What types of pairs cause low recall? Since the proposed method prefers precision over recall, it tends to discard a certain number of acceptable utterance pairs during filtering. To investigate the characteristics of such discarded (yet acceptable) pairs, we analyzed 27 pairs.[11] These pairs were selected from those that obtained a human score of 4.0 or above (77 pairs) *and* were among the worst 50% as scored by $S_{\mathbf{C+R}}$ (100 pairs). Consequently, we found two potential issues. One is that human annotators may sometimes easily find the connectivity or the content relatedness for the utterance pairs with the low $S_{\mathbf{C+R}}$ scores. This observation indicates that $S_{\mathbf{C}}$ and $S_{\mathbf{R}}$ are still not perfect for scoring functions, and there remains room for improvement. The possible drawbacks we have already noticed in $S_{\mathbf{C}}$ and $S_{\mathbf{R}}$ are that $S_{\mathbf{C}}$ sometimes fails to capture the connectivity because of the limited coverage by a discrete phrase table-based approach, and $S_{\mathbf{R}}$ is not robust for out-of-vocabulary of word vector. The other case is that the human annotators gave high scores, but we found no connectivity and content relatedness in the utterance pairs. We found that some utterance pairs without any connectivity and content relatedness can be judged as acceptable by the human annotators since they can imagine the underlying context and situation of the utterance pairs using human world knowledge, such as commonsense. We think this is a challenging issue that exceeds our focus in this paper, and thus, remains as future work.

Scored data	len	distinct-1	distinct-2
Top 50% (remained)	9.02	0.028	0.472
Worst 50% (removed)	9.00	0.030	0.470

Table 4: Comparison of the top and the worst utterance pairs' responses in the training data scored by our method (English).

Does our filtering undermine diversity? One might think that our method succeeds in filtering by assigning high scores to generic responses such as dull responses. This concern makes sense since it is

---

[10] See Appendix E.2 for score distributions on training data.

[11] Some examples are listed in Appendix E.3

Training data	# of pairs	Automatic evaluation				Human evaluation		
		len	distinct-1	distinct-2	BLEU-1	Avg.	✗$^{\downarrow}$	✔$^{\uparrow}$

Table 5: Evaluation results for generated responses (English; filtered out 50%). **Bold** denotes the best results. The ✗/✔ shows the percentages of the low/high scored responses (i.e., human scores in $[1, 3)$ or in $[3, 5)$).

known that dialogue systems learned from the training data, including many generic utterances, tend to generate bland responses (Csáky et al., 2019). To answer this interesting question, we confirmed the diversity of utterance pairs with a high score (i.e., remained as training data) and a low score (i.e., removed from training data) in our $S_{\mathbf{C+R}}$ (Table 4).[12] As a result, there was no significant difference between them. Therefore, we conclude that the proposed method does not prefer only generic responses and maintains the diversity of data. It is an essential future attempt to improve the quality of dialogue data further (e.g., more diversity) after using the proposed method to remove unacceptable pairs.

7 Experiments: Response Generation

This section reports on the effectiveness of the proposed method for filtering noisy data in neural response generation.

7.1 Experimental Setup

Training. We obtained the filtered training data $\mathcal{D}'$ by removing utterance pairs with low scores from the original dataset $\mathcal{D}$ (approximately 10% or 50% of total utterance pairs were removed). As a response generation model, we used a Transformer (Vaswani et al., 2017) based encoder-decoder model implemented in the `fairseq` toolkit (Ott et al., 2019).[13] Transformer has demonstrated high performance in response generation (Dinan et al., 2019) and other NLP tasks.

Automatic evaluation. Here, we report the following metrics: the average response length in tokens (len), type-token ratio for $\{1, 2\}$-grams

1 : **Well, I thought we'd wait for Mr. Oliver.**
A : I don't think so.
B : I'll be right back.
C : I'm sorry, but I have to get back to work.
D : No, I don't think so.
Ours : Oh, I'm sorry.

2 : **Are you heading home?**
A : No, I don't think so.
B : No, I don't think so.
C : No, no, no, no, no, no, no, no, no, no, no, no.
D : No, I don't think so.
Ours : No, I'm not.

3 : **Because we want to keep him safe.**
A : I don't know what you're talking about.
B : I don't know what you're talking about.
C : I don't care if he's dead or alive or dead.
D : I don't know what you're talking about.
Ours : We need to get him out of here.

4 : **Quite soon, now, you'll be able to travel.**
A : I don't think so.
B : I'll be back in a minute.
C : I'll be back in a few days, then I'll be back.
D : I don't want to see you again.
Ours : No, I'm not going anywhere.

