: We analyze the paraphrases annotators use through manual categorization. The "Copy" category includes cherry-picked verbatim phrases, verbatim copies, and contextualized copies (e.g., changing a named entity to "it"). The majority of paraphrases are correct and only incorporate the provided fact, but a few weave in other information. 7.2% of paraphrases are either unrelated to the selected facts or paraphrase the fact incorrectly. Overall, 51.2% of messages have valid paraphrases.

Entity	Section	Fact	
Anchorage, Alaska	Economy	Military bases are a significant component of the economy in the Fairbanks North Star , Anchorage and Kodiak Island boroughs , as well as Kodiak .	Fact Used
United States	Economy	The Trans-Alaska Pipeline can transport and pump up to 2.1 Moilbbl of crude oil per day , more than any other crude oil pipeline in the United States .	Fact Used
United States	Body	United States armed forces bases and tourism are also a significant part of the economy .	Fact Used
Alaska Natives	Economy	Many Alaskans take advantage of salmon seasons to harvest portions of their household diet while fishing for subsistence , as well as sport .	Click to Use Fact
Yakutat, Alaska	Cities, towns and boroughs	Yakutat City , Sitka , Juneau , and Anchorage are the four largest cities in the U.S. by area .	Click to Use Fact
Unorganized Borough, Alaska	Cities, towns and boroughs	The remaining population was scattered throughout Alaska , both within organized boroughs and in the Unorganized Borough , in largely remote areas .	Click to Use Fact
Oregon Territorial Legislature	State symbols	The willow ptarmigan is common in much of Alaska . , State fish : king salmon , adopted 1962 . , State flower : wild / native forget-me-not , adopted by the Territorial Legislature in 1917 .	Click to Use Fact
Pacific Ocean	Body	The Pacific Ocean lies to the south and southwest .	Click to Use Fact
Arctic	Geography	The climate in the extreme north of Alaska is Arctic (Köppen : ET) with long , very cold winters and short , cool summers .	Click to Use Fact
			Click for No Fact

THEM: Thats cool, I love salmon. What are their other main exports economically speaking?

YOU: The US armed forces through military bases and tourism are large parts of the economy. Alaska also has a large oil business with the Trans Alaska pipeline transporting more oil than any other crude oil pipeline.

Figure 9: The assistant could incorporate any number of facts into their reply to the user. Their goal was to answer the user's immediate questions, and anticipate what information they would be most interested in.



Topic: Sambalpur

Aspect: Education

Aspect: Politics

Sender	Message
user	I've never heard of Sambalpur. Can you tell me some fact about it.
assistant	The Sambalpur lies on the bank of the river Mahanadi.
user	Is this a country?
assistant	Its a new Indian Institute of Management, Sambalpur is a city.
user	I see! You've mention Indian Institute of Management, tell me more about its education system
assistant	Schools are affiliated with either the Orissa State Board, Indian Certificate of Secondary Education and the Central Board for Secondary Education.
user	And how about its politics?
assistant	The city is part of Sambalpur (Lok Sabha constituency).
user	Who governs the city?
assistant	The current MLA from Sambalpur Assembly Constituency is Dr. Raseswari Panigrahi of BJD.
user	Thank you for your information.
assistant	Thank you.

Figure 10: To annotate dialog acts, we develop an interface that showed each utterance on a separate line. Annotators assign zero or more dialog acts to each utterance using grouped dropdowns.

Label: paraphrase-correct
Message: I do not have the information available but I can tell you 10 million tones were exported annually for, Cardiff dock in the years leading up to the First World War.
Fact: In the years leading up to the First World War , more than 10 million tonnes of coal was exported annually from Cardiff Docks .

Label: copy
Message: Media and journalists in Namibia are represented by the Namibia chapter of the Media Institute of 'southern Africa and the Editors Forum of Namibia.
Fact: Media and journalists in Namibia are represented by the Namibian chapter of the Media Institute of Southern Africa and the Editors ' Forum of Namibia .

Label: paraphrase-multiple
Message: The film industry has a rich history in Indonesian culture and the Indonesian Film Festival has been held regularly since 1955.
Fact: Indonesia has held annual film festivals and awards , including the Indonesian Film Festival (Festival Film Indonesia) that has been held intermittently since 1955 .

Label: context
Message: EU means European Union. GDP per capital ranges from 188% of EU average in Bratislava to 54% in eastern Slovakia
Fact: GDP per capita ranges from 188 % of EU average in Bratislava to 54 % in Eastern Slovakia .

Label: paraphrase-correct
Message: Sudan was considered the 17th growing economy in the world. Its faster development of the country from oil profits.
Fact: Sudan , officially the Republic of the Sudan , is a country in Northeast Africa .

Label: paraphrase-correct
Message: There is a mountain range called the Annamite Range that runs along eastern border to Vietnam and another range, named Luang Prabang Range, near the Thailand border.

Queens are Powerful too: Mitigating Gender Bias in Dialogue Generation

Abstract

Social biases present in data are often directly reflected in the predictions of models trained on that data. We analyze gender bias in dialogue data, and examine how this bias is not only replicated, but is also amplified in subsequent generative chit-chat dialogue models. We measure gender bias in six existing dialogue datasets before selecting the most biased one, the multi-player text-based fantasy adventure dataset LIGHT (Urbanek et al., 2019), as a testbed for bias mitigation techniques. We consider three techniques to mitigate gender bias: counterfactual data augmentation, targeted data collection, and bias controlled training. We show that our proposed techniques mitigate gender bias by balancing the genderedness of generated dialogue utterances, and find that they are particularly effective in combination. We evaluate model performance with a variety of quantitative methods—including the quantity of gendered words, a dialogue safety classifier, and human assessments—all of which show that our models generate less gendered, but equally engaging chit-chat responses.

1 Introduction

Machine learning algorithms learn to model patterns present in training datasets. In particular, they make predictions that directly reflect the harmful societal biases present in training datasets, such as racial bias in sports reports (Merullo et al., 2019) and political bias in news data (Fan et al., 2019). Such biases are rife in NLP, for example, in learned word embeddings (Bolukbasi et al., 2016; Brunet et al., 2018; Zhao et al., 2019), visual semantic role labeling (Zhao et al., 2017), natural language inference (He et al., 2019), abusive language classification (Park et al., 2018), and coreference resolution (Zhao et al., 2018a). Although research into bias in NLP writ large is maturing, bias in dialogue utterances has received somewhat less attention (Liu et al., 2019; Sheng et al., 2019; Henderson et al., 2018). As real-world use-cases for dialogue agents, such as interactive assistants, are rapidly developing, bias in dialogue models has the very real potential to invade downstream systems and exacerbate existing social biases. Thus, dialogue debiasing is becoming an increasingly important problem in NLP. In this work, we foreground dataset bias as a crucial cause of gender bias in dialogue models, and explore ways to address it.

Gendered word counts in dialogue datasets

Dataset	% gend. words	% male bias
LIGHT	0.94	**73.4**
Reddit	1.32	69.76
Wizard of Wikipedia	0.076	65.9
Daily Dialog	1.02	59.04
Empathetic Dialogues	2.07	53.45
ConvAI2	1.28	50.05

Table 1: **Counts of gendered words** in several dialogue datasets. We report the percent of gendered words (% gend. words) as well as the percentage of male-gendered words out of all gendered words (% male bias). Datasets are arranged in descending order with respect to *% male bias*. LIGHT has the most *% male bias*; thus we chose it as our main testbed.

Gender bias has been found in many machine learning datasets, in both images and text (Stock and Cissé, 2017; Zhao et al., 2017). Here, we analyze several existing dialogue datasets for gender bias (see Table 1, and §3 for more discussion) for the purpose of finding a good testbed for a deeper dive. Our analysis revealed that the dataset from the LIGHT text adventure world (Urbanek et al., 2019) was the most biased in our sample. LIGHT is also an interesting dataset for measur-

Persona Example (Original LIGHT Dataset)	
daughter:	I spend most of my time doing household chores. I want to find meaning in life. I am energetic and happy.
chief wife:	I am the king's chief wife. Of all the women that he has married, or who are his concubines, I am the principal one. I represent the kingdom of my father, who is the king's biggest ally. My sons are the ones who will most likely become the king after the death of my husband.
women:	I live with my husband and 4 children in the village. I spend my days washing clothing and cleaning our home. My husband works for the royal army defending out town.
farmer Bob's wife:	I am farmer Bob's wife. I like to take care of all our animals. I help Farmer Bob everyday on the farm.
mother:	I am a mother of eight children. I live with my family in a cottage in the countryside. I spend every day tending to the needs of all of my little ones which can be overwhelming, but I always manage to maintain a pleasing disposition and a happy smile.
wife:	I am the wife of a farmer. While I may not be the most attractive woman ever, I am loyal and loving. My husband is a good man, but only seems to stay with me out of duty.

Table 2: **Examples of gender biased personas** in LIGHT. In a review that we conducted in this work (section 3), none of these characters were flagged as sexist or offensive. For male examples, see Appendix Table 11.

Dialogue Example (Original LIGHT Dataset)	
wife: I was married off by my family about five years ago. I spend my days cooking and cleaning so my husband will have something to eat when he returns from his work and can enjoy a clean home. I love my husband dearly because he works very hard to provide for us.	
merchant:	What a great day for more money.
wife:	Oh my. That is some thick dust!
merchant:	Indeed, it is very old.
wife:	This room is going to take a while to clean. You might want to come back later.
merchant:	It is fine I can set my booth up here.
wife:	With all the foot traffic?
merchant:	Yes it should be ok.
wife:	It doesn't appear that anyone ever comes up here!
merchant:	Well they will when they know I am here.
wife:	I have my doubts but I'll just go about my cleaning.
merchant:	Yea sounds like a good idea.
wife:	What is that supposed to mean?
merchant:	I am saying we should both do our jobs.
wife:	Don't take that tone with me!

Table 3: A crowdsourced persona and dialogue from the original LIGHT dataset.

ing and mitigating gender bias for three additional reasons: first, it has multiple potential sources of bias—not just dialogues, but also characters and personas—second, it was crowdsourced, and thus susceptible to reflecting the gender biases known to be present in crowdworkers' annotations (Otterbacher et al., 2018; Barbosa and Chen, 2019), and third, LIGHT's medieval, fantasy setting might encourage crowdworkers to impart text with their gender biases.

After selecting LIGHT for particular scrutiny, we then explore three bias mitigation techniques, one of which is wholly novel, and another which is novel in its application to dialogue: (i) Counterfactual Data Augmentation (CDA) (Hall Maudslay et al., 2019; Zmigrod et al., 2019), (ii) a targeted data collection method, which we refer to as Positive-Bias Data collection, and (iii) Bias Controlled text generation. We show that these techniques are most effective in combination, resulting in dialogue models that produce engaging responses with measurably less gender bias and offensive content (see §5). Models and code are released at `https://parl.ai/projects/genderation_bias/`.

2 Related Work

Recently, the NLP community has focused on exploring gender bias in NLP systems (Sun et al., 2019), uncovering many gender disparities and harmful biases in algorithms and text (Cao and Daumé III 2020; Chang et al. 2019; Chang and McKeown 2019; Costa-jussà 2019; Du et al. 2019; Emami et al. 2019; Garimella et al. 2019; Gaut et al. 2020; Habash et al. 2019; Hashempour 2019; Hoyle et al. 2019; Lee et al. 2019a; Lepp 2019; Qian 2019; Qian et al. 2019; Sharifirad et al. 2019; Sharifirad and Matwin 2019; Stanovsky et al. 2019; O'Neil 2016; Blodgett et al. 2020; Nangia et al. 2020). Particular attention has been paid to uncovering, analyzing, and removing gender biases in word embeddings (Basta et al., 2019; Kaneko and Bollegala, 2019; Zhao et al., 2019, 2018b; Bolukbasi et al., 2016). This word embedding work has even extended to multilingual work on gender-marking (Gonen et al., 2019; Williams et al., 2019; Zhou et al., 2019; Williams et al., 2020). Despite these efforts, many methods for debiasing embeddings have only succeeded in *hiding* word embedding biases as opposed to *removing* them (Gonen and Goldberg, 2019)—making gender debiasing still an open area of research.

Despite the relatively ample literature on gender debiasing for word-level representations, very little work has focused on sentence representations (Liang et al., 2020; Liu et al., 2019; Sheng et al., 2019; Lee et al., 2019b). Until this point, most debiasing work on sentences mainly focus on measuring bias (Lee et al., 2019b; Sheng et al., 2019). Very few foreground the contribution of training data to gender bias in model outputs. For example, Kang et al. collect a corpus of text that is parallel across multiple stylistic categories, one of which is gender. Closer to our work, Liu et al. present a test dataset for dialogue and find that models can produce less diverse dialogues when prompted with sentences containing words describing individuals from underrepresented groups. Still, it differs from our work in that the data was created by combining templates and hand-created lists of word-pairs, rather than using real dialogue data. Liu et al. also proposes two methods for debiasing, one of which we also employ (i.e., CDA), and the other of which extends to sentences a word-embedding post-processing method (Bolukbasi et al., 2016) that has been shown to be ineffective at removing gender bias (Gonen and Goldberg 2019, but see Wang et al. 2020 for a more recent, perhaps more effective attempt). Finally—and as a direct extension of this work—Dinan et al. (2020) decomposes gender bias along three semantic-pragmatic dimensions, and show that train more fine-grained classifiers allow for more accurate classification of dataset gender biases. The novelty of the present contribution lies in how we measure bias, and in the joint application of our three gender debiasing methods.

3 Measuring Bias

Before one can mitigate bias, one must first measure it. As a first pass, we measured the counts of gendered words used (using a word list from Zhao et al. 2018b), and the percent of those which referred to male characters for six datasets (Table 1). We count the number of male and female gendered words in the training sets of several datasets (LIGHT, ConvAI2, Reddit, Wizard of Wikipedia, Daily Dialog, Empathetic Dialogues, and ConvAI2). We use this to calculate the percentage of gendered words out of all words, and the *% male bias*, that is the percentage of male gendered words among all gendered words in a dialogue. We find that LIGHT is the most gender imbalanced dataset among all datasets in this table, with a *% male bias* of 73%, although others, like Reddit, are close behind.

Since LIGHT was found to be the most gender biased, we qualitatively examine it more closely, and find many biased utterances present in the training data. For example, the *queen* persona adheres to negatively stereotyped gender roles when uttering the line *I spend my days doing embroidery and having a talk with the ladies*. Another character admires a *sultry wench with fire in her eyes*. We conclude from examples like this that presenting crowdworkers with gender biased personas often leads them to create even more gender biased dialogues (see Table 3): for example, a *wife* persona contains the text *I spend my days cooking and cleaning so my husband will have something to eat when he returns from his work...*, and, in dialogue with a *merchant*, discusses only her cleaning duties. The *merchant* even derisively refers to cleaning as the *wife's* job. This could be an effect of gender stereotype priming (Blair and Banaji, 1996; Steele and Ambady, 2006; Oswald, 2008; Derks et al., 2011; Verhaeghen et al., 2011).

Given this, we wonder how much biased character names and personas themselves lead to LIGHT dialogues being more biased than the others. Thus, we focus on persona-based dialogue text in particular for the remainder of the paper. Dialogue research has found that, while incorporating personas increases engagingness and improves consistency (Zhang et al., 2018; Shuster et al., 2018; Mazaré et al., 2018; Olabiyi et al., 2018; Li et al., 2016b), they can also crystallize gender bias (Clark et al., 2019; Henderson et al., 2018). Such bias propagates to subsequently generated conversations. Crowdworkers in particular might imbue their annotations with their particular gender biases at every stage of dataset creation. For example, LIGHT (Urbanek et al., 2019) was created by crowdworkers in stages: crowdworkers were first assigned a **character** (with previously crowdsourced names such as "farmer" or "witch"), as well as a previously crowdsourced **persona**, or short textual description of the char-

	# Characters				# Ref.	
	F	*M*	*N*	*All*	*F*	*M*

Orig. Data	1109	1048	4214	6371	1283	1148

Table 4: **Analysis of gender in LIGHT and ConvAI2**: The LIGHT dataset is compared to similar novel datasets obtained after either gender-swapping character and personas or collecting wholly new ones. # Characters refers to the counts of gendered characters and # Ref. refers to counts of gendered references in personas. The original LIGHT dataset is skewed towards male characters, while ConvAI2 contains both male and female in a roughly equal proportions.

acter. Then, they were paired up, and tasked with generating a **dialogue** as those characters.

To determine with more granularity precisely how bias manifests in persona-based dialogue datasets, we investigate the text for (i) characters such as *fisherman* (Table 1), and (ii) personas such as *I love fishing* (Table 2). We ask: (i) do crowdworkers generate male and female characters at an equal rate, (ii) do they imbue characters' personas with sexism or undesirable gender biases?

Bias in Number of Characters. We first determine whether crowdworkers create an equal number of male and female characters. To quantify this, we asked annotators on Amazon Mechanical Turk to label the gender of each character name based on its persona description (choosing *neutral* if the gender was not explicit). This annotation is possible because many personas include text such as *I am a young woman.*[1] Since this measurement requires personas, we consider the two persona-based dialogue datasets in our sample: LIGHT and ConvAI2 (Zhang et al., 2018). LIGHT is highly gender imbalanced: there are over 1.6 times as many male characters as female ones[2]. LIGHT is also considerably less gender-balanced than ConvAI2, which has a nearly equal number of male and female gendered personas (see Table 4).

Bias in Personas. In addition to the stark underrepresentation of female characters, the medieval setting in LIGHT is likely to encourage crowdworkers to generate dialogues accentuating historical biases and inequalities of the time period (Bowman, 2010; Garcia, 2017). We investigate the number of references to men or women in the text of personas, as another source of bias. Take for example, a female persona that contains a gendered reference such as *I want to follow in my* ***father's*** *footsteps* rather than *in my* ***mother's***. Although using gendered **relational nouns** (Barker, 1992; Williams, 2018), such as *father*, doesn't always signal sexism, if female characters are predominantly defined in reference to male characters, it becomes a problem. We count the appearance of gendered words in personas using the list compiled by Zhao et al. (2018b), and find that men are disproportionately referred to in the personas: there are nearly 3x as many mentions of men than women, which suggests that a large number of characters are defined by their relationships to men (see Table 2 for examples, and Table 4 for counts).

Gender bias and sexism are clearly present in many dialogue datasets (Henderson et al., 2018), but finding a clear way to define these terms (and others that categorize unsafe text), let alone measure their effects at scale, is very challenging. For example, the persona for the character *girl* contains the line *I regularly clean and cook dinner* (see Table 2 for more examples), which strikes us as stereotypical and sexist, but it might not be noticed by others. In this paper, we rely on each annotator's own, subjective, definition(s) of the term but aggregate multiple opinions. Three naïve annotators examined each persona for unsafe content. If annotators detected content was 'offensive' or 'maybe offensive', they were asked to select one of four categories—racist, sexist, classist, other—and to provide a reason for their response. Just over 2% of personas were flagged by at least one annotator, and these personas and their resulting dialogues were removed.

4 Mitigating Bias in Generative Dialogue

In this section, we present a *general* framework for mitigating bias in generative dialogue. More specifically, we explore data augmentation and other algorithmic methods to mitigate bias in generative Transformer models. We (i) extend counterfactual data augmentation to dialogue

---

[1] Note that our procedure doesn't preclude annotators from implicitly assuming genders for ungendered personas, such as "doctor", which may widen the gender gap.

[2] When we use "female" and "male"—rather than "woman" and "man"—we want our reference to include characters that are binarily gendered, but not necessarily human.

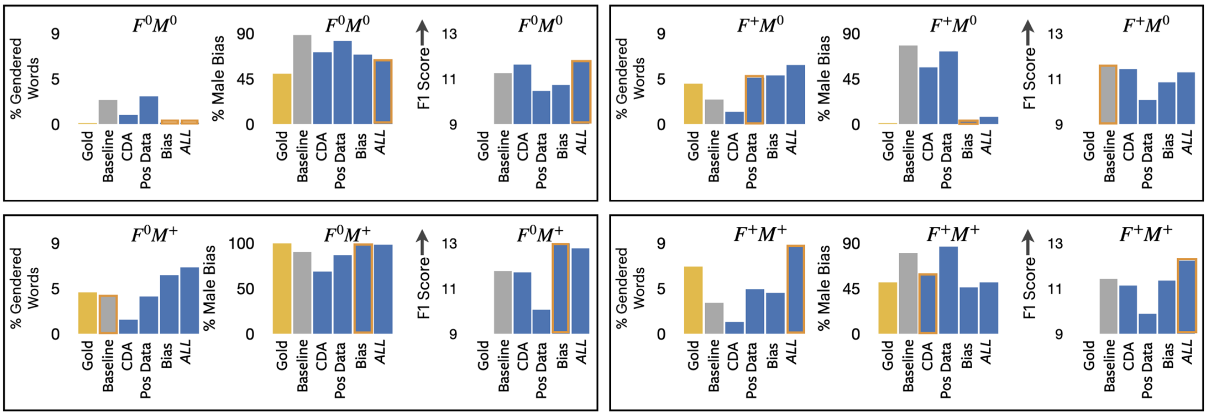

Figure 1: We compare the **performance of various bias mitigation methods**: Counterfactual Data Augmentation (CDA), Positive-Bias Data Collection (Pos. Data), Bias Control Model (Bias Ctrl), and combining these methods (*ALL*). We split test set across the four genderedness bins: $F^{0/+}M^{0/+}$. X^0 indicates there are no X-gendered words in the gold response, while X^+ indicates that there is at least one. We measure the percent of gendered words generated in the dialogue (% gend. words) and the percent of male bias (% male bias), i.e. the percent of male-gendered words out of all generated gendered words. While each of these methods yield some improvement, *combining them yields the best control over the genderedness of the utterances while improving the F1-score.* The orange outline represents the best performing model. For % Gendered words, lower is better. For % Male Bias, closer to 50 is better. For F1 Score, higher is better.

(Hall Maudslay et al., 2019; Zmigrod et al., 2019) following (Liu et al., 2019), (ii) perform positive data collection by augmenting the existing dataset via targeted data collection with crowdworkers, and lastly, (iii) apply controllable generation techniques to gender bias to control how many male and female gendered words models produce.

4.1 Counterfactual Data Augmentation

A straightforward solution for gender bias in embeddings is *Counterfactual Data Augmentation* (CDA) (Hall Maudslay et al., 2019; Zmigrod et al., 2019; Liu et al., 2019). CDA swaps, say, all instances of *grandmother* with *grandfather*, *she* with *he*, etc. We apply this word-based augmentation to dialogue by first copying every dialogue, then swapping all gendered words with their counterpart from the paired list in Zhao et al. (2018b). The augmentation is limited to words on the list, and the swapping is performed automatically. The model is then retrained on the augmented data. While CDA is somewhat effective strategy for mitigating bias in word embeddings, this method has several pitfalls: it may result in ungrammatical sentences, and it relies on existing (and perhaps incomplete) lists to determine and swap gender.

4.2 Positive-Bias Data Collection

To resolve the issues with CDA, we use humans to collect additional dialogue data via a two-pronged Positive-Bias Data Collection (Pos. Data) strategy. We first collect additional personas by having humans (i) manually swap the gender of the character name and all gendered references in the character's persona text (rather than relying on brittle word lists) and (ii) write additional, diversified personas. We then use these personas to seed the collection of additional, positively biased dialogue data, which we refer to as Pos. Data throughout.

New Characters & Personas. When a dataset contains more male characters and references to male characters than it contains female characters and references to female characters (see Table 4), we balance existing characters and personas with **gender swapping**. For every gendered character-persona pairing, annotators create a new opposite-gendered character-persona pairing for which animate nouns or pronouns are changed, but the rest of the persona remains unchanged. For example, for every persona describing a male character like a king, annotators will create a new one describing a female character like a queen. Annotators are instructed to swap the gender(s) of other animate references in the text (e.g., if an original persona describes a woman in relation to her father, the new male persona will describe a man in relation to his mother). This method ensures that the created sentences will be grammatical, unlike heuristic data augmentation.

However, simply balancing references to men and women is insufficient, as female characters might be specifically described in sexist ways (see §3). As detecting sexism is challenging (also see §3), we take our qualitative analysis to be sufficient motivation, and moved to further offset the bias by collecting a new set of *interesting* and *independent* female characters. We primed workers by showing examples of gender underspecified character names like *adventurer* with personas like *I am a woman passionate about exploring a world I have not yet seen. I embark on ambitious adventures*. We also provided crowdworkers with additional instruction to encourage them to create diverse characters: *We're looking for strong and diverse descriptions. Avoid descriptions that could be considered hateful, offensive, or stereotypical.* Even with explicit instruction, annotators created 3 times as many male characters as female characters, revealing the stubbornness of the inherent gender biases of the available crowdworker pool. We ultimately exclude all male-gendered personas created in this fashion from the new dataset, as including them would worsen the gender balance of the dataset. Our new dataset is approximately balanced then in the number of male or female characters and in the number of references to male or female characters (see Table 4). In total, we add 2,629 new characters and release the data for optional inclusion in the LIGHT dataset.

New Dialogues. After gender-balancing the personas, we moved on to using the gender-balanced personas to crowdsource additional, hopefully gender-balanced, dialogues. We selected more female-gendered characters for new dialogue collection, and explicitly instructed annotators to be mindful of gender bias. In particular, we encouraged them to assume *equality*—social, economic, political, or otherwise—between genders (Note: this is uniquely possible with a dataset like LIGHT, which is situated in a fully fictional world). We collected a total of 507 new dialogues containing 6,658 utterances (approximately 6% of the original dataset size). We refer to this additional dialogue data as Pos. Data.

4.3 Bias Controlled Training

Gender bias in dialogue can take the form of imbalanced use of gendered words. To create dialogue models that can generate an equal number of gendered words, we control model output with Bias Control (Bias Ctrl) via conditional training. Previous conditional training models learn to associate specific control tokens with some desired text properties (Kikuchi et al., 2016; Fan et al., 2018a; Oraby et al., 2018; See et al., 2019), but have not been applied to address bias issues.

	F^0M^0	F^0M^+	F^+M^0	F^+M^+
% of test set	60.65	27.21	7.61	4.63

Table 5: **Percentage of dialogue examples in each of the four genderedness bins** —$F^{0/+}M^{0/+}$— for the LIGHT dialogue data test set.

We apply conditional training techniques to control gender bias in generative dialogue by learning to associate control tokens with properties of gender bias. Any general function that takes as input a dialogue utterance and outputs a continuous or discrete value that provides information about gender bias could be used as a control variable. In our case, prior to training, each dialogue response is binned into one of four bins—$F^{0/+}M^{0/+}$ —where X^0 indicates that there are zero X-gendered words in the response. X^+ indicates the presence of one or more X-gendered word. The percentage of test set examples that fall into each bin is in Table 5. Nouns and adjectives are binned into gendered bins via an aggregation of existing gendered word lists (Zhao et al., 2018b,a; Hoyle et al., 2019). Note that other functions could be used as well, such as a bias classifier (Dinan et al., 2020).

We append a special token to the input that indicates which bin the response falls into. During Bias Ctrl training, the model should learn to associate the special token with the genderedness of the dialogue response, such that at inference time, we could append different special tokens to control the genderedness of the model output. For example, a model trained with multiple gender control bins could be set to the gender neutral (in this case, F^0M^0) setting at inference time, to produce a response containing few (or no) gendered words.

4.4 Implementation Details

Following Urbanek et al. (2019), we fine-tune a large, pre-trained Transformer encoder-decoder on the dialogues in the LIGHT dataset for all generation experiments. Following Humeau et al. (2019), we pre-trained on Reddit conversations extracted and obtained by a third party, and made avail-

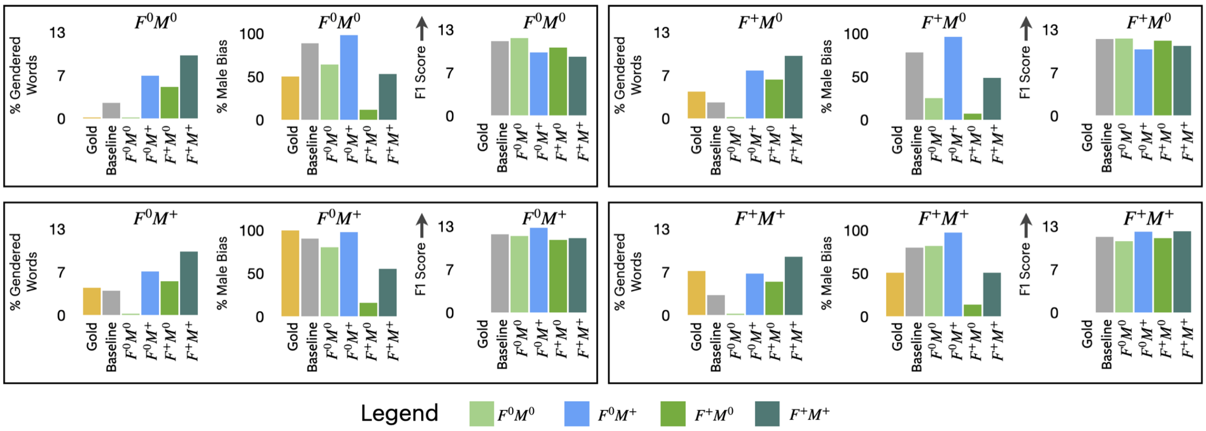

Figure 2: **Performance of the *ALL* debiasing model** controlled by indicating specific bins for all examples at test time. We report results for each possible conditioning bin choice. Across bins (at the top of graphs), the model maintains performance as measured by F1 whilst *radically changing the genderedness of the language generated.*

able on `pushshift.io`. During pre-training, models learned to generate a comment conditioned on the preceding conversation thread. All comments that contained URLs or were shorter than 5 characters long were removed, along with child comments, resulting in approximately 2.2 billion training examples. Similarly during fine-tuning, models were conditioned on the full preceding dialogue history. All models are 8-layer encoders, 8-layer decoders, with 512 dimensional embeddings and 16 attention heads based on the ParlAI transformer implementation (Miller et al., 2017). We decode with a beam search size of 5.

5 Results

We train five Transformer models: one baseline trained only on original LIGHT without any mitigation techniques, one Transformer for each of our three methods (see §4.1 for CDA, §4.2 for Positive-Bias Data Collection, and §4.3 for Bias Control), and a final one combining all three methods (*ALL*) that achieves the best results.

Bias is Amplified in Generation. Figure 1 compares the performance of the various techniques. We compare our methods to the gold labels from the test set and to the baseline. To do this, we divide the test set into four *genderedness bins* (as defined in §4.3)—F^0M^0, F^0M^+, F^+M^0, and F^+M^+—and calculate: (i) the F1 word overlap with the gold response, (ii) the percentage of gendered words generated (% gend. words), and (iii) the percentage of male-gendered words generated (relative to the sum total of gendered words generated by the model). We find that Transformer models not only reflect dataset biases, but also they *amplify* them. When the model produces gendered words, it generates male-gendered words the vast majority of the time. Even when the gold label only contains female-gendered words (F^+M^0), it still generates male-gendered words nearly 78% of the time.

Comparing Debiasing Methods As shown in Figure 1, each method improves on the metrics—*% gendered words*, *% male bias*, and F1—over the baseline Transformer, but we find that combining all methods (*ALL*) is most advantageous. While *ALL* has more data than CDA and Bias Ctrl, more data alone is not enough—the Positive-Bias Data Collection model does not achieve as strong results as *ALL* despite also having more data. Both the Bias Ctrl and *ALL* models benefit from knowing the data split (F^0M^0, for example), and both yield a gender ratio closest to ground truth.

Bias Controlled Training Controls Gendered Words. Our Bias Ctrl method can control the number of gendered words in generated dialogues (Figure 2). We examine the effect of Bias Ctrl by generating responses conditioning the *ALL* model on each bin. We observe that changing the bin radically changes the genderedness of generated text with only small differences in overall F1, which shows that the Bias Ctrl method is efficacious.

Examples of generated text from both the baseline and the *ALL* model are shown in Table 6. Further examples are provided in the Appendix in Table 12. The baseline model generates male-gendered words when the gold response contains no gendered words or only female-gendered

Generation Examples	
Bin	F^0M^0
Context	*[P1:]* I don't remember anything I was hoping you could find out. *[P2:]* Your form is very hazy. Do you remember if you are a man or woman?
Baseline:	*i am not a man. i am a man of the forest.*
ALL:	*no, i don't remember.*
Gold:	*I don't know what's wrong with me!*
Bin	F^+M^0
Context	*[P1:]* I do not believe my eyes, for an angel is upon me! Angel, please tell me your name. *[P2:]* My name is Abigail!
Baseline:	*my name is abigail. i am the king of this kingdom.*
ALL:	*i am the queen's daughter!*
Gold:	*Abigail! Such a beautiful name. To what do I owe the pleasure of meeting you?*

Table 6: **Example generations** from the baseline model and the proposed debiased models. Ground truth ('Gold') either contains no gendered words or only female-gendered words, but the baseline model still generates male-gendered words.

	Gold Labels	Baseline	*ALL*
% Offensive	13.0	14.25	**10.37**

Table 7: **Offensive language classification** of model responses on the LIGHT dialogue test set. The *ALL* model generates a lower percentage of offensive utterances.

words, even generating unlikely sequences such as *my name is abigail. i am the king of this kingdom*. For various methods, we compute the top 20 words generated on the test set (after removing stop words), shown in Appendix Table 8. We denote gendered nouns using an asterisk. Among the top 20 words generated by the baseline, there are only two gendered nouns—*knight* and *king*—both male-gendered. The *ALL* model generates similar words, but also features *queen* in its top 20, another indication that gender is more balanced.

5.1 Safety of Generated Text

To further evaluate our techniques, we investigate whether the *ALL* model generates fewer offensive utterances than (i) the baseline, and (ii) the human-generated gold labels. Our bias mitigation techniques have the ancillary benefit of producing models that generate proportionately fewer offensive utterances; see Table 7 for results.

We use a Transformer-based dialogue safety classifier to classify model-generated utterances as offensive or safe following Liu et al. (2019). The classifier was fine-tuned on an offensive language classification task (Dinan et al., 2019), and achieves state-of-the-art results. We apply this classifier to each utterance generated by the *ALL* model and baseline models on the test set, in addition to the gold (human generated) labels from the test set. The dialogue safety classifier rates our proposed *ALL* model as less offensive than both the baseline model and the ground truth (gold) labels, which argues in favor of the efficacy of our debiasing methods.

5.2 Human Evaluation: Bias and Quality

We compare the quality of our debiasing methods using human evaluation. One might hypothesize that some gender debiasing methods work by replacing contentful words (e.g., *witch*) with bleached or uninteresting ones (e.g., *person*, *thing*), effectively trading off gender bias with engagingness. Generative models in particular are well-known to produce generic text (Li et al., 2016a; Fan et al., 2018b), which is often less engaging. Overreliance on generic text might increase the chances of biases such as **androcentrism**, or the propensity of societies to consider men central but women peripheral (Bem, 1993; Bailey et al., 2020); in language, male-gendered words often act as a gender-neutral standard (Bailey et al., 2019), as in Neil Armstrong's 1969 quote "one small step for a *man*, one giant leap for *man*kind". We use the dialogue evaluation system Acute-Eval (Li et al., 2019) to ask evaluators to compare pairs of conversations from models and decide which model generates (i) more biased dialogues and (ii) more engaging dialogues. We collect 100 model conversations with crowdworkers per method. Then, we compare conversations between a human and the baseline model to conversations between a human and the *ALL* model with all generations set to the F^0M^0 gender-neutral control bin. We found that asking for predictions of speaker gender was more effective than asking about sexism directly.

As shown in Figure 3, predicting the gender accurately of *ALL* model generations is more challenging (significant at $p < 0.01$ with a t-test), but the responses are just as engaging according to human evaluators. We conclude our proposed methods are able to help mitigate gender bias without degrading dialogue quality.

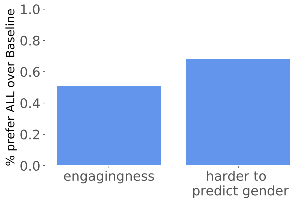

Figure 3: **Human Evaluation of *ALL* model** (F^0M^0) compared to baseline Transformer generative model. Evaluators choose which model output they prefer for dialogue engagingness and difficulty of predicting speaker gender. The ALL model produces less gendered text while engagingness is not affected.

6 Conclusion

We analyze gender bias in dialogue data and resulting model generations for models trained on dialogue data. We propose general purpose techniques for reducing gender bias in generated text. The methods described in this paper combine data augmentation, positive-bias data collection, and bias controlled training. We note that our results show that data collection techniques help mitigate issues, so when it is possible, bias should be considered at the earliest stages of a project. Newly collected or constructed datasets should consider how to carefully craft the collection to mitigate bias issues from the very start. When this is not possible, however, such as in the case of using real-world data or a dataset that already exists, the techniques presented in this paper are shown to be effective at reducing gender bias. They are especially effective when combined, producing less gendered, more balanced, safer utterances that maintain the engagingness of the dialogue.

A Appendix

A.1 Discussion of Generation Quality

Generality of Gendered Words. The gendered word lists used may not be comprehensive (Zhao et al., 2018a,b; Hoyle et al., 2019). For example, they do not include *hag* or *wench*, which are common in LIGHT. Further, a more continuous representation of gender should be used in the future.

More Fine-Grained Control. We present an effective method to control the quantity of gendered words generated by manipulating control bins. This technique is general and could be used to control other properties of generated utterances. For example, a sexism or bias classifier could be used instead of the gendered word list.

Quality of Generated Dialogue. Generative dialogue models are prone to overuse frequent words and produce generic utterances, the so-called *I don't know* problem (Li et al., 2016a). We also observe these effects which can affect bias.

Model	**Top 20 generated words**
Baseline	sorry, hear, not, what, glad, doing, don, king*, thank, sure, will, your, can, much, do, know, but, knight*, blacksmith, going
ALL	sorry, hear, sure, not, what, help, doing, your, course, trying, glad, thank, queen*, don, good, king*, but, yes, know, sir*
ALL F^0M^0	sorry, hear, sure, what, not, doing, glad, thank, your, yes, course, but, don, do, know, help, have, enjoying, fool, much
ALL F^0M^+	sorry, hear, help, trying, sure, good, king*, sir*, not, your, day, course, father*, he*, don, thank, happy, guard*, glad, have
ALL F^+M^0	sorry, hear, queen*, sure, miss*, not, your, thank, how, hello, today, guard*, she*, yes, course, kind, woman*, help, glad, what
ALL F^+M^+	sorry, queen*, hear, guard*, help, trying, your, sure, good, course, day, knight*, not, protect, yes, friend, king*, woman*, she*, thank

Table 8: **Genderedness bins control the genderedness of generated text**. The top 20 words (test set) with stop words removed. * indicates gendered nouns.

Abstract

While discriminative neural network classifiers are generally preferred, recent work has shown advantages of generative classifiers in term of data efficiency and robustness. In this paper, we focus on natural language inference (NLI). We propose GenNLI, a generative classifier for NLI tasks, and empirically characterize its performance by comparing it to five baselines, including discriminative models and large-scale pretrained language representation models like BERT. We explore training objectives for discriminative fine-tuning of our generative classifiers, showing improvements over log loss fine-tuning from prior work (Lewis and Fan, 2019). In particular, we find strong results with a simple unbounded modification to log loss, which we call the "infinilog loss". Our experiments show that GenNLI outperforms both discriminative and pretrained baselines across several challenging NLI experimental settings, including small training sets, imbalanced label distributions, and label noise.

1 Introduction

Natural language inference (NLI) is the task of identifying the relationship between two fragments of text, called the *premise* and the *hypothesis* (Dagan et al., 2005; Dagan et al., 2013). The task was originally defined as binary classification, in which the labels are *entailment* (the premise implies the hypothesis) or *not entailment*. Subsequent variations added a third *contradiction* label. Most models for NLI are trained and evaluated on standard benchmarks (Bowman et al., 2015; Williams et al., 2018; Wang et al., 2018) in a discriminative manner (Conneau et al., 2017; Chen et al., 2017a). These benchmarks typically have relatively clean, balanced, and abundant annotated data, and there is no distribution shift between the training and test sets.

However, when data quality and conditions are not ideal, there is a substantial performance decrease for existing discriminative models, including both simple model architectures and more complex ones. Prior work on document classification and question answering has shown that **generative classifiers** have advantages over their discriminative counterparts in non-ideal conditions (Yogatama et al., 2017; Lewis and Fan, 2019; Ding and Gimpel, 2019).

In this paper, we develop generative classifiers for NLI. Our model, which we call GenNLI, defines the conditional probability of the hypothesis given the premise and the label, parameterizing the distribution using a sequence-to-sequence model with attention (Luong et al., 2015) and a copy mechanism (Gu et al., 2016). We explore training objectives for discriminative fine-tuning of our generative classifiers, comparing several classical discriminative criteria. We find that several losses, including hinge loss and softmax-margin, outperform log loss fine-tuning used in prior work (Lewis and Fan, 2019) while similarly retaining the advantages of generative classifiers. We also find strong results with a simple unbounded modification to log loss, which we call the "infinilog loss".

Our evaluation focuses on challenging experimental conditions: small training sets, imbalanced label distributions, and label noise. We empirically compare GenNLI with several discriminative baselines and large-scale pretrained language representation models (Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019) on five standard datasets. GenNLI has better performance than discriminative classifiers under the small data setting. Moreover, when limited to 100 instances per class, GenNLI consistently outperforms all BERT-style pretrained models on four of the five datasets. These results

November 16–20, 2020.

are appealing especially in comparison with BERT-style pretrained baselines. Large-scale pretrained language models have achieved state-of-the-art results on a wide range of NLP tasks, but they still require hundreds or even thousands of annotated examples to outperform GenNLI.

GenNLI also outperforms discriminative classifiers when the training data shows severe label imbalance and when training labels are randomly corrupted. We additionally use GenNLI to generate hypotheses for given premises and labels. While the generations tend to have low diversity due to high lexical overlap with the premise, they are generally fluent and comport with the given labels, even in the small data setting.

2 Background and Related Work

2.1 Generative Classifiers

While discriminative classifiers directly model the posterior probability of the label given the input, i.e., $p(y \mid x)$, generative classifiers instead model the joint probability $p(x, y)$, typically factoring it into $p(x \mid y)$ and $p(y)$ and making decisions as follows:

$$\hat{y} = \operatorname*{argmax}_{y} p(x \mid y)p(y)$$

Most neural network classifiers are trained as discriminative classifiers as these work better when conditions are favorable for supervised learning, namely that training data is plentiful and that the training and test data are drawn from the same distribution. While discriminative classifiers are generally preferred in practice, there is certain prior work showing that generative classifiers can have advantages in certain conditions, especially when training data is scarce, noisy, and imbalanced (Yogatama et al., 2017; Lewis and Fan, 2019; Ding and Gimpel, 2019).

Ng and Jordan (2002) proved theoretically that generative classifiers can approach their asymptotic error much faster, as naïve Bayes is faster than its discriminative analogue, logistic regression. Yogatama et al. (2017) compared the performance of generative and discriminative classifiers and showed the advantages of neural generative classifiers in terms of sample complexity, data shift, and zero-shot and continual learning settings. Ding and Gimpel (2019) further improved the performance of generative classifiers on document classification by introducing discrete latent variables into the generative story. Lewis and Fan (2019) developed generative classifiers for question answering and achieved comparable performance to discriminative models on the SQuAD (Rajpurkar et al., 2016) dataset, and much better performance in challenging experimental settings.

In this paper, we develop generative models for natural language inference inspired by models for sequence-to-sequence tasks. We additionally contribute an exploration of several discriminative objectives for fine-tuning our generative classifiers, finding multiple choices to outperform log loss used in prior work. We also compare our generative classifiers with fine-tuning of large-scale pretrained models, and characterize performance under other realistic settings such as imbalanced and noisy datasets.

2.2 Natural Language Inference

Early methods for NLI mainly relied on conventional, feature-based methods trained from small-scale datasets (Dagan et al., 2013; Marelli et al., 2014). The release of larger datasets, such as SNLI, made neural network methods feasible. Such methods can be roughly categorized into two classes: sentence embedding bottleneck methods which first encode the two sentences as vectors and then feed them into a classifier for classification (Conneau et al., 2017; Nie and Bansal, 2017; Choi et al., 2018; Chen et al., 2017b; Wu et al., 2018), and more general methods which usually involve interactions while encoding the two sentences in the pair (Chen et al., 2017a; Gong et al., 2018; Parikh et al., 2016). Recently, NLI models are shown to be biased towards spurious surface patterns in the human annotated datasets (Poliak et al., 2018; Gururangan et al., 2018; Liu et al., 2020a), which makes them vulnerable to adversarial attacks (Glockner et al., 2018; Minervini and Riedel, 2018; McCoy et al., 2019; Liu et al., 2020b).

3 A Generative Classifier for NLI

Each example in a natural language inference dataset consists of two natural language texts, known as the premise and the hypothesis, and a label indicating the relation between the two texts. Formally, we denote an instance $\langle x^{(p)}, x^{(h)}, y\rangle$ as a tuple consisting of a premise $x^{(p)} = \{x_1^{(p)}, x_2^{(p)}, ..., x_N^{(p)}\}$, a hypothesis $x^{(h)} = \{x_1^{(h)}, x_2^{(h)}, ..., x_T^{(h)}\}$, and a label $y \in Y$.

Most existing NLI models are trained in a discriminative manner by maximizing the conditional log-likelihood of the label given the input, i.e., $\log p(y \mid x^{(p)}, x^{(h)})$. In this paper, we propose generative classifiers for NLI that are trained instead to estimate the probability of the hypothesis given the premise and the label, i.e., $p(x^{(h)} \mid x^{(p)}, y)$, typically by maximizing log-likelihood. We decompose this conditional probability using the chain rule, and our final training objective is to minimize the following negative log likelihood:

$$L(x^{(p)}, x^{(h)}, y) = -\sum_{t=1}^{T} \log p(x_t^{(h)} \mid x_{<t}^{(h)}, x^{(p)}, y) \tag{1}$$

At inference time, the prediction is made as follows:

$$\operatorname*{argmax}_{y \in Y} \log p(y) + \sum_{t=1}^{T} \log p(x_t^{(h)} \mid x_{<t}^{(h)}, x^{(p)}, y) \tag{2}$$

Throughout all of the experiments in this paper, we assume a uniform label prior $p(y)$, so $p(y)$ will not affect the argmax in Eq. (2) and can be omitted.

3.1 Parameterization

Our model, which we refer to as GenNLI, is parameterized with a standard RNN-based sequence-to-sequence architecture with attention and a copy mechanism between the encoder and the decoder.[1]

Encoder. Our encoder uses a standard bidirectional recurrent neural network (RNN) using long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997):

$$\mathbf{s}_n = [f_{e_1}(\mathbf{v}_n, \overrightarrow{\mathbf{s}_{n-1}}); f_{e_2}(\mathbf{v}_n, \overleftarrow{\mathbf{s}_{n+1}})]$$

where f_{e_1} and f_{e_2} are forward and backward LSTM recurrences, respectively, $\mathbf{v}_n$ is the word embedding of $x_n^{(p)}$, and $\mathbf{s}_n$ is the concatenation of the forward and backward RNN hidden states at position n in the premise.

Decoder. Our decoder uses an RNN with dot product attention from Luong et al. (2015) and a copy mechanism (Gu et al., 2016). The decoder hidden state at step t is computed as $\mathbf{h}_t = f_d(\mathbf{w}_t, \mathbf{h}_{t-1})$, where f_d is the forward LSTM recurrence in the decoder and $\mathbf{w}_t$ is the word embedding of $x_t^{(h)}$. The word distribution at position $t+1$ is computed as follows:

$$\mathbf{p}_{vocab} = \mathrm{softmax}(\mathbf{V}'(\mathbf{V}[\mathbf{h}_t, \mathbf{s}_t^*, \mathbf{v}_y] + b) + b')$$

where $\mathbf{v}_y$ is the label embedding of y, $\mathbf{s}_t^*$ is the context vector at step t computed using attention (full details of the attention mechanism are omitted for brevity but can be found in Luong et al., 2015), and $\mathbf{V}$, $\mathbf{V}'$, b, and b' are learnable parameters. Note the presence of the label embedding $\mathbf{v}_y$ concatenated to $\mathbf{h}_t$ and $\mathbf{s}_t^*$ to form the input to the $\mathrm{softmax}$ layer. This enables the label to directly influence the word distribution. We also use label-specific beginning-of-sentence (BOS) tokens as the initial symbol fed to the decoder RNN. Concretely, we create the embeddings for all BOS symbols BOS_y ($y \in Y$) and prepend $BOS_{y'}$ to the hypothesis where y' is the label for the instance.

Copy mechanism. In some datasets, hypotheses are written by humans when provided a premise and label (Bowman et al., 2015). We observed that these hypotheses sometimes appear to be written by slightly modifying the premise according to the label, e.g., adding "not" to negate the premise, or by replacing a phrase with a phrasal hypernym, such as replacing "soccer game" with "sport" (Marelli et al., 2014; Bowman et al., 2015). The tokens in a premise/hypothesis pair often show a large degree of overlap. So we use a copy mechanism (Gu et al., 2016) to (1) reduce the difficulty of word prediction when training sequence-to-sequence models on small datasets and (2) encourage the model to pay more attention to the token differences between the textual input of the encoder and decoder. We compute:

$$p_{copy} = \sigma(\mathbf{w}_{copy}^{\top}[\mathbf{h}_t, \mathbf{s}_t^*, \mathbf{v}_y] + b_{copy}) \tag{3}$$

where $p_{copy} \in [0, 1]$ is the probability of copying a word from the input sequence, the vector $\mathbf{w}_{copy}$ and scalar b_{copy} are learnable parameters, and σ represents the logistic sigmoid function. We use an extended vocabulary for a specific sentence pair which includes all the words appearing in the input sentence so that the decoder can copy specific words from the input sentence instead of generating out-of-vocabulary (OOV) words.

---

[1] We also experimented with transformer architectures (Vaswani et al., 2017) and found similar results.

$$\begin{aligned}
\text{perceptron loss:}\quad & -\log p(x^{(h)} \mid x^{(p)}, y) + \max_{y' \in Y} \log p(x^{(h)} \mid x^{(p)}, y') \\
\text{hinge loss:}\quad & -\log p(x^{(h)} \mid x^{(p)}, y) + \max_{y' \in Y} \{\log p(x^{(h)} \mid x^{(p)}, y') + \text{cost}(y, y')\} \\
\text{log loss:}\quad & -\log p(x^{(h)} \mid x^{(p)}, y) + \log \sum_{y' \in Y} p(x^{(h)} \mid x^{(p)}, y') \\
\text{softmax-margin:}\quad & -\log p(x^{(h)} \mid x^{(p)}, y) + \log \sum_{y' \in Y} \exp\{\log p(x^{(h)} \mid x^{(p)}, y') + \text{cost}(y, y')\} \\
\text{Bayes risk:}\quad & \mathbb{E}_{p(y' \mid x^{(h)}, x^{(p)})}[\text{cost}(y, y')] = \sum_{y' \in Y} \text{cost}(y, y') \frac{p(x^{(h)} \mid x^{(p)}, y')}{\sum_{y'' \in Y} p(x^{(h)} \mid x^{(p)}, y'')} \\
\text{infinilog loss:}\quad & -\log p(x^{(h)} \mid x^{(p)}, y) + \log \sum_{y' \in Y, y' \neq y} p(x^{(h)} \mid x^{(p)}, y')
\end{aligned}$$

Table 1: Discriminative objectives considered for fine-tuning GenNLI in this paper. Each is defined for a single training example $\langle x^{(p)}, x^{(h)}, y \rangle$, where $x^{(p)}$ is the premise, $x^{(h)}$ is the hypothesis, and $y \in Y$ is the label.

4 Discriminative Fine-Tuning

Lewis and Fan (2019) showed that generative classifiers for question answering can be improved by a discriminative fine-tuning step after estimating the generative classifier distributions. They used log loss as their discriminative objective. We also consider using a discriminative fine-tuning step when training our model, specifically we compare log loss to four other discriminative losses:

- **Perceptron loss**: the loss function underlying the perceptron algorithm (Rosenblatt, 1958)
- **Hinge loss**: the loss function underlying support vector machines (SVMs) and structured SVMs (Wahba et al., 1999; Taskar et al., 2004)
- **Softmax-margin**: which combines log loss with a cost function as in hinge loss (Povey et al., 2008; Gimpel and Smith, 2010)
- **Bayes risk**: the expectation of the cost function with respect to the model's conditional distribution (Kaiser et al., 2000; Smith and Eisner, 2006)

Table 1 shows these discriminative losses.[2] Some losses use a **cost function**, which can be chosen by the practitioner to penalize different errors differently. In our experiments, we define it as $\text{cost}(y, y') = 1$ for $y \neq y'$ and $\text{cost}(y, y') = 0$ if $y = y'$, where y is the gold label and y' is a candidate label.

In addition, we introduce a very simple loss that is inspired by these other discriminative losses while performing quite well overall in our experiments. We call it the **infinilog loss** and define it as follows:

$$-\log p(x^{(h)} \mid x^{(p)}, y) + \log \sum_{\substack{y' \in Y \\ y' \neq y}} p(x^{(h)} \mid x^{(p)}, y') \tag{4}$$

The infinilog loss is different from log loss in that the gold label is excluded from the sum. Therefore, infinilog is not bounded below by zero, unlike all other discriminative losses we consider. It does not approach zero as the model becomes increasingly confident in the correct classification, as is the case with log loss and softmax-margin. Rather, infinilog is unbounded, causing learning to continually seek to increase the score of the correct label and decrease the score of the incorrect labels.

We can view infinilog as softmax-margin with a cost function that returns $-\infty$ when $y = y'$ and 0 otherwise. However, the convention usually assumed when defining cost functions for softmax-margin is for the cost function to be nonnegative (Gimpel and Smith, 2010), and similar conventions are assumed with hinge loss. So we choose to use a distinct name for this loss.

Our results in Section 7 show that fine-tuning using infinilog or one of the investigated discriminative losses leads to better performance than log loss fine-tuning, which was proposed for generative classifiers by Lewis and Fan (2019).

Though the above objectives appear discriminative due to their direct penalization of incorrect labels, they do so by using the key building blocks of generative classifiers. Thus, this fine-tuning achieves some of the benefits of discriminative classifiers while retaining the advantages of generative classifiers, as shown for question answering by Lewis and Fan (2019) and also shown in our experiments below.

---

[2] Again, the label prior $p(y)$ ends up canceling out because it is uniform over labels, so we do not show it.

5 Experiments

5.1 Datasets

We experiment with five sentence pair datasets, namely the Stanford Natural Language Inference corpus (SNLI; Bowman et al., 2015), the SICK dataset (Marelli et al., 2014), the Multi-Genre Natural Language Inference corpus (MultiNLI; Williams et al., 2018), the binary Recognizing Textual Entailment (RTE; Dagan et al., 2005) dataset from the GLUE benchmark (Wang et al., 2018), and the Microsoft Research Paraphrase Corpus (MRPC; Dolan et al., 2004) also from GLUE.[3] The statistics of the datasets can be found in the Appendix. For MultiNLI, we use the matched dev set and mismatched dev set as our validation and test sets, respectively. Otherwise, we use the standard train, validation, and test splits from the original papers (for SNLI and SICK) or the GLUE benchmark (for RTE and MRPC).[4]

5.2 Baseline Models

We compare our GenNLI model to two baseline discriminative models, and three pretrained models as described below.

We consider InferSent (Conneau et al., 2017) and ESIM (Chen et al., 2017a) as our discriminative baselines. InferSent uses a BiLSTM network with max pooling (Collobert and Weston, 2008) to learn generic sentence embeddings that perform well on several NLI tasks. ESIM has a relatively complicated network structure, including a recursive architecture of local inference modeling (MacCartney, 2009; Parikh et al., 2016) and inference composition. The pretrained models we compare to are BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and XLNet (Yang et al., 2019).

We select these models as our baselines because (1) they are open-source and are frequently used as baselines for NLI tasks in related work (Peters et al., 2018; Williams et al., 2018), and (2) their performance is strong on standard leaderboards.[5]

5.3 Training Details

Both generative and discriminative models are initialized with GloVe pretrained word embeddings (Pennington et al., 2014).[6] The word embedding dimension and the LSTM hidden state dimension are set to 300. All parameters, including the word embeddings, are updated during training. The label embedding dimensionality for GenNLI is set to 100. All the experiments are conducted 5 times with different random seeds and we report the median scores.

GenNLI. The training includes two steps: the model is first trained with the generative objective only (Equation 1) for 20 epochs, followed by the discriminative fine-tuning objective only (one of the objectives in Table 1) for 15 epochs. Unless otherwise specified, we use infinilog for discriminative fine-tuning. Section 7 compares fine-tuning objectives.[7]

Discriminative baselines. We run the open source code of InferSent[8] and ESIM.[9] Following their implementation, training stops when the performance on the dev set does not improve across 5 consecutive epochs or the learning rate sufficiently decays (e.g,. less than e^{-5}).

For both GenNLI and discriminative baselines, we use the Adam (Kingma and Ba, 2015) optimizer with learning rates of 0.001 and 0.1, and SGD with learning rates 0.1, 0.5, 1, and 2, and select the model with the best performance on the dev set.

Pretrained baselines. We use the Hugging Face PyTorch implementation (Wolf et al., 2019) of pretrained transformer (Vaswani et al., 2017) models.[10] BERT, XLNet, and RoBERTa are configured with ‘bert-base-uncased’, ‘xlnet-base-cased’, and ‘roberta-base’, respectively. We use the vector at the position of the [CLS] token in the last layer as the output of pretrained models, and map the output to NLI classification with a linear transformation. We fine-tune the pretrained models on our training sets for 10 epochs. We observe that the models usually converge within the first 3-5 epochs.

---

[3] While MRPC is a binary paraphrase classification task rather than an NLI or entailment task, we treat it as a binary entailment task by choosing one of the sentences arbitrarily as the premise and using the other as the hypothesis.

[4] MRPC and RTE have no public test set, so we report their performances on the development sets.

The percentages are the fractions of training instances with flipped labels. 0% is the unchanged training set. The best result for each task and each noisy setting is shown in bold, and the second-best one is underlined.

6 Results

6.1 Data Efficiency

We first empirically characterize GenNLI, discriminative baselines, and pretrained baselines in terms of data efficiency. We construct smaller training sets by randomly selecting 5, 20, 100, 500, and 1000 instances per class, and then train separate models across these different-sized training sets. Table 2 shows the results.[11]

When using training sets with 100 or fewer instances per class, GenNLI outperforms the pretrained baselines on all datasets except for MRPC. We would hope that pretrained models like BERT would produce generalized text representations that would perform well after fine-tuning with a relatively small number of examples, but here we observe that a thousand or more examples is required to outperform GenNLI on most datasets.

With small training sets, GenNLI also has better performance than the other discriminative baselines, though the performance gap does shrink as the training set gets larger. The accuracies become comparable when we have 1000 instances per label. We also see that on the full training set, the discriminative baselines outperform GenNLI, which accords with our expectations and the findings of prior work (Ding and Gimpel, 2019).

6.2 Training Label Noise

To measure robustness to label noise, we construct noisy datasets by randomly flipping the labels of 10%, 30%, or 50% of the training instances in the binary classification tasks. The labels of other instances are unchanged. Evaluation is done on the original validation and test sets.

---

[11] SICK does not have results in the 1000 column because the 'contradiction' label has only 665 instances.

Table 3 shows a comparison of GenNLI, InferSent, and RoBERTa on noisy datasets. In addition, we report the value of the Matthews Correlation Coefficient (MCC) (Matthews, 1975). The value of MCC ranges from -1 to 1, with higher value indicating a better classification model. MCC considers all values in the confusion matrix and describes it with a single number. It is viewed as a balanced measurement when the classes are of very different sizes (Boughorbel et al., 2017).

We find all of the models are robust to slight noise, as the accuracy does not drop dramatically with 10% noisy training data. However, as we increase the proportion of the label noise, the performance of InferSent decreases more rapidly than GenNLI. The results are consistent between the two metrics. It is worth noting that GenNLI works better than RoBERTa under the 50%-noisy-data setting, even though RoBERTa has much stronger performance with the unchanged training set. In other words, GenNLI is more robust as the performance drops only slightly with extremely noisy training data.

In general, training deep neural networks requires abundant clean data. When dealing with potentially noisy data, it may be worthwhile to build both generative and discriminative classifiers.

6.3 Imbalanced Label Distributions

We also perform experiments in a setting with label imbalance in the training set. Each imbalanced training set is constructed by random sampling and keeping only 10%, 20%, or 50% of the instances from one selected class, and keeping all the instances from the other classes. We use the original validation and test sets. We still use a uniform prior for GenNLI.

Table 4 shows the comparison of generative, discriminative, and BERT-based classifiers under various imbalanced training sets.[12] Aside from the 10%-non-entailment RTE dataset, RoBERTa always performs the best. This is unsurprising because, even after subsampling, the training set sizes are on a similar order of magnitude as the full sets, with which RoBERTa excels (Table 2). However, RoBERTa does show degradation as the subsampling rate becomes more extreme (more than 10% in MRPC, 8-18% in RTE, and 4-5% on MNLI). GenNLI shows a smaller or comparable decrease in performance, though its overall accuracies are lower. In comparing the generative and discriminative classifiers, GenNLI always outperforms InferSent when keeping only 10% of the instances for the selected class. However, as the percentage of instances in the selected class increases, InferSent begins to perform better than GenNLI.

Another finding is that the different labels have different effects under the imbalanced setting. For example, the performance of RTE/non-entailment decreases more slowly than RTE/entailment for both GenNLI and InferSent, which might suggest that the non-entailment label requires fewer training examples than entailment.

Data efficiency might also affect performance under the label imbalanced setting. We believe it is not the only factor for a performance difference between the generative and discriminative models, as the MNLI dataset has 130k instances per class and the training set still has more than 270k instances in total even under the 10% setting, indicating GenNLI has certain advantages over InferSent when the label distribution is imbalanced.

7 Analysis

7.1 Modeling and Training Decisions

We now empirically assess the importance of major components of modeling and training. As shown in Table 5, the copy mechanism is essential, which meets our expectation because we observe a lot of lexical overlap between the premise and hypothesis in many pairs.[13] We find both generative training and fine-tuning objectives to be helpful, as better results are achieved by training with both objectives.

GenNLI defines the conditional distribution of hypotheses given a premise and label. We could instead model $p(x^{(p)} \mid x^{(h)}, y)$. The final two rows of Table 5 compare the two, showing better performance with $p(x^{(h)} \mid x^{(p)}, y)$. The difference is larger in SNLI, which may be due in part to how the dataset was created. If annotators are provided with a premise and label and asked to write hypotheses, as in SNLI, we would expect that a generative model that matches this process would excel. The difference may also be due to the fact

---

[12] We report the results on these three datasets since they represent different characteristics in terms of training set size, number of candidate labels, and performance difference between GenNLI and InferSent on the full training set.

[13] All the experiments in our paper are in-domain testing. We also test GenNLI in out-of-domain (OOD) datasets to see whether the copy mechanism is helpful in this case. For example, we train on MNLI and test on SICK. The trend is not consistent across different OOD settings.

that in the entailment pairs, the premise often has more information than the hypothesis, and it is expected to be easier to remove information (when generating the hypothesis from the premise) than to add it.

7.2 Discriminative Fine-Tuning Comparison

Table 6 compares discriminative fine-tuning objectives.[14] Several choices, including hinge, softmax-margin, and infinilog, consistently outperform the log loss used as discriminative fine-tuning objective by Lewis and Fan (2019). The perceptron loss and Bayes risk also often outperform log loss. It is worth noting that infinilog performs the best when using the full training set on four out of five datasets (see Appendix for full results), while softmax-margin is best with smaller training sets. These results suggest that improving discriminative fine-tuning does not harm the data efficiency benefits of generative classifiers, but rather is able to accentuate them.

7.3 Data Generation

One advantage of generative models is that they can be used to generate samples in order to inter-

---

[14] Note that all models are trained with the generative objective before discriminative fine-tuning. Results for other datasets are provided in the Appendix.

Table 7: Generated hypotheses for premises with given labels (N = neutral, E = entailment, C = contradiction).

pret how the model works. Since we include label information in the decoder of GenNLI, we are able to generate various hypotheses for a premise by specifying the label. Table 7 shows example generations from two models, one using the full dataset for training and the other using a small training set with only 500 examples per class. We use greedy decoding for these generations.

We observe that the generated examples comport with the labels and premises we have specified, and the generation is of high quality in terms of fluency. However, the diversity is relatively low, with the generated samples looking similar to the premise. This is not surprising since we assume the decoder relies heavily on the copy mechanism when trained on NLI pairs, as some hypotheses differ only slightly from their corresponding premises. The generations are relatively short compared to the gold hypotheses, which is likely due in part to greedy decoding. The model might require more training data and/or a different decoding algorithm to be able to produce more diverse generations. We also note that generations for the entailment label generally look better than those for contradiction.[15]

8 Conclusions and Future Work

We proposed GenNLI, a discriminatively-finetuned generative classifier for NLI tasks, and empirically characterized its performance by comparing it to discriminative models and pretrained models. We found several discriminative fine-tuning objectives to outperform log loss, including infinilog, a simple but effective choice. We conducted extensive experiments with GenNLI, showing its robustness across challenging empirical conditions. We also showed its ability to generate hypotheses given premises and particular labels. Future work may explore generating of diverse sets of hypotheses for a given premise and label, with the goal of performing data augmentation. Other future work will be to measure the performance of GenNLI on adversarial and similarly challenging NLI datasets.

Acknowledgments

We would like to thank Sam Wiseman for contributions to an earlier version of this manuscript, and the anonymous reviewers for their helpful feedback. Z. Sui and B. Chang thank NSFC (No. 61876004, No. U19A2065) and Beijing Academy of Artificial Intelligence (BAAI) for their generous support.

A Appendix

A.1 Dataset

We present our results on the five publicly available NLI datasets shown in Table 8, which include the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015), the SICK corpus (Marelli et al., 2014), the Multi-Genre Natural Language Inference corpus (MultiNLI) (Williams et al., 2018), the Recognizing Textual Entailment (RTE) (Dagan et al., 2005) corpus, and the Microsoft Research Paraphrase Corpus (MRPC) from the GLUE benchmark (Wang et al., 2018).[16] For MultiNLI, we use the matched dev set and mismatched dev set as our validation and test sets, respectively. Table 8 shows the statistics of the datasets in our paper.

Dataset	#Train	#Valid	#Test	#Class
SNLI	549K	9.8K	9.8K	3
MultiNLI	392K	9.8K	9.8K	3
SICK	4.5K	0.5K	4.9K	3
RTE	2.4K	0.2K	-	2
MRPC	4.0K	1.7K	-	2

Table 8: Dataset statistics.

We use the standard train, validation, and test divisions from the original papers (SNLI, MultiNLI and SICK) or GLUE benchmark (RTE and MRPC). These datasets can be downloaded at `https://nlp.stanford.edu/projects/snli/`, `https://gluebenchmark.com`, and `http://marcobaroni.org/composes/sick.html`.

A.2 Discriminative Fine-Tuning Comparison

Table 9 lists the full comparison results of different discriminative fine-tuning objectives. Several choices, including hinge, softmax-margin, and infinilog, consistently outperform the log loss used as discriminative fine-tuning objective by Lewis and Fan (2019). It is worth noting that infinilog performs the best when using the full training set on four out of five datasets.

A.3 Data Generation

Table 10 shows example generations from two models, one using the full dataset for training and the other using a small training set with only 500 examples per class.

A.4 Ablation of Copy Mechanism in Generation

Table 11 shows the generated hypotheses of the proposed generative classifier. Comparing the generative classifiers with and without copy mechanism, we find that the copy mechanism can help the model capture key differences between premise and hypothesis sentences given the specified labels. For example, we see 'There is no child' versus 'A child' given the label 'contradiction', and 'another animal' versus 'a brown dog' given the label 'neutral'. The copy mechanism also helps to avoid excessive semantic drift, e.g., generating the same subject as the premise and maintaining a reasonable amount of text with the premise.

Although classification accuracy increases by adopting discriminative finetuning after generative training, the finetuning method can lead to ungrammatical or repetitive generated sentences, as demon-

Abstract

Natural language inference (NLI) data has proven useful in benchmarking and, especially, as pretraining data for tasks requiring language understanding. However, the crowdsourcing protocol that was used to collect this data has known issues and was not explicitly optimized for either of these purposes, so it is likely far from ideal. We propose four alternative protocols, each aimed at improving either the ease with which annotators can produce sound training examples or the quality and diversity of those examples. Using these alternatives and a fifth baseline protocol, we collect and compare five new 8.5k-example training sets. In evaluations focused on transfer learning applications, our results are solidly negative, with models trained on our baseline dataset yielding good transfer performance to downstream tasks, but none of our four new methods (nor the recent ANLI) showing any improvements over that baseline. In a small silver lining, we observe that all four new protocols, especially those where annotators edit *pre-filled* text boxes, reduce previously observed issues with annotation artifacts.

1 Introduction

The task of natural language inference (NLI; also known as textual entailment) has been widely used as an evaluation task when developing new methods for language understanding tasks, and it has recently become clear that high-quality NLI data can be useful in transfer learning as well, driving much of the recent use of the task: Several recent papers have shown that training large neural network models on natural language inference data, then fine-tuning them for other language understanding tasks often yields substantially better results on those target tasks (Conneau et al., 2017; Subramanian et al., 2018). This result holds even when starting from large models like BERT (Devlin et al., 2019) that have *already* been pretrained extensively on unlabeled data (Phang et al., 2018; Clark et al., 2019; Liu et al., 2019b; Wang et al., 2019b).

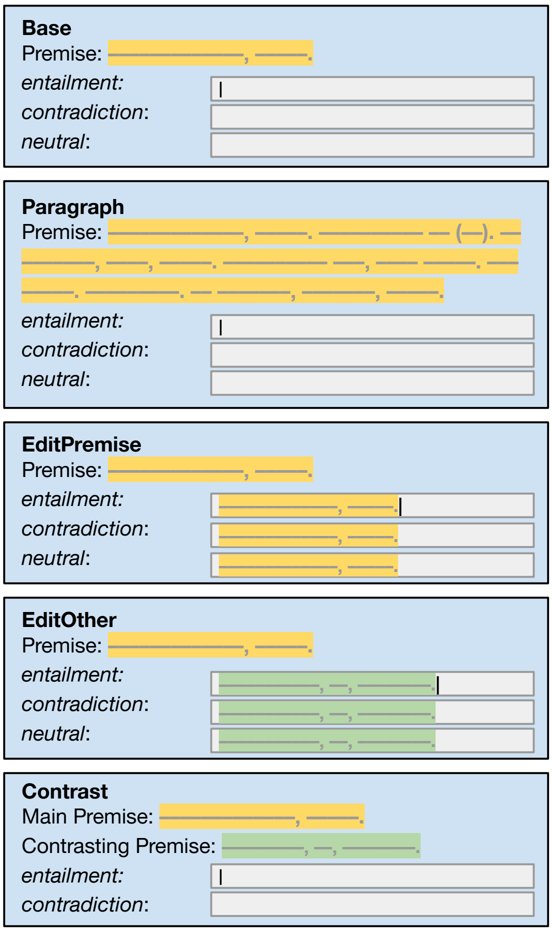

Figure 1: The annotation interfaces we evaluate.

The largest general-purpose corpus for NLI, and the one that has proven most successful in this setting, is the Multi-Genre NLI Corpus (MNLI Williams et al., 2018). MNLI was designed informally for use in a benchmark task (with no consideration of transfer learning), and in any case,

no explicit experimental research went into its design. Further, data collected under MNLI's data collection protocol has known issues with *annotation artifacts* which make it possible to perform much better than chance using only one of the two sentences that make up each example (Tsuchiya, 2018; Gururangan et al., 2018; Poliak et al., 2018).

This work experimentally evaluates four potential changes to the original MNLI data collection protocol that are designed to improve either the ease with which annotators can produce sound training examples or the quality and diversity of those examples. We collect a baseline dataset of 8.5k examples that follows the MNLI protocol with our annotator pool, followed by four additional datasets of the same size which isolate each of our candidate changes. (See Figure 1 for a schematic.) We then compare all five in a set of experiments, focused on transfer learning, that look at our ability to use each of these datasets to improve performance on the eight downstream language understanding tasks in the SuperGLUE (Wang et al., 2019b) benchmark.

All five of our datasets are consistent with the task definition that was used in MNLI, which is in turn based on the definition introduced by Dagan et al. (2006). In this task, each example consists of a pair of short texts: a *premise* and a *hypothesis*. The model is asked to read both texts and make a three-way classification decision: Given the premise, would a reasonable person infer that hypothesis must be true (*entailment*), that it must be false (*contradiction*), or that there is not enough information to judge (*neutral*)? While it is certainly not clear that this design is optimal for any application, we leave a more broad-based exploration of task definitions for future work.

Our **BASE** data collection protocol follows MNLI closely in asking annotators to read a premise sentence and then write three corresponding hypothesis sentences in empty text boxes corresponding to the three different labels (*entailment*, *contradiction*, and *neutral*). When an annotator follows this protocol, they produce three sentence pairs at once, all sharing a single premise.

Our **PARAGRAPH** protocol tests the effect of supplying annotators with complete paragraphs, rather than sentences, as premises. Longer texts offer the potential for discourse-level inferences, the addition of which should yield a dataset that is more difficult, more diverse, and less likely to contain trivial artifacts. However, one might expect that asking annotators to read full paragraphs should increase the time required to create a single example; time which could potentially be better spent creating *more* examples.

Our **EDITPREMISE** and **EDITOTHER** protocols test the effect of pre-filling a single seed text in each of the three text boxes that annotators are asked to fill out. By reducing the raw amount of typing required, this could allow annotators to produce good examples more quickly. By encouraging them to keep the three sentences similar, it could also indirectly facilitate the construction of minimal-pair-like examples that minimize artifacts, in the style of Kaushik et al. (2020). We test two variants of this idea: One uses a copy of the premise sentence as a seed text and the second retrieves a new sentence from an existing corpus that is similar to the premise sentence, and uses that.

Our **CONTRAST** protocol tests the effect of adding artificial constraints on the kinds of hypothesis sentences annotators can write. Giving annotators difficult and varying constraints could encourage creativity and prevent annotators from falling into patterns in their writing that lead to easier or more repetitive data. However, as with the use of longer contexts in PARAGRAPH, this protocol risks substantially slowing the annotation process. We experiment with a procedure inspired by that used to create the language-and-vision dataset NLVR2 (Suhr et al., 2019), in which annotators must write sentences that show some specified relationship (entailment or contradiction) to a given premise, but do *not* show that relationship to a second similar distractor premise.

Because we see transfer learning as the primary application area for which it would be valuable to collect additional large-scale NLI datasets, we focus our evaluation on this setting, and do not collect or designate test sets for the experimental datasets we collect. In transfer evaluations on the SuperGLUE benchmark (Wang et al., 2019b), our BASE dataset and the datasets collected under our four new protocols offer substantial improvements in transfer ability over a plain RoBERTa or XLNet model, comparable to the gains seen with an equally-sized sample of MNLI. However, BASE reliably shows the strongest transfer results. This finding, combined with a low variance across runs, strongly suggests that none of these four interventions improves the suitability of NLI data for transfer learning. We also observe that Base, Paragraph, EditPremise, and EditOther all require very similar amounts of annotator time, reducing the potential downside of Paragraph, but also invalidating the primary motivation behind EditPremise and EditOther. While our primary results are negative, we also observe that all four of these methods produce data of comparable subjective quality to Base while significantly reducing the incidence of previously reported annotation artifacts.

2 Related Work

Existing NLI datasets have been built using a wide range of strategies: FraCaS (Cooper et al., 1996) and several targeted evaluation sets were constructed manually by experts from scratch. The RTE challenge corpora (Dagan et al., 2006, et seq.) primarily used expert annotations on top of existing premise sentences. SICK (Marelli et al., 2014) was created using a structured pipeline centered on asking crowdworkers to edit sentences in prescribed ways. MPE (Lai et al., 2017) uses a similar strategy, but constructs unordered *sets* of sentences for use as premises. SNLI (Bowman et al., 2015) introduced the method, also used in MNLI, of asking crowdworkers to compose labeled hypotheses for a given premise. SciTail (Khot et al., 2018) and SWAG (Zellers et al., 2018) used domain-specific resources to pair up existing sentences as potential entailment pairs for annotation, with SWAG additionally using trained models to select the examples most worth annotating. There has been little work directly evaluating and comparing these many methods. In that absence, we focus on the SNLI/MNLI approach, because it has been shown to be effective for the collection of pretraining data and because its reliance on only crowdworkers and unstructured source text makes it simple to scale.

Two recent papers have investigated methods that could augment the base MNLI protocol we study here. ANLI (Nie et al., 2020) collects new examples following this protocol, but adds an incentive for crowdworkers to produce sentence pairs on which a baseline system will perform poorly. Kaushik et al. (2020) introduce a method for expanding an already-collected dataset by making minimal edits to existing examples that change their labels, with the intent to better teach models to isolate the factors that are causally responsible for the label assignments. Both of these papers offer methodological changes that are potentially complementary to the changes we investigate here, and neither evaluates the impact of their methods on transfer learning. Since ANLI is large and roughly comparable with MNLI, we include it in our transfer evaluations here.

Table 1: Randomly selected examples from the datasets under study. Neither the MNLI training set nor any of our collected data are filtered for quality in any way, and errors or debatable judgments are common in both.

In addition to NLVR2 (which motivated our Contrast protocol), WinoGrande (Sakaguchi et al., 2019) also showed promising results from the use of artificial constraints during the annotation process for another style of dataset.

The observation that NLI data can be effective in pretraining was first reported for SNLI and MNLI by Conneau et al. (2017) on models pretrained from scratch on NLI data. This finding was replicated in the setting of multi-task pretraining by Subramanian et al. (2018). This was later extended to the context of *intermediate training*—where a model is pretrained on unlabeled data, then on relatively abundant labeled data (MNLI), and finally scarce task-specific labeled data—by Phang et al. (2018), Clark et al. (2019), Liu et al. (2019a), Yang et al. (2019), and Liu et al. (2019b) across a range of large pretrained models models and target language-understanding tasks. Similar results have been observed with transfer from the other reasoning-oriented datasets (Sap et al., 2019; Bhagavatula et al., 2020), especially to target tasks centered on common sense. Another related body of work (Mou et al., 2016; Bingel and Søgaard, 2017; Wang et al., 2019a; Pruksachatkun et al., 2020) has explored the broader empirical landscape of which supervised NLP tasks can offer effective pretraining for other supervised NLP tasks.

3 Data Collection

The annotation interface for our tasks is similar to that used for SNLI and MNLI: We provide a premise from a preexisting text source and ask human annotators to provide three hypothesis sentences: one that says something true about the fact or situation in the prompt (*entailment*), one that says something that may or may not be true about the fact or situation in the prompt (*neutral*)—with the additional instruction that this sentence should discuss the same topic as the prompt but could be either true or false because the prompt does not provide enough information to be sure—and one that definitely does not say something true about the fact or situation in the prompt (*contradiction*).

We evaluate five variants of this interface:

BASE We show annotators a premise sentence and ask them to compose one new sentence for each label.

PARAGRAPH We use the same instructions as BASE, but with full paragraphs, rather than single sentences, as the supplied premises.

EDITPREMISE We pre-fill three text boxes with editable copies of the premise sentence, and ask annotators to edit each text field to compose sentences that match the three different labels. Annotators may delete the pre-filled text.

EDITOTHER We follow the same procedure as EDITPREMISE, but rather than pre-filling the premise as a seed sentence, we instead use a similarity search method to retrieve a new sentence that is similar to the premise.

CONTRAST We again retrieve a second sentence that is similar to the premise, but we display it as a *contrasting premise* rather than using it to seed an editable text box. We then ask annotators to compose two new sentences: One sentence must be true *only* about the fact or situation in the first premise (that is, contradictory or neutral with respect to the contrasting premise). The other sentence must be *false* only about the fact or situation in the first premise (and *true* or neutral with respect to the contrasting premise). This yields an entailment pair and a contradiction pair, both of which use only the first premises, with the contrasting premise serving only as a constraint on the annotation process. We could not find a sufficiently intuitive way to collect neutral sentence pairs under this protocol and opted to use only two classes rather than increase the difficulty of an already unintuitive task.

3.1 Text Source

MNLI uses the small but stylistically diverse OpenANC corpus (Ide and Suderman, 2006) as its source for premise sentences, but uses nearly every available sentence from its non-technical sections, making it impractical for our use. To avoid re-using premise sentences, We instead draw on English Wikipedia.[1]

Similarity Search The EDITOTHER and CONTRAST protocols require pairs of similar sentences as their inputs. To construct these, we assemble a heuristic sentence-matching system intended to generate pairs of highly similar sentences that can be minimally edited to construct entailments or contradictions: Given a premise, we retrieve its closest 10k nearest neighbors according to dot-product similarity over Universal Sentence Encoder (Cer et al.,

---

[1] We use the 2019-06-20 downloadable version, remove markup and tables with Apertium's WikiExtractor feature (Forcada et al., 2011), sentence-tokenize it with SpaCy (Honnibal and Montani, 2017), and randomly sample sentences (or paragraphs) for annotation.

	Label	**Length** μ (σ)	**Unique** μ (σ)

Table 2: Key text statistics. Premises are drawn from essentially the same distribution in all our tasks except PARAGRAPH, so are shown only once. The *Unique* column shows the number of tokens that appear in a hypothesis but not in the corresponding premise.

2018) embeddings. Using a parser and an NER system, we then select those neighbors which share a subject noun phrase in common with the premise (dropping premises for which no such neighbors exist). From those filtered neighbors, we retrieve the single non-identical neighbor that has the highest overlap with the premise in both raw tokens and entity mentions, preferring sentences with similar length to the hypothesis.[2]

3.2 The Annotation Process

We start data collection for each protocol with a pilot of 100 items, which are not included in the final datasets. We use these to refine task instructions and to provide feedback to our annotator pool on the intended task definition. We continue to provide regular feedback throughout the annotation process to clarify ambiguities in the protocols and to discourage the use of systematic patterns—such as consistently composing shorter hypotheses for entailments than for contradictions—that could make the resulting data artificially easy.

Annotators are allowed to skip prompts which they deem unusable for any reason. These generally involve either non-sentence strings that were mishandled by our sentence tokenizer or premises with inaccessible technical language. Skip rates ranged from about 2.5% for EDITOTHER to about 10% for CONTRAST (which can only be completed when the two premises are both comprehensible and sufficiently different from one another).

A pool of 19 professional annotators located in the United States worked on our tasks, with about ten working on each protocol. As a consequence of this relatively small annotation team, many annotators worked under more than one protocol, which we ran consecutively. This introduces a modest potential bias against BASE, in that annotators start the later tasks having seen somewhat more feedback.

Because of our focus on collecting training data for transfer learning applications, we do not use any kind of second-pass annotation process for quality control, and we neither designate a test set nor recommend the use of our released datasets for system evaluation. We aim to use our limited annotation time budget to collect the largest and best possible sample of (pre)training data, and we are motivated by work like Khetan et al. (2018) which calls into question the value of second-pass quality-control annotations for training data.

3.3 The Resulting Data

Using each protocol, we collect a training set of exactly 8,500 examples and a small validation set of at least 300 examples.[3] Table 1 shows examples.

Hypotheses are mostly fluent, full sentences that adhere to writing conventions for US English. In

---

[2] For dependency parse and named entity recognition annotations, we use the Google Natural Language API: `https://cloud.google.com/natural-language/`.

[3] available for download at `https://github.com/google-research-datasets/Textual-Entailment-New-Protocols`

constructing hypotheses, annotators often reuse words or phrases from the premise, but rearrange them, alter their inflectional forms, or substitute synonyms or antonyms. Hypotheses tend to differ from premises both grammatically and stylistically.

Table 2 shows some statistics for the collected text. The two methods that use seed sentences tend to yield longer hypotheses and tend not to show a clear relationship between hypothesis–premise token overlap and label. CONTRAST tends to produce shorter hypotheses.

Time Cost Annotators completed each of the five protocols at a similar rate, taking 3–4 minutes per prompt. This goes against our expectations that the longer premises in PARAGRAPH should substantially slow the annotation process, and that the pre-filled text in EDITPREMISE and EDITOTHER should speed annotation. Since the relatively complex CONTRAST produces only two sentence pairs per prompt rather than three, it yields fewer examples per minute.

Label–Word Associations Table 3 shows the four words in each dataset that are most predictive of example labels, using the smoothed PMI method of Gururangan et al. (2018). We also include results for two baselines: 8.5k-example samples from MNLI, and from MNLI's the *government documents* single-genre section, which is meant to to be maximally comparable to the single-genre datasets we collect.

BASE shows similar associations to MNLI, but all four of our interventions reduce these associations at least slightly. The use of seed sentences, especially in EDITPREMISE, largely eliminates the strong association between negation and contradiction seen in MNLI, and no new strong associations appear to take its place.

4 Modeling Experiments

We run three types of machine learning experiments: Sanity check experiments where we train and test on the NLI task—both in a standard setting and in a *hypothesis-only* limited-input setting to measure relevant annotation artifacts—and our primary evaluation experiments in which we train models on NLI before evaluating them on other tasks through transfer learning.

These experiments generally compare models trained on ten NLI datasets: Each of the five 8.5k-example training sets introduced in this paper; the full 393k-example MNLI training set; the full 1.1m-example ANLI training set (which combines the SNLI training set, the MNLI training set, and the supplemental ANLI training examples);[4] 8.5k-

Table 3: The top four words most associated with specific labels in each dataset, sorted by the PMI between the word and the label. The *counts* column shows how many of the instances of each word occur in hypotheses matching the specified label. We compare the two-class CONTRAST with a two-class version of MNLI Gov.

---

[4] In these runs, we use only the original ANLI validation set for evaluation and early stopping.

example samples from the MNLI training set and from the combined ANLI training set, meant to control for the size differences between these existing datasets and our baselines; and finally an 8.5k-example sample from the government section of the MNLI training set, meant to control (as much as possible) for the difference between our single-genre Wikipedia datasets and MNLI's relatively diverse text.

Our models are trained starting from pretrained RoBERTa (*large* variant) or XLNet (*large*, *cased*; Yang et al., 2019). RoBERTa was at or near the state of the art on most of our target tasks as of the launch of our experiments. XLNet is competitive with RoBERTa on most tasks, it offers a natural replication, and because of its substantially different design, it mitigates issues with evaluating ANLI that arise because ANLI was collected with a model-in-the-loop procedure using RoBERTa.

We run our experiments using `jiant` 1.2 (Wang et al., 2019d), which implements the SuperGLUE tasks, MNLI, and ANLI, and in turn builds on `transformers` (Wolf et al., 2019), AllenNLP (Gardner et al., 2017), and PyTorch (Paszke et al., 2017). To make it possible to train these large models on single consumer GPUs, we use small-batch ($b = 4$) training and a maximum total sequence length of 128 word pieces.[5] We train for up to 2 epochs for the very large ReCoRD, 10 epochs for the very small CB, COPA, and WSC, and 4 epochs for the remaining tasks. Except where noted, all results reflect the median final performance from three random restarts of training.[6]

Direct NLI Evaluations As a preliminary sanity check, Table 4 shows the results of evaluating models trained in each of the settings described above on their own validation sets, on the MNLI validation set, and on the expert-constructed GLUE diagnostic set (Wang et al., 2019c). As NLI classifiers trained on CONTRAST cannot produce the *neutral* labels used in MNLI, we evaluate them separately and compare them with two-class variants of the MNLI models.

Our BASE data yields a model that performs somewhat worse than a comparable MNLI Gov. 8.5k model, both on the full MNLI validation set and on the GLUE diagnostic set. This suggests, at least tentatively, that the new annotations are significantly less consistent with the MNLI labeling standard. This is disconcerting, but does not interfere with our key comparisons. Precise comparisons between MNLI and our new data on in-domain test sets are not possible, since only MNLI has in-domain evaluation data that has undergone substantial quality control.

Training Data	Self	MNLI	GLUE Diag.
BASE	84.8	81.5	40.5
PARAGRAPH	78.3	78.2	31.7
EDITPREMISE	82.9	79.8	35.5
EDITOTHER	82.5	82.6	33.9
MNLI8.5k	87.5	87.5	44.6
MNLIGov8.5k	87.7	85.4	40.7

MNLI	90.4	**90.4**	49.2
ANLI	61.5	90.1	**49.7**
MNLI (two-class)	94.0	**94.0**	–
MNLI8.5k (two-class)	92.4	92.4	–
CONTRAST	91.6	80.6	–

Table 4: NLI modeling experiments with RoBERTa, reporting results on the validation sets for MNLI and for the task used for training each model (Self), and the GLUE diagnostic set (shown as Matthews Corr.). We compare the two-class CONTRAST with a two-class version of MNLI.

The main conclusion we draw from these results is that none of the first three interventions improve performance on the out-of-domain GLUE diagnostic set, suggesting that they do not help in the collection of high-quality training data that is consistent with the MNLI label definitions. We also observe that the newer ANLI data yields *worse* performance than MNLI on the out-of-domain evaluation data when we control for dataset size.

Hypothesis-Only Models To further investigate the degree to which our hypotheses contain artifacts that reveal their labels, Table 5 shows results with single-input versions of our models trained on hypothesis-only versions of the datasets under study and evaluated on the datasets' validation sets.

Our first three interventions, especially EDITPREMISE, show much lower hypothesis-only performance than BASE. This drop is much larger than the drop seen in our standard NLI experiments in the *Self* column of Table 4. This indicates that these results cannot be explained away as a consequence of the lower label consistency of the evaluation sets for these three new datasets. This adds

---

[5] We cut this to a slightly lower number on a few individual runs as needed to satisfy memory constraints. Note that this potentially limits the gains observable for PARAGRAPH, which has a longer mean premise length of 66.7 words.

[6] Scripts implementing our experiments are available at `https://github.com/nyu-mll/jiant/tree/nli-data`.

further evidence, alongside our PMI results, that these interventions reduce the presence of such artifacts. While we do not have a direct baseline for the two-class CONTRAST in this experiment, comparisons with MNLI 8.5k are consistent with the encouraging PMI results seen above.

Transfer Evaluations For our primary evaluation, we use the training sets from our datasets in STILTs-style intermediate training (Phang et al., 2018): We fine-tune a large pretrained model on our collected data using standard fine-tuning procedures, then fine-tune copies of the resulting model again on each of the target task datasets we use. We then measure the aggregate performance of the resulting models across those evaluation datasets.

We evaluate on the target tasks in the SuperGLUE benchmark (Wang et al., 2019b): which consists of standardized splits and metrics for the question answering tasks BoolQ (Clark et al., 2019), MultiRC (Khashabi et al., 2018), ReCoRD (Zhang et al., 2018); the entailment and reasoning tasks CommitmentBank (CB; De Marneffe et al., 2019), Choice of Plausible Alternatives (COPA; Roemmele et al., 2011), Recognizing Textual Entailment (RTE; Dagan et al., 2006; Bar Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009), and the Winograd Schema Challenge (WSC; Levesque et al., 2012); and the word sense disambiguation task WiC (Pilehvar and Camacho-Collados, 2019). These tasks were selected to be difficult for BERT but relatively easy for crowdworkers, and are meant to replace the largely-solved GLUE benchmark (Wang et al., 2019c).

SuperGLUE does not include labeled test data, and does not allow for substantial ablation analyses on its test sets. Since we have no single final model whose performance we aim to show off, we do not use the test sets. We train our WSC model in the standard way without adding data or modifying the format (as in Kocijan et al., 2019; Liu et al., 2019b). Without these modifications, few of our models exceed chance accuracy.

Results are shown in Table 6. Our first observation is that our overall data collection pipeline worked well for our purposes: Our BASE data yields models that transfer substantially better than the plain RoBERTa or XLNet baseline, and at least slightly better than 8.5k-example samples of MNLI, MNLI Government or ANLI. However, all four of our interventions yield *worse* transfer performance than BASE. The variances across runs are small, and this pattern is consistent across both RoBERTa and XLNet, and across most individual target tasks. We believe that this is a genuine negative result: At least under the broad experimental setting outlined here, we find that none of these four interventions is helpful for transfer learning.