5 : **Which is where exactly?**
A : I don't know.
B : I don't know.
C : I don't know what you're talking about, but I don't know where you are.
D : I don't know.
Ours : I don't know.

Table 6: Samples of input utterances **(bold)** and responses generated by models trained on filtered data by proposed method $S_{\mathbf{C+R}}$ (Ours). Other responses are generated by models trained on (A) non-filtered data and filtered data by baselines; (B) Csáky et al. (2019)'s SRC method, (C) their TRG method, and (D) Junczys-Dowmunt (2018)'s method, respectively.

[13] See Appendix D for training details.

(distinct-$\{1, 2\}$), and and BLEU-1 (Papineni et al., 2002). The latter was used as a reference-based metric; while it is widely used in previous studies (Zhao and Eskenazi, 2017; Baheti et al., 2018; Csáky et al., 2019), some studies (e.g., (Liu et al., 2016)) have reported that BLEU-1 may not be highly correlated with the human evaluation of response generation.[14]

Human evaluation. We evaluated the quality of the generated responses manually. We asked human evaluators recruited via Amazon Mechanical Turk to evaluate responses that are generated for 100[15] input utterances randomly sampled from the test data. We used the same task setting and protocol as described in Section 6.1 to obtain the human scores for each pair. Higher human scores indicate that the better results.

7.2 Results and Analysis

Table 5 shows the results of automatic and human evaluations of the generated responses. The model trained on the data filtered using the proposed method $S_{\mathbf{C+R}}$ produced more than three times as many distinct $\{1, 2\}$-grams as the model trained on non-filtered data. Furthermore, it outperformed the model trained on non-filtered data in the human evaluation, achieving the highest percentage of acceptable responses of 85%. Additionally, these results of our $S_{\mathbf{C+R}}$ were better than other baselines. To conclude, these experimental results indicate that the proposed scoring method can help generate diverse responses that are judged as acceptable by humans.

This experiment provides empirical evidence for supporting our hypothesis that the performance of neural response generation models can be improved by just removing unacceptable utterance pairs from training data, which answers the research question formulated at the start of this paper.

8 Multilingual Availability

While the proposed method $S_{\mathbf{C+R}}$ was tested on an English corpus, it can potentially work for other languages as well. To demonstrate this, we selected Japanese dialogue data as another case study.[16] The linguistic phenomena in Japanese are quite different from those in English, thus making this experiment to be a good test of the applicability of the proposed method to non-English languages.

Scoring method	Spearman's ρ	p-value
Csáky et al. (2019) SRC	-0.0553	4.4×10^{-1}
Csáky et al. (2019) TRG	-0.0366	6.1×10^{-1}
Junczys-Dowmunt (2018)	0.1074	1.3×10^{-1}
Ours $S_{\mathbf{C+R}}$	**0.2491**	$\mathbf{3.8 \times 10^{-4}}$
Ours $S_{\mathbf{C}}$ (ablation study)	0.1395	4.9×10^{-2}
Ours $S_{\mathbf{R}}$ (ablation study)	0.1504	3.3×10^{-2}

Table 7: Correlation coefficient between human scores and automatically computed scores (Japanese).

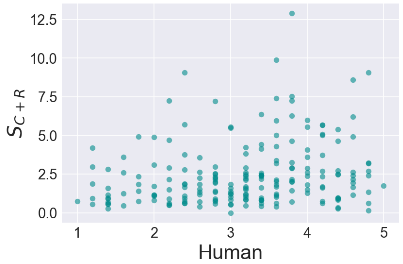

Figure 3: Distribution between human scores and our $S_{\mathbf{C+R}}$ (Japanese).

Japanese dataset. We prepare the Japanese dialogue data from Japanese OpenSubtitles (Lison et al., 2018) containing roughly 3M lines. We obtain 1,893,477 utterance pairs as our training data, which excludes our test and validation data.[17]

8.1 Data Scoring

Settings. To compute $S_{\mathbf{C}}$, we defined a low co-occurrence frequency as less than 20, considering the size of the Japanese corpus, and consequently obtained the key phrase pairs $|\mathcal{P}| = 19{,}992$. To compute $S_{\mathbf{R}}$, we used pre-trained fastText (Grave et al., 2018) and learned common components from all sentences in the training data.

For human evaluation, we used Yahoo! crowdsourcing[18] to hire native Japanese-speaking workers. The task setting and protocol are the same as those for English (Section 6.1), regardless of the crowdsourcing platform.