We chose to collect 8,500-example samples because of the prior observation that this approximate amount was sufficient to show clear results on transfer learning, and we reproduce that finding here: Both MNLI 8.5k and the BASE dataset yield large improvements over plain RoBERTa or XLNet through transfer learning. If any of our interventions were to be helpful in general, we would expect them to be harmless or helpful in our regime relative to BASE. This is not what we observe.

We believe that this is the first study to evaluate ANLI as a pretraining task in transfer learning, and we observe that the large combined ANLI training set yields consistently better transfer than the original MNLI dataset. However, we observe (to our surprise) that this result reverses when we control for ANLI's larger size, with an 8.5k-example sample of MNLI yielding consistently better performance than an equivalently small sample of ANLI.

Our best overall result uses only 8.5k NLI training examples, suggesting either that this size is enough to maximize the gains available through NLI pretraining, or that the potential for models to forget skills learned in pretraining makes using larger intermediate datasets more challenging.

Finally, we replicate the finding from Phang et al. (2018) that intermediate-task training with NLI data substantially reduces the variance across restarts seen in target task tuning.

Table 6: Model performance on the SuperGLUE task validation sets. The Avg. column shows the overall SuperGLUE score—an average across the eight tasks —as a mean and standard deviation across three restarts.

5 Conclusion

Our chief results on transfer learning are conclusively negative: All four interventions yield substantially worse transfer performance than our base MNLI data collection protocol. However, we also observe promising signs that all four of our interventions help to reduce the prevalence of artifacts in the generated hypotheses that reveal the label. While these interventions may be helpful for future *evaluation* data, it appears that the type of creativity induced by our relatively open-ended BASE prompt works well for pretraining, and the resulting artifacts are a tolerable side-effect of that creativity.

The need and opportunity that motivated this work remains compelling: Human-annotated data like MNLI has already proven itself as a valuable tool in teaching machines general-purpose skills for language understanding, and discovering ways to more effectively build and use such data could further accelerate the field's already fast progress toward robust, general-purpose language understanding technologies.

On another note, most available text corpora, including our Wikipedia source text and comparable past NLI datasets, contain evidence of social inequalities and stereotypes, which models can easily learn to reproduce (Wagner et al., 2015; Rudinger et al., 2017). Our interventions are not meant to address this, and are likely orthogonal. Bias mitigation in models and datasets remains a crucial direction for future work if systems based on datasets like the ones we study are to be widely deployed.

Beyond this: Work on incentive structures and task design could facilitate the creation of crowdsourced datasets that are both creative and consistently labeled. Machine learning methods work on transfer learning could help to better understand and exploit the effects that drive the successes we have seen with NLI data so far. Finally, there remains room for further empirical work investigating the kinds of task definitions and data collection protocols most likely to yield training data that teaches models transferrable skills.

Acknowledgments

We thank the annotators who spent time and effort on this project and the many members of the natural language processing community at Google who provided feedback.

Abstract

We find that the performance of state-of-the-art models on Natural Language Inference (NLI) and Reading Comprehension (RC) analysis/stress sets can be highly unstable. This raises three questions: (1) How will the instability affect the reliability of the conclusions drawn based on these analysis sets? (2) Where does this instability come from? (3) How should we handle this instability and what are some potential solutions? For the first question, we conduct a thorough empirical study over analysis sets and find that in addition to the unstable final performance, the instability exists all along the training curve. We also observe lower-than-expected correlations between the analysis validation set and standard validation set, questioning the effectiveness of the current model-selection routine. Next, to answer the second question, we give both theoretical explanations and empirical evidence regarding the source of the instability, demonstrating that the instability mainly comes from high inter-example correlations within analysis sets. Finally, for the third question, we discuss an initial attempt to mitigate the instability and suggest guidelines for future work such as reporting the decomposed variance for more interpretable results and fair comparison across models.[1]

1 Introduction

Neural network models have significantly pushed forward performances on natural language processing benchmarks with the development of large-scale language model pre-training (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Radford et al., 2019; Liu et al., 2019b). For example, on two semantically challenging tasks, Natural Language Inference (NLI) and Reading Comprehension (RC), the state-of-the-art results have reached or even surpassed the estimated human performance on certain benchmark datasets (Wang et al., 2019; Rajpurkar et al., 2016a, 2018). These astounding improvements, in turn, motivate a new trend of research to analyze what language understanding and reasoning skills are actually achieved, versus what is still missing within these current models. Following this trend, numerous analysis approaches have been proposed to examine models' ability to capture different linguistic phenomena (e.g., named entities, syntax, lexical inference, etc.). Those studies are often conducted in 3 steps: (1) proposing assumptions about a certain ability of the model; (2) building analysis datasets by automatic generation or crowd-sourcing; (3) concluding models' ability using results on these analysis datasets.

Past analysis studies have led to many key dis-

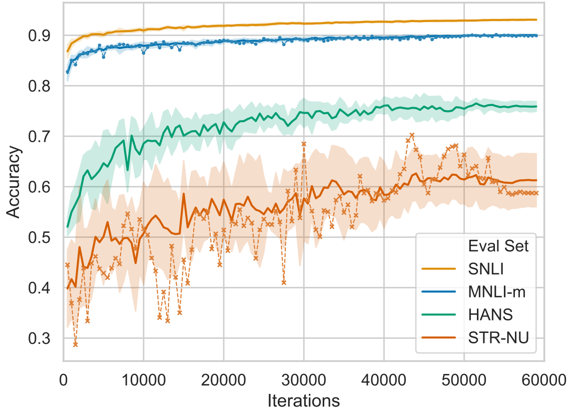

Figure 1: The trajectories of BERT performance on SNLI, MNLI-m, HANS (McCoy et al., 2019b), and the Numerical subcategory of the Stress Test dataset (Naik et al., 2018a) (from the topmost line to the bottom, respectively). The solid lines represent the means of ten runs and the shadow area indicates a distance within a standard deviation from the means. The two dashed lines show the trajectories of one single run for MNLI-m and Numerical Stress Test using the same model.

[1] Our code is publicly available at: `https://github.com/owenzx/InstabilityAnalysis`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8215–8228,
November 16–20, 2020.

coveries in NLP models, such as over-stability (Jia and Liang, 2017), surface pattern overfitting (Gururangan et al., 2018), but recently McCoy et al. (2019a) found that the results of different runs of BERT NLI models have large non-negligible variances on the HANS (McCoy et al., 2019b) analysis datasets, contrasting sharply with their stable results on standard validation set across multiple seeds. This finding raises concerns regarding the reliability of individual results reported on those datasets, the conclusions made upon these results, and lack of reproducibility (Makel et al., 2012). Thus, to help consolidate further developments, we conduct a deep investigation on model instability, showing how unstable the results are, and how such instability compromises the feedback loop between model analysis and model development.

We start our investigation from a thorough empirical study of several representative models on both NLI and RC. Overall, we observe four worrisome observations in our experiments: (1) The final results of the same model with different random seeds on several analysis sets are of significantly **high variance**. The largest variance is more than 27 times of that for standard development set; (2) These large instabilities on certain datasets is **model-agnostic**. Certain datasets have unstable results across different models; (3) The instability not only occurs at the final performance but exists **all along training trajectory**, as shown in Fig. 1; (4) The results of the same model on analysis sets and on the standard development set have **low correlation**, making it hard to draw any constructive conclusion and questioning the effectiveness of the standard model-selection routine.

Next, in order to grasp a better understanding of this instability issue, we explore theoretical explanations behind this instability. Through our theoretical analysis and empirical demonstration, we show that inter-examples correlation within the dataset is the dominating factor causing this performance instability. Specifically, the variance of model accuracy on the entire analysis set can be decomposed into two terms: (1) the sum of single-data variance (the variance caused by individual prediction randomness on each example), and (2) the sum of inter-data covariance (caused by the correlation between different predictions). To understand the latter term better, consider the following case: if there are many examples correlated with each other in the evaluation set, then the change of prediction on one example will influence predictions on all the correlated examples, causing high variances in final accuracy. We estimate these two terms with multiple runs of experiments and show that inter-data covariance contributes significantly more than single-data variance to final accuracy variance, indicating its major role in the cause of instability.

Finally, in order for the continuous progress of the community to be built upon trustworthy and interpretable results, we provide initial suggestions on how to perceive the implication of this instability issue and how we should potentially handle it. For this, we encourage future research to: (1) when reporting means and variance over multiple runs, also report two decomposed variance terms (i.e., sum of single data variance and sum of inter-data covariance) for more interpretable results and fair comparison across models; (2) focus on designing models with better inductive and structural biases, and datasets with higher linguistic diversity.

Our contribution is 3-fold. First, we provide a thorough empirical study of the instability issue in models' performance on analysis datasets. Second, we demonstrate theoretically and empirically that the performance variance is attributed mostly to inter-example correlations. Finally, we provide suggestions on how to deal with instability, including reporting the decomposed variance for more interpretable evaluation and better comparison.

2 Related Work

NLI and RC Analysis. Many analysis works have been conducted to study what the models are actually capturing alongside recent improvements on NLI and RC benchmark scores. In NLI, some analyses target word/phrase level lexical/semantic inference (Glockner et al., 2018; Shwartz and Dagan, 2018; Carmona et al., 2018), some are more syntactic-related (McCoy et al., 2019b; Nie et al., 2019; Geiger et al., 2019), some also involved logical-related study (Minervini and Riedel, 2018; Wang et al., 2019). Naik et al. (2018a) proposed a suite of analysis sets covering different linguistic phenomena. In RC, adversarial style analysis is used to test the robustness of the models (Jia and Liang, 2017). Most of the work follows the style of Carmona et al. (2018) to diagnose/analyze models' behavior on pre-designed analysis sets. In this paper, we analyze NLI and RC models from a broader perspective by inspecting models' performance across different analysis sets, and their inter-dataset and intra-dataset relationships.

Dataset-Related Analysis. Another line of works study the meta-issues of the dataset. The most well-known one is the analysis of undesirable bias. In VQA datasets, unimodal biases were found, compromising their authority on multi-modality evaluation (Jabri et al., 2016; Goyal et al., 2017). In RC, Kaushik and Lipton (2018) found that passage-only models can achieve decent accuracy. In NLI, hypothesis bias was also found in SNLI and MultiNLI (Tsuchiya, 2018; Gururangan et al., 2018). These findings revealed the spurious shortcuts in the dataset and their harmful effects on trained models. To mitigate these problems, Liu et al. (2019a) introduced a systematic task-agnostic method to analyze datasets. Rozen et al. (2019) further explain how to improve challenging datasets and why diversity matters. Geva et al. (2019) suggest that the training and test data should be from exclusive annotators to avoid annotator bias. Our work is complementary to those analyses.

Robustifying NLI and RC Models. Recently, a number of works have been proposed to directly improve the performance on the analysis datasets both for NLI through model ensemble (Clark et al., 2019; He et al., 2019), novel training mechanisms (Pang et al., 2019; Yaghoobzadeh et al., 2019), adversarial data augmentation (Nie et al., 2020), enhancing word representations (Moosavi et al., 2019), and for RC through different training objectives (Yeh and Chen, 2019; Lewis and Fan, 2019). While improvements have been made on certain analysis datasets, the stability of the results is not examined. As explained in this paper, we highly recommend those result variances be scrutinized in future work for fidelity considerations.

Instability in Performance. Performance instability has already been recognized as an important issue in deep reinforcement learning (Irpan, 2018) and active learning (Bloodgood and Grothendieck, 2013). However, supervised learning is presumably stable especially with fixed datasets and labels. This assumption is challenged by some analyses recently. McCoy et al. (2019a) show high variances in NLI-models performance on the analysis dataset. Phang et al. (2018) found high variances in fine-tuning pre-trained models in several NLP tasks on the GLUE Benchmark. Reimers and Gurevych (2017, 2018) state that conclusions based on single run performance may not be reliable for machine learning approaches. Weber et al. (2018) found that the model's ability to generalize beyond the training distribution depends greatly on the random seed. Dodge et al. (2020) showed weight initialization and training data order both contribute to the randomness in BERT performance. In our work, we present a comprehensive explanation and analysis of the instability of neural models on analysis datasets and give general guidance for future work.

3 The Curse of Instability

3.1 Tasks and Datasets

In this work, we target our experiments on NLI and RC for two reasons: 1) their straightforwardness for both automatic evaluation and human understanding, and 2) their wide acceptance of being benchmarks evaluating natural language understanding.

For NLI, we use SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018) as the main standard datasets and use HANS (McCoy et al., 2019b), SNLI-hard (Gururangan et al., 2018), BREAK-NLI (Glockner et al., 2018), Stress Test (Naik et al., 2018a), SICK (Marelli et al., 2014), EQUATE (Ravichander et al., 2019) as our auxiliary analysis sets. Note that the Stress Test contains 6 subsets (denoted as 'STR-X') targeting different linguistic categories. We also splite the EQUATE dataset to two subsets (denoted as 'EQU-NAT/SYN') based on whether the example are from natural real-world sources or are controlled synthetic tests. For RC, we use SQuAD1.1 (Rajpurkar et al., 2016b) as the main standard dataset and use AdvSQuAD (Jia and Liang, 2017) as the analysis set. All the datasets we use in this paper are English. Detailed descriptions of the datasets are in Appendix.

3.2 Models

Since BERT (Devlin et al., 2019) achieves state-of-the-art results on several NLP tasks, the pretraining-then-finetuning framework has been widely used. To keep our analysis aligned with recent progress, we focused our experiments on this framework. Specifically, in our study, we used the two most typical choices: BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019).[2] Moreover, for NLI, we additionally use RoBERTa (Liu et al., 2019b)

---

[2] For all the transformer models, we use the implementation in `https://github.com/huggingface/transformers`. BERT-B, BERT-L stands for BERT-base and BERT-large, respectively. The same naming rule applies to other transformer models.

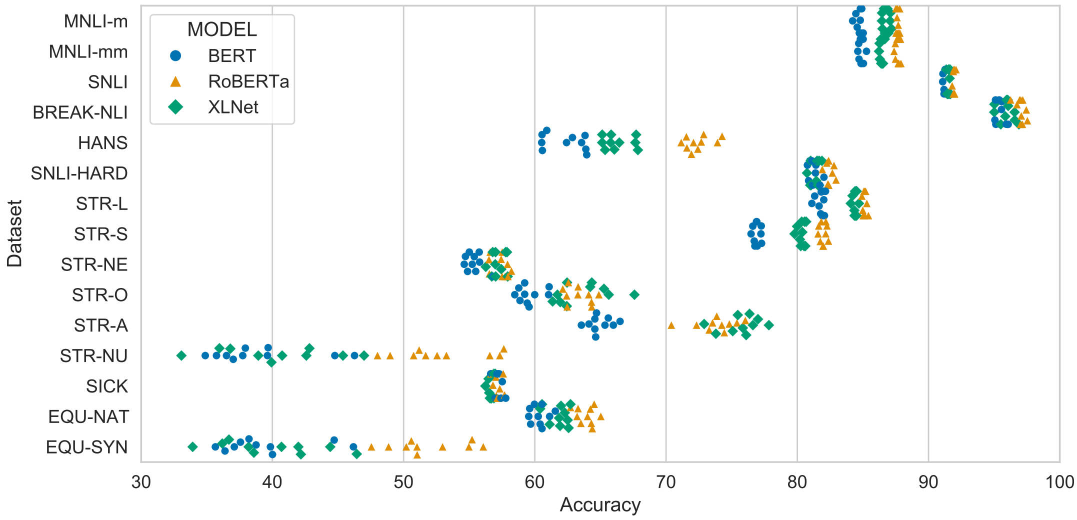

Figure 2: The results of BERT, RoBERTa, and XLNet on all datasets with 10 different random seeds. Large variance can be seen at certain analysis datasets (e.g. STR-NU, HANS, etc.) while results on standard validation sets are always stable.

and ESIM (Chen et al., 2017) in our experiments. RoBERTa is almost the same as BERT except that it has been trained on 10 times more data during the pre-training phrase to be more robust. ESIM is the most representative pre-BERT model for sequence matching problem and we used an ELMo-enhanced-version (Peters et al., 2018).[3] All the models and training details are in Appendix.

3.3 What are the Concerns?

Instability in Final Performance. Models' final results often serve as a vital measurement for comparative study. Thus, we start with the question: "How unstable are the final results?" To measure the instability, we train every model 10 times with different random seeds. Then, we evaluate the performances of all the final checkpoints on each NLI dataset and compute their standard deviations. As shown in Fig. 2, the results of different runs for BERT, RoBERTa, and XLNet are highly stable on MNLI-m, MNLI-mm, and SNLI, indicating that model performance on standard validation datasets regardless of domain consistency[4] are fairly stable. This stability also holds on some analysis sets, especially on SNLI-hard, which is a strict subset of the SNLI validation set. On the contrary, there are noticeable high variances on some analysis sets. The most significant ones are on STR-NU and HANS where points are sparsely scattered, with a 10-point gap between the highest and the lowest number for STR-NU and a 4-point gap for HANS.

Model-Agnostic Instability. Next, we check if the instability issue is model-agnostic. For a fair comparison, as the different sizes of the datasets will influence the magnitude of the instability, we normalize the standard deviation on different datasets by multiplying the square root of the size of the dataset[5] and focus on the relative scale compared to the results on the MNLI-m development set, i.e., $\frac{STD(dataset)}{STD(MNLI-m)}\sqrt{\frac{SIZE(dataset)}{SIZE(MNLI-m)}}$. The results for all the models are shown in Table 1 (the original means and standard deviations are in Appendix). From Table 1, we can see that the instability phenomenon is consistent across all the models. Regardless of the model choice, some of the analysis datasets (e.g., HANS, STR-O, STR-N) are significantly more unstable (with standard deviation 27 times larger in the extreme case) than the standard evaluation datasets. Similarly, for RC, the normalized deviation of model F1 results on SQuAD almost doubled when evaluated on AddSent, as shown in Table 2 (the original means and standard deviations are in Appendix).

Fluctuation in Training Trajectory. Intuitively, the inconsistency and instability in the final performance of different runs can be caused by the

---

[3] For ESIM, we use the implementation in AllenNLP (Gardner et al., 2018).

[4] Here SNLI and MNLI-m share the same domain as the training set while MNLI-mm is from different domains.

[5] This normalization factor assumes that every prediction is independent of each other.

Model	Standard Datasets			Analysis Sets											
	MNLI-m	MNLI-mm	SNLI	BREAK-NLI	HANS	SNLI-hard	STR-L	STR-S	STR-NE	STR-O	STR-A	STR-NU	SICK	EQU-NAT	EQU-SYN

randomness in initialization and stochasticity in training dynamics. To see how much these factors can contribute to the inconsistency in the final performance, we keep track of the results on different evaluation sets along the training process and compare their training trajectories. We choose HANS and STR-NU as our example unstable analysis datasets because their variances in final performance are the largest, and we choose SNLI and MNLI-m for standard validation set comparison. As shown in Fig. 1, the training curve on MNLI and SNLI (the top two lines) is highly stable, while there are significant fluctuations in the HANS and STR-NU trajectories (bottom two lines). Besides the mean and standard deviation over multiple runs, we also show the accuracy of one run as the bottom dashed line in Fig. 1. We find that two adjacent checkpoints can have a dramatically large performance gap on STR-NU. Such fluctuation is very likely to be one of the reasons for the instability in the final performance and might give rise to untrustworthy conclusions drawn from the final results.

Low Correlation between Datasets. The typical routine for neural network model selection requires practitioners to choose the model or checkpoint hinged on the observation of models' performance on the validation set. The routine was followed in all previous NLI analysis studies where models were chosen by the performance on standard validation set and tested on analysis sets. An important assumption behind this routine is that the performance on the validation set should be correlated with the models' general ability. However, as shown in Fig. 1, the striking difference between the wildly fluctuated training curves for analysis sets and the smooth curves for the standard validation set questions the validity of this assumption.

Figure 3: Spearman's correlations for different datasets showing the low correlation between standard datasets (i.e., MNLI-m, MNLI-mm, and SNLI) and all the other analysis datasets.

Therefore, to check the effectiveness of model selection under these instabilities, we checked the correlation for the performance on different datasets during training. For dataset $\mathcal{D}^i$, we use $a^i_{t,s}$ to denote the accuracy of the checkpoint at t-th time step and trained with the seed $s \in S$, where S is the set of all seeds. We calculate the correlation $\mathrm{Corr}_{i,j}$ between datasets $\mathcal{D}^i$ and $\mathcal{D}^j$ by:

$$\mathrm{Corr}_{i,j} = \frac{1}{|S|} \sum_{s \in S} \mathrm{Spearman} \left[(a^i_{t,s})^T_{t=1}, (a^j_{t,s})^T_{t=1} \right]$$

where T is the number of checkpoints.

The correlations between different NLI datasets are shown in Fig. 3. We can observe high correlation (> 0.95) among standard validation datasets (e.g. MNLI-m, MNLI-mm, SNLI) but low correlations between other dataset pairs, especially when pairing STR-O or STR-NU with MNLI or

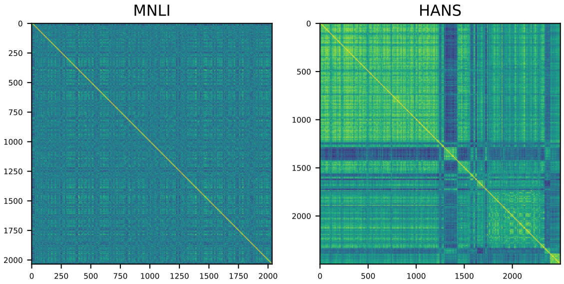

Figure 4: The two heatmaps of inter-example correlations matrices for both MNLI and HANS. Each point in the heatmap represents the Spearman's correlation between the predictions of an example-pair.

SNLI. While these low correlations between standard evaluation sets and analysis sets can bring useful insights for analysis, this also indicates that: 1) performance on the standard validation set is not representative enough for certain analysis set performances; 2) comparison/conclusions drawn from analysis datasets' results from model selection on standard evaluation sets may be unreliable.

4 Tracking Instability

Before answering the question how to handle these instabilities, we first seek the source of the instability to get a better understanding of the issue. We start with the intuition that high variance could be the result of high inter-example correlation within the dataset, and then provide hints from experimental observations. Next, we show theoretical evidence to formalize our claim. Finally, we conclude that the major source of variance is the inter-example correlations based on empirical results.

4.1 Inter-Example Correlations

Presumably, the wild fluctuation in the training trajectory on different datasets might come from two potential sources. Firstly, the individual prediction of each example may be highly unstable so that the prediction is constantly changing. Secondly, there might be strong inter-example correlations in the datasets such that a large proportion of predictions are more likely to change simultaneously, thus causing large instability. Here we show that the second reason, i.e., the strong inter-example prediction correlation is the major factor.

We examine the correlation between different example prediction pairs during the training process. In Fig. 4, we calculated the inter-example Spearman's correlation on MNLI and HANS. Fig. 4 shows a clear difference between the inter-example correlation in stable (MNLI) datasets versus unstable (HANS) datasets. For stable datasets (MNLI), the correlations between the predictions of examples are uniformly low, while for unstable datasets (HANS), there exist clear groups of examples with very strong inter-correlation between their predictions. This observation suggests that those groups could be a major source of instability if they contain samples with frequently changing predictions.

4.2 Variance Decomposition

Next, we provide theoretical support to show how the high inter-example correlation contributes to the large variance in final accuracy. Later, we will also demonstrate that it is the major source of the large variance. Suppose dataset $\mathcal{D}$ contains examples $\{x_i, y_i\}_{i=1}^{N}$, where N is the number of data points in the dataset, x_i and y_i are the inputs and labels, respectively. We use a random variable C_i to denote whether model M predicts the i-th example correctly: $C_i = \mathbb{1}[y_i = M(x_i)]$. We ignore the model symbol M in our later notations for simplicity. The accuracy Acc of model M is another random variable, which equals to the average over $\{C_i\}$, w.r.t. different model weights (i.e., caused by different random seeds in our experiments): $Acc = \frac{1}{N}\sum_i C_i$. We then decompose the variance of the accuracy $\text{Var}(Acc)$ into the sum of data variances $\text{Var}(C_i)$, and the sum of inter-data covariances $\text{Cov}(C_i, C_j)$:

$$\begin{aligned}\text{Var}(Acc) &= \frac{1}{N^2}\text{Cov}\left(\sum_{i=1}^{N} C_i,\ \sum_{j=1}^{N} C_j\right)\\ &= \frac{1}{N^2}\sum_{i=1}^{N}\sum_{j=1}^{N}\text{Cov}\left(C_i,\ C_j\right)\\ &= \frac{1}{N^2}\sum_{i=1}^{N}\text{Var}(C_i) + \frac{2}{N^2}\sum_{i<j}\text{Cov}(C_i,C_j)\end{aligned} \tag{1}$$

Here, the first term $\frac{1}{N^2}\sum \text{Var}(C_i)$ means the instability caused by the randomness in individual example prediction and the second term $\frac{2}{N^2}\sum_{i<j}\text{Cov}(C_i, C_j)$ means the instability caused by the covariance of the prediction between different examples. The latter covariance term is highly related to the inter-example correlation.

Finally, to demonstrate that the inter-example correlation is the major source of high variance, we calculate the total variance, the independent variance (the 1st term in Eq. 1), and the covariance (the

2nd term in Eq. 1) on every dataset in Table 3. In contrast to similar averages of the independent variance on standard and analysis datasets, we found a large gap between the averages of covariances on different datasets. This different trend of total variance and independent variance proves that the inter-example correlation is the major reason for the difference of variance on the analysis datasets.

4.3 Highly-Correlated Cases

From these analyses, we can see that one major reason behind the high variance in certain analysis datasets is high inter-example correlation. Following this direction, the next question is why these highly-correlated example-pairs are more likely to appear in analysis datasets. From Table 1, we can find that the largest variance happens in HANS, several subsets of STR, and EQU-SYN. On the other hand, while datasets like SNLI-hard and EQU-NAT are also analysis datasets, their variance is much smaller than the former ones. One crucial difference among the high-variance datasets is that they are usually created with the help of synthetic rules. This way of well-controlled synthetic-rule based construction can effectively target certain linguistic phenomena in the dataset, but they may also cause many examples to share similar lexicon usage. One example from the HANS dataset is shown in Table 5, and another similar example for RC is also shown in Appendix. These similarities in syntax and lexicon are very likely to cause the prediction in these two examples to be highly-correlated. Another evidence can also be seen from Figure 4, where we can see clear boundaries of blocks of high-correlation examples in the right sub-figure (for HANS dataset). Since the examples in HANS are ordered by its templates, examples in the same block are created using the same template. Hence, the block patterns in the figure also show how synthetic rules may cause predictions to be more correlated with each other.

In conclusion, since analysis datasets are sometimes created using pre-specified linguistic patterns/properties and investigation phenomena in mind, the distributions of analysis datasets are less diverse than the distributions of standard datasets. The difficulty of the dataset and the lack of diversity can lead to highly-correlated predictions and high instability in models' final performances.

5 Implications, Suggestions, and Discussion

So far, we have demonstrated how severe this instability issue is and how the instability can be traced back to the high correlation between predictions of certain example clusters. Now based on all the previous analysis results, we discuss potential ways of how to deal with this instability issue.

We first want to point out that this instability issue is not a simple problem that can be solved by trivial modifications of the dataset, model, or training algorithm. Here, below we first present one initial attempt at illustrating the difficulty of solving this issue via dataset resplitting.

Limitation of Model Selection. In this experiment, we see if an oracle model selection process

Table 6: The comparison of means and standard deviations of the accuracies when model selection are conducted based on different development set. 'MNLI-m' chooses the best checkpoint based on the MNLI-m validation set. 'Re-Split Dev' chooses the best checkpoint based on the corresponding re-splitted analysis-dev set.

can help reduce instability. Unlike the benchmark datasets, such as SNLI, MNLI, and SQuAD, analysis sets are often proposed as a single set without dev/test splits. In Sec. 4, we observe that models' performances on analysis sets have little correlation with model performance on standard validation sets, making the selection model routine useless for reducing performance instability on analysis sets. Therefore, we do oracle model selection by dividing the original analysis set into an 80% analysis-dev dataset and a 20% analysis-test dataset. Model selection is a procedure used to select the best model based on the high correlation between dev/test sets. Hence, the dev/test split here will naturally be expected to have the best performance.

In Table 6, we compare the results of BERT-B on the new analysis-test with model selection based on the results on either MNLI or the corresponding analysis-dev. While model selection on analysis-dev helps increase the mean performance on several datasets[6], especially on HANS, STR-O, and STR-NU, indicating the expected high correlation inside the analysis set, however, the variances of final results are not always reduced for different datasets. Hence, besides the performance instability caused by noisy model selection, different random seeds indeed lead to models with different performance on analysis datasets. This observation might indicate that performance instability is relatively independent of the mean performance and hints that current models may have intrinsic randomness brought by different random seeds which is unlikely to be removed through simple dataset/model fixes.

5.1 Implications of Result Instability

If the intrinsic randomness in the model prevents a quick fix, what does this instability issue imply? At first glance, one may view the instability as a problem caused by careless dataset design or deficiency in model architecture/training algorithms. While both parts are indeed imperfect, here we suggest it is more beneficial to view this instability as an inevitable consequence of the current datasets and models. On the data side, as these analysis datasets usually leverage specific rules or linguistic patterns to generate examples targeting specific linguistic phenomena and properties, they contain highly similar examples (examples shown in 4.3). Hence, the model's predictions of these examples will be inevitably highly-correlated. On the model side, as the current model is not good enough to stably capture these hard linguistic/logical properties through learning, they will exhibit instability over some examples, which is amplified by the high correlation between examples' predictions. These datasets can still serve as good evaluation tools as long as we are aware of the instability issue and report results with multiple runs. To better handle the instability, we also propose some long and short term solution suggestions below, based on variance reporting and analysis dataset diversification.

5.2 Short/Long Term Suggestions

Better Analysis Reporting (Short Term). Even if we cannot get a quick fix to remove the instability in the results, it is still important to keep making progress using currently available resources, and more importantly, to accurately evaluate this progress. Therefore, in the short run, we encourage researchers to report the decomposed variance (Idp Var and Cov) for a more accurate understanding of the models and datasets as in Sec 4.2, Table 3 and Table 4. The first number (independent variance, i.e., Idp Var) can be viewed as a metric regarding how stable the model makes one single prediction and this number can be compared across different models. Models with a lower score can be interpreted as being more stable for one single

---

[6] Although the new selection increase the performance mean, we suggest not use the results on analysis sets as benchmark scores but only as toolkits to probe model/architecture changes since analysis datasets are easy to overfit.

prediction. The values of Cov also help us better understand both the model and the datasets. A high Cov indicates that many examples look similar to the model, and the model may be exploiting some common artifacts in this group of examples. A lower Cov usually means that the dataset is diverse and is preferable for evaluation. By comparing models with both total variance and the Idp Var, we can have a better understanding of where the instability of the models comes from. A more stable model should aim to improve the total variance with more focus on Idp Var. If the target is to learn the targeted property of the dataset better, then more focus should be drawn towards the second term when analysing the results.

Model and Dataset Suggestions (Long Term). In the long run, we should be focusing on improving models (including better inductive biases, large-scale pre-training with tasks concerning structure/compositionality) so that they can get high accuracy stably. Dataset-wise, we encourage the construction of more diverse datasets (in terms of syntax and lexicon). From our previous results and analysis in Section 4, we can see that analysis datasets from natural real-life sources usually lead to lower covariance between predictions and show better stability. Manual verification for synthetic examples also helps reduce the instability of analysis datasets. While controlled synthetic datasets are more accurate and effective in evaluating certain linguistic phenomenon, the lack of diversity may increase the model's ability to guess the answer right and solve only that single pattern/property instead of mastering the systematic capability of those linguistic properties under different contexts (as reflected by the poor correlation between different analysis datasets). Therefore, a very valuable direction in constructing these datasets is to both maintain the specificity of the dataset while having a larger diversity.

6 Conclusions

Auxiliary analysis datasets are meant to be important resources for debugging and understanding models. However, large instability of current models on some of these analysis sets undermine such benefits and bring non-ignorable obstacles for future research. In this paper, we examine the issue of instability in detail, provide theoretical and empirical evidence discovering the high inter-example correlation that causes this issue. Finally, we give suggestions on future research directions and on better analysis variance reporting. We hope this paper will guide researchers on how to handle instability and inspire future work in this direction.

Appendix

A Details of Models

For models, we mainly focus on the current state-of-the-art models with a pre-trained transformer structure. In addition, we also selected several traditional models to see how different structures and the use of pre-trained representations influence the result.

A.1 Transformer Models

BERT (Devlin et al., 2019). BERT is a Transformer model pre-trained with masked language supervision on a large unlabeled corpus to obtain deep bi-directional representations (Vaswani et al., 2017). To conduct the task of NLI, the premise and the hypothesis are concatenated as the input and a simple classifier is added on top of these pre-trained representations to predict the label. Similarly, for RC, the question and the passage are concatenated as a single input and the start/end location of the answer span is predicted by computing a dot product between the start/end vector and all the words in the document. The whole model is fine-tuned on NLI/RC datasets before evaluation.

RoBERTa (Liu et al., 2019b). RoBERTa uses the same structure as BERT, but carefully tunes the hyper-parameters for pre-training and is trained 10 times more data during pre-training. The fine-tuning architecture and process are the same as BERT.

XLNet (Yang et al., 2019). XLNet also adopts the Transformer structure but the pre-training target is a generalized auto-regressive language modeling. It also can take in infinite-length input by using the Transformer-XL (Dai et al., 2019) architecture. The fine-tuning architecture and process are the same as BERT.

A.2 Traditional Models

ESIM (Chen et al., 2017). ESIM first uses BiLSTM to encode both the premise and the hypothesis sentence and perform cross-attention before making the prediction using a classifier. It is one representative model before the use of pre-trained Transformer structure.

B Details of Analysis Datasets

We used the following NLI analysis datasets in our experiments: **Break NLI** (Glockner et al., 2018), **SNLI-hard** (Gururangan et al., 2018), **NLI Stress Test** (Naik et al., 2018b) and **HANS** (McCoy et al., 2019b). We use **AdvSQuAD** (Jia and Liang, 2017) as the RC analysis dataset.

Break NLI.[7] The examples in Break NLI resemble the examples in SNLI. The hypothesis is generated by swapping words in the premise so that lexical or world knowledge is required to make the correct prediction.

SNLI-Hard.[8] SNLI hard dataset is a subset of the test set of SNLI. The examples that can be predicted correctly by only looking at the annotation artifacts in the premise sentence are removed.

NLI Stress.[9] NLI Stress datasets is a collection of datasets modified from MNLI. Each dataset targets one specific linguistic phenomenon, including word overlap (STR-O), negation (STR-NE), antonyms (STR-A), numerical reasoning (STR-NU), length mismatch (STR-L), and spelling errors (STR-S). Models with certain weaknesses will get low performance on the corresponding dataset. In our experiments, we use the mismatched set if there

Table 9: Means and standard deviations of final performance on NLI datasets for all models.

Model	Standard Dataset	Analysis Sets	
	SQuAD	**AddSent**	**AddOneSent**
BERT-B	87.16±0.13	63.70±0.57	72.33±0.48
XLNet-B	89.33±0.39	69.19±1.18	77.20±0.94

Table 10: Means and standard deviations of final F1 on SQuAD dev set for both BERT-B and XLNet-B.

are both a matched version and a mismatched version. For STR-S, we follow the official evaluation script[10] to use the gram_content_word_swap subset.

HANS.[11] The examples in HANS are created to reveal three heuristics used by models: the lexical overlap heuristic, the sub-sequence heuristic, and the constituent heuristic. For each heuristic, examples are generated using 5 different templates.

SICK.[12] SICK is a dataset created for evaluating the compositional distributional semantic models. The sentences in this dataset come from the 8K ImageFlickr dataset and the SemEval 2012 STS MSR-Video Description dataset. The sentences are first normalized and then paired with an expanded version so that the pair can test certain lexical, syntactic, and semantic phenomena.

EQUATE.[13] EQUATE is a benchmark evaluation framework for evaluating quantitative reasoning in textual entailment. It consists of five test sets. Three of them are real-world examples (RTE-Quant, NewsNLI, RedditNLI) and two of them are controlled synthetic tests (AWPNLI, Stress Test). In this work, we use EQU-NAT to denote the real-world subset and EQU-SYN to denote the synthetic tests.

AdvSQuAD.[14] AdvSQuAD is a dataset created by inserting a distracting sentence into the original paragraph. This sentence is designed to be similar to the question but containing a wrong answer in order to fool the models.

C Dataset Statistics

Dataset statistics and categories for all the NLI datasets can be seen in Table 7. Dataset statistics and categories for all the RC datasets can be seen in Table 8.

D Training Details

For all pre-trained transformer models, namely, BERT, RoBERTa, and XLNet, we use the same set of hyper-parameters for analysis consideration. For NLI, we use the suggested hyper-parameters in Devlin et al. (2019). The batch size is set to 32 and the peak learning rate is set to 2e-5. We save checkpoints every 500 iterations, resulting in 117 intermediate checkpoints. In our preliminary experiments, we find that tuning these hyper-parameters will not significantly influence the results. The training set for NLI is the union of SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018)[15] training set and is fixed across all the experiments. This will give us a good estimation of state-of-the-art performance on NLI that is fairly comparable to other analysis studies. For RC, we use a batch size of 12 and set the peak learning rate to 3e-5. RC Models are trained on SQuAD1.1[16] (Rajpurkar et al., 2016b) for 2 epochs. All our experiments are run on Tesla V100 GPUs.

E Means and Standard Deviations of Final Results on NLI/RC datasets

Here we provide the mean and standard deviation of the final performance over 10 different seeds

[16] `rajpurkar.github.io/SQuAD-explorer/`

Original Context:	In February 2010, in response to controversies regarding claims in the Fourth Assessment Report, five climate scientists–all contributing or lead IPCC report authors–wrote in the journal Nature calling for changes to the IPCC. They suggested a range of new organizational options, from tightening the selection of lead authors and contributors to dumping it in favor of a small permanent body or even turning the whole climate science assessment process into a moderated "living" Wikipedia-IPCC. Other recommendations included that the panel employs full-time staff and remove government oversight from its processes to avoid political interference.
Question:	How was it suggested that the IPCC avoid political problems?
Answer:	remove government oversight from its processes
Distractor Sentence 1:	It was suggested that the PANEL avoid nonpolitical problems.
Distractor Sentence 2:	It was suggested that the panel could avoid nonpolitical problems by learning.

Table 11: A highly-correlated example pair in the SQuAD-AddSent dataset based with the BERT model. This example pair have the largest covariance (0.278) among all the pairs.

on NLI and RC datasets in Table 9 and Table 10 respectively.

F High-Correlated Cases for SQuAD

In this section, we show an example to illustrate that the high-correlated cases are similar to NLI datasets for RC datasets. As adversarial RC datasets such as AddSent are created by appending a distractor sentence at the end of the original passage, different examples can look very similar. In Table 11, we see two examples are created by appending two similar distractor sentences to the same context, making the predictions of these two examples highly correlated.

Universal Natural Language Processing with Limited Annotations: Try Few-shot Textual Entailment as a Start

`wyin@salesforce.com`

Abstract

A standard way to address different NLP problems is by first constructing a problem-specific dataset, then building a model to fit this dataset. To build the ultimate artificial intelligence, we desire a single machine that can handle diverse new problems, for which task-specific annotations are limited. We bring up textual entailment as a unified solver for such NLP problems. However, current research of textual entailment has not spilled much ink on the following questions: (i) How well does a pretrained textual entailment system generalize across domains with only a handful of domain-specific examples? and (ii) When is it worth transforming an NLP task into textual entailment? We argue that the transforming is unnecessary if we can obtain rich annotations for this task. Textual entailment really matters particularly when the target NLP task has insufficient annotations.

Universal NLP[1] can be probably achieved through different routines. In this work, we introduce **U**niversal **F**ew-sh**o**t textual **Entail**ment (UFO-ENTAIL). We demonstrate that this framework enables a pretrained entailment model to work well on new entailment domains in a few-shot setting, and show its effectiveness as a unified solver for several downstream NLP tasks such as question answering and coreference resolution when the end-task annotations are limited. Code: `https://github.com/salesforce/UniversalFewShotNLP`

1 Introduction

Nowadays, the whole NLP journey has been broken down into innumerable sub-tasks. We often solve each task separately by first gathering task-specific training data and then tuning a machine learning system to learn the patterns in the data. Constrained by the current techniques, the journey has to be performed in this way. By a forward-looking perspective, instead, a single machine that can handle diverse (seen and unseen) tasks is desired. The reason is that we cannot always rely on expensive human resources to annotate large-scale task-specific labeled data, especially considering the inestimable number of tasks to be explored. Therefore, a reasonable attempt is to map diverse NLP tasks into a common learning problem—solving this common problem equals to solving any downstream NLP tasks, even some tasks that are new or have insufficient annotations.

Textual entailment (aka. natural language inference in Bowman et al. (2015)) is the task of studying the relation of two assertive sentences, Premise (P) and Hypothesis (H): whether H is true given P. Textual entailment (TE) was originally brought up as a unified framework for modeling diverse NLP tasks (Dagan et al., 2005; Poliak et al., 2018). The research on TE dates back more than two decades and has made significant progress. Particularly, with the advances of deep neural networks and the availability of large-scale human annotated datasets, fine-tuned systems often claim surpassing human performance on certain benchmarks.

Nevertheless, two open problems remain. First, the increasing performances on some benchmarks heavily rely on rich human annotations. There is rarely a trained entailment system that can work on benchmarks in other domains. Current textual entailment systems are far from being deployed in new domains where no rich annotation exists. Second, there is an increasing awareness in the community that lots of NLP tasks can be studied in the entailment framework. But it is unclear when it is worth transforming a target NLP tasks to textual

---

[1] "Universal NLP" here means using a single machine to address diverse NLP problems. This is different from using the same machine learning algorithm such as convolution nets to solve tasks because the latter still results in task-specific models which can not solve other tasks.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8229–8239,
November 16–20, 2020.

entailment. We argue that textual entailment particularly matters when the target NLP task has insufficient annotations; in this way, some NLP tasks that share the same inference pattern and annotations are insufficient to build a task-specific model can be handled by a unified entailment system.

Motivated by the two issues, we build UFO-ENTAIL—the first ever generalized few-shot textual entailment system with the following setting. We first assume that we can access a large-scale generic purpose TE dataset, such as MNLI (Williams et al., 2018); this dataset enables us to build a base entailment system with acceptable performance. To get even better performance in any new domain or new task, we combine the generic purpose TE dataset with a couple of domain/task-specific examples to learn a better-performing entailment for that new domain/task. This is a reasonable assumption because in the real-world, any new domain or new task does not typically have large annotated data, but obtaining a couple of examples is usually feasible.

Technically, our UFO-ENTAIL is inspired by the Prototypical Network (Snell et al., 2017), a popular metric-based meta-learning paradigm, and the STILTS (Phang et al., 2018), a framework that makes use of pretraining on indirect tasks to help the target task. UFO-ENTAIL consists of a RoBERTa (Liu et al., 2019) encoder and a proposed cross-task nearest neighbor block. The RoBERTa, pretrained on MNLI, provides a representation space biased to the source domain; the cross-task nearest neighbor block is in charge of mitigating the distribution difference between the source domain and the target task (given only a few examples).

In experiments, we apply UFO-ENTAIL trained on MNLI and k examples from the target domain/task to two out-of-domain entailment benchmarks and two NLP tasks (question answering and coreference resolution). Results show the effectiveness of UFO-ENTAIL in addressing the challenges set forth in the two questions. Overall, we make two contributions:

- We are the first to systematically study textual entailment in open domains, given only a couple of domain-specific examples.
- We follow the argument of some literature that textual entailment is a unified NLP framework. Here, *we make a step further by declaring that we study textual entailment not because some NLP tasks can be transformed into entailment, but because few-shot textual entailment can be a promising attempt for universal NLP when we can not guarantee the accessibility of rich annotations.*

2 Related Work

Textual Entailment. Textual entailment was first studied in Dagan et al. (2005) and the main focus in the early stages was to study lexical and some syntactic features. In the past few years, the research on textual entailment has been driven by the creation of large-scale datasets, such as SNLI (Bowman et al., 2015), science domain SciTail (Khot et al., 2018), and multi-genre MNLI (Williams et al., 2018). Representative work includes the first attentive recurrent neural network (Rocktäschel et al., 2016) and its followers (Wang and Jiang, 2016; Wang et al., 2017), as well as the attentive convolutional networks such as attentive pooling (dos Santos et al., 2016) and attentive convolution (Yin and Schütze, 2018), and self-attentive large-scale language models like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). All these studies result in systems that are overly tailored to the datasets.

Our work differs in that we care more about few-shot applications of textual entailment, assuming that a new domain or an NLP task is not provided with rich annotated data.

Generalization via domain adaptation. Two main types of domain adaptation (DA) problems have been studied in literature: supervised DA and semi-supervised DA. In the supervised case, we have access to a large annotated data in the source domain and a small-scale annotated data in the target domain (Daumé III, 2007; Kang and Feng, 2018). In the semi-supervised case, we have a large but *unannotated* corpus in the target domain (Miller, 2019).

In contrast to semi-supervised DA, our work does not assume the availability of a large unlabeled data from the target domain or task. We also build more ambitious missions than the supervised DA since our work aims to adapt the model to new domains as well as new NLP tasks.

Generalization via few-shot learning. Few-shot problems are studied typically in the image domain (Koch et al., 2015; Vinyals et al., 2016; Snell et al., 2017; Ren et al., 2018; Sung et al., 2018). The core idea in metric-based few-shot learning is similar to nearest neighbors. The predicted probability of a test instance over a set of classes (i.e., only a few supporting examples are seen) is a weighted sum of classes for those supporting samples. Vinyals et al. (2016) compare each test instance with those supporting examples by the cosine distance in a method named Matching Networks. Snell et al. (2017) propose Prototypical Networks which first build prototypical representations for each class by summing up representations of supporting examples, then compare classes with test instances by squared Euclidean distances. Unlike fixed metric measures, the Relation Network (Sung et al., 2018) implements the comparison through learning a matching metric in a multi-layer architecture.

In the language domain, Yu et al. (2018) combine multiple metrics learned from diverse clusters of training tasks for an unseen few-shot text classification task. Han et al. (2018) release a few-shot relation classification dataset "FewRel" and compare a couple of representative methods on it.

These few-shot studies assume that, in the same domain, a part of the classes have limited samples, while other classes have adequate examples. In this work, we make a more challenging assumption that all classes in the target domain have only a couple of examples, and the training classes and testing classes are from different domains.

Unified natural language processing. McCann et al. (2018) cast a group of NLP tasks as question answering over context, such as machine translation, summarization, natural language inference, sequence modeling, etc. Raffel et al. (2019) study transfer learning for broad NLP by converting every language problem into a text-to-text format. Keskar et al. (2019) unify question answering, text classification, and regression via span extraction to get rid of various output layers on top of BERT for different tasks. A concurrent work with ours (Bansal et al., 2019) studies few-shot learning in NLP, but only text classification tasks are involved.

Their unification is mainly from the perspective of system structure, i.e., some distinct NLP tasks can be converted into a common training structure. Rich annotations are still needed. Our entailment paradigm, instead, is driven by the fact that there is a common reasoning pattern behind (Dagan et al., 2005). In addition, we care more about the challenges in realistic scenarios where we have to handle problems with limited annotations.

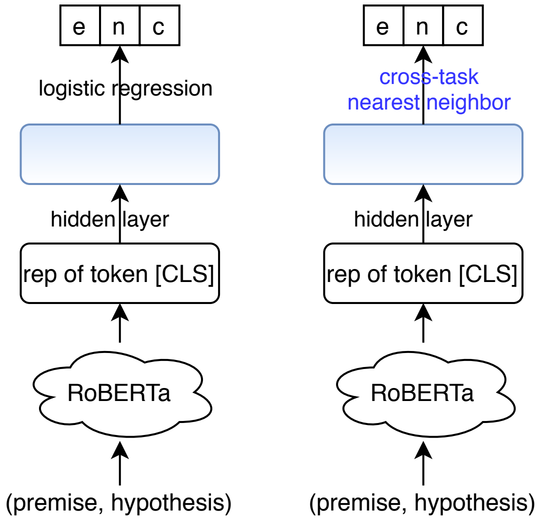

Figure 1: (Left) RoBERTa for textual entailment. "e": entailment, "n": neutral, "c": contradiction. (Right) the skeleton of our UFO-ENTAIL system. It basically replaces the logistic regression layer in RoBERTa classifier by a cross-task nearest neighbor block. RoBERTa learns class representations implicitly in the weight matrix of logistic regression, while UFO-ENTAIL first explicitly builds class representations for both source and target tasks, then composes the cross-task probability distributions to get the prediction.

3 Method

3.1 Problem formulation

Provided the large-scale generic textual entailment dataset MNLI (Williams et al., 2018) and a few examples from a target domain or a target task, we build an entailment predictor that can work well in the target domain/task even if only a few examples are available.

The inputs include: MNLI, the example set (i.e., k examples for each type in {"entailment", "non-entailment"} or {"entailment", "neutral", "contradiction"} if applicable). The output is an entailment classifier, predicting a label for each instance in the new domain/task. Please note that we need to convert those examples into labeled entailment instances if the target task is not a standard entailment problem. The entailment-style outputs can be easily converted to the prediction format required by the target tasks, as introduced in Section 4.2.

3.2 Our model UFO-ENTAIL

Hereafter, we refer to MNLI as S (source domain), and the new domain or task as T. Before launching the introduction of UFO-ENTAIL, we first give a brief description: UFO-ENTAIL, *shown in Figure*

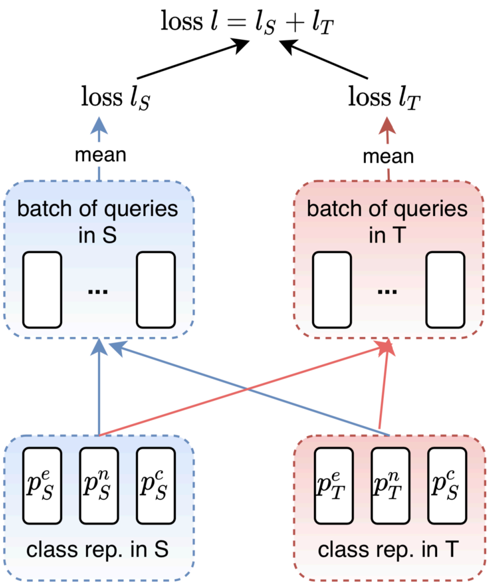

Figure 2: Loss computation in cross-domain/task nearest neighbor framework.

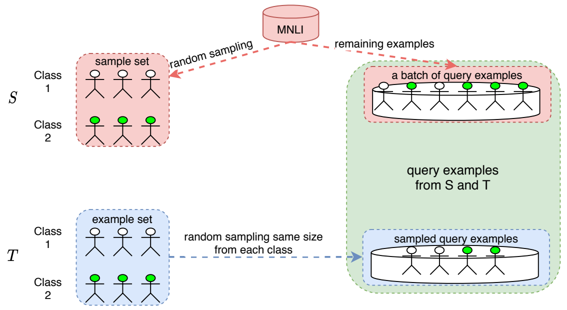

Figure 3: Generating the example set in T, the sample set in S and the query examples by both S and T. Here we only show two classes in S and T just for simplicity.

1, is stacking a cross-task nearest neighbor block over a RoBERTa encoder.

Encoder RoBERTa. For textual entailment, RoBERTa, shown in Figure 1, takes the pair (premise, hypothesis) as an input. RoBERTa first outputs a representation vector (e.g., the one corresponding to the token "CLS") to denote the input pair, then maps this representation into a new space by a hidden layer, finally conducts classification on that space through logistic regression. Overall, RoBERTa works with the hidden layer together as the encoder. For convenience, we still name this "RoBERTa+HiddenLayer" encoder as "RoBERTa".

We prepare RoBERTa by pretraining it on the source data S. This pretrained entailment encoder will act as a base system to deal with any new tasks (with the help of k examples).

Cross-task nearest neighbor. Shown in Figure 2, the first step in the cross-task nearest neighbor is to build representations for each class in the S and T, then batches of query instances from S as well as T compare with those class representations by a matching function to compute loss and train the system. The reason we emphasize "cross-task" here is that both the classes and the query examples cover the two tasks S and T. This is the core of UFO-ENTAIL in dealing with any new NLP problems of scarce annotations from textual entailment.

- **Class representations.** We use p_w^e, p_w^n and p_w^c to denote the representations for the three classes {"entailment", "neutral", "contradict"} in w, $w \in \{S, T\}$. When the target task T can only be converted into two classes, i.e., "entail vs. non-entail", we let $p_T^n = p_T^c$, both denoting the class "non-entail".

For the target T, each class has k labeled examples (example set). For the source domain S, similar with the episode training in meta learning (Snell et al., 2017), we randomly sample k examples ("sample set") of each class in S. Then,

$$p_w^j = \frac{1}{k}\sum_{i=1}^{k} \text{RoBERTa}(x_n^i) \tag{1}$$

where $\{x_n^i\}$, $i = 1 \cdots k$, are the labeled k examples for class $j \in$ {e, n, c} in T or S, RoBERTa$(\cdot) \in \mathbb{R}^d$ and $p_w^j \in \mathbb{R}^d$. Overall, UFO-ENTAIL keeps representations for six classes.

- **Query examples.** As Figure 3 illustrates, a query batch is composed of two sub-batches, one from S, the other from T. For S, apart from its "sample set", the remaining labeled examples are grouped as mini-batches. For T, since all the labeled examples it has are those k supporting examples per class, we randomly sample m examples from the k supporting examples for each class ($m < k$), and finally incorporate them into a S's mini-batch as a bigger batch of queries.

Since UFO-ENTAIL is to cope with new tasks given a textual entailment task. We assume that the source entailment task provides valuable knowledge to warm up the model learning. For a testing instance in T, we want it to compose the reasoning conclusions derived from both S and the example set in T.

For training, we include examples from S as queries because we treat the classes in S and T equally, and the queries in S and T equally as well. This leads to a higher-level abstract task in which

```
Input: MNLI as $D_S$, $k \times |C|$ examples from $T$
       denoted as $D_T$
Output: A 3-way entailment classifier
Sample $k$ example from $S$'s class "e", "n" and "c" as
  $D_S^e$, $D_S^n$ and $D_S^c$, respectively; remaining examples
  in $D_S$ form minibatches $B_S = \{B_S^i\}$.
while each mini-batch $B_S^i$ do
    build a mini-batch $B_T^i$={$\hat{D}_T^e$,$\hat{D}_T^n$, $\hat{D}_T^c$ } from
      $D_T$, $|\hat{D}_T^i| = m$ and $m < k$.
    build class representation:
      $p_w^j = \sum$ RoBERTa($D_w^j$), $w \in \{S, T\}$ and
      $j \in \{e, n, c\}$
    build a query batch $B^i = \{B_S^i, B_T^i\}$
    while each query $q$ in $B_S^i$ do
        compare $q$ with class representations $\{p_w^j\}$
          to get probability distribution $g$
        get loss for $q$
    end
    loss $l_S$ is the mean loss in $B_S^i$
    while each query $q$ in $B_T^i$ do
        compare $q$ with class representations $\{p_w^j\}$
          to get probability distribution $g$
        get loss for $q$
    end
    loss $l_T$ is the mean loss in $B_T^i$
    loss $l = l_S + l_T$ for this query batch $B^i$
    update the RoBERTa and nearest neighbor block
end
```

Algorithm 1: UFO-ENTAIL algorithm.

S and T learns from each other to mitigate the difference.

Matching function. Assuming a query example gets its representation q through RoBERTa, then a matching score, between this query example and one class (class representation p), $s_{p,q}$ is learnt as follows:

$$I = [p, q, p \circ q, p - q] \tag{2}$$

$$r_1 = \text{dropout}(\tanh(W_1 \times I)) + I \tag{3}$$

$$r_2 = \text{dropout}(\tanh(W_2 \times r_1)) + r_1 \tag{4}$$

$$r_3 = \text{dropout}(\tanh(W_3 \times r_2)) \tag{5}$$

$$r_4 = \text{dropout}(\tanh(W_4 \times r_3)) \tag{6}$$

$$s_{p,q} = \text{sigmoid}(W_5 \times r_4) \tag{7}$$

where $I \in \mathbb{R}^{4d}$, W_1 and $W_2 \in \mathbb{R}^{4d \times 4d}$, $W_3 \in \mathbb{R}^{4d \times 2d}$, $W_4 \in \mathbb{R}^{2d \times d}$ and $W_5 \in \mathbb{R}^{d}$.

Probability distribution per query. A query example will obtain three matching scores from S ($g_S \in \mathbb{R}^3$) and three matching scores from T ($g_T \in \mathbb{R}^3$). Now we try to combine them as a final probability distribution of thee dimensions. Instead of linear combination with artificial weights, we let the system learn automatically the contribution of g_S and g_T in a new space. Therefore, the final probability distribution $g \in \mathbb{R}^3$ is learned as follows:

$$\hat{g}_S = \text{sigmoid}(W_6 \times g_S) \tag{8}$$

$$\hat{g}_T = \text{sigmoid}(W_6 \times g_T) \tag{9}$$

$$\lambda = \text{sigmoid}(W_7 \times [g_S, g_T]) \tag{10}$$

$$g = \text{softmax}(\lambda \circ \hat{g}_S + (1 - \lambda) \circ \hat{g}_T) \tag{11}$$

where $W_6 \in \mathbb{R}^3$ and $W_7 \in \mathbb{R}^6$. g is used to compute loss to train the system in training and predict the class in testing.

Training loss. In training, a query batch actually contains two sub-batches, one from S, the other from T. To balance the contribution, we first compute the mean loss in S's and T's sub-batches respectively, obtaining l_S and l_T, then the overall loss for that batch is $l = l_S + l_T$, demonstrated in Figure 2,

The whole UFO-ENTAIL system is a stack of the RoBERTa and the cross-task nearest neighbor block. Its learning algorithm is summarized in the Algorithm 1;. UFO-ENTAIL can be trained end-to-end.

3.3 UFO-ENTAIL vs. other related models

- **UFO-ENTAIL vs. Prototype. Net.** Prototypical network (Snell et al., 2017) assumes that training tasks and test tasks are in the same distribution. So, it focuses on the matching function learning and hopes a well-trained matching function in training tasks (i.e., S in this work) works well in the target tasks (i.e., T here). However, the presumption does not apply to the cross-domain/task scenarios in this work.

Similarly, UFO-ENTAIL also builds class representation by averaging the representations of some class-specific labeled examples, as prototypical network does. In training, prototypical network builds class representations in training tasks and query examples come from the training tasks only; in testing, the query examples from the testing tasks only compare with the few labeled examples specific to the testing task (training tasks do not participate anymore). In short, prototypical network only builds nearest neighbor algorithm *within a task*. UFO-ENTAIL differs in that *it is based on cross-task nearest neighbor* – keeping class representations for both S and T in training as well as in testing; query examples in training also comes from S and T. Because of the mismatch of the distributions in S and T, the goal of UFO-ENTAIL is to not only learn the matching function, but also map the instances in S and T to the same space.

UFO-ENTAIL vs. STILTS. Given the source data S and a couple of labeled examples from the target T, STILTS (Phang et al., 2018) first trains RoBERTa on S, then fine-tune on the labeled examples of T. Both the pretraining and fine-tuning use the same RoBERTa system in Figure 1. It has been widely used as the state of the art technique for making use of related tasks to improve target tasks, especially when the target tasks have limited annotations (Liu et al., 2019; Sap et al., 2019; Clark et al., 2019). By the architecture, STILTS relies on the standard RoBERTa classifier which consists of a RoBERTa encoder and a logistic regression on the top; UFO-ENTAIL instead has a cross-task nearest neighbor block on the top of the RoBERTa encoder.

STILTS tries to learn the target-specific parameters by tuning on the k labeled examples. However, this is very challenging if k is over small, like values $\{1, 3, 5, 10\}$ we will use in our problems. We can also think STILTS learns class prototypical representations implicitly (i.e., the weights in the logistic regression layer), however, the bias term in the logistic regression layer reflect mainly the distribution in the source S, which is less optimal for predicting in the target T.

4 Experiments

We apply UFO-ENTAIL to entailment tasks of open domain and open NLP tasks.

Experimental setup. Our system is implemented with Pytorch on the transformers package released by Huggingface[2]. We use "RoBERTa-large" initialized by the pretrained language model.

To mitigate the potential bias or artifacts (Gururangan et al., 2018) in sampling, *all numbers of k-shot are average of five runs in seeds $\{42, 16, 32, 64, 128\}$.*

Due to GPU memory constraints, we only update the nearest neighbor block, the hidden layer and top-5 layers in RoBERTa. For other training configurations, please refer to our released code.

Baselines. The following baselines are shared by experiments on open entailment tasks and open NLP tasks.

- **0-shot.** We assume zero examples from target domains. We train a RoBERTa classifier[3] on MNLI, and apply it to the respective test set of target domains without fine-tuning.
- **Train on k examples.** We build a RoBERTa classifier on the k labeled examples directly. *No MNLI data is used.* When k is increased to cover all the labeled examples of the target domain or task, this baseline is referred as "train on target data".
- **STILTs (Phang et al., 2018).** This is a learning paradigm: for any target task, first pretrain the model on intermediate tasks, then fine-tune on the target task. Here, it means pretraining on MNLI, then fine-tuning on k examples ($k >= 1$ until it reaches the full labeled data of the target domain/task). When $k = 0$, "STILTS" equals to "0-shot" baseline.
- **Prototypical Network** (Snell et al., 2017). It is a representative episode-training algorithms for few-shot problems, introduced in Section 2.
- **State-of-the-art.** STILTS is widely used as the state-of-the-art technique to promote the performance of a target problem with indirect supervision and task-specific fine-tuning. According to the definition of STILTS, its paradigm is applicable to any Transformer-based models. Since RoBERTa is used as the main Transformer model, applying STILTS to RoBERTa, which pretrains on MNLI then fine-tunes on the full target data, is the state of the art for this work.

4.1 UFO-ENTAIL in open domains

We test the few-shot setting on two out-of-domain entailment datasets: GLUE RTE (Wang et al., 2019) and SciTail (Khot et al., 2018). Examples in GLUE-RTE mainly come from the news and Wikipedia domains. SciTail is from the science domain, designed from the end task of multiple-choice QA. Our source dataset MNLI covers a broad range of genres such as conversation, news reports, travel guides, fundraising letters, cultural articles, fiction, etc. RTE has 2,490/277/2,999 examples in train/dev/test; SciTail has 23,596/1,304/2,126 respectively.

4.2 UFO-ENTAIL in open NLP tasks

In this section, we apply UFO-ENTAIL as a universal framework to other distinct NLP tasks with limited annotations. An alternative approach to handle a task in which the annotations are scarce is to do transfer learning based on existing datasets of rich annotations and high relevance. However, we argue that this still results in "training separate models for different tasks", and it is unrealistic to

Table 1: Applying UFO-ENTAIL to two entailment benchmarks (RTE and SciTail) and two other NLP tasks (question answering (QA) and coreference resolution (Coref.)), each providing k examples ($k = \{1, 3, 5, 10\}$). Numbers for "STILTS (SOTA)" are upperbound performance while using full labeled data; bold numbers are our top numbers when the few-shot hyperparamter $k <= 10$.

presume, for T, that a related and rich-annotation dataset always exists. As we discussed, the final goal of NLP (or even AI) is to develop a single machine to solve diverse problems. To the end, we try few-shot entailment here as an attempt.

For each downstream NLP task, we provide k examples for helping the learning of the textual entailment system. Next, we describe in detail how some representative NLP problems are converted to be textual entailment. Our work provides a new perspective to tackle these NLP issues, especially given only a couple of labeled examples.

Question Answering. We attempt to handle the QA setting in which only a couple of labeled examples are provided. A QA problem can be formulated as a textual entailment problem—the document acts as the premise, and the (question, answer candidate), after converting into a natural sentence, acts as the hypothesis. Then a true (resp. false) hypothesis can be translated into a correct (resp. incorrect) answer. We choose the QA benchmark MCTest-500 (Richardson et al., 2013) which releases an entailment-formatted corpus. MCTest-500 is a set of 500 items (split into 300 train, 50 dev and 150 test). Each item consists of a document, four questions followed by one correct answer, and three incorrect answers.

Deep learning has not achieved significant success on it because of the limited training data (Trischler et al., 2016)—this is exactly our motivation that applying few-shot textual entailment to handle annotation-scarce NLP problems.

For MCTest benchmark, we treat one question as one example. K-shot means we randomly sample k annotated questions (each corresponds to a short article and has four answer candidates). We obtain k entailment pairs for the class "entailment" and $3k$ pairs for the class "non-entailment". The official evaluation metrics in MCTest include accuracy and NDCG_4. Here, we report accuracy.

Coreference Resolution. Coreference resolution aims to cluster the entities and pronouns that refer to the same object. This is a challenging task in NLP, and greatly influences the capability of machines in understanding the text.

We test on the coreference resolution benchmark GAP (Webster et al., 2018), a human-labeled corpus from Wikipedia for recognizing ambiguous pronoun-name coreference. An example from the GAP dataset is shown here:

"**McFerran**'s horse farm was named Glen View. After his death in 1885, **John E. Green** acquired the farm."

For a specific pronoun in the sentence, GAP provides two entity candidates for it to link. To correctly understand the meaning of this sentence, a machine must know which person ("McFerran" or "John E. Green") the pronoun "his" refers to. GAP has such kind of annotated examples of sizes split as 2k/454/2k in *train*/*dev*/*test*. Please note that some examples have both entity candidates as negative (201 in train, 62 in dev and 227 in testing).

In this work, we transform the coreference resolution problem into an entailment problem by replacing the pronoun with each entity candidate. For example, the above example will lead to the following two hypotheses:

"**McFerran**'s horse farm was named Glen View. After McFerran's death in 1885, **John E. Green** acquired the farm." ["entailment"]

"**McFerran**'s horse farm was named Glen View. After John E. Green's death in 1885, **John E. Green** acquired the farm." ["non-entailment"]

It is worth mentioning that we append a "'s" to the person entity string if the pronoun is one of {"his", "His", "her", "Her"}. Otherwise, using the entity string to replace the pronoun directly. Each replacement will yield a hypothesis—the problem ends up being predicting whether this hypothesis is correct or not, given the original sentence.

We randomly choose k examples from *train* to learn the entailment system; each example will produce two labeled entailment pairs. The GAP benchmark evaluates the F1 score by gender (masculine and feminine) and the overall F1 by combining the two gender-aware F1 scores. We use the official evaluation script and report the overall F1.

4.3 Results and Analyses

Table 1 lists the numbers in k-shot settings ($k = \{1, 3, 5, 10\}$) and the full-shot competitor which uses the full labeled data of T. To start, the "0-shot" setting, compared with the "majority or random" baseline, indicates that using MNLI as training set and test on various target T has already shown some transferability; but this is far behind the SOTA. We are further interested in three main comparisons:

- Comparing UFO-ENTAIL with the typical metric-based meta learning approach: prototypical networks. Interestingly, prototypical network is worse than STILTS on the two entailment benchmarks while mostly outperforming STILTS slightly on QA and coreference tasks. Our system UFO-ENTAIL consistently surpasses it with big margins. Prototypical network is essentially a nearest neighbor algorithm (Yin, 2020) pretrained on S only. A testing example in T searches for its prediction by comparing with the T-specific class representations constructed by the k examples. A pretrained nearest neighbor algorithm does not necessarily work well if S and T are too distinct.

- Comparing UFO-ENTAIL with the SOTA technique STILTs in k-shot settings. Our algorithm outperforms the STILTs across all the tasks. Note that STILTs trains on S and the k examples of T sequentially. What STILTS does is to adapt the pretrained space to the target space, guided by k examples. In contrast, UFO-ENTAIL unifies the RoBERTa encoder and the nearest neighbor algorithm by building cross-task class prototypical representations, then tries to train an unified space on S and T.

- Comparing UFO-ENTAIL in k-shot settings with the full-shot settings. "Full-shot" has two systems: one pretrains on S then fine-tunes on T, the other fine-tune on T directly. Generally, we notice that pretraining on S can finally promote the performance (e.g., in RTE and QA) or get similar numbers (e.g., in SciTail and Coreference tasks). Our system by 10-shot even beats the "full-shot, train on target data" with 5.3% in RTE and is very close to the SOTA number by "full-shot STILTS" (85.28 vs. 86.26). In other three tasks (SciTail, QA, Coref.), although UFO-ENTAIL by 10-shot hasn't shown better performance than any full-shot settings, its big improvements over other 10-shot baselines across all the tasks (~4% in SciTail, ~6% in QA and >4% in coreference) demonstrate its superiority of handling open NLP problems in few-shot scenarios.

Please keep in mind that the UFO-ENTAIL system for all the reported NLP tasks originated from the same entailment classifier pretrained on MNLI.

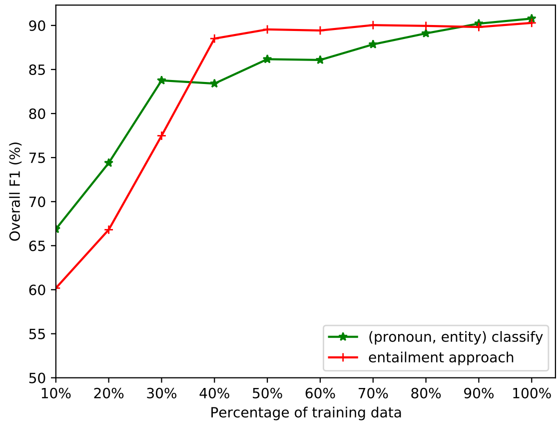

Figure 4: Comparing "entailment" approach with non-entailment approach (i.e., classify (pronoun, entity) pairs in RoBERTa) in coreference's benchmark GAP when using different percentages of training data.

Our experiments indicate: to deal with any open NLP tasks, instead of building large-scale datasets for them separately and let models to fit each of them, it is promising to employ a single entailment system which can generalize well with only a few annotated examples per task.

4.4 Reformulating NLP problems as textual entailment: better or worse?

In Table 1, we reported performance of dealing with open entailment and NLP tasks by entailment approach always. We may have another question: for any NLP task, is that better to reformulate it as textual entailment? In this subsection, we compare textual entailment with other popular systems in modeling the coreference task which usually is not modeled in an entailment framework.

To be specific, we feed each instance in the GAP dataset into RoBERTa which will generate a representation for each token in the instance. To obtain representations for the pronoun and an entity candidate, we sum up the representations of all tokens belonging to the pronoun or the entity string. RoBERTa is able to provide the pronoun/entity representations with context in the sentence. Finally, we do binary classification for each (pronoun, entity) pair. We compare this system with the entailment approach (i.e., "train on target data") when using different sizes of training set: [10%, 20%, $\cdots$, 100%]. To keep a fair comparison, both systems do not pretrain on any other tasks. The result for each percentage is the average of three runs with different seeds.

Figure 4 demonstrates interesting findings: (i) When using all the GAP training data, both entailment and the (pronoun, entity) classification system reach pretty similar results; (ii) When the training size is below 30%, the non-entailment approach shows better performance. However, the entailment system converges much earlier than the competing system — starting with 40% training data, it can get performance almost as good as using 100% data.

This coreference example shows that transforming an NLP task as textual entailment may obtain surprising advantages. There are more NLP tasks that can fit the entailment framework easily, such as text classification (Yin et al., 2019), relation extraction, summarization, etc. However, we also need to admit that reformulating into entailment may also need to fight against new challenges. Taking text classification as an example, how to convert classification labels into hypotheses influences the results a lot. In addition, the hypothesis generation from some NLP tasks may require human efforts to guarantee the quality.

5 Summary

In this work, we studied how to build a textual entailment system that can work in open domains given only a couple of examples, and studied the common patterns in a variety of NLP tasks in which textual entailment can be used as a unified solver. Our goal is to push forward the research and practical use of textual entailment in a broader vision of natural language processing. To that end, we proposed utilizing MNLI, the largest entailment dataset, and a few examples from the new domain or new task to build an entailment system via cross-task nearest neighbor. The final entailment system UFO-ENTAIL generalizes well to open domain entailment benchmarks and downstream NLP tasks including question answering and coreference resolution.

Our work demonstrates an example that exploring the uniform pattern behind various NLP problems, enabling us to understand the common reasoning process and create potential for machines to learn across tasks and make easy use of indirect supervision.

CONJNLI: Natural Language Inference Over Conjunctive Sentences

Swarnadeep Saha **Yixin Nie** **Mohit Bansal**
UNC Chapel Hill
`{swarna, yixin1, mbansal}@cs.unc.edu`

Abstract

Reasoning about conjuncts in conjunctive sentences is important for a deeper understanding of conjunctions in English and also how their usages and semantics differ from conjunctive and disjunctive boolean logic. Existing NLI stress tests do not consider non-boolean usages of conjunctions and use templates for testing such model knowledge. Hence, we introduce CONJNLI, a challenge stress-test for natural language inference over conjunctive sentences, where the premise differs from the hypothesis by conjuncts removed, added, or replaced. These sentences contain single and multiple instances of coordinating conjunctions ("and", "or", "but", "nor") with quantifiers, negations, and requiring diverse boolean and non-boolean inferences over conjuncts. We find that large-scale pre-trained language models like RoBERTa do not understand conjunctive semantics well and resort to shallow heuristics to make inferences over such sentences. As some initial solutions, we first present an iterative adversarial fine-tuning method that uses synthetically created training data based on boolean and non-boolean heuristics. We also propose a direct model advancement by making RoBERTa aware of predicate semantic roles. While we observe some performance gains, CONJNLI is still challenging for current methods, thus encouraging interesting future work for better understanding of conjunctions.[1]

1 Introduction

Coordinating conjunctions are a common syntactic phenomenon in English: 38.8% of sentences in the Penn Tree Bank have at least one coordinating word between "and", "or", and "but" (Marcus et al., 1993). Conjunctions add complexity to the sentences, thereby making inferences over such sentences more realistic and challenging. A sentence can have many conjunctions, each conjoining two or more conjuncts of varied syntactic categories such as noun phrases, verb phrases, prepositional phrases, clauses, etc. Besides syntax, conjunctions in English have a lot of semantics associated to them and different conjunctions ("and" vs "or") affect the meaning of a sentence differently.

Recent years have seen significant progress in the task of Natural Language Inference (NLI) through the development of large-scale datasets like SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018). Although large-scale pre-trained language models like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019b) have achieved super-human performances on these datasets, there have been concerns raised about these models exploiting idiosyncrasies in the data using tricks like pattern matching (McCoy et al., 2019). Thus, various stress-testing datasets have been proposed that probe NLI models for simple lexical inferences (Glockner et al., 2018), quantifiers (Geiger et al., 2018), numerical reasoning, antonymy and negation (Naik et al., 2018). However, despite the heavy usage of conjunctions in English, there is no specific NLI dataset that tests their understanding in detail. Although SNLI has 30% of samples with conjunctions, most of these examples do not require inferences over the conjuncts that are connected by the coordinating word. On a random sample of 100 conjunctive examples from SNLI, we find that 72% of them have the conjuncts unchanged between the premise and the hypothesis (e.g., "Man and woman sitting on the sidewalk" → "Man and woman are sitting") and there are almost no examples with non-boolean conjunctions (e.g., "A total of five men and women are sitting." → "A total of 5 men are sitting." (contradiction)). As discussed below, inference over conjuncts directly translates to boolean and non-

Table 1: Examples from our CONJNLI dataset consisting of single and multiple occurrences of different coordinating conjunctions (and, or, but), boolean or non-boolean in the presence of negations and quantifiers. Typical SNLI and MNLI examples do not require inference over conjuncts. † = Non-boolean usages of different conjunctions.

boolean semantics and thus becomes essential for understanding conjunctions.

In our work, we introduce CONJNLI, a new stress-test for NLI over diverse and challenging conjunctive sentences. Our dataset contains annotated examples where the hypothesis differs from the premise by either a conjunct removed, added or replaced. These sentences contain single and multiple instances of coordinating conjunctions (and, or, but, nor) with quantifiers, negations, and requiring diverse boolean and non-boolean inferences over conjuncts. Table 1 shows many examples from CONJNLI and compares these with typical conjunctive examples from SNLI and MNLI. In the first two examples, the conjunct "a Worcester resident" is removed and added, while in the third example, the other conjunct "a member of the Democratic Party" is replaced by "a member of the Republican Party". Distribution over conjuncts in a conjunctive sentence forms multiple simple sentences. For example, the premise in the first example of Table 1 can be broken into "He is a Worcester resident." and "He is a member of the Democratic Party.". Correspondingly, from boolean semantics, it requires an inference of the form "A and $B \rightarrow A$". Likewise, the third example is of the form "A and $B \rightarrow A$ and C". While such inferences are rather simple from the standpoint of boolean logic, similar rules do not always translate to English, e.g., in non-boolean cases, i.e., an inference of the form "A and $B \rightarrow A$" is not always entailment or an inference of the form "A or $B \rightarrow A$" is not always neutral (Hoeksema, 1988). Consider the three examples marked with a † in Table 1 showing non-boolean usages of "and", "or" and "but" in English. In the fifth example, the total time is a single entity and cannot be separated in an entailed hypothesis. In the sixth example, "or" is used as "exclusive-or" because the person began recording in either 1889 or 1890.

We observe that state-of-the-art models such as BERT and RoBERTa, trained on existing datasets like SNLI and MNLI, often fail to make these inferences for our dataset. For example, BERT predicts entailment for the non-boolean "and" example #5 in Table 1 as well. This relates to the lexical overlap issue in these models (McCoy et al., 2019), since all the words in the hypothesis are also part of the premise for the example. Conjunctions are also challenging in the presence of negations. For example, a sentence of the form "not A or B" translates to "not A and not B", as shown in example #8 of Table 1. Finally, a sentence may contain multiple conjunctions (with quantifiers), further adding to the complexity of the task (example #7 in Table 1). Thus, our CONJNLI dataset presents a new and interesting real-world challenge task for the community to work on and allow development of deeper NLI models.

We also present some initial model advancements that attempt to alleviate some of these challenges in our new dataset. First, we create synthetic training data using boolean and non-boolean heuristics. We use this data to adversarially train RoBERTa-style models by an iterative adversarial fine-tuning method. Second, we make RoBERTa aware of predicate semantic roles by augmenting the NLI model with the predicate-aware embeddings of the premise and the hypothesis. Predicate arguments in sentences can help distinguish between two syntactically similar inference pairs with different target labels (Table 5 shows an example). Overall, our contributions are:

- We introduce CONJNLI, a new stress-test for NLI in conjunctive sentences, consisting of boolean and non-boolean examples with single and multiple coordinating conjunctions ("and", "or", "but", "nor"), negations, quantifiers and requiring diverse inferences over conjuncts (with high inter-annotator agreement between experts).
- We show that BERT and RoBERTa do not understand conjunctions well enough and use shallow heuristics for inferences over such sentences.
- We propose initial improvements for our task by adversarially fine-tuning RoBERTa using an iterative adversarial fine-tuning algorithm and also augmenting RoBERTa with predicate-aware embeddings. We obtain initial gains but with still large room for improvement, which will hopefully encourage future work on better understanding of conjunctions.

2 Related Work

Our work is positioned at the intersection of understanding the semantics of conjunctions in English and its association to NLI.

Conjunctions in English. There is a long history of analyzing the nuances of coordinating conjunctions in English and how these compare to boolean and non-boolean semantics (Gleitman, 1965; Keenan and Faltz, 2012). Linguistic studies have shown that noun phrase conjuncts in "and" do not always behave in a boolean manner (Massey, 1976; Hoeksema, 1988; Krifka, 1990). In the NLP community, studies on conjunctions have mostly been limited to treating it as a syntactic phenomenon. One of the popular tasks is that of conjunct boundary identification (Agarwal and Boggess, 1992). Ficler and Goldberg (2016a) show that state-of-the-art parsers often make mistakes in identifying conjuncts correctly and develop neural models to accomplish this (Ficler and Goldberg, 2016b; Teranishi et al., 2019). Saha and Mausam (2018) also identify conjuncts to break conjunctive sentences into simple ones for better downstream Open IE (Banko et al., 2007). However, we study the semantics of conjunctions through our challenging dataset for NLI.

Analyzing NLI Models. Our research follows a body of work trying to understand the weaknesses of neural models in NLI. Poliak et al. (2018b); Gururangan et al. (2018) first point out that hypothesis-only models also achieve high accuracy in NLI, thereby revealing weaknesses in existing datasets. Various stress-testing datasets have been proposed since, focusing on lexical inferences (Glockner et al., 2018), quantifiers (Geiger et al., 2018), biases on specific words (Sanchez et al., 2018), verb verdicality (Ross and Pavlick, 2019), numerical reasoning (Ravichander et al., 2019), negation, antonymy (Naik et al., 2018), pragmatic inference (Jeretic et al., 2020) and systematicity of monotonicity (Yanaka et al., 2020). Besides syntax, other linguistic information have also been investigated (Poliak et al., 2018a; White et al., 2017) but none of these focus on conjunctions. The closest work on conjunctions is by Richardson et al. (2020) where they probe NLI models through semantic fragments. However, their focus is only on boolean "and", allowing them to assign labels automatically through simple templates. Also, their goal is to get BERT to master semantic fragments, which, as they mention, is achieved with a few minutes of additional fine-tuning on their templated data. CONJNLI, however, is more diverse and challenging for BERT-style models, includes all common coordinating conjunctions, and captures non-boolean usages.

Adversarial Methods in NLP. Adversarial training for robustifying neural models has been

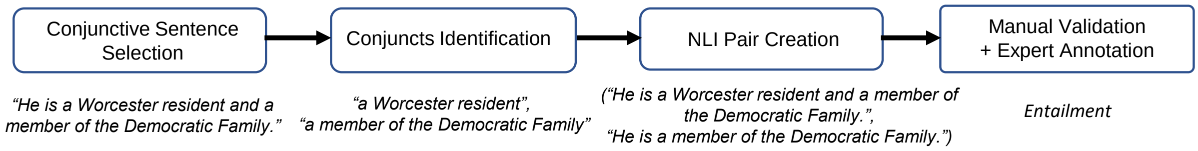

Figure 1: Flow diagram of CONJNLI dataset creation.

proposed in many NLP tasks, most notably in QA (Jia and Liang, 2017; Wang and Bansal, 2018) and NLI (Nie et al., 2019). Nie et al. (2020) improve existing NLI stress tests using adversarially collected NLI data (ANLI) and Kaushik et al. (2020) use counter-factually augmented data for making models robust to spurious patterns. Following Jia and Liang (2017), we also create adversarial training data by performing all data creation steps except for the expensive human annotation. Our iterative adversarial fine-tuning method adapts adversarial training in a fine-tuning setup for BERT-style models and improves results on CONJNLI while maintaining performance on existing datasets.

3 Data Creation

Creation of CONJNLI involves four stages, as shown in Figure 1. The (premise, hypothesis) pairs are created automatically, followed by manual verification and expert annotation.

3.1 Conjunctive Sentence Selection

We start by choosing conjunctive sentences from Wikipedia containing all common coordinating conjunctions ("and", "or", "but", "nor"). Figure 1 shows an example. We choose Wikipedia because it contains complex sentences with single and multiple conjunctions, and similar choices have also been made in prior work on information extraction from conjunctive sentences (Saha and Mausam, 2018). In order to capture a diverse set of conjunctive phenomena, we gather sentences with multiple conjunctions, negations, quantifiers and various syntactic constructs of conjuncts.

3.2 Conjuncts Identification

For conjunct identification, we process the conjunctive sentence using a state-of-the-art constituency parser implemented in AllenNLP[2] and then choose the two phrases in the resulting constituency parse on either side of the conjunction as conjuncts. A conjunction can conjoin more than two conjuncts, in which case we identify the two surrounding the conjunction and ignore the rest. Figure 1 shows an example where the two conjuncts "a Worcester resident" and "a member of the Democratic Party" are identified with the conjunction "and".

3.3 NLI Pair Creation

Once the conjuncts are identified, we perform three operations by removing, adding or replacing one of the two conjuncts to obtain another sentence such that the original sentence and the modified sentence form a plausible NLI pair. Figure 1 shows a pair created by the removal of one conjunct. We create the effect of adding a conjunct by swapping the premise and hypothesis from the previous example. We replace a conjunct by finding a conjunct word that can be replaced by its antonym or co-hyponym. Wikipedia sentences frequently contain numbers or names of persons in the conjuncts which are replaced by adding one to the number and randomly sampling any other name from the dataset respectively. We apply the three conjunct operations on all collected conjunctive sentences.

3.4 Manual Validation & Expert Annotation

Since incorrect conjunct identification can lead to the generation of a grammatically incorrect sentence, the pairs are first manually verified for grammaticality. The grammatical ones are next annotated by two English-speaking experts (with prior experience in NLI and NLP) into entailment, neutral and contradiction labels. We refrain from using Amazon Mechanical Turk for the label assignment because our NLI pairs' labeling requires deeper understanding and identification of the challenging conjunctive boolean versus non-boolean semantics (see examples #1 and #5 in Table 1 where the same conjunct removal operation leads to two different labels). Expert annotation has been performed in previous NLI stress-tests as well (Ravichander et al., 2019; McCoy et al., 2019) so as to ensure a high-quality dataset.

Annotator Instructions and Agreement: Each annotator is initially trained by showing 10 examples, of which some have boolean usages and others non-boolean. The examples are further accompanied with clear explanations for the choice of labels.

---

	Ent	Neu	Contra	Total
Conj Dev	204	281	138	623
Conj Test	332	467	201	1000
Conj All	536	748	339	1623

Table 2: Dataset splits of CONJNLI.

	and	or	but	multiple	quant	neg
Conj Dev	320	293	99	152	131	70
Conj Test	537	471	135	229	175	101
Conj All	857	764	234	381	306	171

Table 3: Data analysis by conjunction types, presence of quantifiers and negations.

The appendix contains a subset of these examples. The annotations are done in two rounds – in the first, each annotator annotated the examples independently and in the second, the disagreements are discussed to resolve final labels. The inter-annotator agreement between the annotators has a high Cohen's Kappa (κ) of 0.83 and we keep only those pairs that both agree on.

4 Data Analysis

Post-annotation, we arrive at a consolidated set of 1623 examples, which is a reasonably large size compared to previous NLI stress-tests with expert annotations. We randomly split these into 623 validation and 1000 test examples, as shown in Table 2. CONJNLI also replicates the approximate distribution of each conjunction in English (Table 3). Thus, "and" is maximally represented in our dataset, followed by "or"[3] and "but". Sentences with multiple conjunctions make up a sizeable 23% of CONJNLI to reflect real-world challenging scenarios. As we discussed earlier, conjunctions are further challenging in the presence of quantifiers and negations, due to their association with boolean logic. These contribute to 18% and 10% of the dataset, resp.

We note that conjunctive sentences can contain conjuncts of different syntactic categories, ranging from words of different part of speech tags to various phrasal constructs to even sentences. Table 4 shows a small subset of the diverse syntactic constructs of conjuncts in CONJNLI. The conjuncts within a sentence may belong to different categories – the first example conjoins a noun phrase with an adjective. Each conjunct can be a clause, as shown in the fifth example.

Sentence	CT
Historically, the Commission was run by **three commissioners** or **fewer**.	NP + Adj
Terry Phelps and **Raffaella Reggi** were the defending champions but did not compete that year.	NP + NP
Terry Phelps and Raffaella Reggi **were the defending champions** but **did not compete that year**.	VP + VP
It is for Orienteers **in** or **around** North Staffordshire and South Cheshire.	Prep + Prep
It is a white solid, but **impure samples can appear yellowish**.	Clause + Clause
Pantun were originally not written down, the bards often being **illiterate** and **in many cases blind**.	Adj + PP
A queue is **an example of a linear data structure**, or **more abstractly a sequential collection**.	NP + AdvP

Table 4: CONJNLI sentences consist of varied syntactic conjunct categories (bolded). CT = Conjunct Types, NP = Noun Phrase, VP = Verb Phrase, AdvP = Adverbial Phrase.

5 Methods

In this section, we first describe our iterative adversarial fine-tuning method (including the creation of adversarial training data), followed by some initial predicate-aware models to try to tackle CONJNLI.

5.1 Iterative Adversarial Fine-Tuning

Automated Adversarial Training Data Creation. Creation of large-scale conjunctive-NLI training data, where each example is manually labeled, is prohibitive because of the amount of human effort involved in the process and the diverse types of exceptions involved in the conjunction inference labeling process. Hence, in this section, we first try to automatically create some training data to train models for our challenging CONJNLI stress-test and show the limits of such rule-based adversarial training methods. For this automated training data creation, we follow the same process as Section 3 but replace the expert human-annotation phase with automated boolean rules and some initial heuristics for non-boolean[4] semantics so as to assign labels to these pairs automatically. For "boolean and", if "A and B" is true, we assume that A and B are individually true, and hence when-

---

[3] We consider sentences with "nor" as part of "or".

[4] Non-boolean usages of conjunctions, to the best of our knowledge, cannot be identified automatically; and in fact, that is the exact motivation of CONJNLI, which encourages the development of such models.

Algorithm 1 Iterative Adversarial Fine-Tuning

```
$model$ = finetune($RoBERTa$, $MNLI_{train}$)
$adv\_train$ = get_adv_data()
$k$ = len($adv_{train}$)
for $e = 1$ to $num\_epochs$ do
    $MNLI\_small$ = sample_data($MNLI_{train}$, $k$)
    $all\_data$ = $MNLI\_small \bigcup adv\_train$
    Shuffle $all\_data$
    $model$ = finetune($model$, $all\_data$)
end for
```

ever we remove a conjunct, we assign the label entailment and whenever we add a conjunct, we assign the label neutral. Examples with conjunct replaced are assigned the label contradiction. As already shown in Table 1, there are of course exceptions to these rules, typically arising from the "non-boolean" usages. Hoeksema (1988); Krifka (1990) show that conjunctions of proper names or named entities, definite descriptions, and existential quantifiers often do not behave according to general boolean principles. Hence, we use these suggestions to develop some initial non-boolean heuristics for our automated training data creation. First, whenever we remove a conjunct from a named entity ("Franklin and Marshall College" → "Franklin College"), we assign the label neutral because it typically refers to a different named entity. Second, "non-boolean and" is prevalent in sentences where the conjunct entities together map onto a collective entity and often in the presence of certain trigger words like "total", "group", "combined", etc. (but note that this is not always true). For example, removing the conjunct "flooding" in the sentence "In total, the flooding and landslides killed 3,185 people in China." should lead to contradiction. We look for such trigger words in the sentence and heuristically assign contradiction label to the pair. Like "and", the usage of "or" in English often differs from boolean "or". The appendix contains details of the various interpretations of English "or", and our adversarial data creation heuristics.

We create a total of 15k adversarial training examples using the aforementioned shallow heuristics, with an equal number of examples for "and", "or" and "but". A random sample of 100 examples consisting of an equal number of "and", "or" and "but" examples are chosen for manual validation by one of the annotators, yielding an accuracy of 70%. We find that most of the errors either have challenging non-boolean scenarios which cannot be handled by our heuristics or have ungrammatical hypotheses, originating from parsing errors.

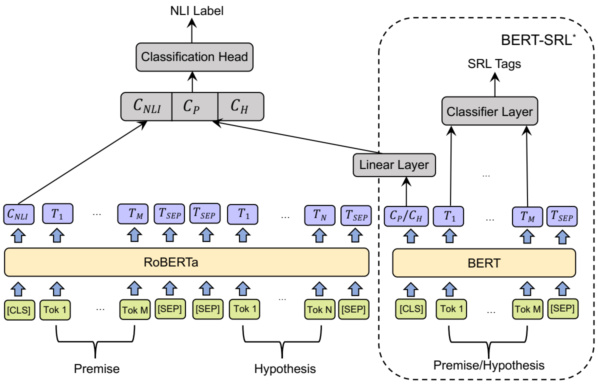

Figure 2: Architecture diagram of predicate-aware RoBERTa model for ConjNLI. * = BERT-SRL weights are frozen while fine-tuning on the NLI task.