Results and analysis. Table 7 shows the correlation between human scores and those automatically computed by each method. Our method $S_{\mathbf{C+R}}$ has the highest correlation with human scores, although the overall result is lower than that obtained for the English dataset. Figure 3 shows the distribution of

Table 8: Evaluation results for generated responses (Japanese; filtered out 10%). **Bold** denotes the best results. The ✘/✔ shows the percentages of the low/high scored responses (i.e., human scores in $[1, 3)$ or in $[3, 5)$).

our $S_{\mathbf{C+R}}$ corresponding to human scores. Similar to the result obtained for English as presented in Figure 2 (c), $S_{\mathbf{C+R}}$ rarely overestimates utterance pairs with low human scores but underestimates those with high human scores in Japanese.

8.2 Response Generation

Settings. We used the same experimental settings described in Section 7.1 for the preparation of filtered data $\mathcal{D}'$ and model training.

Results and analysis. Table 8 shows the results of evaluations of the generated responses. The filtered data generated by $S_{\mathbf{C+R}}$ provided the best results in terms of almost all the metrics, including human evaluation. It supports our hypothesis that the proposed method is also suitable for non-English languages.

9 Relationship with Evaluation Metric

The proposed method $S_{\mathbf{C+R}}$ maps an utterance pair to a score (scalar value) in terms of the quality of dialogue. That is, formally, our method is similar to the reference-free automatic evaluation metrics for dialogue agents; both of them evaluate the response given an input utterance and also map into a score. Recently, the novel reference-free metrics for evaluating generated responses such as USR (Mehri and Eskenazi, 2020) or MAUDE (Sinha et al., 2020) ware developed. While it is possible to use them as a scoring method for filtering noisy data, in theory, there are some concerns with applying them in practice. One is the difference of the data of interest; since evaluation metrics are intended for responses generated as dialogue, i.e., somewhat valid dialogue data, it is unclear whether they also work for apparently noisy data. Another one is the difference of desired properties; evaluation metrics need to be sensitive to "how good is it?" while the filtering requires to detect "is it a dialogue?" with high accuracy. It would be interesting to investigate the effectiveness of reference-free metrics for noisy dialogue data filtering tasks, and vice versa. We leave these investigations for future work.

In contrast, reference-based metrics require a reference response (i.e., ground truth) when they calculate scores; such metrics include the traditional overlap-based BLEU, ROUGE, METEOR, embedding-based metrics (Liu et al., 2016), and neural network-based RUBER (Tao et al., 2018) and ADEM (Lowe et al., 2017a) Thus, these methods cannot straightforwardly be considered as alternatives to the proposed method, which aims at filtering.

10 Conclusion

In light of the success of noisy corpus filtering in neural machine translation, we attempted to filter out unacceptable utterance pairs from large dialogue corpora in an unsupervised manner. The proposed scoring method estimates the quality of utterance pairs by focusing on the two crucial aspects of dialogue, namely, the *connectivity* and *content relatedness* of utterance pairs. We demonstrated that our scoring method has a higher correlation with human judgment than recently proposed methods. Furthermore, we provided empirical evidence that our method improves the performance of a response generation model by removing unacceptable utterance pairs from its training data. We hope that this study will facilitate discussions in the dialogue response generation community regarding the issue of filtering noisy corpora.

A Preliminary Experiment Settings

Dataset. For our preliminary experiment (Section 1), we use OpenSubtitles (Lison et al., 2018)[19] in English, one of the largest corpora of movie scripts that are freely available and has been used in many data-driven dialogue response generations. We automatically obtained dialogue paired-data from the corpus which does not contain speaker annotations on the dialogue turns *following the previous methods* (Vinyals and Le, 2015; Li et al., 2016). Specifically, we extracted the consecutive two lines as an utterance pair based on the assumption that each line corresponds to a full-speaker's turn. We collected pairs from the dataset in which the length of the utterance and response was 3-25 words each and obtained the dialogue dataset. For counting the number of words, we used SpaCy[20] to tokenize each utterance and response.

Evaluation settings. We used Amazon Mechanical Turk (MTurk) to evaluate the data manually. In our experiments, randomly sampled 100 utterance pairs were evaluated by native English speakers. We filtered out unreliable workers by integrating attention checks. We requested five workers to evaluate each pair with a five-point Likert scale (5: Strongly agree to 1: Strongly disagree) (Likert, 1932) as an answer to the following question: *Is the sequence of the two utterances acceptable as a dialogue?*.

Result. As a result of our preliminary experiment, we discover that, out of all scores given for utterance pairs, 25% was unacceptable (scored as 1: Strongly disagree or 2: Disagree) and almost half was acceptable (scored as 5: Strongly agree or 4: Agree). The inter-annotator agreement (Krippendorff's alpha) was 0.33.