Algorithm for Iterative Adversarial Fine-Tuning. Our adversarial training method is outlined in Algorithm 1. We look to improve results on ConjNLI through adversarial training while maintaining state-of-the-art results on existing datasets like MNLI. Thus, we first fine-tune RoBERTa on the entire MNLI training data. Next, at each epoch, we randomly sample an equal amount of original MNLI training examples with conjunctions as the amount of adversarial training data. We use the combined data to further fine-tune the MNLI fine-tuned model. At each epoch, we iterate over the original MNLI training examples by choosing a different random set every time, while keeping the adversarial data constant. The results section discusses the efficacy of our algorithm.

As shown later, adversarial training leads to limited improvements on ConjNLI due to the rule-based training data creation. Since real-world conjunctions are much more diverse and tricky, our dataset encourages future work by the community and also motivates a need for direct model development like our initial predicate-aware RoBERTa.

5.2 Initial Predicate-Aware (SRL) RoBERTa

We find that ConjNLI contains examples where the inference label depends on the predicate and the predicate roles in the sentence. Consider the two examples in Table 5. The two premises are syntactically similar and both undergo the conjunct replacement operation for creating the hypothesis. However, their respective predicates "premiered" and "played" have different arguments, notably one referring to a premier date while the other describing playing in a location. Motivated by the need to better understand predicates and predicate roles in

Premise	**Hypothesis**	**Label**	**SRL Tags**

BERT-M	84.10/83.90	-	58.10	61.40
RoBERTa-S	-	**91.87**	60.99	63.50
RoBERTa-M	**87.56/87.51**	-	**64.68**	**65.50**

Table 6: Comparison of BERT and RoBERTa trained on SNLI and MNLI and tested on respective dev sets and CONJNLI. MNLI Dev (MD) results are in match/mismatched format. SD = SNLI Dev, CD = Conj Dev, CT = Conj Test.

NLI pairs, we propose a predicate-aware RoBERTa model, built on top of a standard RoBERTa model for NLI. Figure 2 shows the architecture diagram. We make the model aware of predicate roles by using representations of both the premise and the hypothesis from a fine-tuned BERT model on the task of Semantic Role Labeling (SRL).[5] Details of the BERT-SRL model can be found in the appendix. Let the RoBERTa embedding of the $[CLS]$ token be denoted by C_{NLI}. The premise and hypothesis are also passed through the BERT-SRL model to obtain predicate-aware representations for each. These are similarly represented by the corresponding $[CLS]$ token embeddings. We learn a linear transformation on top of these embeddings to obtain C_P and C_H. Following Pang et al. (2019), where they use late fusion of syntactic information for NLI, we perform the same with the predicate-aware SRL representations. A final classification head gives the predictions.

5.3 Predicate-Aware RoBERTa with Adversarial Fine-Tuning

In the last two subsections, we proposed enhancements both on the data side and the model side to tackle CONJNLI. Our final joint model now combines predicate-aware RoBERTa with iterative adversarial fine-tuning. We conduct experiments to analyze the effect of each of these enhancements as well as their combination.

6 Experiments and Results

We perform experiments on three datasets - (1) CONJNLI, (2) SNLI (Bowman et al., 2015) and (3) MNLI (Williams et al., 2018). The appendix contains details about our experimental setup.

6.1 Baselines

We first train BERT and RoBERTa on the SNLI (BERT-S, RoBERTa-S) and MNLI (BERT-M, RoBERTa-M) training sets and evaluate their performance on the respective dev sets and CONJNLI, as shown in Table 6. We observe a similar trend for both MNLI and CONJNLI, with MNLI-trained RoBERTa being the best performing model. This is perhaps unsurprising as MNLI contains more complex inference examples compared to SNLI. The results on CONJNLI are however significantly worse than MNLI, suggesting a need for better understanding of conjunctions. We also experimented with older models like ESIM (Chen et al., 2017) and the accuracy on CONJNLI was much worse at 53.10%. All our successive experiments are conducted using RoBERTa with MNLI as the base training data, owing to its superior performance.

In order to gain a deeper understanding of these models' poor performance, we randomly choose 100 examples with "and" and only replace the "and" with "either-or" (exclusive-or) along with the appropriate change in label. For example, "He received bachelor's degree in 1967 and PhD in 1973." → "He received bachelor's degree in 1967." (entailment) is changed to "He either received bachelor's degree in 1967 or PhD in 1973." → "He received bachelor's degree in 1967." (neutral). We find that while RoBERTa gets most of the "and" examples correct, the "or" examples are mostly incorrect because the change in conjunction does not lead to a change in the predicted label for any of the examples. This points to the lexical overlap heuristic (McCoy et al., 2019) learned by the model that if the hypothesis is a subset of the premise, the label is mostly entailment, while ignoring the type of conjunction.

---

[5] Our initial experiments show that BERT marginally outperforms RoBERTa for SRL.

	Conj Dev	MNLI Dev	Conj Test
BERT	58.10	84.10/83.90	61.40
RoBERTa	64.68	**87.56/87.51**	65.50
AFT	67.57	76.61/76.68	66.40
IAFT	**69.18**	86.93/86.81	**67.90**

Table 7: Table showing the effectiveness of IAFT over AFT and other baseline models.

6.2 Iterative Adversarial Fine-Tuning

We compare our proposed Iterative Adversarial Fine-Tuning (IAFT) approach with simple Adversarial Fine-Tuning (AFT) wherein we start with the MNLI fine-tuned RoBERTa model and fine-tune it further with the adversarial data, in a two-step process.[6] Table 7 shows that IAFT obtains the best average results between CONJNLI and MNLI with 2% improvement on the former and retaining state-of-the-art results on the latter. In the simple AFT setup, the model gets biased towards the adversarial data, resulting in a significant drop in the original MNLI results. The slight drop in CONJNLI results also indicates that the MNLI training data is useful for the model to learn about basic paraphrasing skills required in NLI. IAFT achieves that, by mixing the adversarial training data with an equal amount of MNLI examples in every epoch. We also analyze a subset of examples fixed by IAFT and find that unsurprisingly (based on the heuristics used to automatically create the adversarial training data in Sec. 5.1), it corrects more boolean examples than non-boolean (65% vs 35%) and the non-boolean examples either have named entities or collective conjuncts.

We note that IAFT is a generic approach and can be used to improve other stress-tests in an adversarial fine-tuning setup. As an example, we apply it on the boolean subset of the dataset by Richardson et al. (2020) containing samples with "boolean and" and find that our model achieves a near perfect accuracy on their test set. Specifically, RoBERTa, trained on only MNLI, achieves a low accuracy of 41.5% on the test set, but on applying IAFT with an equal mix of MNLI and their training data in every epoch, the test accuracy improves to 99.8%, while also retaining MNLI matched/mismatched results at 86.45/86.46%.

	Conj Dev	MNLI Dev	Conj Test
BERT	58.10	84.10/83.90	61.40
RoBERTa	64.68	87.56/87.51	65.50
PA	64.88	**87.75/87.63**	66.30
IAFT	**69.18**	86.93/86.81	**67.90**
PA-IAFT	68.89	87.07/86.93	67.10

Table 8: Comparison of all our final models on CONJNLI and MNLI.

6.3 Predicate-Aware RoBERTa with Adversarial Fine-Tuning

Table 8 consolidates our final results on both the datasets. We compare the baselines BERT and RoBERTa with (1) Predicate-aware RoBERTa (PA), (2) RoBERTa with Iterative Adversarial Fine-Tuning (IAFT), and (3) Predicate-aware RoBERTa with Iterative Adversarial Fine-tuning (PA-IAFT). Our first observation is that PA marginally improves results on both the datasets. This is encouraging, as it shows that NLI in general, can benefit from more semantic information. However, we obtain a larger gain on CONJNLI with adversarial training. This, however, is unsurprising as the adversarial training data is specifically curated for the task, whereas PA is only exposed to the original MNLI training data. On combining both, our results do not improve further, thus promoting future work by the community on better understanding of conjunctions. Finally, all our models encouragingly maintain state-of-the-art results on MNLI.

6.4 Amount of Adversarial Training Data

We investigate the amount of training data needed for RoBERTa-style models to learn the heuristics used to create the adversarial data. We experiment with the IAFT model on CONJNLI dev and linearly increase the data size from 6k to 18k, comprising of an equal amount of "and", "or" and "but" examples. Figure 3 shows the accuracy curve. We obtain maximum improvements with the first 12k examples (4 points), marginal improvement with the next 3k and a slight drop in performance with the next 3k. Early saturation shows that RoBERTa learns the rules using a small number of examples only and also exposes the hardness of CONJNLI.

6.5 Instability Analysis

Zhou et al. (2020) perform an in-depth analysis of the various NLI stress tests like HANS (McCoy et al., 2019), BREAK-NLI (Glockner et al., 2018), etc and find that different random initializa-

---

[6] AFT, in principle, is similar to the `Inoculation by Fine-Tuning` strategy (Liu et al., 2019a), with the exception that they inject some examples from the challenge set for training, while we have a separate heuristically-created adversarial training set.

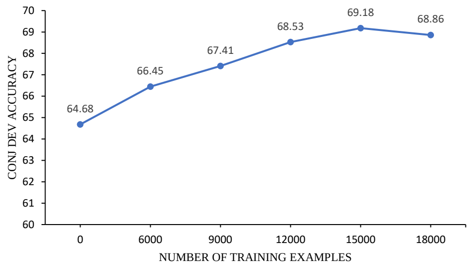

Figure 3: Effect of amount of adversarial training data.

tion seeds can lead to significantly different results on these datasets. They show that this instability largely arises from high inter-example similarity, as these datasets typically focus on a particular linguistic phenomenon by leveraging only a handful of patterns. Thus, following their suggestion, we conduct an instability analysis of CONJNLI by training RoBERTa on MNLI with 10 different seeds (1 to 10) and find that the results on CONJNLI are quite robust to such variations. The mean accuracy on CONJNLI dev is 64.48, with a total standard deviation of 0.59, independent standard deviation of 0.49 and a small inter-data covariance of 0.22. CONJNLI's stable results compared to most previous stress-tests indicate the diverse nature of conjunctive inferences captured in the dataset.

6.6 Analysis by Conjunction Type

In Table 9, we analyze the performance of the models on the subset of examples containing "and", "or", "but" and multiple conjunctions. We find that "or" is the most challenging for pre-trained language models, particularly because of its multiple interpretations in English. We also note that all models perform significantly better on sentences with "but", owing to the lack of non-boolean usages in such sentences. Our initial predicate-aware model encouragingly obtains small improvements on all conjunction types (except "but"), indicating that perhaps these models can benefit from more linguistic knowledge. Although single conjunction examples benefit from adversarial training, multiple conjunctions prove to be challenging mainly due to the difficulty in automatically parsing and creating perfect training examples with such sentences (Ficler and Goldberg, 2016b).

6.7 Analysis of Boolean versus Non-Boolean Conjunctions

One of the expert annotators manually annotated the CONJNLI dev set for boolean and non-boolean examples. We find that non-boolean examples contribute to roughly 34% of the dataset. Unsurprisingly, all models perform significantly better on the boolean subset compared to the non-boolean one. Specifically, the accuracies for RoBERTa, IAFT and PA on the boolean subset are 68%, 72% and 69% respectively, while on the non-boolean subset, these are 58%, 61% and 58% respectively. Based on these results, we make some key observations: (1) Non-boolean accuracy for all models are about 10% less than the boolean counterpart, revealing the hardness of the dataset, (2) IAFT improves both boolean and non-boolean subsets because of the non-boolean heuristics used in creating its adversarial training data, (3) PA only marginally improves the boolean subset, suggesting the need for better semantic models in future work. In fact, CONJNLI also provides a test bed for designing good semantic parsers that can automatically distinguish between boolean and non-boolean conjunctions.

	And	Or	But	Multiple	All
RoBERTa	65.36	59.87	**81.48**	65.93	65.60
PA	66.29	60.93	**81.48**	**66.81**	66.30
IAFT	**67.59**	**62.20**	80.00	62.88	**67.90**

Table 9: Comparison of all models on the subset of each conjunction type of CONJNLI.

7 Conclusion

We presented CONJNLI, a new stress-test dataset for NLI in conjunctive sentences ("and", "or", "but", "nor") in the presence of negations and quantifiers and requiring diverse "boolean" and "non-boolean" inferences over conjuncts. Large-scale pre-trained LMs like RoBERTa are not able to optimally understand the conjunctive semantics in our dataset. We presented some initial solutions via adversarial training and a predicate-aware RoBERTa model, and achieved some reasonable performance gains on CONJNLI. However, we also show limitations of our proposed methods, thereby encouraging future work on CONJNLI for better understanding of conjunctive semantics.

Table 10: Some examples from CONJNLI with gold labels and explanations, used for training the annotators.

A Appendix

A.1 Annotation Examples

In Table 10, we list a subset of examples from CONJNLI, shown to the annotators with the purpose of training them. In the first example, the “or” means “boolean exclusive-or” while in the second, it is used to establish equivalence between two phrases. The fourth example is a non-boolean usage of “and” as it appears as part of a named entity.

A.2 Automated “Or” Adversarial Data Creation

In this section, we explain the heuristics used to create the “or” part of the automated adversarial training data for the IAFT model in Sec. 5.1. We observe that “or” in English is used in sentences in multiple different contexts - (1) establishing exclusivity between options, translating to “exclusive-or” in boolean semantics (“He was born in 1970 or 1971.”), (2) establishing equivalence between two words or phrases (“Upon completion, it will rise 64 stories or 711 ft.”), and (3) “or” interpreted as “boolean or” (“He can play as a striker or a midfielder.”). Note that the inference label varies between cases (1) and (2) for a particular conjunct operation. For example, in case (1), removal of a conjunct is neutral while for case (2), removal of a conjunct is entailment. Differentiating between these is again challenging due to the lack of any particular trigger in such sentences. We observe that the latter two cases are more frequent in our dataset and thus we heuristically label a pair as entailment when we remove a conjunct and neutral when we add a conjunct. Finally, whenever “or” is present in a named entity, we heuristically label the example as neutral.

A.3 BERT-SRL Model

SRL is the task of predicting the semantic roles for each predicate in the sentence. We follow the standard BIO encoding to denote the span of each argument and model it as a token classification problem. The input to BERT is the tokenized sentence with a $[CLS]$ token at the beginning and a $[SEP]$ token at the end.

$$[CLS]\ Sent\ [SEP][SEP]\ Pred\ [SEP]$$

Since BERT converts each word into word pieces, we first propagate the gold SRL tags, which are for each word, to word pieces. Thus, for a word with multiple word pieces, we assign the tag B-ARG to the first word piece, and the tag I-ARG to the subsequent word pieces. For tags of the form I-ARG and O, we assign the original word tag to all the word pieces. The $[CLS]$ and the $[SEP]$ tokens of the input are assigned the tag O. Predicate information is fed to BERT through the segment ids, by assigning 1 to the predicate token and 0 for others. Finally, we add a classification layer at the top and the model is fine-tuned to predict the tag for each token using cross-entropy loss. Unlike Shi and Lin (2019), our model refrains from using additional LSTM layers at the top, thus making it

consistent with other downstream fine-tuning tasks. At inference time, we predict the most probable tag sequence by applying Viterbi Algorithm with two constraints - (1) a sequence cannot start with an I-ARG tag and (2) an I-ARG tag has to be preceded by a B-ARG tag. The tag for each word is taken to be the predicted tag of the first word piece of that word. We train the SRL model on the CoNLL 2005 dataset (Carreras and Màrquez, 2005) for 5 epochs with a learning rate of $5 * 10^-5$ and obtain a near state-of-the-art F1 of 86.23% on the dev set.[7] The BERT-SRL model's weights are frozen for the NLI task.

A.4 Experimental Setup

Our implementation builds on top of the Pytorch implementations (Wolf et al., 2019) of BERT-base uncased (Devlin et al., 2019) and RoBERTa-base (Liu et al., 2019b). We train the models for a maximum of 3 epochs using an initial learning rate of $2 * 10^{-5}$, with linear decay and a weight decay of 0.1. The dropout probability is chosen to be 0.1. The size of the predicate-aware representations of the premise and the hypothesis is set to 40. The maximum sequence length is 128 for both the NLI models and the SRL model. The random seed used in all the experiments is 42. Each epoch takes 45 minutes (base models) to 1.5 hours (predicate-aware models) to run on four V100 GPUs. The total number of parameters in our models is similar to that of BERT-base or RoBERTa-base, depending on the choice of the model. All hyperparameters, the amount of adversarial training and the adversarial training algorithm are chosen based on the best average accuracy of CONJNLI and MNLI dev sets. Batch size and learning rate are manually tuned in the range $\{16{,}32\}$ and $\{10^{-5}, 2 * 10^{-5}\}$ respectively. Following previous works, we report accuracy for all our models.

A.5 Success and Error Analysis

In Table 11, we present four examples from CONJNLI and the predictions from each of the models and the target label. In the first example, predicate-aware RoBERTa understands the roles of the predicate "measures" and outputs the correct label contradiction, which RoBERTa cannot. The second example shows the effect of adversarial training – the model learns from adversarial examples that "War and Peace" is a named entity and removing a conjunct from it is neutral.[8] The third example is however, an exception to the previous rule and only adversarial training fails to make the distinction. On combining predicate-aware RoBERTa with adversarial training, our model learns to associate the predicate "released" to its roles and predicts the correct label. Finally, for the fourth example, we find that our model still fails to make the difficult inferences over "non-boolean and" cases. Note that there is no obvious trigger like "total" in the sentence, thus causing all the models to fail. This also shows that we need a deeper understanding of conjunctive sentential semantics to correctly predict these tricky real-world cases where boolean semantics do not hold.

---

[7] The state-of-the-art F1 score for SRL on this dataset is 87.4% (Ouchi et al., 2018)

[8] Note that the gold label is neutral because a person can appear in two Television series with slightly different names.

Data and Representation for Turkish Natural Language Inference

Abstract

Large annotated datasets in NLP are overwhelmingly in English. This is an obstacle to progress in other languages. Unfortunately, obtaining new annotated resources for each task in each language would be prohibitively expensive. At the same time, commercial machine translation systems are now robust. Can we leverage these systems to translate English-language datasets automatically? In this paper, we offer a positive response for natural language inference (NLI) in Turkish. We translated two large English NLI datasets into Turkish and had a team of experts validate their translation quality and fidelity to the original labels. Using these datasets, we address core issues of representation for Turkish NLI. We find that in-language embeddings are essential and that morphological parsing can be avoided where the training set is large. Finally, we show that models trained on our machine-translated datasets are successful on human-translated evaluation sets. We share all code, models, and data publicly.

1 Introduction

Many tasks in natural language processing have been transformed by the introduction of very large annotated datasets. Prominent examples include paraphrase (Ganitkevitch et al., 2013), parsing (Nivre et al., 2016), question answering (Rajpurkar et al., 2016), machine translation (MT; Bojar et al., 2014), and natural language inference (NLI; Bowman et al., 2015; Williams et al., 2018a).

Unfortunately, outside of parsing and MT, these datasets tend to be in English. This is not only an obstacle to progress on other languages, but it also limits the field of NLP itself: English is generally not a representative example of the world's languages when it comes to morphology, syntax, or spelling conventions and other kinds of standardization (Munro, 2012), so it's risky to assume that models and results for English will generalize to other languages.

A natural response to these gaps in our dataset coverage might be to launch new annotation efforts for multiple languages. However, this would likely be prohibitively expensive. For example, based on the costs of SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018a), we estimate that each large dataset for NLI would cost upwards of US $50,000 if created completely from scratch.

At the same time, commercial MT systems have improved dramatically in recent years (Wu et al., 2016; Johnson et al., 2017; Hieber et al., 2017, 2018; Tomasello, 2019; Hieber et al., 2020). They now offer high-quality translations between hundreds of language pairs. This raises the question: can we use these MT systems to translate English-language datasets and use the translated versions to drive more genuinely multilingual development in NLP? In this paper, we offer evidence that the answer is "yes".

Using Amazon Translate, we translated SNLI and MultiNLI from English into Turkish to create the first large Turkish NLI data sets, NLI-TR, at a tiny fraction of the cost of creating them from scratch. Turkish is an interesting challenge in this context since it is very different from English, most notably in its very free word order and complex morphology. A word in Turkish bears morpho-syntactic properties in the sense that phrases formed of several words in languages like English can be expressed with a single word form.

In our validation phase (Section 3), a team of Turkish–English bilingual speakers assessed the quality of a large sample of the translations in NLI-TR. They found the quality to be very high, which suggests that translated datasets can provide a foundation for NLI research on a resource-constrained language, even if it has significantly different characteristics from English.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8253–8267,
November 16–20, 2020.

We then use these datasets to study the roles of pre-trained language models and morphological parsing in successful NLI systems for Turkish (Section 4). For these experiments, we fit classifiers on top of pre-trained BERT parameters (Devlin et al., 2019) and compare the original BERT-base release, the multilingual BERT embeddings released by the BERT team, and the Turkish BERT (BERTurk) embeddings of Schweter (2020). We find BERTurk to be superior to the others for NLI-TR.

Morphological parsing is a natural preprocessing step for Turkish due to its complex morphology. Thus, we assess the use of three morphological parsers as the second case study: Zemberek (Akın and Akın, 2007), BOUN parser (Sak et al., 2011), and Turkish Morphology (Öztürel et al., 2019). We find that the parsers help where training data is sparse, but the need for a parser disappears as the training data increases. This is a striking finding: one might expect that Turkish would require morphological parsing given its complex word-formation processes. It might be regarded as welcome news, though, since the parsers are expensive to run. In Section 4.2, we report on some new optimizations of existing tools to make the relevant parsing jobs feasible, but we would still like to avoid these steps if possible, and it seems that we can for NLI.

Finally, we investigate how models trained on the machine translated datasets perform on the human translations from XNLI (Conneau et al., 2018). We find that machine translated and human translated sentences yield similar results, suggesting that it is safe to apply models trained on machine-translated datasets to human-written sentences.

2 Related Work

Early in the development of textual entailment tasks, Mehdad et al. (2010) argued for multilingual versions of them. This led to subsequent explorations of a variety of techniques, including crowdsourcing translations (Negri and Mehdad, 2010; Negri et al., 2011), relying on parallel corpora to support reasoning across languages (Mehdad et al., 2011), and automatically translating datasets using MT systems (Mehdad et al., 2010; Real et al., 2018; Rodrigues et al., 2020). This research informed SemEval tasks in 2012 (Negri et al., 2012) and 2013 (Negri et al., 2013) followed by ASSIN 1 (Fonseca et al., 2016) and 2 (Real et al., 2020) shared tasks exploring the viability of multilingual NLI. From the perspective of present-day NLI models, these datasets are very small, but they could be used productively as challenge problems.

More recently, Conneau et al. (2018) reinvigorated work on multilingual NLI with their XNLI dataset. XNLI provides expert-translated evaluation sets from English into 14 other languages, including Turkish. Though they are valuable resources to push NLI research beyond English, test sets alone are insufficient for in-language training on target languages, which is likely to lower the performance of the resulting systems.

Although it was not the main focus of the XNLI effort, Conneau et al. (2018) distributed machine translations of MultiNLI into other languages, including Turkish, which we call MultiNLI-TR$^{\text{XNLI}}$ in this paper. The translations helped them form a strong baseline for their cross-lingual models, which proved superior in their assessments. However, the quality of the translations is crucial, as the authors note. Our hope for NLI-TR is that it supports effective in-language training.

XNLI's primary focus on test sets rather than training is justified by a wide body of recent results on cross-lingual transfer learning. Multilingual embeddings (embeddings trained on multilingual corpora) have played an important role in these developments. The BERT team (Devlin et al., 2019) released multilingual embeddings and demonstrated their value using XNLI. At the same time, BERT models have been released for a variety of individual languages (see Wolf et al., 2019) and specialized domains (Alsentzer et al., 2019; Lee et al., 2020). While we might expect the language- and domain-specific embeddings to be superior for the kind of data they were trained on, the multilingual versions might be more efficient in large-scale deployments in diverse environments. Balancing these trade-offs is challenging. Here, we offer some insight into these trade-offs for Turkish.

Turkish is a morphologically-rich language in which new word forms are freely created using suffixation. Several morphological parsers (Akın and Akın, 2007; Öztürel et al., 2019; Sak et al., 2009) and morphological disambiguation systems (Akın and Akın, 2007; Sak et al., 2011) have been developed for Turkish. The state-of-the-art morphological analyzers can parse with success rates around 95%. We use three of these parsers in this work to evaluate the role of morphology in NLI systems (Section 4.2).

3 Creating and Validating NLI-TR

3.1 English NLI Datasets

We translated the Stanford Natural Language Inference Corpus (SNLI; Bowman et al., 2015) and the Multi-Genre Natural Language Inference Corpus (MultiNLI; Williams et al., 2018b) to create labeled NLI datasets for Turkish, NLI-TR.

SNLI contains ≈570K semantically related English sentence pairs. The semantic relations are entailment, contradiction, and neutral. The premise sentences for SNLI are image captions from the Flickr30K corpus (Young et al., 2014), and the hypothesis sentences were written by crowdworkers. SNLI texts are mostly short and structurally simple. We translated SNLI while respecting the train, development (dev), and test splits.

MultiNLI comprises ≈433K sentence pairs in English, and the pairs have the same semantic relations as SNLI. However, MultiNLI spans a broader range of genres, including travel guides, fiction, dialogue, and journalism. As a result, the texts are generally more complex than SNLI. In addition, MultiNLI contains *matched* and *mismatched* dev and test sets, where the sentences in the former set are from the same sources as the training set, whereas the latter consists of texts from different genres than those found in the training set. We translated the training set and both dev sets for NLI-TR.

3.2 Automatic Translation Effort

As we noted in Section 1, Turkish is a resource-constrained language with few labeled data sets compared to English. Furthermore, Turkish has a fundamentally different grammar from English that could hinder transfer-learning approaches. These facts motivate our effort to translate SNLI and MultiNLI from English to Turkish. We employ an automatic MT system and hope that it will deliver high-quality translations that we can use for NLI research and system development in Turkish.

We used Amazon Translate, a commercial neural machine translation service. Translation of all folds of SNLI and MultiNLI cost just US $2K (vs. the ≈US $100K we would expect for replicating these two datasets from scratch) and five days with no parallelization. We refer to the translated datasets as SNLI-TR and MultiNLI-TR, and collectively as NLI-TR. Translation examples are provided in Table 1. We publicly share NLI-TR.[1]

SNLI-TR and MultiNLI-TR are different from SNLI and MultiNLI in terms of token counts and vocabulary sizes. Table 2 illustrates these features before and after translation. For each fold in each dataset, translation decreased the number of tokens in the corpus, but it increased the vocabulary sizes drastically, in both the cased and uncased versions. Both of these differences are expected: many multiword expressions in English are translated into individual words due to the agglutinating nature of Turkish. For instance, the four-word English expression “when in your home” can be translated to the single word “evinizdeyken”.

Table 2 also reflects the complexity difference between SNLI and MultiNLI that we noted in Section 3.1. Though SNLI contains more sentence pairs than MultiNLI, it has fewer tokens and a smaller vocabulary.

3.3 Translation Quality Assurance

Two major risks arise when using MT systems to translate NLI datasets. First, the translation quality might be low. Second, even if the individual sentences are translated correctly, the nature of the mapping from the source to the target language might affect the semantic relations between sentences. For example, English has the words “boy” and “girl” to refer to male and female children, and both those words can be translated to a gender-neutral Turkish word “çocuk”. Now, consider a premise sentence “A boy is running” and its contradiction pair “A girl is running”. Both sentences can be translated fluently into the same Turkish sentence, “Çocuk koşuyor”, which changes the semantic relation from contradiction to entailment.

Thus, to determine the viability of NLI-TR as a tool for NLI research, we must assess both translation quality and the consistency of the NLI labels. To do this, we assembled a team of ten Turkish–English bilingual speakers who were familiar with the NLI task and were either MSc. candidates or graduates in a relevant field.

For expert evaluation, we grouped the translations into example sets of four sentences as in Table 1, where the first sentence (premise) is semantically related to the rest (hypotheses). We distributed the sets to the experts so that each set (and sentence) was examined by five randomly chosen experts and each expert co-examined approx-

Table 2: Comparative statistics for the English and Turkish NLI datasets. The Turkish translations have larger vocabularies and lower token counts due to the highly agglutinating morphology of Turkish as compared to English.

imately the same number of sets with each other expert. Each expert evaluated the translation by (i) grading the translation quality between 1 and 5 (inclusive; 5 the best) and (ii) checking if the translation altered the semantic relation. We distributed an annotation guide[2] to the team to standardize the criteria. In total, 500 example sets (2,000 translated sentences) were examined by five experts, yielding 10,000 annotations.

We use the average translation score of the annotations to estimate translation quality. For label consistency, there are two comparisons we can make, since we have five new annotations per example. The *annotation-level* analysis compares each new annotation with the gold label on the original English example. The *majority-level* analysis compares only the majority label (if any) of the five new annotations with the English gold label. The annotation-level analysis is more stringent, whereas the majority-level analysis directly connects with how we expect NLI-TR to be most commonly used. Table 3 reports these analyses for SNLI and MultiNLI. The results are extremely reassuring. First, average translation quality is near 5 (ceiling) for all the splits. Second, annotation-level label consistency is over 90% and majority-level label consistency is over 95%, indicating that the linguistic differences between English and Turkish are not a major issue for preserving NLI labels.

To assess the reliability of the translation quality scores, we calculated the Intra-Class Correlation (ICC; McGraw and Wong 1996). ICC is frequently adopted in medical studies to assess ordinal annotations provided by experts randomly drawn from a team. Its assumptions align well with our evaluation scheme. We obtained an ICC of 0.8426, which suggests excellent agreement (Cicchetti, 1994; Hallgren, 2012).

We also computed Krippendorff's alpha (Krippendorff, 1970), which is an inter-annotator agreement metric used more commonly in NLP. This metric is suitable for both nominal and ordinal annotations involving multiple annotators. We calculated intercoder reliability of the ordinally-scaled translation quality score as 0.47. Our annotation-level label consistency yielded a score of 0.78 whereas our majority-level label consistency resulted in a score of 0.99. In contrary to the perfect agreement in the majority-level label consistency, the Krippendorff's alpha values of annotation-level

	All	4.51 (0.82)	90.72%	96.73%

Table 3: Translation quality and label consistency of the translations in SNLI-TR and MultiNLI-TR based on expert judgements. For the quality ratings (1–5), we report mean and standard deviation (in parentheses). For label consistency, we report the percentage of labels in SNLI-TR and MultiNLI-TR judged consistent with the original label, both in annotation- and sentence-level.

labels and translation quality scores suggest less overall agreement than our ICC values do, but they are still acceptable, and ICC is arguably the more appropriate metric for our study. Krippendorff's alpha is generally used for large, diverse annotation teams, and its penalties for disagreements are known to be harsh.

Overall, it seems that the very high estimates of translation quality and label consistency of NLI-TR are trustworthy, and only a small percentage of premise–hypothesis have inconsistent semantic labels between their original and translated forms. Still, we would like to better understand why inconsistencies do arise. To this end, we inspected all 49 label-inconsistent pairs in our annotations. We find that low translation quality is the leading source of such errors, which further emphasizes how essential it is to work with high-quality translations.

Of the label-inconsistent pairs with good translations, we find that about 20 probably trace to differing perspectives on how to apply the NLI annotation guidelines. Relatedly, Conneau et al. (2018) find that NLI labels often cannot be completely recovered by different annotators even with no sentence modifications.

Finally, we did find one example of label inconsistency that traces to a subtle difference between the English and Turkish lexicons. In this example, the premise "Your speeches are inflammatory" was translated to Turkish as "Konuşmalarınız çok kışkırtıcı", which can be back-translated as "Your speeches are provocative", while its entailment hypothesis "Your speeches upset people" was translated as "Konuşmaların insanları üzüyor", equivalent to "Your speeches make people sad". Annotators agreed that both of these translations are of maximum quality, but also stated that the Turkish pair should be labeled neutral. As bilingual speakers, we feel that this is essentially correct; the relevant English and Turkish adjectives are subtly different in ways that affect the NLI label. However, such examples seem to be rare and so pose minimal risk for conducting research using NLI-TR.

4 Experiments

4.1 Case Study I: Comparing BERT models on Turkish NLI Datasets

The arrival of pre-trained model-sharing hubs (e.g., Tensorflow Hub,[3] PyTorch Hub,[4] and Hugging Face Hub[5]) has democratized access to Transformer-based models (Vaswani et al., 2017), which are mostly in English. Combined with the abundance of labeled English datasets for fine-tuning, this has increased the performance gap between English and resource-constrained languages.

Here, we use NLI-TR to analyze the effects of pretraining Transformer-based models. We compare three BERT models trained on different corpora by fine-tuning them on NLI-TR. The results quantify the importance of having high-quality, language-specific resources.

4.1.1 Experimental Settings

We compared cased BERT-English (BERT-En), BERT-Multi, and BERTurk (Schweter, 2020). BERT-En is the original BERT-base model released by Devlin et al. (2019), which used an English-only

---

[3] `https://github.com/tensorflow/hub`

[4] `https://pytorch.org/hub`

[5] `https://huggingface.co/models`

corpus for training. BERT-Multi was released by the BERT team as well, and was trained on a corpus containing texts from 104 languages, including Turkish. Schweter's BERTurk also uses the same model architecture and is trained on a Turkish corpus (≈30GB).

We fine-tuned each model on train folds of NLI-TR separately and fixed the maximum sequence length to 128 for all experiments. Similarly, we used a common learning rate of 2×10^{-5} and batch size of 8 with no gradient accumulation. We fine-tuned each model for 3 epochs using HuggingFace's Transformers Library (Wolf et al., 2019). We evaluated the models on the test set of SNLI-TR and the *matched* and *mismatched* dev splits of MultiNLI-TR. Table 4 reports the accuracy of each model on the evaluation sets.

4.1.2 Results

Table 4 demonstrates that NLI-TR can be used to train high quality Turkish NLI models. We observe that every model performed better on the dev and test folds of SNLI-TR than the dev folds of MultiNLI-TR, which is an expected outcome given the greater complexity of MultiNLI compared to SNLI. The translation effort seems to have preserved this fundamental difference between the two datasets.

In addition, BERTurk, which was trained on a Turkish corpus, achieved the highest accuracy, and BERT-Multi, which used a smaller Turkish corpus, was ranked the second, consistently on every evaluation fold. The ranking emphasizes the importance of having a Turkish corpus for pre-training.

4.2 Case Study II: Comparing Morphological Parsers on Turkish NLI Datasets

In this case study, we use NLI-TR to compare three morphological parsers with regular tokenization. We train a BERT model from scratch utilizing each approach for pretraining and use NLI-TR for fine-tuning. This leads to the striking result that morphology adds additional information where training data is sparse, but its importance shrinks as the dataset grows larger.

4.2.1 Experimental Settings

Morphological Parsers We use Zemberek (Akın and Akın, 2007), BOUN (Sak et al., 2011), and Turkish Morphology (Öztürel et al., 2019) as parsers and compare them with an approach that does not do morphological parsing.

Zemberek is a mainstream Turkish NLP library used in research (Büyük, 2020; Kuyumcu et al., 2019; Özer et al., 2018; Can, 2017; Dehkharghani et al., 2016; Gulcehre et al., 2015) and applications such as iOS 12.2 and Open Office. It has 67,755 entries in its lexicon and uses a rule-based parser. BOUN implements the Turkish morphology rules described by Oflazer (1994) with a Finite State Transducer, and its lexicon has 55,278 entries. Finally, Turkish Morphology is an OpenFST-based (Allauzen et al., 2007) morphological parser that was recently released by Google Research and uses a lexicon with 47,202 entries.

Out of the box, Zemberek and BOUN can parse 398K and 51K tokens per minute respectively, whereas Turkish Morphology can process only 1K tokens. We sped up Turkish Morphology to parse 11 times more tokens per minute by implementing a dynamic programming wrapper (Bellman, 1952) that increased the cache hit ratio to 89.9%. This technique is already used by Zemberek.

Pretraining To conduct a wide range of experiments on a limited budget, we opted to use one-tenth (≈4GB, 500M tokens) of the Turkish corpus used by BERTurk (Schweter, 2020) to pretrain BERT models. We analyzed each token morphologically using Zemberek, BOUN, and Turkish Morphology and trained a BERT model using the stems of the tokens only. For the model that does not utilize morphological information, we used tokens as they are. We used the `BertWordPieceTokenizer` class of HuggingFace Tokenizers[6] with the same set of parameters for each model.

We trained each model on a single Tesla V100 GPU of an NVIDIA DGX-1 system, allocating 128GB memory for 1 day. We split the dataset into 30 equal shards for parallel processing, where each shard comprises 1M sentences, and shuffled the shards prior to training to reduce the adverse effects of variance across the sentence styles in the different shards (Goodfellow et al., 2016). We used an effective batch size of 128 with gradient accumulation to address memory limitations.

Fine-tuning We fine-tuned each model on NLI-TR with the same setting as in Section 4.1, with the exception that we trained for only 1 epoch. We measured the accuracy on the evaluation sets

Table 5: Accuracy results for different morphology approaches on NLI-TR. To facilitate running many experiments, these results are for pretraining on just one-tenth of the Turkish corpus used by BERTurk and fine-tuning on NLI-TR for just one epoch.

with an interval of 1,000 training steps to observe the effect of morphological parsing as the dataset grew. Figure 1 reports the accuracy of all models with respect to fine-tuning steps on NLI-TR development sets, and Table 5 shows the final accuracies.

4.2.2 Results

Figure 1 suggests that morphological parsing is beneficial where the training set is small, but its importance largely disappears for large training sets. This is reflected also in the final results in Table 5. We relate this to the fact that BERT models create contextual embeddings of both word and subword tokens (Kudo, 2018; Kudo and Richardson, 2018; Sennrich et al., 2016). Given a sufficiently large dataset, BERT models can approximate the effects of morphological parsing even for Turkish, a morphologically-rich language.

The trends are not uniform for SNLI-TR and MultiNLI-TR. For SNLI-TR, all three models display a similar learning curve, with a slight edge for Zemberek early on. For MultiNLI-TR, models with morphological parsers are more differentiated. However, all three converge to similar performance at the end of training on both datasets (Table 5).

In light of these findings, we suggest avoiding the use of morphological parsers for Turkish NLI where the training set is large, since the benefits of such parsers are generally not enough to offset the cost of running them.

4.3 Case Study III: Evaluating NLI-TR on Human-Translated Sentences

Thus far, we have used NLI-TR for both training and assessment. One might worry that machine-translated test sets are not reliable tools for measuring how models will perform on examples written by humans. In this section, we address this concern using the Turkish dev and test portions of XNLI, which were translated entirely by humans. The models we assess on XNLI are those from our first case study as well as models trained on a different machine-translated training dataset, MultiNLI-TR$^{\text{XNLI}}$. Overall, we find that performance on XNLI is consistently very similar to performance on NLI-TR.

4.3.1 Datasets

MultiNLI-TR$^{\text{XNLI}}$ was created to investigate the performance of cross-lingual sentence embeddings compared to in-language ones (Conneau et al., 2018). It provides machine translations of only the MultiNLI training set, so we report comparisons with just the corresponding section of NLI-TR, and we train models only on these two training sets.

4.3.2 Models

We used the BERT models from Case Study I (Section 4.1) for evaluation. We fine-tuned each model on the training sets of MultiNLI-TR and MultiNLI-TR$^{\text{XNLI}}$ separately, following the same

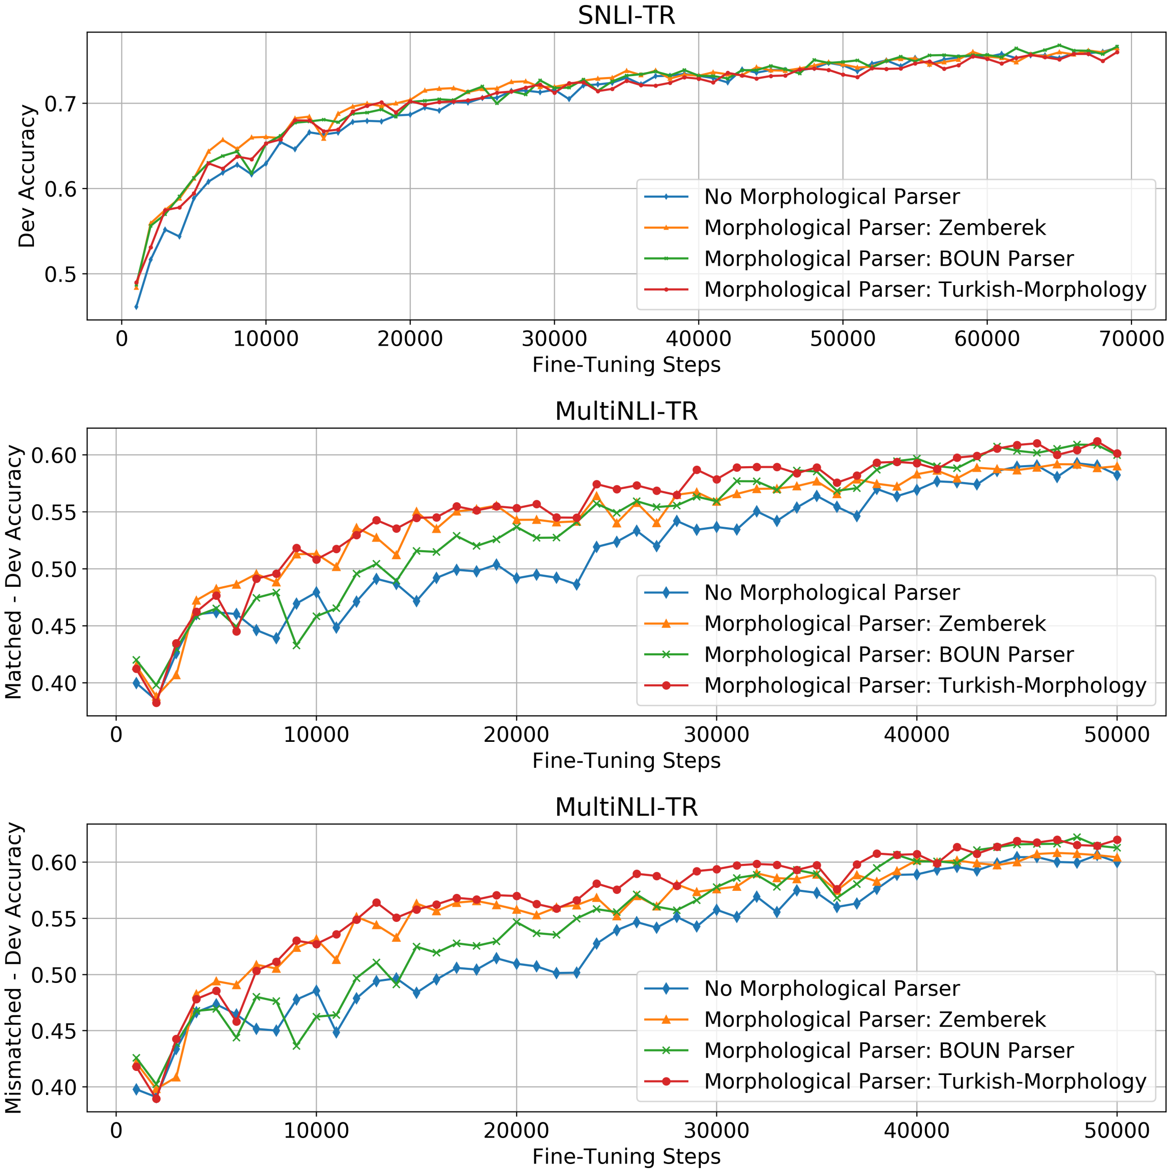

Figure 1: Development set accuracy for the three morphological parsers and a model without morphological parsing. The x-axis tracks the size of the training set. We find that morphological parsing is generally helpful in early rounds, when the training set is very small, but that its importance diminishes as the training set increases. These effects are especially clear for the two MultiNLI-TR dev sets.

fine-tuning steps as in Section 4.1, and computed their accuracy on XNLI-Dev and XNLI-Test.

4.3.3 Results

Table 6 provides the results of the experiments. All three models consistently achieve higher accuracy on XNLI-Dev and XNLI-Test when fine-tuned with MultiNLI-TR, but the performance difference is modest. Table 6 also illustrates that BERTurk, backed by a Turkish-only training corpus, outperforms the other two models on all eight evaluations. Its performance is followed by BERT-Multi, which is trained on a corpus with texts in multiple languages, including Turkish. The same result was also shown in Case Study I using the evaluation splits of NLI-TR. Therefore, machine-translated MultiNLI-TR and human-translated XNLI display similar characteristics across evaluations, which lends further credence to our claim that MT can help provide a viable path to robust Turkish NLI.

To better understand how in-language pretraining (BERTurk) helps, we investigated the 57 hypotheses from XNLI-Dev and XNLI-test where BERTurk was successful and BERT-Multi was

	MultiNLI-TR		MultiNLI-TR$^{\text{XNLI}}$	
Model Name	**XNLI-Dev**	**XNLI-Test**	**XNLI-Dev**	**XNLI-Test**
BERT-En	66.99%	67.74%	65.66%	65.71%
BERT-Multi	73.82%	72.95%	71.61%	71.20%
BERTurk	**76.75%**	**78.72%**	**76.43%**	**76.43%**

Table 6: Accuracy results comparing NLI-TR with another machine translated dataset. NLI-TR performed better, but the gap is modest, suggesting that both datasets have value for Turkish NLI. Figure 2 in our supplementary materials provides full learning curves. The results are very similar to those of Table 4 for MultiNLI, in overall quality and in the ranking of models.

not. For these sentences, we observed that the BERT-Multi tokenizer was often unable to segment the words into meaningful Turkish subword units, most likely due to its training on a multilingual corpus. For instance, BERT-Multi often could not segment the suffix "-me/ma", which negates a verb in Turkish, and thus bears crucial semantics for many contradiction examples (Gururangan et al., 2018). This shows that in-language training is essential not only for good vector representations but also for effective tokenization.

We also hypothesize that subtle lexical distinctions are another factor in the performance difference between BERTurk and BERT-Multi. For example, though BERT-Multi successfully identified the semantic relations created by frequent pairs such as "hiç" ('any') and "hepsi" ('all'), it missed many other distinctions like these. We propose that this is due to the more limited vocabulary of BERT-Multi for Turkish and the more robust word representations in BERTurk.

In addition to manual inspection, we computationally analyzed the pairs where BERT-Multi was unsuccessful and BERTurk was successful. We computed the frequency of each semantic class in the BERT-Multi predictions for these sentences and observed that the neutral class is the most common. This perhaps reflects the fact that neutral is the default choice where the model cannot robustly identify a semantic relation.

5 Conclusion

We created and released the first large Turkish NLI dataset, NLI-TR, by machine translating SNLI and MultiNLI. Though English and Turkish have very different grammars and thus stress-test automatic approaches, our team of experts judged the translations to be of very high quality and to preserve the original NLI labels consistently. These results suggest that MT can help address the paucity of datasets for Turkish NLI. We release code, models, and data publicly for further research.

We also used NLI-TR to investigate central issues in Turkish NLI. First, we used NLI-TR to analyze the effects of in-language pretraining. Second, we compared three morphological parsers for Turkish with simpler tokenization schemes. We found that a Turkish-only pretraining regime can enhance Turkish models significantly, and that morphological parsing is arguably worth its costs only when the training dataset is small. In our final case study, we returned to the general issue of translation quality, but now from the perspective of developing NLI systems. We showed that models trained on MultiNLI-TR perform well on the expert-translated test set from XNLI.

On the basis of these findings, we argue that MT can be more widely adopted for advancing NLP studies on resource-constrained languages. Though language-dependent tasks like dependency parsing are challenging to translate, MT can efficiently transfer large and expensive-to-create labeled datasets from English to other languages in many NLP tasks, including text classification, question answering, and text summarization. In addition, MT will presumably get cheaper, faster, and better over time, thereby further strengthening our core claims.

Acknowledgments

This research was supported by the AWS Cloud Credits for Research Program (formerly AWS Research Grants). E.Budur is thankful for the support provided by The Scientific and Technological Research Council of Turkey (TÜBİTAK) and Council of Higher Education (YÖK) under BİDEB 2214/A and 100/2000 graduate research scholarship programs, respectively. R.Özçelik gratefully acknowledges the graduate research scholarship by TÜBİTAK under BİDEB 2211/A program.

The authors gratefully acknowledge that the computational parts of this study has been mostly performed at Boğaziçi TETAM DGX-1 GPU Cluster and partially carried out at TÜBİTAK ULAKBİM High Performance and Grid Computing Center (TRUBA resources) and Stanford Research Computing Center (FarmShare).

We thank Alara Dirik, Almira Bağlar, Berfu Büyüköz, Berna Erden, Fatih Mehmet Güler, Gökçe Uludoğan, Gözde Aslantaş, Havva Yüksel, Melih Barsbey, Melike Esma İlter, Murat Karademir, Ramazan Pala, Selen Parlar, Tuğçe Ulutuğ, Utku Yavuz for their annotation support and vital contributions. We are grateful also to Stefan Schweter and Kemal Oflazer for sharing the dataset that BERTurk was trained on and Omar Khattab, Dallas Card, Yiwei Luo, and many more researchers including the anonymous reviewers for their valuable advice, discussion and insightful comments.

Abstract

We describe a method for developing broad-coverage semantic dependency parsers for languages for which no semantically annotated resource is available. We leverage a multitask learning framework coupled with annotation projection. We use syntactic parsing as the auxiliary task in our multitask setup. Our annotation projection experiments from English to Czech show that our multitask setup yields 3.1% (4.2%) improvement in labeled F1-score on in-domain (out-of-domain) test set compared to a single-task baseline.

1 Introduction

Broad-coverage semantic dependency parsing (SDP)[1] was first introduced in the SemEval shared task (Oepen et al., 2014) and aims to provide semantic analysis of sentences by capturing semantic relations between all content-bearing words in a sentence. The rich graph structure introduced by SDP allows the model to cover a wide range of semantic phenomena such as negation, comparatives, possessives and various types of modifications that have not been previously analyzed in other models such as semantic role labeling (Baker et al., 1998).

Despite all advantages provided by SDP, resources with annotated semantic dependencies are limited to the three languages released in the SemEval shared tasks (Oepen et al., 2014, 2015; Che et al., 2016) namely English, Czech and Chinese. This data scarcity motivates us to use well-known and traditionally used transfer methods such as *annotation projection* for building SDP models for languages without semantically annotated data. In annotation projection, we assume that we have access to sentence-aligned corpora that can be used for transferring semantic annotations from a rich-resource source language to the target language through word alignment links. Figure 1 shows an example of annotation projection for semantic dependencies.

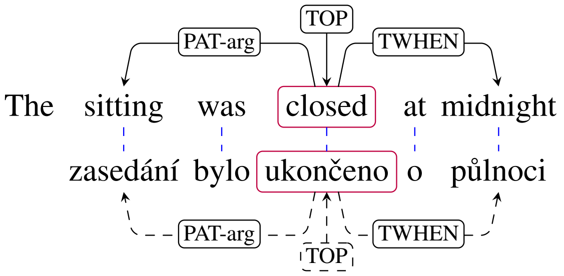

Figure 1: Projecting SDP annotations from an English to a Czech sentence. Semantic dependencies of the English sentence (top) are projected using alignments (dashed lines in the middle) to obtain projected semantic dependencies (bottom) for the target sentence.

Motivated by the large amount of similarities between syntactic and semantic dependencies, we further propose a simple but effective multitask learning framework to leverage supervised syntactic parse information and improve the representation learning capability in the intermediate layers of our semantic parser. Our multitask learning approach, despite its simplicity, yields significant improvements in the performance of the vanilla semantic dependency parser built using annotation projection. We conducted annotation projection experiments from English to Czech. Our experiments show that our multitask setup yields 3.1% and 4.2% improvement in the labeled F1 results on in-domain and out-of-domain evaluation sets respectively. Furthermore, we explore the efficacy of contextualized word representations, BERT (Devlin et al., 2019) and ELMO (Peters et al., 2018) as features in our annotation projection model and find a marginal gain by using those contextual features. To the best of our knowledge, this work is the first study to develop an enhanced semantic depen-

---

November 16–20, 2020.

dency parser through multitasking in the absence of annotated data.

2 Related Work

After the SemEval shared tasks on broad-coverage semantic dependency parsing (Oepen et al., 2014, 2015; Che et al., 2016), there have been many studies to build supervised SDP models (Du et al., 2015; Chen et al., 2018; Almeida and Martins, 2015; Wang et al., 2018; Dozat and Manning, 2018; Stanovsky and Dagan, 2018; Kurita and Søgaard, 2019), however, all efforts were restricted to the three languages released through SemEval shared tasks. There have been extensive number of studies that use annotation projection to cure data scarcity in different tasks such as part-of-speech tagging (Täckström et al., 2013), syntactic parsing (McDonald et al., 2011), semantic role labeling (Padó and Lapata, 2005) and semantic parsing (Hershcovich et al., 2019). Nevertheless, none of the previous works, to the best of our knowledge, looked into using annotation projection for building SDP models for languages without semantically annotated data.

Motivated by the fact that different semantic representations or formalisms cover different aspects of sentence-level semantics, there has been a line of studies to apply multitask learning over different semantic annotations (Peng et al., 2017, 2018; Hershcovich et al., 2018; Kurita and Søgaard, 2019) or target cross-framework meaning representation (Oepen et al., 2019). These studies use the shared semantic information across different representations to enhance the SDP model for a given language, however, none of them addressed the case that no semantically annotated data is available for a language. This paper is the first work that aims to build an SDP model based on cross-lingual transfer without any annotation in the target language of interest.

3 The Parsing Model

For an input sentence $x = x_1, \cdots, x_n$ with n words, the goal of a semantic dependency parsing model is to learn binary dependency decisions $y_{i,j} \in \{0, 1\}$ for every head index $0 \leq i \leq n$ and dependent index $1 \leq j \leq n$, where x_0 is the dummy *root* token. For every head-dependent pair (i, j), such that $y_{i,j} = 1$, the parser finds a label $l_{i,j}$ from a set of predefined semantic dependency labels $\mathcal{L}$. In most cases, the parsing decision is decomposed in two steps: unlabeled dependency parsing, and labeling each dependency edge. The only constraint here is that the final semantic graph should be acyclic.

We use the standard model of Dozat and Manning (2018) for which the parsing model is based on a simple head selection algorithm. This model learns dependency edge scores $s^{\texttt{edge}}(i, j)$ for all possible head-dependent pairs (i, j). The final parsing decision is a sign function:

$$y_{i,j} = \{s^{\texttt{edge}}(i, j) \geq 0\}$$

Similarly, the parser learns a labeling function $s_{\texttt{l}}^{\texttt{label}}(i, j)$ for every pair that $y_{i,j} = 1$:

$$l_{i,j} = \arg\max_{\texttt{l} \in \mathcal{L}} s_l^{\texttt{label}}(i, j)$$

Our parsing model uses a deep neural model in which the first layer is the embedding layer that consists of word, part-of-speech tag, and character representations. The second layer consists of deep bidirectional LSTMs (Hochreiter and Schmidhuber, 1997) that construct recurrent representations r_i for every word. The third layer uses four single-layer feed-forward neural networks (FNN) as attention mechanisms for head and dependent binary decisions and label assignments. The final layer uses a bilinear function to score the FNN outputs. For training the model, the sigmoid cross-entropy function is used for the edges, and the softmax cross-entropy function is used for the labels. The two losses are interpolated to calculate the final loss value with a coefficient $0 < \lambda < 1$.

4 Projecting Semantic Dependencies

For a source sentence $x' = x'_1, \cdots, x'_m$ with m words, and a target sentence $x = x_1, \cdots, x_n$ with n words, we obtain one-to-one alignments by running an unsupervised word alignment algorithm on both directions. We use the intersected alignments $a = a_1, \cdots, a_m$ such that $0 \leq a_i \leq n$ where $a_i = 0$ indicates a `null` or empty alignment. For every source dependency relation $y'_{i,j} \in \{0, 1\}$ where $a_i, a_j \neq 0$, we project the dependency edge and label to the target sentence $y_{a_i,a_j} = y'_{i,j}$ and $l_{a_i,a_j} = l'_{i,j}$ (if $i = 0$ then $a_i = 0$). We then train a supervised parsing model on the projected dependencies. These projected dependencies are usually partial and contain some noise that are caused by different reasons such as translation shifts and alignment errors.

5 Multitask Learning with Syntax

Modeling auxiliary tasks in a multitask learning framework allows the main task to benefit from structural or statistical similarities found in one or more auxiliary tasks to improve the model learned for a target task (Caruana, 1997). Given the large amount of (labeled and unlabeled) correlations existing among syntactic and semantic dependencies, we consider syntactic dependency parsing as the auxiliary task for semantic dependency parsing.

In order to find out the best parameter sharing structure, we try the following parameter sharing variations: 1) sharing embedding and recurrent layers, 2) sharing embedding and recurrent layers with an additional task-specific recurrent layer, 3) sharing all three layers, but with an additional task-specific recurrent layer, and 4) sharing all intermediate layers. Figure 2 shows the first case for which only the first two layers are shared between the two tasks. The overall loss value for the multitask model is computed by interpolating semantic and syntactic losses using an interpolation coefficient ω which is tuned on the development data. We use projected semantic dependencies and syntactic dependency parses generated using a supervised parser to train the multitask model. Thus the training data for the target language has projected semantic annotations plus fully parsed syntactic trees.

6 Experiments and Results

We consider English as the source language and Czech as the target language. We use the SemEval 2015 (Oepen et al., 2015) in-domain and out-of-domain test sets to evaluate our models. Since the PSD (Prague semantic dependencies) annotation is available for both English and Czech, we use that throughout our experiments. We use Giza++ (Och and Ney, 2003) with its default configuration to obtain intersected word alignments on the Europarl parallel corpus (Koehn, 2005). The training data used in our projection experiments is drawn from Europarl which contains text from the political domain. The in-domain Czech test set provided by the SemEval 2015 contains translated texts from corresponding sections of WSJ in the newswire domain, whereas the out-of-domain evaluation set for Czech (also provided by SemEval 2015) is drawn from Prague Dependency Treebank 3.0 (Hajič et al., 2012) which mainly contains text from journals and scientific articles, thus considered of a fairly different domain compared to Europarl (political).

We explore efficacy of multitasking in our annotation projection model by comparing the multitask results with the single-task baseline model that does not use any multitasking. The training corpus of Czech with projected annotations contains 612k sentences but due to computational limitations, we train all models on a sample of 80k sentences[2] randomly selected from original projections. In order to simulate a fully unsupervised approach, we use 5% of the projected data as the held-out data during training.

Parsing Parameters We use the structural skip-gram model of Ling et al. (2015) for English word embeddings and run word2Vec (Mikolov et al., 2013) on Wikipedia text to acquire the word vectors for Czech. We use UDpipe (Straka and Straková, 2017) pretrained models v1.2.0 (trained on the Universal Dependencies v2.0) to produce automatic part-of-speech tags. We train the biaffine dependency parser of Dozat and Manning (2017) on the Universal Dependencies corpus v2.0 (Nivre et al., 2017) to generate supervised syntactic parses in our multitask learning experiments. All modules are implemented using the Dynet library (Neubig et al., 2017).

We mainly use the hyper-parameters used in Dozat and Manning (2018) except that we use a character BiLSTM without any linear transformation layers. We use word and part-of-speech vectors of size 100, with 3-layer LSTMs of size 600, and feed-forward layers of size 600. We use a dropout of probability of 0.2 for words and part-of-speech tags, and 0.25 for the recurrent and unlabeled feed-forward layers, and 0.33 for the labeled feed-forward layers. The interpolation constants λ and ω are set to 0.025 and 0.975 respectively to prioritize the semantic task as our main task in the multitask framework. We use the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 on minibatches of approximately thousand tokens. We also concatenate the contextual vectors to the input layer as additional features to the parser. We use the pretrained ELMO embeddings (Peters et al., 2018) of size 1024 from (Che et al., 2018; Fares et al., 2017). Their model is trained on the set of 20-million-words data randomly sampled from the raw texts released by the CoNLL 2018 shared task for Czech and uses the same model and

Table 1: Results on the Czech SemEval test data. LF and UF denote Labeled and Unlabeled F1 respectively. The Transfer column does not use contextualized word embeddings. *Task RNN* refers to an extra task-specific embedding in the multitask setting. The shaded rows show results on out-of-domain test data.

hyper-parameters as Peters et al. (2018). We use the pretrained multilingual BERT models (Devlin et al., 2019) of size 768 from Xiao (2018) with 12 layers and 12 heads. Due to computational limitations, we only use the pretrained BERT models in the input layer without finetuning.

6.1 Results

Table 1 shows the results on in-domain and out-of-domain data with and without contextual word embeddings. The Single row shows the baseline where we use Czech projection data to train the model. The Multitask rows show the results when we utilize syntactic parses through multitasking. The last column shows results of the supervised model trained on the gold data provided as part of the SemEval 2015 shared task, whereas other columns are trained on the transferred/projected annotations. The + ELMO and + mBERT columns in Table 1 show results when we add ELMO and BERT pretrained embeddings as additional features in the input layer. It is worth emphasizing that the ELMO and BERT embeddings are not cumulative and their results are reported from separate models.

Comparing the labeled F1 scores for different multitask models, we observe that all multitask models outperform the Single baseline, regardless of the architecture used to train the model.

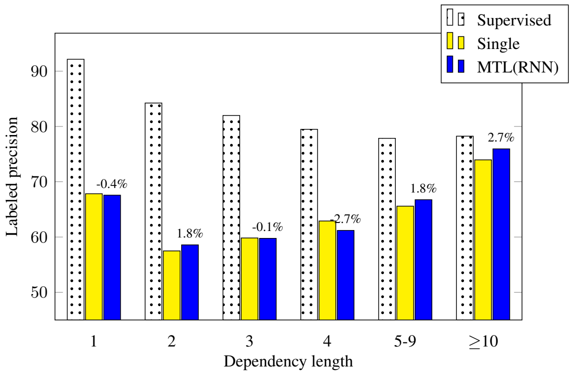

Figure 3: Labeled precision of the best-performing multitask model compared to the single-task and supervised model for different dependency lengths.

We also observe that multitask models yield a larger increase on the out-of-domain test set compared to the in-domain test set which illustrates the particular power of multitask model to improve SDP model in truly low-resource settings where in-domain training data might not be available. As we see in the results, the multitask model with a shared recurrent layer slightly outperforms other models. We also see marginal gains from using the ELMO embeddings, and some gain in unlabeled score in using BERT without seeing improvement in labeled accuracy.

Comparing our results with the supervised model, we observe that multitasking helps the target SDP model obtain closer performance to the supervised model on out-of-domain data which further highlights the power of multitasking for low-resource settings.

Analyzing Different Dependency Lengths We analyze the performance of our best performing multitask model on different semantic dependencies. Figure 3 illustrates labeled precision of the best performing multitask model compared to the single-task and supervised models for different semantic dependency lengths. Length of a dependency is defined as number of tokens located between the semantic head and its dependent. Numbers shown above each plot denotes the improvement obtained from the multitask model compared to the single-task model. Interestingly, the multitask model yields larger improvement on longer semantic dependencies compared to the shorter ones, such that its precision for semantic dependencies with length ≥10 is noticeably close to the supervised results. This finding further highlights the power of syntactic representations in capturing long distance relations which is injected to our model through the shared RNN layer between syntax and semantics.

7 Conclusion

We have described a semantic dependency parsing model based on annotation projection that do not use any annotated semantic data in the target language. We enhance the target semantic model by incorporating syntax in a multitask learning framework. We demonstrate that our multitask model outperforms the single-task model on both in-domain and out-of-domain test sets on the Czech language.

Precise Task Formalization Matters in Winograd Schema Evaluations

Abstract

Performance on the Winograd Schema Challenge (WSC), a respected English commonsense reasoning benchmark, recently rocketed from chance accuracy to 89% on the SuperGLUE leaderboard, with relatively little corroborating evidence of a correspondingly large improvement in reasoning ability. We hypothesize that much of this improvement comes from recent changes in task formalization—the combination of input specification, loss function, and reuse of pretrained parameters—by users of the dataset, rather than improvements in the pretrained model's reasoning ability. We perform an ablation on two Winograd Schema datasets that interpolates between the formalizations used before and after this surge, and find (i) framing the task as multiple choice improves performance by 2-6 points and (ii) several additional techniques, including the reuse of a pretrained language modeling head, can mitigate the model's extreme sensitivity to hyperparameters. We urge future benchmark creators to impose additional structure to minimize the impact of formalization decisions on reported results.

1 Introduction

Over the last couple of years, large pretrained models have achieved human performance on a large share of established natural language understanding benchmark datasets (Devlin et al., 2019). Recent results report a surge in performance to near-human levels on the Winograd Schema Challenge (WSC; Levesque, 2011) in particular(Liu et al., 2019). However, variations in task formulation across papers and evaluations makes it hard to understand the true degree of recent progress.

The WSC is an English commonsense reasoning evaluation that requires a model to resolve carefully-constructed ambiguous pronouns. For example, in the sentence "*Jim yelled at Kevin because* ***he*** *was so upset.*" the reader will likely have to consider the motivation of the query noun phrase (NP) to recognize whether the pronoun ***he*** refers to *Jim*.

The accuracy of WSC has seen an abrupt increase from 64% to 89% on the SuperGLUE (Wang et al., 2019) leaderboard upon the release of RoBERTa (Liu et al., 2019). While many works (Kocijan et al., 2019; Liu et al., 2019; Raffel et al., 2020) attribute such improvements to improved pretraining and the use of auxiliary training datasets, the impact of the task formalization—the combination of input specification, task specific layer design, and loss function—has not yet been seriously studied.

The SuperGLUE WSC baseline with BERT (64%) resolves pronoun references for individual examples by concatenating the pronoun and query NP embeddings and making a binary prediction for the NP span. Meanwhile, RoBERTa (89%) uses a pretrained masked language modeling (MLM) head as part of the output layer and treats the task as a multiple-choice (MC) decision between candidate NPs. We refer to these two task formalizations as pointwise span (**P-Span**) and multiple choice masked language modeling (**MC-MLM**).

In our work, we interpolate between P-Span and MC-MLM using both BERT and RoBERTa to understand tasks' sensitivity to formalization and the components contributing to MC-MLM's improvement. We find MC-MLM outperforms P-Span and reduces sensitivity to hyperparameters and random restarts. We also see large variances of scores spanning random guessing to state-of-the-art (SotA) performance. The biggest gain comes from including MC inference. Further, paired training with query and candidate NPs, using a softmax over candidates, and using a pretrained MLM head all

No MC Evaluation	P-Sent			$-[y \log \mathbb{P}(\text{True} \mid \text{s}) + (1-y) \log \mathbb{P}(\text{False} \mid \text{s})]$	✗	Binary
Predict from Span (SuperGLUE method)	P-Span	`[CLS]` Jim yelled at Kevin because he was so upset. `[SEP]`	`[CLS]`, PRON, NP	$-[y \log \mathbb{P}(\text{True} \mid \text{s}) + (1-y) \log \mathbb{P}(\text{False} \mid \text{s})]$	✗	Binary

Table 1: Overview of the formalizations. When *MC* (multiple choice) is ✓, the model predicts positive if the query NP $\mathbb{P}(\cdot)$ is highest among all candidates; when *MC* is ✗, the model predicts positive if $\mathbb{P}(\cdot) > 0.5$. *Emb* indicates which RoBERTa output layer embeddings are used. In the loss function, y is the index of the correct input when *Label* is *Index* and 0 or 1 when *Label* is *Binary*. *s* is a sequence of input tokens, we use subscript to indicate multiple input sequences. $\delta_{y,i}$ is 1 when $y = i$ i.e. the i-th input is correct and 0 otherwise. In the MC-MLM input example, the underline marks NPs to predict. For P-Span, the underline marks the NP and PRON spans.

lead to reductions in variance. We show that these formalization choices impact performance differences between the BERT and RoBERTa approaches on SuperGLUE WSC, with validation accuracy increasing between P-Span and MC-MLM by 21.1% using RoBERTa and 10.5% using BERT.

The effect of task formalization may incentivize gains from supplemental MC options and aggressive hyperparameter tuning. To avoid this, we suggest future benchmarks impose more structure, such as in this case either explicitly distributing gold candidate NPs or enforcing rules against their use. For system developers, this result highlights the value of fine-tuning pretrained language modeling heads to target tasks in low-resource settings (Raffel et al., 2020), at least where the task format makes this an option.

2 Related Work

WSC Datasets Levesque et al. (2012) launch the WSC with 108 handbuilt question-answer pairs, which has since grown to 273 examples, often called WSC273. Since then, several similar or derived datasets have emerged (Kocijan et al., 2020). The SuperGLUE version of the task recasts examples from WSC273 and the Pronoun Disambiguation Problems dataset (Morgenstern et al., 2016) into 554 training and 104 validation binary classification problems. 146 test examples are derived from fiction books and handcrafted by the original WSC authors. Sakaguchi et al. (2020) collect a larger dataset of fill-in-the-blank-format problems, called WinoGrande, via crowdsourcing with adversarial filtering. The dataset has five training sets, ranging from 160 to 41k examples, and shared validation and test sets with 1.3k and 1.8k examples, respectively.

Approaches Trinh and Le (2018) generate inputs for their recurrent neural network language model by replacing the PRON with either the query or candidate NP and compare the probability of the two sentences, yielding 64% accuracy on WSC273. Radford et al. (2019) use this method with a transformer language model, boosting accuracy to 71%. Ruan et al. (2019) fine-tune BERT in a similar way, reaching 71% as well. Kocijan et al. (2019) also use BERT, but include additional Winograd-like training data and use the model's pretrained MLM head to achieve 74% accuracy. In another style of approach, Klein and Nabi (2019) experiment with BERT pretrained *attention* weights without fine-tuning, and achieve an accuracy of 60%.

For SuperGLUE WSC, the official baseline uses BERT and a linear classifier on BERT's output embeddings for the `[CLS]` token, pronoun token, and query NP span representations but fail to exceed the majority-class baseline, only matching it at 64%. Liu et al. (2019) use the newer RoBERTa and adapt the Kocijan et al. (2019) approach with cross entropy loss to raise this accuracy to 89%. T5 (Raffel et al., 2020) marks the pronoun in the input and fine-tune a transformer encoder-decoder model to generate the target NP, achieving the current state of the art at 94%.

Looking to WinoGrande, Sakaguchi et al. (2020) adapt Ruan et al. (2019)'s method with RoBERTa as the baseline model, achieving 68% accuracy on WinoGrande-Medium and 79% accuracy on the full test set.

3 Methods under Study

We evaluate six formalizations—three existing ones and three that we introduce—to interpolate between P-Span and MC-MLM. These all use an output layer on top of an MLM pretrained transformer model, but differ in the input specification, loss function, prediction method, contextual embeddings used by the output layer, and label type. Table 1 presents an overview.

MC-MLM This approach follows that of Liu et al. (2019) in the introduction of RoBERTa. Here, the pronoun in the input is replaced by `[MASK]`. The model then uses its pretrained MLM head to evaluate the probability NP_i should replace `[MASK]` and uses a softmax over the log probabilities. For multi-token NPs the model compares the *geometric mean* of these probabilities.

MC-Sent This approach follows the WinoGrande baselines. Here, we specify the inputs by replacing the pronoun with an NP candidate and marking it with an additional `[SEP]` token. The output head feeds each option's `[CLS]` embedding into a linear layer and applies a softmax over the outputs. MC-Sent trains a linear layer from scratch, while MC-MLM may take advantage of the embedding model's MLM pretraining.

MC-Sent-NoSoftmax MC-Sent-NoSoftmax only differs from MC-Sent by replacing the final softmax with a sigmoid and computes the probabilities of whether each input sequence is correct. Without softmax, MC-Sent-NoSoftmax is unable to provide larger gradients for examples with smaller margins between candidates. We refer to this as softmax scaling.

MC-Sent-NoPairLoss MC-Sent-NoPairLoss and MC-Sent-NoSoftmax differ by loss function, where MC-Sent-NoPairLoss only considers the query input. MC-Sent-NoPairLoss is unable to use gradients from multiple candidates to neutralize signals from shared words and focus on NP options. We refer to this as paired training.

P-Sent In P-Sent, we further remove *MC evaluation* by restricting the model to a single binary classification question. This forces P-Sent to resolve pronoun references without implicitly learning to detect and eliminate NPs.

P-Span Instead of replacing PRON with NPs to determine the validity of the input sentence, P-Span follows the SuperGLUE baseline to determine whether the NP reference is correct. It first averages over the representations from the PRON and NP spans to create span representations. The span representations are then concatenated with the `[CLS]` token embedding and used by a logistic regression classifier.

4 Experiments

Implementation Our code[1] builds on Huggingface Transformers (Wolf et al., 2019) and fairseq (Ott et al., 2019). All our experiments use either pretrained RoBERTa-large or BERT-large-cased models. We evaluate on the validation set every epoch with early stopping. We conduct a random hyperparameter search of 60 trials over the space of learning rate {1e-5, 2e-5, 3e-5}, epoch limit {10, 20, 40}, batch size {8, 16, 32, 64}, and random seed.

Datasets We run experiments on SuperGLUE WSC and WinoGrande-Medium. We do not cover larger WinoGrande sizes due to computation constraints. Each WSC example includes a sentence, a PRON span, and a *single* marked NP span. Following Liu et al., for MC-based formalizations, we mine candidate NPs with spaCy[2] and only keep one example from the group of examples that only differ by query NP to avoid redundancy.

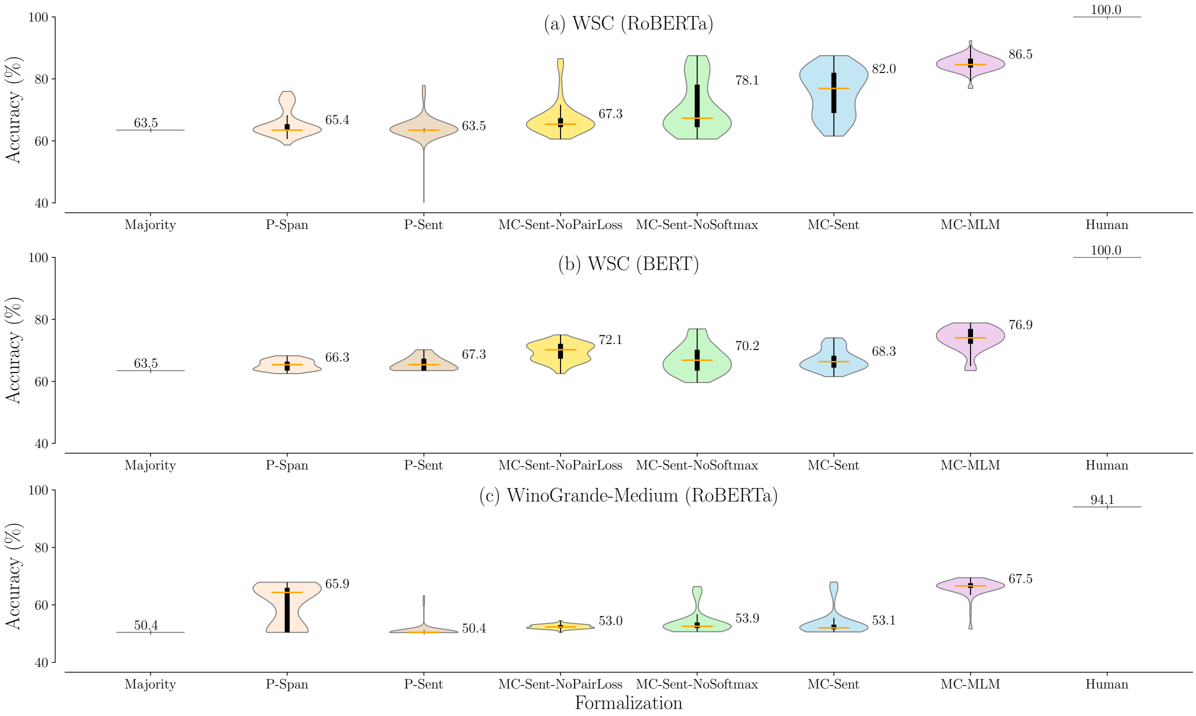

Figure 1: Plots of validation accuracy from 60 runs on each corpus. The orange line marks the median number and label marks 75th percentiles.

		WSC		WinoGrande	
Formalization	Test	Std	Kurt	Std	Kurt
MC-MLM	86	2	3	3	13
MC-Sent	77	7	-1	5	4
MC-Sent-NoSoftmax	77	8	-1	4	3
MC-Sent-NoPairLoss	86	6	5	1	1
P-Sent	67	5	24	2	28
P-Span	80	4	0	7	-2

Table 2: Validation accuracy standard deviation (*Std*) and excess kurtosis (*Kurt*) for WSC and WinoGrande and test accuracy for WSC using RoBERTa. Test results are from an ensemble of the top five models.

For WinoGrande, each example provides a sentence with two marked NP spans and a fill-in-the-blank to represent the PRON. When using asymmetric formalizations like P-Sent, we duplicate each example, making one option the query and the other the candidate. For P-Span, we use the first appearance of query or candidate NP in the sentence as the NP span and use the blank as PRON span.

RoBERTa Results Figures 1a and 1c and Table 2 show the distribution over validation accuracies from 60 runs with each formalization using RoBERTa. We do not report WinoGrande test results since submissions require test set predictions from all five training sets and we only train using WinoGrande-Medium. We also include the majority-class baseline and human performance. From the WSC test results, we find MC-MLM outperforms P-Span. The 6% gain between P-Sent and MC-Sent-NoPairLoss indicates MC evaluation alone may improve accuracy. However, we also find most formalizations are sensitive to hyperparameter choices and random seeds. Given the small size of the SuperGLUE WSC test set at 146 examples, we find it more informative to focus on the distribution of validation results.

In both datasets, we see three main changes. First, including paired training with MC-Sent-NoSoftmax increases performance variance by adding more weight to the tail of higher scores. Second, we see the weight of higher performances increase even more with softmax scaling in MC-Sent. In WSC, the higher scores become the body of the distribution with smaller variance. In WinoGrande, the distribution of MC-Sent has an increased excess kurtosis indicating the tail of higher scores occur more frequently. Finally, the model achieves higher scores with significantly lower variance using MLM in MC-MLM. This may be a result of fine-tuning the pretrained MLM head rather than a new initialization.

We see two main differences between WSC and

WinoGrande results. First, P-Sent performs significantly worse than P-Span on WinoGrande. We suspect this is due to WinoGrande's adversarial filtering removing examples that are easy to classify from sentence representations. Second, MC-Sent-NoPairLoss does not benefit WinoGrande and may indicate the benefit from MC evaluation may not extend to other Winograd like corpora.

BERT Results Figure 1b shows ablation results using BERT and WSC. We find that RoBERTa outperforms BERT with both models using the same MC-MLM formalization, which is in line with leaderboard performances. We also find similar trends across task formalizations in Figure 1a, further highlighting the impact of formalization decisions on performance gains. Most formalizations are still sensitive to hyperparameter choices and random seed, MC evaluation alone provides a benefit over P-Span at the 75th percentile of roughly 6%, and incorporating MLM provides additional benefits in performance.

However, we also find that using BERT's pretrained MLM head does not provide the lower variance displayed with RoBERTa. Comparing the performances of intermediate formalizations, we see that BERT generally performs worse than RoBERTa. This is consistent with the findings from Tenney et al. (2019) that show BERT embeddings encode information less suited for coreference resolution during pretraining. Consequently, BERT's pretrained MLM head would be less optimized for a coreference resolution task like WSC than RoBERTa's and may not provide the same stability benefits.

5 Conclusion

By only varying task formalization, we observe a wide range of results among reasonable task formalizations on WSC and WinoGrande evaluations. Having access to candidate NPs during inference alone improves the performance on SuperGLUE WSC. However, models with MC evaluation are highly sensitive to hyperparameters and fail to perform better on WinoGrande. We find training with paired inputs, using a softmax over candidates, and reusing a pretrained MLM head all help to learn commonsense reasoning and reduce this sensitivity. While we find evidence that these formalization choices can largely influence WSC performance, we do not see obvious evidence of similar occurrences on other task comparisons with RoBERTa.

For MC formalizations, we follow Liu et al. for WSC and use spaCy to mine candidate NPs. This extrinsic preprocessing step yields dramatic gains without significantly changing the reasoning ability of the model. We view such gains as orthogonal to the intent of the task and urge benchmark creators to minimize the opportunity for these insubstantial improvements by imposing as much structure as is possible in the released data, for example, by providing candidate NPs explicitly.

We also encourage future reports of system performances to use the same task formalization whenever possible. At a minimum, greater emphasis should be given to task formalization decisions when they deviate from the prevailing standard. We believe this will help disentangle gains due to models' reasoning abilities, especially in situations where these decisions significantly impact performance, such as in WSC.

Finally, we find that differences between reasonable formalizations can have big impacts on performance with our case study using WSC. For example, using a pretrained MLM task head as the basis for a downstream task classifier yields strong results with very little hyperparameter sensitivity. This echoes the strong results seen with T5 and offers further motivation to explore these kinds of design decisions in other tasks.

Abstract

Natural Language Inference (NLI) datasets contain annotation artefacts resulting in spurious correlations between the natural language utterances and their respective entailment classes. These artefacts are exploited by neural networks even when only considering the hypothesis and ignoring the premise, leading to unwanted biases. Belinkov et al. (2019b) proposed tackling this problem via adversarial training, but this can lead to learned sentence representations that still suffer from the same biases. We show that the bias can be reduced in the sentence representations by using an ensemble of adversaries, encouraging the model to jointly decrease the accuracy of these different adversaries while fitting the data. This approach produces more robust NLI models, outperforming previous de-biasing efforts when generalised to 12 other NLI datasets (Belinkov et al., 2019a; Mahabadi et al., 2020). In addition, we find that the optimal number of adversarial classifiers depends on the dimensionality of the sentence representations, with larger sentence representations being more difficult to de-bias while benefiting from using a greater number of adversaries.

1 Introduction

NLI datasets are known to contain artefacts associated with their human annotation processes (Gururangan et al., 2018). Neural models are particularly prone to picking up on artefacts, relying on these biases and spurious correlations rather than acquiring a true understanding of the task. Because these artefacts are often dataset specific (Poliak et al., 2018; Tsuchiya, 2018), models that rely on these artefacts consequently generalise poorly when tested on other datasets (Belinkov et al., 2019a).

One way to alleviate this problem is via *adversarial training*: the task classifier and an adversarial classifier jointly share an encoder, with the adversarial classifier trained to produce the correct predictions by analysing the artefacts in the training data. The encoder optimises the training objective while also reducing the performance of the adversarial classifier. In this context, adversarial training aims to produce sentence representations that do not incorporate information about the artefacts (or *bias*) in the data, resulting in less biased models that generalise better.

Previous studies show that adversarial training is associated with better generalisation performance across other datasets, although there are concerns that the biases are not removed from the model sentence representations, with classifiers able to relearn such biases from the representations after these are frozen (Belinkov et al., 2019b; Elazar and Goldberg, 2018). It is therefore unclear whether any improvements are as a result of the de-biasing, and whether actually removing these biases from the model representations will further improve generalisation. We focus our effort on this discrepancy and argue that, in order to show de-biasing is effective, improvements in performance should also correspond to an observed reduction of the bias in the model representations, therefore creating representations that generalise better to other data.

In this paper we show that NLI models can avoid learning from the hypothesis-only bias, using an *ensemble of adversarial classifiers* to prevent the bias being relearnt from a model's representations. Furthermore, we show that the more bias is removed from the model representations, the better these models generalise to other NLI datasets. Removing the bias from the representations proves to be a highly effective strategy, producing more robust NLI models that outperform previous de-biasing efforts when tested on 12 different NLI datasets (Belinkov et al., 2019a; Mahabadi et al., 2020). In addition, we show that the ability to de-bias a sentence representation depends on its dimensionality, with large sentence representations being harder to de-bias and requiring more adversarial classifiers

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8281–8291,
November 16–20, 2020.

during training.

In summary, this paper makes the following core contributions: *i)* We investigate whether using an ensemble of adversarial classifiers can remove the hypothesis-only bias within NLI models. For large enough dimensions, this method achieves a statistically significant reduction of the bias. *ii)* We test whether removing more of the bias improves how well the model generalises. Our method improves model accuracy across 12 NLI datasets and outperforms previous research (Belinkov et al., 2019a; Mahabadi et al., 2020). *iii)* We inspect the optimal number of adversaries to use depending on the dimensionality of the sentence representations. We find that as this dimensionality is increased, more adversaries are required to de-bias a model. *iv)* We compare the effect of adversarial training with a linear classifier to using a non-linear multi-layer perceptron as the adversary, showing that using a more complex adversarial classifier is not always beneficial. Instead, the best choice of adversary depends on the classifier being used to relearn the bias. [1]

2 Related Work

The Hypothesis-Only Bias Gururangan et al. (2018) and Tsuchiya (2018) demonstrate how models can predict the class within the SNLI dataset when only processing the hypothesis, reaching accuracy scores as high as twice the majority baseline (67% vs. 34%). This is possible due to hypothesis-only biases, such as the observation that negation words ("no" or "never") are more commonly used in contradicting hypotheses (Gururangan et al., 2018; Poliak et al., 2018). The hypothesis sentence length is another example of an artefact that models can learn from, with entailment hypotheses being, on average, shorter than either contradiction or neutral hypotheses (Gururangan et al., 2018).

Tsuchiya (2018) show that the hypothesis-only bias predictions are significantly better than the majority baseline for SNLI, although this is not the case for the SICK dataset (Marelli et al., 2014). Poliak et al. (2018) find that human-elicited datasets such as SNLI and MultiNLI have the largest hypothesis-only bias. As a result, our paper focuses on removing the hypothesis-only bias from SNLI, the dataset with the largest hypothesis-only bias reported by Poliak et al. (2018). This bias is also dataset specific, with Belinkov et al. (2019a) finding that only MultiNLI shares some of the same hypothesis-only bias as the SNLI dataset.

Generalisation to Other Datasets Bowman et al. (2015) and Williams et al. (2018) show that models trained on the SNLI and MultiNLI datasets do not necessarily learn good representations for other NLI datasets, such as SICK. Analogous results were also reported by Talman and Chatzikyriakidis (2018) for more complex models. Gururangan et al. (2018) and Tsuchiya (2018) identify how NLI models perform worse on *hard* examples, which are defined as the examples that a hypothesis-only model has misclassified. This suggests that the success of NLI models may be overstated, with models relying on artefacts in their training data to achieve high performance (Gururangan et al., 2018). Our paper will assess whether NLI models that no longer learn from the hypothesis-only bias can still retain this high level of accuracy.

Biases and Artefacts SNLI and MultiNLI are not the only datasets that suffer from the presence of annotation artefacts and biases. In the past, machine reading datasets were also found to contain syntactic clues that were giving away the correct prediction (Vanderwende and Dolan, 2005; Snow et al., 2006). For instance, Kaushik and Lipton (2018) show that, in several reading comprehension datasets such as bAbI (Weston et al., 2016) and Children's Books Test (Hill et al., 2016), it is possible to get non-trivial results by considering only the last passage of the paragraph. In visual question answering datasets, several studies find it is often possible to answer the question without looking at the corresponding image (Zhang et al., 2016; Kafle and Kanan, 2016; Goyal et al., 2017; Agrawal et al., 2018). Similarly, for the ROCStories corpus (Mostafazadeh et al., 2016), Schwartz et al. (2017) and Cai et al. (2017) show it is possible to achieve non-trivial prediction accuracy by only considering candidate endings and without taking the stories in account. The de-biasing approach introduced in this paper could be applied in any of these situations where a model involves a classifier based on latent representations.

Learning Robust Models Neural models are known to be vulnerable to so-called *adversarial examples*, *i.e.* instances explicitly crafted by an adversary to cause the model to make a mistake (Szegedy et al., 2014). Most recent work focuses on sim-

---

[1] `https://github.com/joestacey/robust-nli`

ple semantic-invariant transformations, showing that neural models can be overly sensitive to small modifications of the inputs and paraphrasing. For instance, Ribeiro et al. (2018) use a set of simple syntactic changes, such as replacing *What is* with *What's*. Other semantics-preserving perturbations include typos (Hosseini et al., 2017), the addition of distracting sentences (Wang and Bansal, 2018; Jia and Liang, 2017), character-level perturbations (Ebrahimi et al., 2018), and paraphrasing (Iyyer et al., 2018). Minervini and Riedel (2018) propose searching for violations of constraints, such as the symmetry of *contradiction* and transitivity of *entailment*, for identifying where NLI models make mistakes and then creating more robust models by training on these adversarial examples. Alternatively, Clark et al. (2019), He et al. (2019) and Mahabadi et al. (2020) create naive models that make predictions based on known dataset biases, and then train robust models in an ensemble with the naive models to focus on other patterns in the data that generalise better.

Adversarial Training Another procedure for creating more robust models is through adversarial training with latent representations, with a classifier trained to learn the bias from the model sentence representations which in turn update to reduce the performance of the bias classifier (Wang et al., 2019). For example, Ganin and Lempitsky (2015) use adversarial training to improve domain adaption, allowing models to learn features helpful for the model task but which are also invariant with respect to changes in the domain. This was achieved by jointly training two models, one to predict the class label and one to predict the domain, and then regularising the former model to decrease the accuracy of the latter via gradient reversal.

Belinkov et al. (2019b) use adversarial training to remove the hypothesis-only bias from models trained on SNLI. While this approach produced models that generalised better to other datasets, these same models show degraded performance on SNLI-hard (Belinkov et al., 2019a), which is supposedly the ideal dataset to test for generalisation as it resembles SNLI the most in terms of domain and style while lacking the examples with the largest bias (Gururangan et al., 2018). Moreover, the bias is not removed from the model sentence representations and can be almost fully recovered if these representations stop updating (Belinkov et al., 2019b). It is therefore unclear whether any improvements are caused by de-biasing, or are instead a result of perturbations from the adversarial training procedure. Similarly, Elazar and Goldberg (2018) find that adversarial training and gradient reversal does not remove demographic information such as age or gender, with this information still present in the de-biased sentence representations. Here, we propose using an ensemble of multiple adversaries to avoid the hypothesis-only bias, significantly reducing the bias stored within a model's representations and outperforming previous de-biasing research efforts when testing model generalisation.

Using Model Ensembles Grefenstette et al. (2018) find that using ensembles of models is a better use of computational budget when training from adversarial examples compared to using a larger model with more parameters. Elazar and Goldberg (2018) show that using an ensemble of up to 5 adversarial classifiers helped remove demographic information contained within Twitter messages, however beyond this they were not able to re-learn the main task. Mahabadi et al. (2020) provide further support for using model ensembles after implementing a Product of Experts approach with multiple hypothesis-only models, producing more robust NLI models despite not attempting to remove the bias from the underlying representations. We compare our results with Mahabadi et al. (2020) to quantify the benefits of removing the bias from the sentence representations.