B Dialogue Data Constructions

English Dataset. In our experiments (Section 6, 7), we used the OpenSubtitles as an example of the noisy million-scales English dialogue corpus. In addition to the previous method for the extraction of pair data (as described in Appedix A), we cleaned the data with some heuristic preprocesses. Some processings were inspired by the technique of noisy-parallel corpus filtering on NMT fields. The additional preprocesses that we conducted are as follows:

- Using languid[21], which is a tool that detects the language for given sentences, we removed the utterance pairs judged as any language other than the target language.
- Removed the parrot-back utterance pairs.
- Removed duplicate utterance pairs in order to remove the completely repeated conversational sequences, such as the opening scenes of serial dramas.

Eventually, we obtained 79,621,506 utterance pairs as our English dialogue corpus. For our experiments, we divided them into training/validation/test data. Table 9 shows the statistics of our English dataset. The "# pairs" indicates the number of utterance pairs obtained by the previous method described in Appedix A.

Data	# works	# lines	# pairs	# our pairs
Corpus	446,612	441,452,475	230,597,913	79,621,506
Train	442,433	441,065,310	230,392,431	79,445,453
Valid	200	195,297	104,007	90,317
Test	200	191,868	101,475	85,736

Table 9: The statistics of our English dataset.

Japanese Dataset. For our other experiment (Section 8), we prepared our Japanse corpus from OpenSubtitles. The data construction process, including preprocesses, is the same as those for English (as described in Appendix A and the previous paragraph). We used mecab[22] to tokenize the Japanese utterances. Eventually, we obtained 1,917,721 utterance pairs as our Japanese dialogue corpus. For our experiments, we divided them into training/validation/test data. Table 10 shows the statistics of our Japanese dataset. The "# pairs" indicates the number of utterance pairs obtained by the previous method described in Appedix A.

Data	# works	# lines	# pairs	# our pairs
Corpus:	3,546	3,170,155	2,266,127	1,917,721
Train	3,506	3,135,812	2,240,847	1,893,477
Valid	20	15,489	11,939	11,486
Test	20	18,854	13,341	12,758

Table 10: The statistics of our Japanese dataset.

C Experimental Details of Proposed Method

C.1 Computing Connectivity as S_{C}

To compute alignment points with fastAlign, we set the null alignment probability to 0.5 and used the 'grow-diag-final' heuristics. To extract phrase pairs with Moses using the information of alignment points, we used the following settings: alignment='grow-diag-final-and', reordering='msd-bidirectional-fe', and first-step=4. Furthermore, we extended the standard phrase extraction algorithm (Algorithm 1) to only extract phrases that have at least one alignment point for every row and column when considering the matrix view of phrases (Algorithm 2). This is because unaligned words should not be positively dealt with in the evaluation of connectivity.

C.2 Computing Content relatedness as S_{R}

For SIF weighting in Japanese data, we obtained word frequency data from jawiki dataset[23] following English word frequency data provided in the author's implementation.[24]

D Training Details for Response Generation Model

To obtain the response generation model, we used a Transformer (Vaswani et al., 2017) based encoder-decoder model implemented in the `fairseq` toolkit[25] (Ott et al., 2019). We used '`--arch transformer_wmt_en_de_big`' option with its default configuration, and set the number of maximum training steps to 100K. We used the byte pair encoding[26] (Sennrich et al., 2016) for token segmentation and set its vocabulary size to 16K. The numbers of parameters in our models were roughly 223M. We trained our models on 8 NVIDIA DGX-1 Tesla V100 GPUs. It took approximately 6 hours for training one model.

E Experimental Results on English

E.1 Distributions between Human and Automatic Scoring

Figure 4 shows that, for all the models including ablations, the distributions between human scores and automatically computed scores.