3 Ensemble Adversarial Training

We follow an adversarial training approach for reducing the hypothesis-only bias contained within the sentence representations. Specifically, we generalise the adversarial training framework proposed by Belinkov et al. (2019a) to make use of *multiple adversaries*: n hypothesis-only adversaries are jointly trained for predicting the relationship between the premise and hypothesis given only the representation of the hypothesis from the sentence encoder. At the same time, the sentence encoder together with an hypothesis-premise model are jointly trained to fit the training data, while decreasing the accuracy of these adversaries. Formally, given a hypothesis $\mathbf{h}$ and a premise $\mathbf{p}$, the predictions of the hypothesis-premise model $\hat{y}$ and the i-th hypothesis-only adversary $\hat{y}_{a_i}$ can be formalised as follows:

$$\begin{aligned}\mathbf{e}_h &= \text{encoder}_{\theta_e}(\mathbf{h}), \quad \mathbf{e}_h \in \mathbb{R}^k\\ \mathbf{e}_p &= \text{encoder}_{\theta_e}(\mathbf{p}), \quad \mathbf{e}_p \in \mathbb{R}^k\\ \hat{y} &= \text{MLP}_{\theta_c}\left([\mathbf{e}_h; \mathbf{e}_p; \mathbf{e}_h - \mathbf{e}_p; \mathbf{e}_h \odot \mathbf{e}_p]\right)\\ \hat{y}_{a_i} &= \text{MLP}_{\theta_{a_i}}\left(\mathbf{e}_h\right),\end{aligned}$$

where $\hat{y}, \hat{y}_{a_i} \in \mathbb{R}^3$ are (unnormalised) score distributions over the three NLI classes, *i.e. entailment*, *contradiction*, and *neutral*, and $\theta_e, \theta_c, \theta_{a_i}$ respectively denote the parameters of the encoder, the hypothesis-premise model, and the i-th hypothesis-only adversary. The adversarial training procedure can be formalised as optimising the following *minimax objective*:

$$\begin{aligned}\min_{\theta_e,\theta_c} \max_{\theta_a} \sum_{\langle \mathbf{h},\mathbf{p},y\rangle \in \mathcal{D}} (1-\lambda)\mathcal{L}_{ce}(y,\hat{y})\\ -\frac{\lambda}{n}\sum_{i=1}^{n}\mathcal{L}_{ce}(y,\hat{y}_{a_i}),\end{aligned} \tag{1}$$

where $\mathcal{D}$ is a dataset, and $\mathcal{L}_{ce}$ denotes the cross-entropy loss (Goodfellow et al., 2016), and $n \in \mathbb{N}_+$ is the number of adversaries. The hyperparameter $\lambda \in [0, 1]$ denotes the trade-off between the losses of the hypothesis-premise model and the hypothesis-only adversaries. Similarly to Belinkov et al. (2019a), we optimise the minimax objective in Eq. (1) using gradient reversal (Ganin and Lempitsky, 2015), which leads to an optimisation procedure equivalent to the popular gradient descent ascent algorithm (Lin et al., 2019). The gradient reversal multiplies the gradient from the adversarial classifiers by a negative constant, training the encoder to reduce the performance of these classifiers.

To test the impact of using multiple adversarial classifiers when changing the dimensionality of the representations, we train with $\{1, 5, 10, 20\}$ bias classifiers for $\{256, 512, 1024, 2048\}$ dimensional sentence representations. The learned sentence representation is then frozen, and 20 adversarial classifiers are randomly reinitialised before they attempt to re-learn the hypothesis-only bias from the frozen de-biased sentence representation. The maximum accuracy from across the 20 adversarial classifiers is then reported after trying to remove the bias, showing the maximum bias that can still be learnt from the representation.

The ability of adversarially trained models to de-bias sentence representations is tested across a range of λ hyper-parameters $\{0.001, 0.01, 0.1, 0.2, 0.3, ...0.8, 0.9, 0.99, 0.999\}$. This shows whether any improvement is due to the choice of λ, or whether there is an improvement regardless.

Model Architecture Following the same experimental set-up as Belinkov et al. (2019a) and Poliak et al. (2018), we use an InferSent model (Conneau et al., 2017) with pretrained GloVe 300-dimensional word embeddings. The InferSent model architecture consists of a Long Short-Term Memory network (LSTM, Hochreiter and Schmidhuber, 1997) encoder which creates a 2048 dimensional sentence representation.

3.1 Significance Testing

We perform statistical testing to assess whether the differences between using one or five adversarial classifiers is significant. This involves repeating the experiments for both one and five adversarial classifiers with ten different random seeds. For each experiment, the de-biasing is performed before a classifier attempts to learn the bias again from the frozen sentence representations.

We use bootstrapping hypothesis testing (Efron and Tibshirani, 1993) to test the statistical significance by comparing the means from the two samples. We also provide p-values from a Mann Whitney U-test (Mann and Whitney, 1947). The bootstrapping considers the null hypothesis that there is no difference between the mean bias re-learnt from using five adversarial classifiers compared to just using one adversarial classifier. In addition, we use a Bonferroni correction factor (Shaffer, 1995) of four when evaluating the p-values, taking into account multiple hypothesis testing across each different dimension. P-values smaller than 0.05 are considered significant.

3.2 Using Deeper Adversaries

We also investigate using a multi-layer perceptron as a more complex adversarial classifier to understand whether the bias that can be re-learnt depends on the type of classifier used. The experiments are repeated using non-linear classifiers instead of linear classifiers, both during the adversarial training and also afterwards when the classifiers try to re-learn the biases from the frozen representations. In addition to testing 2048 dimensions using ten adversaries, a 512 dimensional representation is also tested using a smaller number of adversaries (five).

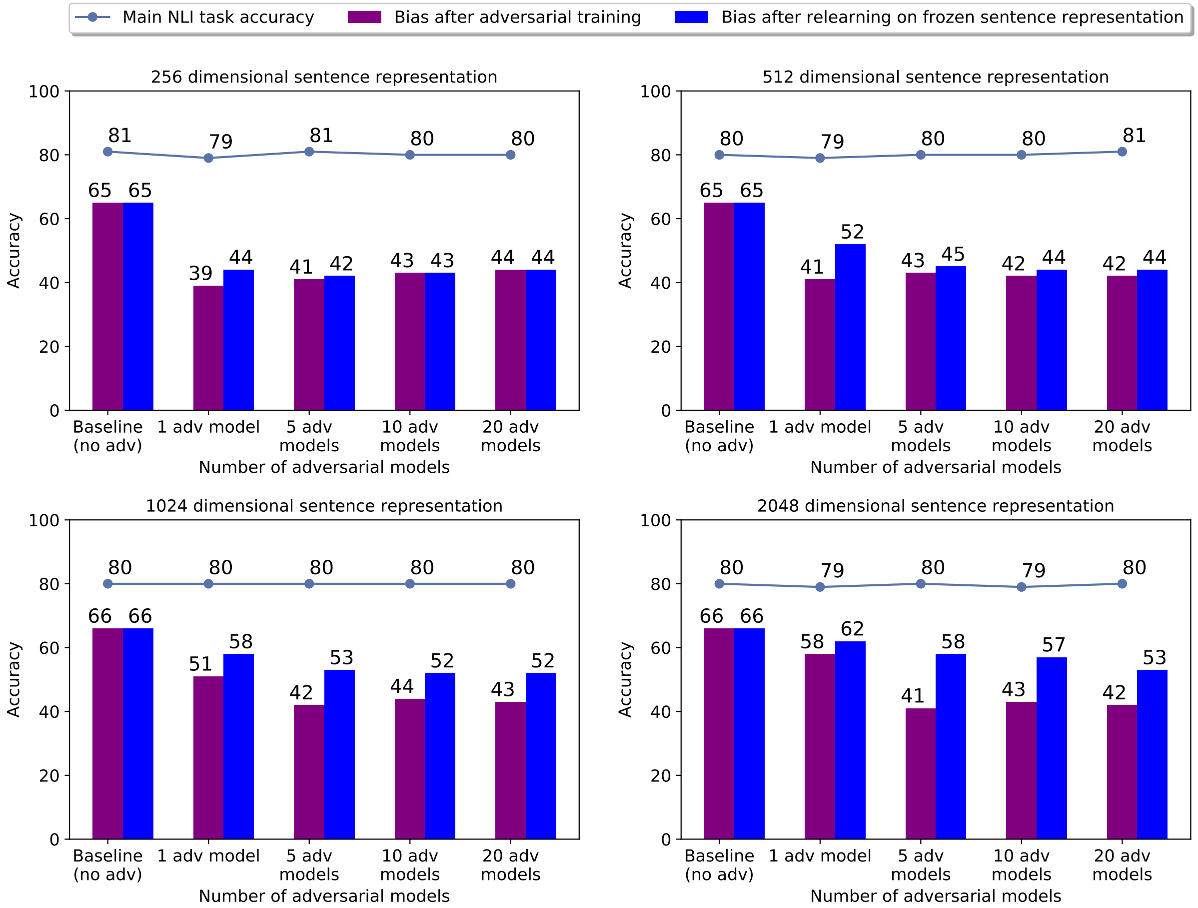

Figure 1: The maximum bias classifier accuracy after the bias is re-learnt from the frozen de-biased representations (in blue), compared to the accuracy of an independent bias classifier (not an adversary) at the end of the adversarial training (in purple). The main NLI task accuracy is also displayed.

We perform the experiments with three scenarios: *i)* Using the non-linear classifiers during the adversarial training, but not afterwards, and instead trying to re-learn the bias with a linear classifier. *ii)* Using linear classifiers during the adversarial training but then non-linear classifiers are used to try to re-learn the biases after the sentence representation is frozen. *iii)* Finally, non-linear classifiers are used both during adversarial training and afterwards when trying to re-learn the biases from the frozen sentence representation. The non-linear multi-layer perceptron classifier consists of three linear layers, and two non-linear layers using $\tanh$.

3.3 Evaluating De-biased Sentence Encoders

After training the models on SNLI with adversarial training, we test these de-biased models on a range of different datasets to see whether they generalise better. The performance of the de-biased models is compared to a baseline model trained on SNLI where no adversarial training has been performed.

By using different random seeds, we compare ten baseline SNLI-trained models with models using one adversary and 20 adversaries, with each of these models tested on SNLI-hard. We perform bootstrap hypothesis testing to understand whether there is a significant difference between using one adversary and the baseline models with no adversarial training. We have repeated this hypothesis testing to compare models de-biased using 20 adversaries to the baseline models.

Additionally, we evaluate the de-biased models on 12 different datasets to understand whether models trained with an ensemble of adversaries perform better than the baseline and models trained with one adversary. The datasets in these experiments are the same datasets tested by Belinkov et al. (2019a): ADD-ONE-RTE (Pavlick and Callison-Burch, 2016), GLUE (Wang et al., 2018), JOCI (Zhang et al., 2017), MNLI (Williams et al., 2018), MPE (Lai et al., 2017), SCITAIL (Khot et al., 2018), SICK (Marelli et al., 2014), SNLI-

Dimensions	Number of adversaries **0**	**1**	**5**	**10**	**20**
256	65	44	**42**	43	44
512	65	52	45	**44**	**44**
1,028	66	58	53	**52**	**52**
2,048	66	62	58	57	**53**

Table 1: Maximum accuracy (%) from 20 bias classifiers when re-learning the hypothesis-only bias from the frozen de-biased sentence representation. The lowest accuracy figure for each dimension is highlighted, after testing 0, 1, 5, 10 and 20 adversaries.

hard (Gururangan et al., 2018), and three datasets recast by White et al. (2017): DPR (Rahman and Ng, 2012), FN+ (Pavlick et al., 2015) and SPR (Reisinger et al., 2015).

While the previous results in this paper use an LSTM encoder, a bidirectional LSTM has been used when testing other datasets to ensure the experiments are a like-for-like comparison with Belinkov et al. (2019a). We select the hyper-parameters that yield the highest accuracy on a validation set, in line with the experiments conducted by Belinkov et al. (2019a). Finally, the model results are compared to the Product of Experts (PoE) de-biasing approach proposed by Mahabadi et al. (2020).

4 Results

We use an ensemble of multiple adversarial classifiers during model training to understand whether it is possible to reduce the bias within the model sentence representations. Our results show that training a model with an ensemble of adversaries does reduce the model bias, doing so across each dimensionality of sentence representations tested. Moreover, more adversaries are required for de-biasing larger dimensional sentence representations.

When using just one adversarial classifier for a 2,048 dimensional sentence representation, after the representation was frozen and the bias classifiers had a chance to re-learn the hypothesis-only bias, the accuracy of the bias classifiers increased to 62% (see Table 1). This result mirrors the findings of Belinkov et al. (2019b), where using one adversarial classifier does not remove the bias from the model sentence representations. We additionally show that an independent bias classifier can still reach 58% accuracy at the end of the adversarial training, without needing to freeze the representation in order to relearn the bias (see Fig. 1).

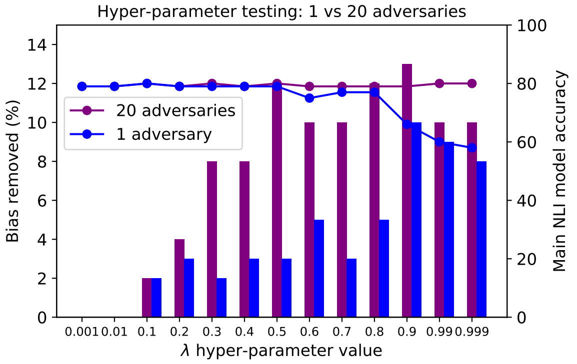

Figure 2: The fall in accuracy of hypothesis-only classifiers when using 1 or 20 adversaries to remove the hypothesis-only bias (compared to a baseline with no adversaries). This is shown alongside the overall accuracy of the de-biased NLI models.

For 2,048 dimensional sentence representations, as the number of adversaries are increased up to 20, less bias can be found in the resulting de-biased sentence representation. When the number of adversarial classifiers are increased from 1 to 20, the accuracy of the hypothesis-only bias classifiers reduces from 62% to 53% (see Table 1).

The higher the dimensionality of the sentence representation, the more difficult it is to remove its bias. Additionally, the optimal number of adversarial classifiers depends on the dimensionality of the representations, with more adversaries required for higher dimensions. For 2,048 dimensions this is 20 adversaries, while for 256 dimensions this reduces to 5 adversaries (see Table 1). For 256, 512 and 1,028 dimensions, the improvements plateau after a set number of adversaries, and therefore scaling up the number of adversaries beyond 20 is unlikely to lead to further improvements.

The improvements in de-biasing when using an ensemble of adversaries is consistent across different λ hyper-parameter values: when comparing a model trained with one adversary to a model trained with 20 adversaries, the model trained with 20 consistently removes more bias. Using a single adversary does reduce the bias for λ values of 0.9 and above, but at the expense of the overall model accuracy which reduces dramatically (Fig. 2). This suggests that valuable information about the hypothesis is being removed instead of just the bias. Interestingly, when using 20 adversaries, even for the largest values of λ, the overall model accuracy does not start to decrease.

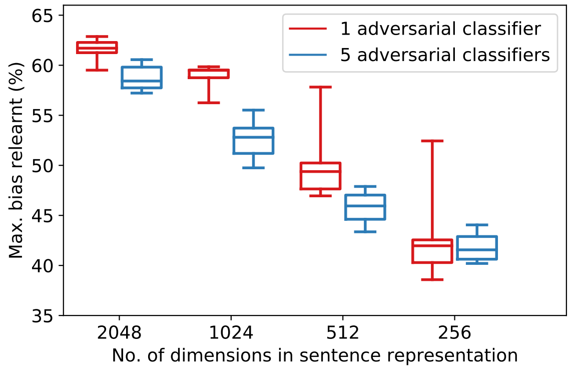

Figure 3: Maximum accuracy scores of the bias classifiers when they are retrained on de-biased sentence representations for each of the experiments tested. Ten experiments were performed for each condition, using one or five adversaries for each dimension.

4.1 Evaluating Multiple Adversaries

We applied statistical testing to understand whether the improvements seen using an ensemble of adversarial classifiers is statistically significant. For sentence representations with 2,048, 1,024 or 512 dimensions this is a statistically significant result. Although the results are not statistically significant for a smaller 256 dimensional representation.

For 2,048, 1,024 and 512 dimensional sentence representations, the statistical testing provides p-values smaller than 0.05. The null hypothesis is therefore rejected in these cases, with the alternative hypothesis stating that using five adversaries reduces the mean bias re-learnt from the sentence representations compared to using just one adversarial classifier (see Table 2). Fig. 3 displays these results in a boxplot diagram.

4.2 Using Deeper Adversaries

To investigate the impact of changing the strength of the adversary, multi-layer perceptrons are used during model training as the adversarial classifiers. The results show that more complex multi-layer perceptrons do not always perform better, and that the best choice of adversary depends on the type of classifier used to relearn the bias.

When a non-linear model is used to re-learn the bias from the frozen sentence representation, less bias can be recovered if a non-linear model was used as the adversarial classifier during training instead of a linear adversarial classifier (see Table 3). Therefore, when using a more complex classifier to re-learn the bias, a model of at least the same complexity should be used in the adversarial training to remove these biases. If a linear classifier is used as the adversary, a non-linear classifier can find more bias when learning from the de-biased representation than a linear classifier can.

The results also show that if a linear model is being used to re-learn the bias, then using a linear model as the adversary instead of a multi-layer perceptron reduces the amount of bias that can be recovered (see Table 3). This could suggest that the best approach is to use the same type of classifier for both the adversarial model and the classifier used to re-learn the bias. However, more adversarial classifiers may be required when using non-linear classifiers as adversaries, and therefore more experimentation is required to test this hypothesis.

The classifier chosen to relearn the bias will depend on the model that is being de-biased. If a classifier cannot relearn the bias from the sentence representations, this is a guarantee that a model using the de-biased representations and this classifier will not be influenced by the bias.

4.3 Evaluating De-biased Encoders

The models trained with an ensemble of adversaries are applied to 12 different NLI datasets to test whether these de-biased models generalise better than models trained with either one or no adversarial classifier. The datasets tested include SNLI-hard, where models that are no longer influenced by the hypothesis-only bias are expected to perform better. Models trained using an ensemble of adversaries performed better across most of these datasets, including SNLI-hard where there is a statistically significant improvement compared to a baseline model with no adversarial training.

Models trained with one adversary were not significantly better than a baseline model when tested on SNLI-hard (1.1% improvement, corresponding to a p-value of 0.07). On the other hand, there is a statistically significant improvement when using an ensemble of 20 adversarial classifiers (achieving a 1.6% improvement with a p-value of 0.015). As a result, we accept the alternative hypothesis that models trained with 20 adversaries have a higher mean accuracy than the baseline models.

Across 8 of the 13 datasets analysed, models trained with an ensemble of 20 adversarial classifiers performed better than when using only one adversarial classifier (see Table 4). For three of the remaining datasets, the performance was the same between using one adversary and 20 adversaries.

	P-Value		Accuracy of bias classifier	
Dim.	**Mann-Whitney**	**Bootstrapping**	**Mean (Median), 1 Adv.**	**Mean (Median), 5 Adv.**
256	1	1	42.4 (42.0)	41.8 (41.6)
512	0.0009*	<0.0001*	49.8 (49.4)	**45.8** (45.9)
1,028	0.0008*	<0.0001*	58.9 (59.5)	**52.6** (52.8)
2,048	0.0005*	0.0105*	61.6 (61.7)	**58.7** (58.4)

Table 2: p-values after performing Bootstrapping and Mann-Whitney hypothesis tests, using a Bonferroni correction factor of 4. * indicates a statistically significant result with a p-value below 0.05. Highlighted values indicate that the mean is significantly smaller than its comparison mean value, using the bootstrapping p-values.

Adversary type	Class. type	Accuracy
2,048 dim (10 adv)		
Linear	Linear	56
Linear	Non-linear	66
Non-Linear	Linear	61
Non-Linear	Non-linear	62
512 dim (5 adv)		
Linear	Linear	44
Linear	Non-linear	66
Non-Linear	Linear	55
Non-Linear	Non-linear	60

Table 3: Accuracy of bias classifiers when relearning the bias after using either a linear or non-linear adversary, when the classifier used to re-learn the bias (*class. type*) is also either linear or nonlinear.

The performance when using an ensemble of adversaries was on average 0.9 points higher than when using one adversary, which in turn outperformed the baseline by 1.6 points. The ensemble of adversaries also outperforms the Product of Experts approach proposed by Mahabadi et al. (2020).

4.4 Discussion

We find that the higher the dimensionality of the representations, the less effective a single adversary is at removing the bias, with the de-biasing also dependant on the strength of the classifier. These differences explain why past research has found that biases can remain hidden within the model representations (Elazar and Goldberg, 2018; Belinkov et al., 2019b), with Elazar and Goldberg (2018) using a model with a non-linear classifier while Belinkov et al. (2019b) use a single adversary with 2,048 dimensional sentence representations.

Dataset	Baseline	PoE	1 Adv.	Ens.
AOR	61.24	+1.8	-2.3	+1.3
DPR	46.30	+0	+2.9	+0.9
FN+	38.43	+0.7	+6.8	+12.2

SPRL	30.35	+9.2	+10.3	+13.5
Average		+1.2	+1.6	**+2.5**

Table 4: Accuracy of the de-biased models when tested on 12 different NLI datasets, comparing models trained with one adversary (1 Adv.) as per Belinkov et al. (2019a), to models trained with an ensemble of adversaries (Ens.). The Product of Experts (PoE) approach proposed by Mahabadi et al. (2020) is also included.

5 Conclusions

We set out to prevent NLI models learning from the hypothesis-only bias by using an ensemble of adversarial classifiers. Our method produced sentence representations with significantly less bias, and these more robust models generalised better to 12 different NLI datasets, improving over previous approaches in the literature (Belinkov et al., 2019b; Mahabadi et al., 2020).

The higher the dimensionality of the sentence representations, the harder it is to de-bias these representations and the higher the optimal number of adversarial classifiers appears to be. Furthermore, the models trained with an ensemble of adversaries also performed better when tested on SNLI-hard compared to using only one adversarial classifier.

This is the behaviour expected from de-biased models that no longer use the hypothesis-only bias to inform their predictions.

By preventing a linear classifier from learning the bias from the de-biased representations, we conclusively show that a model using such a classifier with these representations will not make decisions based on the bias. However, after implementing the adversarial training, a non-linear classifier may still be able to detect the bias in the sentence representations where linear classifiers are not able to. While we illustrate the conditions under which biases are removed from a linear classifier, preventing a non-linear classifier from learning the biases is more difficult and merits further experimentation.

Acknowledgements

We would like to thank Yonatan Belinkov and Rabeeh Karimi Mahabadi for providing us with their code and hyper-parameters so that we could reproduce and review their previous work. We would also like to thank Adam Poliak for publishing a quality code base that we were able to adapt. We also thank the anonymous reviewers for their thoughtful feedback and the amazing UCL NLP group for all their encouragement along the way. Pasquale Minervini's work is supported by the EU Horizon 2020 Research and Innovation Programme under the grant 875169.

Abstract

Entity set expansion and synonym discovery are two critical NLP tasks. Previous studies accomplish them separately, without exploring their interdependences. In this work, we hypothesize that these two tasks are tightly coupled because *two synonymous entities tend to have similar likelihoods of belonging to various semantic classes*. This motivates us to design SynSetExpan, a novel framework that enables two tasks to mutually enhance each other. SynSetExpan uses a synonym discovery model to include popular entities' infrequent synonyms into the set, which boosts the set expansion recall. Meanwhile, the set expansion model, being able to determine whether an entity belongs to a semantic class, can generate pseudo training data to fine-tune the synonym discovery model towards better accuracy. To facilitate the research on studying the interplays of these two tasks, we create the first large-scale Synonym-Enhanced Set Expansion (SE2) dataset via crowdsourcing. Extensive experiments on the SE2 dataset and previous benchmarks demonstrate the effectiveness of SynSetExpan for both entity set expansion and synonym discovery tasks.

1 Introduction

Entity set expansion (ESE) aims to expand a small set of seed entities (e.g., {"*United States*", "*Canada*"}) into a larger set of entities that belong to the same semantic class (*i.e.*, `Country`). Entity synonym discovery (ESD) intends to group all terms in a vocabulary that refer to the same real-world entity (e.g., "*America*" and "*USA*" refer to the same country) into a synonym set (hence called a *synset*). Those discovered entities and synsets include rich knowledge and can benefit many downstream applications such as semantic search (Xiong et al., 2017), taxonomy construction (Shen et al., 2018a), and online education (Yu et al., 2019a).

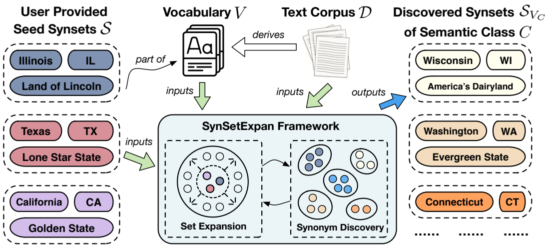

Figure 1: An illustrative example of joint entity set expansion and synonym discovery.

Previous studies regard ESE and ESD as two independent tasks. Many ESE methods (Mamou et al., 2018b; Yan et al., 2019; Huang et al., 2020; Zhang et al., 2020; Zhu et al., 2020) are developed to iteratively select and add the most confident entities into the set. A core challenge for ESE is to find those infrequent long-tail entities in the target semantic class (e.g., "*Lone Star State*" in the class `US_States`) while filtering out false positive entities from other related classes (e.g., "*Austin*" and "*Dallas*" in the class `City`) as they will cause semantic shift to the set. Meanwhile, various ESD methods (Qu et al., 2017; Ustalov et al., 2017a; Wang et al., 2019; Shen et al., 2019) combine string-level features with embedding features to find a query term's synonyms from a given vocabulary or to cluster all vocabulary terms into synsets. A major challenge here is to combine those features with limited supervisions in a way that works for entities from all semantic classes. Another challenge is how to scale a ESD method to a large, extensive vocabulary that contains terms of varied qualities.

To address the above challenges, we hypothesize that ESE and ESD are two tightly coupled tasks and can mutually enhance each other because *two synonymous entities tend to have similar likelihoods of belonging to various semantic classes and vice versa*. This hypothesis implies that (1)

knowing the class membership of one entity enables us to infer the class membership of all its synonyms, and (2) two entities can be synonyms only if they belong to the same semantic class. For example, we may expand the `US_States` class from a seed set {"*Illinois*", "*Texas*", "*California*"}. An ESE model can find frequent state full names (e.g., "*Wisconsin*", "*Connecticut*") but may miss those infrequent entities (e.g., "*Lone Star State*" and "*Golden State*"). However, an ESD model may predict "*Lone Star State*" is the synonym of "*Texas*" and "*Golden State*" is synonymous to "*California*" and directly adds them into the expanded set, which shows synonym information help set expansion. Meanwhile, from the ESE model outputs, we may infer ⟨"*Wisconsin*", "*WI*"⟩ is a synonymous pair while ⟨"*Connecticut*", "*SC*"⟩ is not, and use them to fine-tune an ESD model on the fly. This relieves the burden of using one single ESD model for all semantic classes and improves the ESD model's inference efficiency because we refine the synonym search space from the entire vocabulary to only the ESE model outputs.

In this study, we propose SynSetExpan, a novel framework jointly conducting two tasks (cf. Fig. 1). To better leverage the limited supervision signals in seeds, we design SynSetExpan as an iterative framework consisting of two components: (1) *a ESE model* that ranks entities based on their probabilities of belonging to the target semantic class, and (2) *a ESD model* that returns the probability of two entities being synonyms. In each iteration, we first apply the ESE model to obtain an entity rank list from which we derive a set of *pseudo training* data to fine-tune the ESD model. Then, we use this fine-tuned model to find synonyms of entities in the currently expanded set and adjust the above rank list. Finally, we add top-ranked entities in the adjusted rank list into the currently expanded set and start the next iteration. After the iterative process ends, we construct a synonym graph from the last iteration's output and extract entity synsets (including singleton synsets) as graph communities.

As previous ESE datasets are too small and contain no synonym information for evaluating our hypothesis, we create the first Synonym Enhanced Set Expansion (SE2) benchmark dataset via crowdsourcing. This new dataset[1] is one magnitude larger than previous benchmarks. It contains a corpus of the entire Wikipedia, a vocabulary of 1.5 million terms, and 1200 seed queries from 60 semantic classes of 6 different types (e.g., Person, Location, Organization, *etc.*).

Contributions. In summary, this study makes the following contributions: (1) we hypothesize that ESE and ESD can mutually enhance each other and propose a novel framework SynSetExpan to jointly conduct two tasks; (2) we construct a new large-scale dataset SE2 that supports fair comparison across different methods and facilitates future research on both tasks; and (3) we conduct extensive experiments to verify our hypothesis and show the effectiveness of SynSetExpan on both tasks.

2 Problem Formulation

We first introduce important concepts in this work, and then present our problem formulation. A **term** is a string (*i.e.*, a word or a phrase) that refers to a real-world entity[2]. An **entity synset** is a set of terms that can be used to refer to the same real-world entity. For example, both "USA" and "America" can refer to the entity *United States* and thus compose an entity synset. We allow the singleton synset and a term may locate in multiple synsets due to its ambiguity. A **semantic class** is a set of entities that share a common characteristic and a **vocabulary** is a term list that can be either provided by users or derived from a corpus.

Problem Formulation. Given (1) a text corpus $\mathcal{D}$, (2) a vocabulary $\mathcal{V}$ derived from $\mathcal{D}$, and (3) a seed set of user-provided entity synonym sets $\mathcal{S}_0$ that belong to the same semantic class C, we aim to (1) select a subset of entities $\mathcal{V}_C$ from $\mathcal{V}$ that all belong to C; and (2) clusters all terms in $\mathcal{V}_C$ into entity synsets $\mathcal{S}_{\mathcal{V}_C}$ where the union of all clusters is equal to $\mathcal{V}_C$. In other words, we expand the seed set $\mathcal{S}_0$ into a more complete set of entity synsets $\mathcal{S}_0 \cup \mathcal{S}_{\mathcal{V}_C}$ that belong to the same semantic class C. A concrete example is presented in Fig. 1.

3 The SynSetExpan Framework

In this study, we hypothesize that entity set expansion and synonym discovery are two tightly coupled tasks and can mutually enhance each other.

Hypothesis 1. *Two synonymous entities tend to have similar likelihoods of belonging to various semantic classes and vice versa.*

The above hypothesis has two implications. First, if two entities e_i and e_j are synonyms and

---

[1] `http://bit.ly/SE2-dataset`.

[2] In this work, we use "term" and "entity" interchangeably.

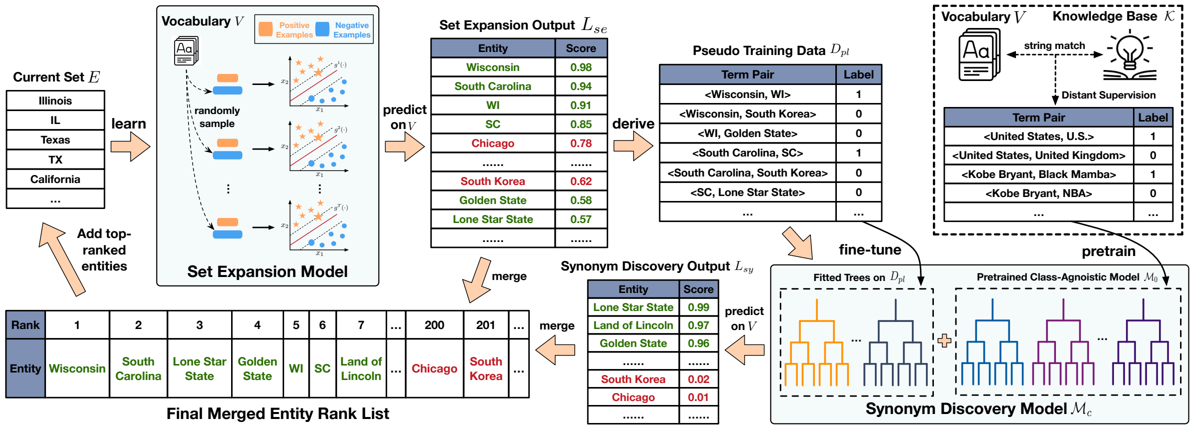

Figure 2: Overview of one iteration in our proposed SynSetExpan framework. Starting from the current set E, we first run a set expansion model to obtain an entity rank list L_{se} based on which we generate pseudo training data D_{pl} to fine-tune a generic synonym discovery model $\mathcal{M}_0$. We then apply this fine-tuned model to get a new rank list L_{sy}; merge it with L_{se} to obtain the final entity rank list, and add top ranked entities into the current set E.

e_i belongs to semantic class C, e_j likely also belongs to class C even if it is currently outside C. This reveals how synonym information can help set expansion by directly introducing popular entities' infrequent synonyms into the set and thus increasing the expansion recall. The second implication is that if two entities are *not* from the same class C, then they are likely not synonyms. This shows how set expansion can help synonym discovery by restricting the synonym search space to set expansion outputs and generating additional training data to fine tune the synonym discovery model.

At the beginning, when we only have limited seed information, this hypothesis may not be directly applicable as we do not have complete knowledge of either entity class memberships or entity synonyms. Therefore, we design our SynSetExpan as an iterative framework, shown in Fig. 2.

Framework Overview. Before the iterative process starts, we first learn a general synonym discovery model $\mathcal{M}_0$ using distant supervision from a knowledge base (cf. Sect. 3.1). Then, in each iteration, we learn a set expansion model based on the currently expanded set E (initialized as all entities in user-provided seed synsets $\mathcal{S}_0$) and apply it to obtain a rank list of entities in $\mathcal{V}$, denoted as L_{se} (cf. Sect. 3.2). Next, we generate *pseudo training data* from L_{se} and use it to construct a new *class-dependent* synonym discovery model $\mathcal{M}_c$ by fine-tuning $\mathcal{M}_0$. After that, for each entity in $\mathcal{V}$, we apply $\mathcal{M}_c$ to predict its probability of being the synonym of *at least one* entity in E and use such synonym information to adjust L_{se} (cf. Sect. 3.3). Finally, we add top-ranked entities in the adjusted rank list into the current set and start the next iteration. After the iterative process ends, we identify entity synsets from the final iteration's output using a graph-based clustering method (cf. Sect. 3.4).

3.1 Proposed Synonym Discovery Model

Given a pair of entities, our synonym discovery model returns the probability that they are synonymous. We use two types of features for entity pairs[3]: (1) *lexical features* based on entity surface names (e.g., Jaro-Winkler similarity (Wang et al., 2019), token edit distance (Fei et al., 2019), etc), and (2) *semantic features* based on entity embeddings (e.g., cosine similarity between two entities' SkipGram embeddings). As these feature values have different scales, we use a tree-based boosting model XGBoost (Chen and Guestrin, 2016) to predict whether two entities are synonyms. Another advantage of XGBoost is that it is an additive model and supports incremental model fine-tuning. We will discuss how to use set expansion results to fine-tune a synonym discovery model in Sect. 3.2.

To learn the synonym discovery model, we first acquire distant supervision data by matching each term in the vocabulary $\mathcal{V}$ with the canonical name of one entity (with its unique ID) in a knowledge base (KB). If two terms are matched to the same entity in KB and their embedding similarity is larger than 0.5, we treat them as synonyms. To generate a non-synonymous term pair, we follow the same "mixture" sampling strategy proposed in (Shen et al., 2019), that is, 50% of negative pairs come from random sampling and the other 50% of negative pairs are those "hard" negatives which are required to share at least one token. Some concrete

---

[3] We list all features in supplementary materials Section A.

examples are shown in Fig. 2. Finally, based on such generated distant supervision data, we train our XGBoost-based synonym discovery model using binary cross entropy loss.

3.2 Proposed Set Expansion Model

Given a set of seed entities E_0 from a semantic class C, we aim to learn a set expansion model that can predict the probability of a new entity (term) $e_i \in \mathcal{V}$ belonging to the same class C, *i.e.*, $\mathbf{P}(e_i \in C)$. We follow previous studies (Melamud et al., 2016; Mamou et al., 2018a) to represent each entity using a set of 6 embeddings learned on the given corpus $\mathcal{D}$, including SkipGram, CBOW in word2vec (Mikolov et al., 2013), fastText (Bojanowski et al., 2016), SetExpander (Mamou et al., 2018b), JoSE (Meng et al., 2019) and averaged BERT contextualized embeddings (Devlin et al., 2019). Given the bag-of-embedding representation $[\mathbf{f}^1(e_i), \mathbf{f}^2(e_i), \dots, \mathbf{f}^B(e_i)]$ of entity e_i and the seed set E_0, we define the entity feature $\mathbf{x}_i = \|_{b=1}^{6} \|_{j=1}^{|E_0|} \left[\sqrt{d_{ij}^b},\ d_{ij}^b,\ (d_{ij}^b)^2\right]$, where "$\|$" represents the concatenation operation, and $d_{ij}^b = \cos(\mathbf{f}^b(e_i), \mathbf{f}^b(e_j))$ is the cosine similarity between two embedding vectors. One challenge of learning the set expansion model is the lack of supervision signals — we only have a few "positive" examples (*i.e.*, entities belonging to the target class) and no "negative" examples. To solve this challenge, we observe that *the size of target class is usually much smaller than the vocabulary size*. This means if we randomly select one entity from the vocabulary, most likely it will not belong to the target semantic class. Therefore, we can construct a set of $|E_0| \times K$ negative examples by random sampling. We also test selecting only entities that have a low embedding similarity with the entities in the current set. However, our experiment shows this restricted sampling does not improve the performance. Therefore, we choose to use the simple yet effective "random sampling" approach and refer to K as "negative sampling ratio". Given a total of $|E_0| \times (K+1)$ examples, we learn a SVM classifier $g(\cdot)$ based on the above defined entity features.

To further improve set expansion quality, we repeat the above process T times (*i.e.*, randomly sample T different sets of $|E_0| \times K$ negative examples for learning T separate classifiers $\{g^t(\cdot)\}|_{t=1}^{T}$) and construct an ensemble classifier. The final classifier predicts the probability of an entity e_i belonging to the class C by averaging all individual classifiers' outputs (*i.e.*, $\mathbf{P}(e_i \in C) = \frac{1}{T}\sum_{t=1}^{T} g^t(e_i)$. Finally, we rank all entities in the vocabulary based on their predicted probabilities.

Algorithm 1: SynSetExpan Framework.

```
Input: A seed set $\mathcal{S}_0$, a vocabulary $\mathcal{V}$, a
       knowledge base $\mathcal{K}$, maximum iteration
       number $max\_iter$, maximum size of
       expanded set $Z$, and model
       hyper-parameters $\{K, T, N, H\}$.
Output: A complete set of entity synsets $\mathcal{S}_{\mathcal{V}_C}$.
Learn a general ESD model $\mathcal{M}_0$ using distant
  supervision in $\mathcal{K}$;
$E \leftarrow$ Union of all synsets in $\mathcal{S}_0$;
for $iter$ from 1 to $max\_iter$ do
    $L_{se} \leftarrow$ ESEModel$(E, \mathcal{V}, K, T)$;
    Generate pseudo training data $D_{pl}$ from $L_{se}$;
    Construct a class-specific ESD model $\mathcal{M}_c$ by
      fine-tuning $\mathcal{M}_0$ on $D_{pl}$;
    Apply $\mathcal{M}_c$ on entities in $\mathcal{V}$ and adjust $L_{se}$;
    Add top $\lceil \frac{Z}{max\_iter} \rceil$ entities in the adjusted rank
      list into $E$;
Construct a synonym graph $\mathcal{G}$ based on final set $E$;
$\mathcal{S}_{\mathcal{V}_C} \leftarrow$ Louvain$(\mathcal{G})$;
Return $\mathcal{S}_{\mathcal{V}_C}$.
```

3.3 Two Models' Mutual Enhancements

Set Expansion Enhanced Synonym Discovery. In each iteration, we generate a set of *pseudo training* data D_{pl} from the ESE model output L_{se}, to fine-tune the general synonym discovery model $\mathcal{M}_0$. Specifically, we add an entity pair $\langle e_x, e_y \rangle$ into D_{pl} with label 1, if they are among the top 100 entities in L_{se} and $\mathcal{M}_0(e_x, e_y) \geq 0.9$. For each positive pair $\langle e_x, e_y \rangle$, we generate N negative pairs by randomly selecting $\lceil N/2 \rceil$ entities from L_{se} whose set expansion output probabilities are less than 0.5 and pairing them with both e_x and e_y. The intuition is that those randomly selected entities likely come from different semantic classes with entity e_x and e_y, and thus based on our hypothesis, they are unlikely to be synonyms. After obtaining D_{pl}, we fine-tune model $\mathcal{M}_0$ by fitting H additional trees on D_{pl} and incorporate them into the existing bag of trees in $\mathcal{M}_0$. We discuss the detailed choices of N and H in the experiment.

Synonym Enhanced Set Expansion. Given a fine-tuned class-specific synonym discovery model $\mathcal{M}_c$, the current set E, we calculate a new score for each entity $e_i \in \mathcal{V}$ as follows:

$$\text{sy-score}(e_i) = \max\{\mathcal{M}_c(e_i, e_j) | e_j \in E\}. \qquad (1)$$

The above score measures the probability that e_i is the synonym of one entity in E. Based on Hypothesis 1, we know an entity with a large sy-score is likely belonging to the target class. Therefore, we use a multiplicative measure to combine this sy-score with the set expansion model's original output $\mathbf{P}(e_i \in C)$ as follows:

$$\text{final-score}(e_i) = \sqrt{\mathbf{P}(e_i \in C) \times \text{sy-score}(e_i)}. \quad (2)$$

An entity will have a large sy-score as long as it is the synonym of *one single* entity in E. Such a property is particularly important for capturing long-tail infrequent entities. For example, suppose we expand `US_States` class from a seed set {"*Illinois*", "*IL*", "*Texas*", "*TX*"}. The original set expansion model, biased toward popular entities, assigns a low score 0.57 to "*Lone Star State*" and a large score 0.78 to "*Chicago*". However, the synonym discovery model predicts, with over 99% probability, that "*Lone Star State*" is the synonym of "*Texas*" and thus has a sy-score 0.99. Meanwhile, "*Chicago*" has no synonym in the seed set and thus has a low sy-score 0.01. As a result, the final score of "*Lone Star State*" is larger than that of "*Chicago*". Moreover, we emphasize that Eq. 2 uses synonym scores to enhance, not replace, set expansion scores. A correct entity $e^\star$ that has no synonym in current set E will indeed be ranked after other correct entities that have synonyms in E. However, this is not problematic because (1) all compared entities are correct, and (2) we will not remove $e^\star$ from final results because it still outscores other erroneous entities that have the same low sy-score as $e^\star$ but much lower set expansion scores.

3.4 Synonym Set Construction

After the iterative process ends, we have a synonym discovery model $\mathcal{M}_c$ that predicts whether two entities are synonymous and an entity list E that includes entities from the same semantic class. To further derive entity synsets, we first construct a weighted synonym graph $\mathcal{G}$ where each node n_i represents one entity $e_i \in E$ and each edge (n_i, n_j) with weight w_{ij} indicates $M_c(e_i, e_j) = w_{ij}$. Then, we apply the Louvain algorithm (Blondel et al., 2008) (a popular non-overlapping community detection method) to find all clusters in $\mathcal{G}$ and treat them as entity synsets. Note here we narrow the original full vocabulary $\mathcal{V}$ to the set expansion model's final output E based on our hypothesis. We summarize our whole framework in Algorithm 1 and discuss its computational complexity in supplementary materials.

Corpus Size	# Entities	# Classes	# Queries
1.9B Tokens	1.5M	60	1200

Table 1: Our SE2 dataset statistics

4 The SE2 Dataset

To verify our hypothesis and evaluate the SynSetExpan framework, we need a dataset that contains a corpus, a vocabulary with labeled synsets, a set of complete semantic classes, and a list of seed queries. However, to the best of our knowledge, there is no such a public benchmark dataset[4]. Therefore, we build the first Synonym Enhanced Set Expansion (**SE2**) benchmark dataset in this study[5].

4.1 Dataset Construction

We construct the SE2 dataset in four steps.

1. Corpus and Vocabulary Selection. We use the Wikipedia 20171201 dump as our evaluation corpus as it contains a diverse set of semantic classes and enough context information for methods to discover those sets. We extract all noun phrases with frequency above 10 as our selected vocabulary.

2. Semantic Class Selection. We identify 60 major semantic classes based on the *DBpedia-Entity v2* (Hasibi et al., 2017) and *WikiTable* (Bhagavatula et al., 2015) entities found in our corpus. These 60 classes cover 6 different entity types (e.g., Person, Location, Organization). As such generated classes may miss some correct entities, we enlarge each class via crowdsourcing in the following step.

3. Query Generation and Class Enrichment. We first generate 20 queries for each semantic class. Then, we aggregate the top 100 results from all baseline methods (cf. Sect. 5) and obtain 17,400 $\langle$class, entity$\rangle$ pairs. Next, we employ crowdworkers on Amazon Mechanical Turk to check all those pairs. Workers are asked to view one semantic class and six candidate entities, and to select all entities that belong to the given class. On average, workers spend 40 seconds on each task and are paid \$0.1. All $\langle$class, entity$\rangle$ pairs are labeled by three workers independently and the inter-annotator agreement is 0.8204, measured by Fleiss's Kappa (k). Finally, we enrich each semantic class C_j by adding the entity e_i whose corresponding pair $\langle C_j, e_i \rangle$ is labeled "True" by at least two workers.

---

[4] More discussions on existing set expansion datasets are available in supplementary materials Section C.

[5] More details and analysis can be found in the Section D and E of supplementary materials.

Class Type	ESE	ESD (Lexical)	ESE (Semantic)
Location	0.3789	0.2132	0.6599
Person	0.2322	0.2874	0.5526
Product	0.0848	0.3922	0.4811
Facility	0.0744	0.2345	0.4466
Organization	0.1555	0.2566	0.4935
Misc	0.4282	0.2743	0.5715

Table 2: Difficulty of each semantic class for entity set expansion (ESE) and entity synonym discovery (ESD).

4. Synonym Set Curation. To construct synsets in each class, we first run all baseline methods to generate a candidate pool of possible synonymous term pairs. Then, we treat those pairs with both terms mapped to the same entity in WikiData as positive pairs and ask two human annotators to label the remaining 7,625 pairs. The inter-annotator agreement is 0.8431, measured by Fleiss's Kappa. Then, we construct a synonym graph where each node is a term and each edge connects two synonymous terms. Finally, we extract all connected components in this graph and treat them as synsets.

4.2 Dataset Analysis

We analyze some properties of the SE2 dataset from the following three aspects.

1. Semantic class size. The 60 semantic classes in our SE2 dataset consist on average 145 entities (with a minimum of 16 and a maximum of 864) for a total of 8697 entities. After we group these entities into synonym sets, these 60 classes consist of on average 118 synsets (with a minimum of 14 and a maximum of 800) for a total of 7090 synsets. The average synset size is 1.258 and the maximum size of one synset is 11.

2. Set expansion difficulty of each class. We define the set expansion difficulty of each semantic class as follows:

$$\text{Set-Expansion-Difficulty}(C) = \frac{1}{|C|}\sum_{e \in C}\frac{|C - \text{Top}k(e)|}{|C|}, \tag{3}$$

where $\text{Top}k(e)$ represents the set of k most similar entities to entity e in the vocabulary. We set k to be 10,000 in this study. Intuitively, this metric calculates the average portion of entities in class C that cannot be easily found by another entity in the same class. As shown in Table 2, the most difficult classes are those Location classes[6] and the easiest ones are Facility classes.

3. Synonym discovery difficulty of each class. We continue to measure the difficulty of finding synonym pairs in each class. Specifically, we calculate two metrics: (1) *Lexical difficulty* defined as the average Jaro-Winkler distance between the surface names of two synonyms, and (2) *Semantic difficulty* defined as the average cosine distance between two synonymous entities' embeddings. Table 2 lists the results. We find Product classes have the largest lexical difficulty and Location classes have the largest semantic difficulty.

5 Experiments

5.1 Entity Set Expansion

Datasets. We evaluate SynSetExpan on three public datasets. The first two are benchmark datasets widely used in previous studies (Shen et al., 2017; Yan et al., 2019; Zhang et al., 2020): (1) **Wiki**, which contains 8 semantic classes, 40 seed queries, and a subset of English Wikipedia articles, and (2) **APR**, which includes 3 semantic classes, 15 seed queries, and all news articles published by Associated Press and Reuters in 2015. Note that these two datasets do not contain synonym information and are used primarily to evaluate our set expansion model performance. We decide not to augment these two datasets with additional synonym information (as we did in our SE2 dataset) in order to keep the integrity of two existing benchmarks. The third one is our proposed SE2 dataset which has 60 semantic classes, 1200 seed queries, and a corpus of 1.9 billion tokens. Clearly, our SE2 is an order of magnitude larger than previous benchmarks and covers a wider range of semantic classes.

Compared Methods. We compare the following corpus-based set expansion methods: (1) **EgoSet** (Rong et al., 2016): A method initially proposed for multifaceted set expansion using skip-grams and word2vec embeddings. Here, we treat all extracted entities forming in one set as our queries have little ambiguity. (2) **SetExpan** (Shen et al., 2017): A bootstrap method that first computes entity similarities based on selected quality contexts and then expands the entity set using rank ensemble. (3) **SetExpander** (Mamou et al., 2018b): A one-time entity ranking method based on multi-context term similarity defined on multiple embeddings. (4) **MCTS** (Yan et al., 2019): A bootstrap method combining the Monte Carlo Tree Search algorithm with a deep similarity network to estimate delayed feedback for pattern evaluation and entity scoring. (5) **CaSE** (Yu et al.,

---

[6] We exclude MISC type because by its definition classes of this type will be very random.

Table 3: Set expansion results on three datasets. MCTS and SetCoExpan do not scale to the SE2 dataset. SynSetExpan-Full is inapplicable for Wiki and APR datasets because they contain no synonym information. The superscript * indicates the improvement is statistically significant compared to SynSetExpan-NoSYN.

2019b): Another one-time entity ranking method using both term embeddings and lexico-syntactic features. (6) **SetCoExpan** (Huang et al., 2020): A set expansion framework which generates auxiliary sets that are closely related to the target set and leverages them to guide the expansion process. (7) **CGExpan** (Zhang et al., 2020): Current state-of-the-art method that generates the target set name by querying a pre-trained language model and utilizes generated names to expand the set. (8) **SynSetExpan**: Our proposed framework which jointly conducts two tasks and enables synonym information to help set expansion. (9) **SynSetExpan-NoSYN**: A variant of our proposed SynSetExpan framework without the synonym discovery model. All implementation details and hyperparameter choices are discussed in supplementary materials Section F.

Evaluation Metrics. We follow previous studies and evaluate our results using Mean Average Precision at different top K positions: MAP@K = $\frac{1}{|Q|}\sum_{q\in Q}\text{AP}_K(L_q, S_q)$, where Q is the set of all seed queries and for each query q, we use $\text{AP}_K(L_q, S_q)$ to denote the traditional average precision at position K given a ranked list of entities L_q and a ground-truth set S_q. To compare the performance of multiple models, we conduct statistical significance test using the two-tailed paired t-test with 99% confidence level.

Experimental Results. We analyze the set expansion performance from the following aspects.

1. Overall Performance. Table 3 presents the overall set expansion results. We can see that SynSetExpan-NoSYN achieves comparable performances with the current state-of-the-art methods on Wiki and APR datasets[7], and outperforms previous methods on SE2 dataset, which demonstrates the effectiveness of our set expansion model alone. Besides, by comparing SynSetExpan-NoSYN with SynSetExpan on SE2 dataset, we show that adding synonym information indeed helps set expansion.

Class Type	**MAP@10**	**MAP@20**	**MAP@50**
Person	86.7%	80.0%	93.3%
Organization	83.3%	83.3%	100%
Location	69.2%	65.4%	80.8%
Facility	85.7%	71.4%	100%
Product	100%	66.7%	100%
Misc	66.7%	66.7%	100%
Overall	**78.3%**	**71.7%**	**90.0%**

Table 4: Ratio of semantic classes on which SynSetExpan outperforms SynSetExpan-NoSYN.

SynSetExpan vs. Other	**MAP@10**	**MAP@20**	**MAP@50**
vs. CGExpan	78.9%	85.4%	93.8%
vs. SynSetExpan-NoSYN	72.7%	83.0%	91.4%

Table 5: Ratio of seed queries from the SE2 dataset on which the first method outperforms the second one.

2. Fine-grained Performance Analysis. To provide a detailed analysis on how SynSetExpan improves over SynSetExpan-NoSYN, we group semantic classes based on their types and calculate the ratio of classes on which SynSetExpan outperforms SynSetExpan-NoSYN. Table 4 shows the results and we can see that on most classes SynSetExpan is better than SynSetExpan-NoSYN, especially for the MAP@50 metric. In Table 5, we further analyze the ratio of seed set queries (out of total 1200 queries) on which one method achieves better or the same performance as the other method. We can see that SynSetExpan can win on the majority of queries, which further shows that SynSetExpan can effectively leverage synonym information to enhance set expansion.

3. Case Studies. Figure 3 shows some expanded semantic classes by SynSetExpan. We can see that the set expansion task benefits a lot from the synonym information. Take the semantic class

---

[7] We feel both CGExpan and our method have reached the performance limit on Wiki and APR as both datasets are relatively small and contain only a few coarse-grained classes.

Figure 4: Case studies on synonym discovery. Entities discovered only by SynSetExpan are colored in green.

`NBA_Teams` for example, we find "*L.A. Lakers*" (*i.e.*, the synonym of "*Los Angeles Lakers*") as well as "*St. Louis Hawks*" (*i.e.*, the former name of "*Atlanta Hawks*") and further use them to improve the set expansion result. Moreover, by introducing synonyms, we can lower the rank of those erroneous entities (e.g., "*LA Dodgers*" and "*NBA coach*").

5.2 Synonym Discovery

Datasets. We evaluate SynSetExpan for synonym discovery task on two datasets: (1) **SE2**, which contains 60,186 synonym pairs (3,067 positive pairs and 57,119 negative pairs), and (2) **PubMed**, a public benchmark used in (Qu et al., 2017; Shen et al., 2019), which contains 203,648 synonym pairs (10,486 positive pairs and 193,162 negative pairs). More details can be found in supplementary materials Section G.1.

Compared Methods. We compare following synonym discovery methods: (1) **SVM**: A classification method trained on given term pair features. We use the same feature set described in Sect. 3.1. (2) **XGBoost** (Chen and Guestrin, 2016): Another classification method trained on given term pair features. Here, we test its two variants: **XGB-S** which only leverages lexical features based on entity surface names, and **XGB-E** which only utilizes entity embedding features. (3) **DPE** (Qu et al., 2017): A distantly supervised method integrating embedding features and textual patterns for synonym discovery. (4) **SynSetMine** (Shen et al., 2019): Another distantly supervised framework that learns to represent the entire entity synonym set. (5) **SynSetExpan**: Our proposed framework that fine-tunes synonym discovery model using set expansion results. (6) **SynSetExpan-NoFT**: A variant of SynSetExpan without using the model fine-tuning. More implementation details and hyper-parameter choices are discussed in supplementary materials Section G.

Evaluation Metrics. As all compared methods output the probability of two input terms being synonyms, we first use two threshold-free metrics for evaluation — Average Precision (**AP**) and Area Under the ROC Curve (**AUC**). Second, we transform the output probability to a binary decision using threshold 0.5 and evaluate the model performance using standard **F1** score.

Experimental Results. Table 6 shows the overall synonym discovery results. First, we can see that the SynSetExpan-NoFT model can outperform both XGB-S and XGB-E methods significantly, which shows the importance of using both types of features for predicting synonyms. Second, we find that SynSetExpan can further improve SynSetExpan-NoFT via model fine-tuning, which demonstrates that set expansion can help synonym discovery. Finally, we notice that our SynSetExpan framework, with the fine-tuning mechanism enabled, can achieve the best performance across all evaluation metrics. In Figure 4, we show some synsets discovered by SynSetExpan. We can see that SynSetExpan is able to detect different types of entity synsets across various semantic classes. Furthermore, we highlight those entities discovered only after model fine-tuning, and we can see clearly that with fine-tuning, our SynSetExpan framework can detect more accurate synsets.

6 Related Work

Entity Set Expansion. Entity set expansion can benefit many downstream applications such as question answering (Wang and Cohen, 2008), literature search (Shen et al., 2018b), and online education (Yu et al., 2019a). Traditional entity set expansion systems such as GoogleSet (Tong and Dean, 2008) and SEAL (Wang and Cohen, 2007) require seed-oriented online data extraction, which can be time-consuming and costly. Thus, more recent studies (Shen et al., 2017; Mamou et al., 2018b; Yu et al., 2019c; Huang et al., 2020; Zhang et al., 2020) are proposed to expand the seed set by offline processing a given corpus. These corpus-based methods include two general approaches: (1) *one-time entity ranking* (Pantel et al., 2009; He and Xin, 2011; Mamou et al., 2018b; Kushilevitz et al., 2020) which calculates all candidate entities' distributional similarities with seed entities and makes a one-time ranking without back and forth refinement, and (2) *iterative bootstrapping* (Rong et al., 2016; Shen et al., 2017; Huang et al., 2020; Zhang et al., 2020) which starts from seed entities to extract quality textual patterns; applies the extracted patterns to obtain more quality entities, and iterates this process until sufficient entities are discovered. In this work, in addition to just adding entities into the set, we go beyond one step and aim to organize those expanded entities into synonym sets. Furthermore, we show those detected synonym sets can in turn help to improve set expansion results.

Synonym Discovery. Early efforts on synonym discovery focus on finding entity synonyms from structured or semi-structured data such as query logs (Ren and Cheng, 2015), web tables (He et al., 2016), and synonymy dictionaries (Ustalov et al., 2017b,a). In comparison, this work aims to develop a method to extract synonym sets directly from raw text corpus. Given a corpus and a term list, one can leverage surface string (Wang et al., 2019), co-occurrence statistics (Baroni and Bisi, 2004), textual pattern (Yahya et al., 2014), distributional similarity (Wang et al., 2015), or their combinations (Qu et al., 2017; Fei et al., 2019) to extract synonyms. These methods mostly find synonymous *term pairs* or *a rank list* of query entity's synonym, instead of entity synonym sets. Some studies propose to further cut-off the rank list into a set output (Ren and Cheng, 2015) or to build a synonym graph and then apply graph clustering techniques to derive synonym sets (Oliveira and Gomes, 2014; Ustalov et al., 2017b). However, they all operate directly on the entire input vocabulary which can be too extensive and noisy. Compared to them, our approach can leverage the semantic class information detected from set expansion to enhance the synonym set discovery process.

7 Conclusions

This paper shows entity set expansion and synonym discovery are two tightly coupled tasks and can mutually enhance each other. We present SynSetExpan, a novel framework jointly conducting two tasks, and SE2 dataset, the first large-scale synonym-enhanced set expansion dataset. Extensive experiments on SE2 and several other benchmark datasets demonstrate the effectiveness of SynSetExpan on both tasks. In the future, we plan to study how we can apply SynSetExpan at the entity mention level for conducting contextualized synonym discovery and set expansion.

A Entity Pair Features

Feature Description	**Example**
IsPrefix	(Florida, FL) → 1
IsInitial	(North Carolina, NC) → 1
Edit distance	(North Carolina, Texas) → 13
Jaro-Winkler similarity	(Arizona, Texas) → 0.4476
Characters in common	(Lone Star State, Texas) → 2
Tokens in common	(North Carolina, South Carolina) → 1
Difference in #tokens	(Land of Lincoln, Illinois) → |3-1| = 2
Initial edit distance	(North Carolina, State of North Carolina) → 2
Longest token edit distance	(North Dakota, North Carolina) → 5
Cosine similarity of embedding	(Texas, Lone Star State) → 0.9
Transformed cosine similarities	(Texas, Lone Star State) → $[\frac{1}{0.9}, \sqrt{0.9}, (0.9)^2]$
Multiplication of two entities' PCA-reduced embedding	(Illinois, Land of Lincoln) → [0.006, 0.072, -0.008, 0.074, $\cdots$, -0.004]

Table 7: All entity pair features used in our synonym discovery model.

B SynSetExpan Framework Complexity

From the Algorithm 1 in the main text, we can see our SynSetExpan framework costs $O(T \times (1 + K) \times |S| + |\mathcal{V}|)$ for each iteration, where T is the ensemble times (usually 50), K is the negative sampling size (usually 10-20), S is the currently expanded set (usually of size < 100), and $|\mathcal{V}|$ is the vocabulary size. Although such complexity looks expensive, we can significantly reduce the practical running time in two ways. First, we can learn T separate classifiers in set expansion model in parallel. Second, we can aggregate all words in the vocabulary into one batch and apply synonym discovery model for inference in one run. We report the practical running time for each component in the below experiments.

C Existing ESE Datasets

An ideal set expansion benchmark dataset should contain four parts: a corpus, a vocabulary, a set of complete semantic classes, and a collection of seed queries for each semantic class. One of the earliest corpus-based set expansion work (Pantel et al., 2009) uses "*List of*" pages in Wikipedia to construct 50 semantic classes and applies random sampling to construct 30 queries for each class. Although those classes and queries are still available today, we have no access to its underlying corpus and vocabulary and thus cannot easily reproduce their results. Similarly, SEISA (He and Xin, 2011) and EgoSet (Rong et al., 2016) also release their constructed semantic classes and seed queries but hold the corpus and vocabulary. On the other side, SetExpander (Mamou et al., 2018b) and CaSE (Yu et al., 2019b) clearly describe their corpus and vocabulary but do not release their classes/queries. To the best of our knowledge, SetExpan (Shen et al., 2017) is the only public dataset consisting of all four essential components. However, it only contains 65 queries from 13 classes and has no synonym information. Below Table 8 compares our proposed SE2 with all existing datasets and we can see that our new dataset contains all four key parts for a set expansion benchmark dataset, as well as additional synonym information.

Dataset	Corpus	Vocab	Classes	Queries	Synonyms
Pantel *et al.* (Pantel et al., 2009)	×	×	✓	✓	×
SEISA (He and Xin, 2011)	×	×	✓	✓	×
EgoSet (Rong et al., 2016)	×	×	✓	✓	×

SetExpan (Shen et al., 2017)	✓	✓	✓	✓	×
SE2	✓	✓	✓	✓	✓

Table 8: Comparison of ESE datasets.

D SE2 Dataset Construction Details

We construct our dataset in four stages: (1) Corpus and vocabulary selection, (2) Semantic class selection, (3) Query generation and class enrichment, and (4) Synonym set curation.

Corpus and vocabulary selection. An ideal corpus for set expansion task should contain a diverse set of semantic classes and enough context information for methods to discover those sets. Based on these two criteria, we select Wikipedia 20171201 dump as our evaluation corpus. This corpus is also used in previous studies (Mamou et al., 2018b,a) and contains 1.9 billion tokens of raw size 14GB. Next, we extract all noun phrases with frequency above 10 and filter out those noun phrases that start with either a stopword (e.g., "*a/an*" and "*the*") or a non-word character (e.g., "*(*", and "-"). The remaining 1.47 million noun phrases consist of our vocabulary.

Semantic class selection. To select a diverse set of semantic classes, we first use simple string matching to align our corpus and vocabulary with two benchmark datasets designed for tasks closely related to Set Expansion: (1) *DBpedia-Entity v2* (Hasibi et al., 2017) for Entity Search (particularly entity list search), and (2) *WikiTable* (Bhagavatula et al., 2015; Zhang and Balog, 2018) for Entity Linking in Wikipedia Table. Then, we retain all semantic classes with at least 10 entities and obtain totally 60 classes covering 6 different types (e.g., Person, Location, Organization, etc). Table 9 shows some examples. Such generated classes have high precision but low recall in the sense that some correct entities are not included. In the following stage, we enlarge each semantic class and increase its coverage using crowdsourcing.

Query generation and class enrichment. For each semantic class, we generate 5 queries for each of four query sizes: 2, 3, 4, 5, which results in 20 queries per class and 1200 queries in total. Furthermore, we want those queries to cover both popular and long-tail entities. To achieve this goal, we first sort all entities based on their frequencies within each class. Then, we generate each subgroup of 5 queries (of the same size $M \in \{2, 3, 4, 5\}$) as follows: we select 1 query consisting of the M most frequent entities, 2 queries of entities in frequency quantile top-10%, and 2 queries of entities in frequency quantile [top-10%, top-30%].

After generating queries, we run all baseline methods to retrieval their top 100 results and aggregate all results to a set of 17,400 $\langle \text{class}, \text{entity} \rangle$ pairs. Next, we employ crowdworkers to check all those pairs on Amazon Mechanical Turk. Crowdworkers are required to have a 95% HIT acceptance rate, a minimum of 1000 HITs, and be located in the United States or Canada. Workers are asked to view one semantic class and six candidate entities, and to select all entities that belong to the given class. On average, workers spend 40 seconds on each task and are paid \$0.1, which is equivalent to a \$9 hourly payment. All $\langle \text{class}, \text{entity} \rangle$ pairs are labeled by three workers independently and the inter-annotator agreement is 0.8204, measured by Fleiss's Kappa (k). Finally, we enrich each semantic class C_j by adding the entity e_i whose corresponding pair $\langle C_j, e_i \rangle$ is labeled "True" by at least two workers.

Synonym set curation. To construct synonym sets in each semantic class, we first run all baseline methods to generate a candidate pool of possible synonymous pairs. Then, we enlarge this pool to include all term pairs that form an inflection[8]. After that, we automatically treat those terms that can be mapped to the same entity in WikiData[9] as positive pairs and manually label the remaining 7,625 pairs. The inter-annotator agreement is 0.8431. Note here we do not use Amazon MTurk because labeling synonym pairs are much simpler than labeling entity class membership and also has less ambiguity. Here, we avoid using YAGO KB in order to prevent possible data leakage problem. Next, we construct a synonym graph where each node is a term and each edge connects two synonymous terms. Finally, we extract all connected components in this synonym graph and treat them as synonym sets.

E SE2 Dataset Analysis

We analyze some properties of SE2 dataset from the following aspects: (1) semantic class size, (2) set expansion difficulty of each class, and (3) synonym discovery difficulty of each class.

Semantic class size. The 60 semantic classes in our SE2 dataset consist on average 145 entities (with a minimum of 16 and a maximum of 864) for a total of 8697 entities. After we grouping these entities into synonym sets, these 60 classes consist of on average 118 synsets (with a minimum of 14 and a maximum of 800) for totally 7090 synsets. The average synset size is 1.258 and the maximum size of one synset is 11.

Set expansion difficulty of each class. We define the set expansion difficulty of each semantic class as follows:

$$\text{Set-Expansion-Difficulty}(C) = \frac{1}{|C|} \sum_{e \in C} \frac{|C - \text{Top}k(e)|}{|C|}, \tag{4}$$

where Top$k(e)$ represents the set of k most similar entities to entity e in the vocabulary. We set k to be 10,000 in this study. Intuitively, this metric calculates the average portion of entities in class C that cannot be easily found by another entity in the same class. As shown in Table 2, the most difficult classes are those LOC classes[10] and the easiest ones are FAC classes.

Synonym discovery difficulty of each class. We continue to measure the difficulty of finding synonym pairs in each class. Specifically, we calculate two metrics: (1) *Lexical difficulty* defined as the average Jaro-Winkler distance[11] between the surface names of two synonyms, and (2) *Semantic difficulty* defined as the average cosine distance between two synonymous entities' embeddings. Table 2 lists the results. We find PRODUCT classes have the largest lexical difficulty and LOC classes have the largest semantic difficulty.

---

[8] We check word inflection using: `https://github.com/jazzband/inflect`.

[9] `https://www.wikidata.org/wiki/Wikidata:Main_Page`

[10] We exclude MISC type because by its definition classes of this type will be very random.

[11] We use Jaro-Winkler distance instead of other edit distances because it is symmetric, normalized to range from 0 to 1, and is widely used in previous synonym literature.

F Entity Set Expansion Experiments

F.1 Implementation Details and Hyper-parameter Choices

For Wiki and APR datasets, we directly report each baseline method’s performance obtained in the CG-Expan paper (Zhang et al., 2020). For our proposed SE2 dataset, we tune each method’s hyper-parameters on 6 semantic classes (one for each class type) and use tuned parameters for all the other classes. The implementation details and specific hyper-parameter choices are discussed below:

1. **EgoSet**: There is no open-source code for EgoSet and thus we implement it on our own. We use each entity’s 250 most relevant skip-grams to calculate entity-entity similarity.

2. **SetExpan**[12]: We run SetExpan for 10 iterations and add 10 entities into the set in each iteration. We set ensemble time to be 90 and use the default values for all other hyper-parameters.

3. **SetExpander**[13]: We directly download the pre-trained vectors (as they are trained on the same corpus as ours) and filter out those words that do not exist in our vocabulary.

4. **MCTS**[14]: In each iteration, we perform 1000 MCTS simulations and select 10 patterns to add 10 entities.

5. **CaSE**[15]: We use its CaSE-BERT version where a BERT-base-uncased model is used to calculate entity representations.

6. **CGExpan**[16]: We use BERT-base-uncased as its underlying Language Model for generating class names. We run CGExpan for 5 iterations and each iteration finds 5 candidate classes and adds 10 most confident entities into the currently expanded set.

7. **SynSetExpan**: We set the ensemble times $T = 50$, the negative sampling ratio (in set expansion model) $K = 10$, the maximum iteration number *max_iter*$= 6$, the number of fine-tuning trees $H = 10$, and the negative sampling ratio (in synonym discovery model) $N = 10$. For other (less important) hyper-parameters, we directly discuss their values in the paper and SynSetExpan is robust to those hyper-parameters.

F.2 Hyper-parameter Sensitivity Analysis

Within our SynSetExpan framework, there are two important hyper-parameters in the set expansion model: the ensemble times T and negative sampling ratio K. Figure 5 shows the hyper-parameter sensitivity analysis. We see that the model performance first increases when the ensemble times T increases from 1 to 10 and then becomes stable when T further increases. A similar trend is also witnessed on the negative sampling ratio K. Overall, we can say that SynSetMine is insensitive to

(a) Ensemble Times T (b) Negative Ratio K

Figure 5: Sensitivity analysis of hyper-parameters T and K in SynSetExpan for the set expansion task.

these two hyper-parameters as long as their values are larger than 10.

F.3 Efficiency Analysis

We test the efficiency of our SynSetExpan framework (with T = 50 and K = 10) on a single server with 20 CPU threads. For each query, the first iteration of SynSetExpan on average takes 7.5 seconds, the first three iterations need 27 seconds, and the first six iterations consume 56 seconds. Later iterations take longer time because there are more entities in the already expanded set of that iteration. In comparison, one iteration of EgoSet takes 86 seconds, six iterations of SetExpan need 188 seconds, and CGExpan takes 174 seconds for five iterations on a 1080Ti GPU. This result shows the efficiency of SynSetExpan.

G Synonym Discovery Experiments

G.1 PubMed Dataset Details

Besides using our SE2 dataset, we also evaluate SynSetExpan for synonym discovery task on the public PubMed dataset which consists of a corpus of 1.5 million paper abstracts in biomedical domain, a vocabulary of 357,991 terms, and a collection of 203,648 synonym pairs (10,486 positive pairs and 193,162 negative pairs). All terms involved in synonym pairs are linked to one entity in UMLS knowledge base[17] and we group these terms into 10 semantic classes based on their linked entities' types.

G.2 Implementation Details and Hyper-parameter Choices

All compared synonym discovery methods are tested using the same distant supervision data (c.f. Section 3 in the main text) and hyper-parameter values are obtained using 5-fold cross validation. We discuss the implementation details and hyper-parameter choices of each compared synonym discovery methods below:

1. **SVM**[18]: We use the RBF kernel and set regularization parameter λ to be 0.3.

2. **XGBoost**[19]: We set the maximum tree depth to be 5, $\gamma = 0.1$, $\eta = 0.1$, subsample ratio to be 0.5, and use the default values for all other hyper-parameters.

3. **SynSetMine**[20]: We use two hidden layers (of dimension 250, 500) for its internal set encoder. We learn the model using the "mix sampling" strategy.

4. **DPE**[21]: We set the embedding dimension as 300, $\lambda = 0.3$, and use the default values for all other hyper-parameters.

5. **SynSetExpan**: We use the same hyper-parameter values as XGBoost to obtain the class-agonistic synonym discovery model. During the fine-tuning stage, we fit 10 additional trees in each iteration. For other (less important) hyper-parameters, we directly discuss their values in the paper and SynSetExpan is robust to those hyper-parameters.

G.3 Hyper-parameter Sensitivity Analysis

We study how sensitive SynSetExpan is to the choices of two fine-tuning hyper-parameters in its synonym discovery module: (1) the number of additional fitted trees H, and (2) the negative sampling ratio N in constructing pseudo-labeled dataset for fine-tuning. Results are shown in Figure 6. First, we find that our model is insensitive to the negative sampling ratio N in terms of all three metrics. Second, we notice that the model performance first increases as H increases until it reaches about 15 and then starts to decrease when we further increase H. Although SynSetExpan is somewhat sensitive to the hyper-parameter H, we find that a wide range of H choices are better than $H = 0$ which essentially disables the model fine-tuning.

(c) PubMed Dataset-H (d) PubMed Dataset-N

Figure 6: Sensitivity analysis of hyper-parameters H and N in SynSetExpan framework for the synonym discovery task.

G.4 Efficiency Analysis

By linking SE2 Dataset with YAGO KB, we can obtain 260 thousand synonym pairs based on which training a class-agnostic synonym discovery model takes 15 minutes. Then, each iteration of SynSetExpan generates on average 5000 pseudo-labeled synonym pairs and fitting 10 additional trees needs about 0.75 seconds. After training, our synonym discovery model can predict 4000 term pairs per second.

Evaluating the Calibration of Knowledge Graph Embeddings for Trustworthy Link Prediction

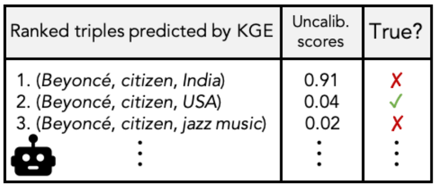
Abstract

Little is known about the trustworthiness of predictions made by knowledge graph embedding (KGE) models. In this paper we take initial steps toward this direction by investigating the *calibration* of KGE models, or the extent to which they output confidence scores that reflect the expected correctness of predicted knowledge graph triples. We first conduct an evaluation under the standard closed-world assumption (CWA), in which predicted triples not already in the knowledge graph are considered false, and show that existing calibration techniques are effective for KGE under this common but narrow assumption. Next, we introduce the more realistic but challenging open-world assumption (OWA), in which unobserved predictions are not considered true or false until ground-truth labels are obtained. Here, we show that existing calibration techniques are much less effective under the OWA than the CWA, and provide explanations for this discrepancy. Finally, to motivate the utility of calibration for KGE from a practitioner's perspective, we conduct a unique case study of human-AI collaboration, showing that calibrated predictions can improve human performance in a knowledge graph completion task.

1 Introduction

Knowledge graphs are essential resources in natural language processing tasks such as question answering and reading comprehension (Shen et al., 2019; Yang et al., 2019). Because they are by nature incomplete, extensive research efforts have been invested into completing them via different techniques (Ji et al., 2020; Belth et al., 2020).

One such technique is knowledge graph embedding (**KGE**), which involves learning latent representations of entities and relations to be used toward predicting new facts. KGE models are most commonly optimized for the **link prediction** task, which tests their ability to "learn to rank" plausible knowledge graph triples higher than implausible ones. While KGE accuracy as measured by ranking-based link prediction metrics has been steadily improving on benchmark datasets over the past decade (Ruffinelli et al., 2020), such evaluation setups can be misleading. As shown in Figure 1, ranking only considers the *ordering* of prediction scores, so models can perform well according to ranking metrics even if they assign high scores to incorrect or nonsensical triples (Wang et al., 2019).



Ranked triples predicted by KGE	Uncalib. scores	True?
1. (*Beyoncé, citizen, India*)	0.91	✗
2. (*Beyoncé, citizen, USA*)	0.04	✓
3. (*Beyoncé, citizen, jazz music*)	0.02	✗
⋮	⋮	⋮

Figure 1: An example of how optimizing for ranking does not necessarily lead to trustworthy prediction scores. Here, an uncalibrated KGE model would perform well according to ranking metrics because the true triple is ranked highly, even though it receives a much lower score than the incorrect top-ranked triple and a similar score to the nonsensical triple below it.

As such, the practical utility of KGE for real-world knowledge graph completion remains limited, especially given that other completion techniques such as relation extraction and manual curation have already been reliably deployed in commercial and scientific settings (Suchanek et al., 2007; Dong et al., 2014; Ammar et al., 2018). The outstanding issue that we address relates to *trustworthiness*: That is, to what degree can one trust the predictions made by KGE? We believe that trustworthiness is an important part of making KGE practical for knowledge graph completion.

In this paper we propose to investigate **confidence calibration** as a technique toward making KGE more trustworthy. Intuitively, calibration is a

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8308–8321,
November 16–20, 2020.

post-processing step that adjusts KGE link prediction scores to be representative of actual correctness probabilities (Guo et al., 2017). Calibration has several benefits. From the *systems* perspective, natural language processing pipelines that include knowledge graphs can rely on calibrated confidence scores to determine which KGE predictions to trust. From a *practitioner*'s perspective, calibrated confidence scores act as decision support for accepting or verifying KGE predictions. Toward this direction we contribute the following:

Task We evaluate KGE calibration for link prediction, which is important for making KGE viable for deployment. While many knowledge graph embedding models exist, their calibration and general trustworthiness are under-explored (§ 2).

Complementary evaluations We first evaluate the calibration of established KGE models under the commonly-used closed-world assumption (**CWA**), in which triples not present in the knowledge graph are considered false (§ 4). We show that existing calibration techniques are highly effective for KGE under this assumption. Next, we introduce the more challenging open-world assumption (**OWA**), which reflects how *practitioners* would use KGE: Triples not present in the knowledge graph are assumed to be *unknown*, rather than false, until ground-truth labels are obtained (§ 5). We show that existing calibration techniques are less effective under the OWA than the CWA, and provide explanations for this discrepancy.

Case study Finally, as a proof of concept on the benefits of KGE calibration, we conduct a case study in which data annotators complete knowledge graph triples with the help of KGE predictions. We show that presenting calibrated confidence scores alongside predictions significantly improves human accuracy and efficiency in the task, motivating the utility of calibration for human-AI tasks.

2 Related work

While knowledge graph embeddings and calibration have both been extensively studied in separate communities—see (Ji et al., 2020; Ruffinelli et al., 2020) for reviews of KGE and (Guo et al., 2017) for an overview of calibration for machine learning—relatively little work on calibration *for* knowledge graph embeddings exists.

In the domain of relation extraction, a few works calibrate predicted knowledge graph triples as components of large-scale relation extraction systems. Dong et al. (2014) used Platt scaling (Platt et al., 1999) to calibrate the probabilities of factual triples in the proprietary Knowledge Vault dataset, and West et al. (2014) used Platt scaling in a search-based fact extraction system. However, we focus on link prediction with KGE models that learn only from the knowledge graph itself (§ 3.1).

We are aware of only two recent works that investigate calibration for KGE, both of which address the task of triple classification (Tabacof and Costabello, 2020; Pezeshkpour et al., 2020). By contrast, we focus on link prediction, which is a different—and much more common (Safavi and Koutra, 2020)—KGE evaluation task. We also contribute an evaluation under the open-world assumption, whereas Tabacof and Costabello (2020) evaluate under the closed-world assumption only. Finally, unique to our work, we conduct a human-AI case study to demonstrate the benefits of calibration from a practitioner's perspective.

3 Preliminaries

3.1 Knowledge graph embeddings

A knowledge graph G comprises a set of entities E, relations R, and (*head*, *relation*, *tail*) triples $(h, r, t) \in E \times R \times E$. A knowledge graph embedding (**KGE**) takes triples (h, r, t) as input and learns corresponding embeddings $(\mathbf{h}, \mathbf{r}, \mathbf{t})$ to maximize a scoring function $f : E \times R \times E \rightarrow \mathbb{R}$, such that more plausible triples receive higher scores.

Models In this paper we consider four KGE models: **TransE** (Bordes et al., 2013), **TransH** (Wang et al., 2014), **DistMult** (Yang et al., 2015), and **ComplEx** (Trouillon et al., 2016). Table 1 gives the scoring function of each model.

We choose these models because they are efficient and representative of two main classes of KGE architecture—translational (TransE, TransH) and bilinear (DistMult, ComplEx)—which allows us to interpret how different types of scoring functions affect calibration. Moreover, these earlier models tend to be used by NLP practitioners. For example, the language model in (Logan et al., 2019) uses TransE embeddings, and the machine reading system in (Yang et al., 2019) uses DistMult embeddings. From our knowledge of the literature, practitioners using KGE are more likely to use earlier, established models. Since our work targets real-world applications, we prioritize such models.

Table 1: Scoring functions of models used in our evaluation. **Bold letters** indicate vector embeddings. + indicates that the scoring function is translational, and × indicates that the scoring function is bilinear.

	Type	Scoring function f	Scoring function notes
TransE (Bordes et al., 2013)	$+$	$-\lVert \mathbf{h} + \mathbf{r} - \mathbf{t} \rVert$	We use the L_2 norm
TransH (Wang et al., 2014)	$+$	$-\lVert \mathbf{h}_\perp + \mathbf{r} - \mathbf{t}_\perp \rVert$	Projects $\mathbf{h}$, $\mathbf{t}$ onto relation-specific hyperplanes to get $\mathbf{h}_\perp$, $\mathbf{t}_\perp$
DistMult (Yang et al., 2015)	$\times$	$\mathbf{h}^\top \mathrm{diag}(\mathbf{r})\mathbf{t}$	$\mathrm{diag}(\cdot)$ turns a vector into a diagonal matrix
ComplEx (Trouillon et al., 2016)	$\times$	$\mathrm{Re}\left(\mathbf{h}^\top \mathrm{diag}(\mathbf{r})\bar{\mathbf{t}}\right)$	$\bar{\mathbf{t}}$: Complex conjugate of $\mathbf{t}$; Re: Real part of a complex number

3.2 Link prediction

The link prediction task, which is most commonly used to evaluate KGE (Safavi and Koutra, 2020), is conducted as follows. Given a test triple (h, r, t), we hold out one of its entities or its relation to form a query $(h, r, ?)$, $(?, r, t)$, or $(h, ?, t)$. The model then scores all tail entities $t_i \in E$, head entities $h_i \in E$, or relations $r_i \in R$ as answers to the respective query such that higher-ranked completions (h, r, t_i), (h_i, r, t), or (h, r_i, t) are more plausible. Prior to computing rankings, all true triples across train, validation, and test beyond the given test triple are filtered out (Bordes et al., 2013).

Under the closed-world assumption (**CWA**, § 4), models are evaluated by their ability to score the true test triples (h, r, t) as high as possible, because it is assumed that all triples not seen in the knowledge graph are incorrect. Under the open-world assumption (**OWA**, § 5), models simply score all predicted completions, and the predictions not seen in the knowledge graph are not considered true or false until ground-truth labels are obtained.

3.3 Confidence calibration

In the context of link prediction, calibration is the extent to which a KGE model outputs probabilistic confidence scores that reflect its expected accuracy in answering queries. For example, for 100 predicted triple completions scored at a confidence level of 0.99 by a perfectly calibrated model, we expect 99 of these predictions to be correct.

Calibration is a *post-processing* step. To calibrate a KGE model, separate calibration parameters are learned on a held-out validation set using the prediction scores of the uncalibrated model. These parameters do not affect the trained, fixed embeddings, but rather transform the model's scores.

Negative samples All calibration methods require negatives to appropriately adjust prediction scores for plausible and implausible triples. However, link prediction benchmarks (§ 4.2) do not contain negatives. Therefore, per positive instance, we assume that only the held-out entity or relation correctly answers the query, and take all other completions as negative samples.

This approach, which has been shown to work well in practice for training KGE models (Ruffinelli et al., 2020), treats link prediction as *multiclass*: The "class" for each query is its true, held-out entity or relation. Since this approach is less faithful to reality for queries that have many entities as correct answers, in this paper we evaluate calibration for the **relation prediction** task—that is, answering $(h, ?, t)$ queries—because there are usually fewer correct answers to relation queries than entity queries.[1] While the methods we describe are general, for brevity we focus on relation prediction in this rest of this section.

3.4 Calibration techniques

Let $(h, ?, t)$ be a relation query, $k = |R|$ be the number of relations in the graph, and

$$\mathbf{z} = [f(h, r_1, t), \ldots, f(h, r_k, t)]^\top \in \mathbb{R}^k \qquad (1)$$

be a vector of uncalibrated KGE prediction scores across all relations $r_i \in R$, such that $z_i = f(h, r_i, t)$. Note that for head or tail queries $(?, r, t)$ or $(h, r, ?)$, $\mathbf{z}$ would instead contain prediction scores across all entities in E.

Our goal is to learn a function that transforms the uncalibrated score vector $\mathbf{z}$ into *calibrated probabilities* $\mathbf{z}' \in \mathbb{R}^k$. Post-calibration, the final predicted answer $\hat{r}$ to the query and corresponding confidence score $\hat{p}$ are taken as

$$\hat{r} = \arg\max\,[\mathbf{z}'] \text{ and } \hat{p} = \max\,[\mathbf{z}'], \qquad (2)$$

where $\hat{p}$ reflects the expectation that $\hat{r}$ correctly answers the query, i.e., is the "class" of the query.

One-versus-all One approach to multiclass calibration is to set up k one-versus-all *binary* calibration problems, and combine the calibrated probabilities for each class afterward. The classic **Platt**

---

[1] For example, in our `FB15K-Wiki` dataset (§ 4.2), the mean number of relations between each unique pair of entities is 1.12, and the median is 1.

scaling technique (Platt et al., 1999), which was originally designed for binary classification, can be extended to the multiclass setting in this manner. For each class, scalar parameters a and b are learned such that the calibrated probability of the query belonging to the i-th class is given by $\hat{p}_i = \sigma_{\text{sig}}(az_i + b)$, where σ_{sig} denotes the logistic sigmoid. The parameters are optimized with negative log-likelihood (i.e., binary cross-entropy) loss, which is standard for obtaining probabilistic predictions (Niculescu-Mizil and Caruana, 2005). Afterward, all $\hat{p}_i$ are gathered into $\mathbf{z}' = [\hat{p}_1, \dots, \hat{p}_k]$ and normalized to sum to 1.

Another well-known calibration technique that fits in the one-versus-all framework is **isotonic regression** (Zadrozny and Elkan, 2002). For each class, a nondecreasing, piecewise constant function g is learned to minimize the sum of squares $[\mathbf{1}(r_i) - g(\sigma_{\text{sig}}(z_i))]^2$ across all queries, where $\mathbf{1}(r_i)$ is 1 if the class of the given query is r_i and 0 otherwise. The calibrated probability of the query belonging to the i-th class is taken as $\hat{p}_i = g(\sigma_{\text{sig}}(z_i))$. Again, these scores are gathered into $\mathbf{z}' = [\hat{p}_1, \dots, \hat{p}_k]$ and normalized to sum to 1.

Multiclass An alternative approach is to use the softmax σ_{sm} to directly obtain probabilities over k classes, rather than normalizing independent logistic sigmoids. To this end, Guo et al. (2017) propose a variant of Platt scaling that learns weights $\mathbf{A} \in \mathbb{R}^{k \times k}$ and biases $\mathbf{b} \in \mathbb{R}^k$ to obtain calibrated confidences $\mathbf{z}' = \sigma_{\text{sm}}(\mathbf{Az} + \mathbf{b})$. $\mathbf{A}$ and $\mathbf{b}$ are optimized with cross-entropy loss.

The weight matrix $\mathbf{A}$ can either be learned with the full k^2 parameters (**matrix scaling**), or can be restricted to be diagonal (**vector scaling**). We compare both approaches in § 4.

4 Closed-world evaluation

We first evaluate KGE calibration under the **closed-world assumption** (CWA), in which we assume triples not observed in a given knowledge graph are false. This assumption, which is standard in KGE evaluation (Ruffinelli et al., 2020), helps narrow evaluation down to a well-defined task in which models are judged solely by their ability to fit known data. It is therefore important to first explore this (restrictive) assumption before moving to the more realistic but challenging OWA (§ 5).

Table 2: Datasets used in our closed-world evaluation.

	# entities	# relations	# triples
`WN18RR`	40,493	11	93,003
`FB15K-Wiki`	14,290	773	272,192

4.1 Task and metrics

As described in § 3.2, link prediction under the CWA is conducted by constructing queries from test triples and evaluating models' abilities to score these test triples as high as possible. We measure accuracy by the proportion of top-ranked predicted relations that correctly answer each query.[2]

We quantify a KGE model's level of calibration with expected calibration error (**ECE**) (Guo et al., 2017). ECE measures the degree to which a model's confidence scores match its link prediction accuracy in bins partitioning [0, 1]. Given M such bins of equal size, ECE is defined as $\sum_{m=1}^{M} \frac{|B_m|}{n} |\text{acc}(B_m) - \text{conf}(B_m)|$, where n is the number of test triples, B_m is the bin containing all predictions with confidence score in a given region of $[0, 1]$, acc(B_m) measures the average link prediction accuracy in bin B_m, and conf(B_m) measures the average confidence score in bin B_m. ECE is in [0, 1], and lower is better. For all reported ECE values, we use 10 bins.

4.2 Data

We use two link prediction benchmarks (Table 2): The `WN18RR` semantic relation network (Dettmers et al., 2018) and a version of the FB15K encyclopedic knowledge graph (Bordes et al., 2013). We refer to this dataset as `FB15K-Wiki` because we link it to Wikidata (Vrandečić and Krötzsch, 2014) to use as an external reference in § 5 for data annotation, discarding entities without entries in Wikidata. Following standard practice, we remove inverse relations from `FB15K-Wiki`, which artificially inflate link prediction accuracy (Dettmers et al., 2018). We randomly split both datasets into 80/10/10 train/validation/test triples to ensure a sufficient number of validation triples for calibration.

Note that there have been recent (concurrent) efforts to construct appropriate datasets for evaluating KGE calibration (Pezeshkpour et al., 2020; Safavi and Koutra, 2020). Analysis on these new datasets is an important direction for future work.

---

[2] Here we use top-1 accuracy because there are relatively few relations in knowledge graphs. However, any binary link prediction metric (i.e., hits@k) may be used.

Table 3: ECE (10 bins) and accuracy on `WN18RR` and `FB15K-Wiki`. ↑: Higher is better. ↓: Lower is better.

		`WN18RR`					`FB15K-Wiki`				
		Uncalib.	One-vs-all		Multiclass		Uncalib.	One-vs-all		Multiclass

4.3 Results and discussion

We implement our methods in an extension of the OpenKE library.[3] To understand "off-the-shelf" calibration, we train models with the original loss functions and optimizers in the respective papers. Appendix A provides details on implementation and model selection.

Calibration error Table 3 gives the ECE of all models before and after calibration using each technique in § 3.4. Confidence scores prior to calibration are scaled via the softmax. Across datasets, standard techniques **calibrate models within 1-2 percentage points of error** under the CWA. In most cases, the strongest methods are the multiclass (softmax) approaches. The only exception is matrix scaling on `FB15K-Wiki`, which overfits due to the large number of classes in the dataset (773 in `FB15K-Wiki` versus only 11 in `WN18RR`, Table 2). Evidently, taking the softmax over k classes leads to more discriminative probabilities than setting up k separate one-versus-all calibration problems and performing post-hoc normalization.

We also observe that off-the-shelf calibration error is correlated with model type, as the bilinear models (DistMult, ComplEx) consistently have lower ECE than the translational models (TransE, TransH). To illustrate these differences, Figure 2 gives reliability diagrams for TransE and DistMult before and after calibration. Reliability diagrams (Guo et al., 2017) bin predictions by confidence level into equally-sized regions of [0, 1] and show the relationship between average confidence level and accuracy in each bin, similar to ECE (§ 4.1). Without calibration, TransE is underconfident because it scores all predictions nearly the same, whereas DistMult is better calibrated. We observe a similar pattern for TransH and ComplEx.

One potential explanation for this difference is that multiplicative scoring functions lead to more discriminative scores due to the composition of dot products, which amplify embedding values. In fact, TransE is the only model that does not apply any dot product-based transformation to embeddings, leading to the worst off-the-shelf calibration. Another explanation relates to losses: All methods except ComplEx are trained with margin ranking loss, which optimizes the ordering of predictions rather than the values of prediction scores. By contrast, ComplEx is trained with binary cross-entropy loss, the same loss that we use to calibrate models in the validation stage.