Algorithm 1 Phrase pair extraction

```
Input: word alignment $\mathcal{A}$ for sentence pair $(x, y)$
Output: set of phrase pair $\overline{\mathcal{P}}$
for $f_{\text{start}} \leftarrow 1, \cdots, |x|$ do
    for $f_{\text{end}} \leftarrow f_{\text{start}}, \cdots, |x|$ do
        $e_{\text{start}} \leftarrow |y|$
        $e_{\text{end}} \leftarrow 0$
        for all $(f, e) \in \mathcal{A}$ do
            if $f_{\text{start}} \leq f \leq f_{\text{end}}$ then
                $e_{\text{start}} \leftarrow \min(e, e_{\text{start}})$
                $e_{\text{end}} \leftarrow \max(e, e_{\text{end}})$
            end if
        end for
        add extract($e_{\text{start}}, e_{\text{end}}, f_{\text{start}}, f_{\text{end}}$) to set $\overline{\mathcal{P}}$
    end for
end for
function extract($e_{\text{start}}, e_{\text{end}}, f_{\text{start}}, f_{\text{end}}$)
return {} if $e_{\text{end}} = 0$
for all $(e, f) \in \mathcal{A}$ do
    return {} if $f < f_{\text{start}}$ or $f > f_{\text{end}}$
end for
$F = \{\}$
$e_{\text{s}} \leftarrow e_{\text{start}}$
repeat
    $e_{\text{e}} \leftarrow e_{\text{end}}$
    repeat
        add phrase pair $(f_{\text{start}} ... f_{\text{end}}, e_{\text{s}} ... e_{\text{e}})$ to set $F$
        $e_{\text{e}} + +$
    until $e_{\text{e}}$ aligned
    $e_{\text{s}} - -$
until $e_{\text{s}}$ aligned
return $F$
```

Algorithm 2 Modified phrase pair extraction

```
Input: word alignment $\mathcal{A}$ for sentence pair $(x, y)$
Output: set of phrase pair $\overline{\mathcal{P}}$
for $f_{\text{start}} \leftarrow 1, \cdots, |x|$ do
    for $f_{\text{end}} \leftarrow f_{\text{start}}, \cdots, |x|$ do
        $e_{\text{start}} \leftarrow |y|$
        $e_{\text{end}} \leftarrow 0$
        $\mathcal{F} = \{\}$
        $\mathcal{E} = \{\}$
        for all $(f, e) \in \mathcal{A}$ do
            if $f_{\text{start}} \leq f \leq f_{\text{end}}$ then
                $e_{\text{start}} \leftarrow \min(e, e_{\text{start}})$
                $e_{\text{end}} \leftarrow \max(e, e_{\text{end}})$
                $\mathcal{F} \leftarrow \mathcal{F} \cup \{f\}$
                $\mathcal{E} \leftarrow \mathcal{E} \cup \{e\}$
            end if
        end for
        add extract($e_{\text{start}}, e_{\text{end}}, f_{\text{start}}, f_{\text{end}}, \mathcal{F}, \mathcal{E}$) to set $\overline{\mathcal{P}}$
    end for
end for
function extract($e_{\text{start}}, e_{\text{end}}, f_{\text{start}}, f_{\text{end}}, \mathcal{F}, \mathcal{E}$)
return {} if $e_{\text{end}} = 0$
for $f \leftarrow f_{\text{start}}, \cdots, f_{\text{end}}$ do
    return {} if $f \notin \mathcal{F}$
end for
for $e \leftarrow e_{\text{start}}, \cdots, e_{\text{end}}$ do
    return {} if $e \notin \mathcal{E}$
end for
return phrase pair $(f_{\text{start}} ... f_{\text{end}}, e_{\text{start}} ... e_{\text{end}})$
```

Table 13: Automatic evaluation results for generated responses (English). BLEU-1 (B1) and its brief penalty (bp), ROUGE (ROU)×100, METEOR×100 (MET), CIDEr×100 (CID). Embedding-based metrics: Embedding Average Cosine Similarity (EA), Vector Extrema Cosine Similarity (VE), Greedy Matching (GM).

E.2 Score Distributions

Figure 5 shows that the score distributions of our $S_{\mathbf{C}}$, $S_{\mathbf{R}}$, $S_{\mathbf{C+R}}$ across our training data. Note that, for computing $S_{\mathbf{C+R}}$, $S_{\mathbf{R}}$ that less than 0 (pale -colored part in (c)) are treated as 0 (Equation 2).

E.3 Qualitative Analysis for Low Recall

Table 11 shows the samples of utterance pairs that cause low recall property. In the 1st and 2nd pairs, humans can observe the connectivity or the content relatedness, but $S_{\mathbf{C}}$ or $S_{\mathbf{R}}$ failed to provide high scores. For example, "Carcharodontosaurus" and "Spinosaurus" were unknown words for $S_{\mathbf{R}}$. Other pairs cannot be correctly determined from only these two perspectives. The 3rd and 4th pairs are acceptable, although they have neither the connectivity nor the content relatedness. The 5th pair needs more external contexts and knowledge to determine whether it is acceptable as dialogue.

E.4 Comparison of Top versus Worst Data

Table 12 shows that the comparison of utterance pairs with a high score (i.e., remained as training data; top 50%) and a low score (i.e., removed from training data; worst 50%) in our $S_{\mathbf{C+R}}$. We confirmed there is almost no difference in diversity between the top and the worst ones in terms of pairs, their utterances, and their responses, respectively.

E.5 Automatic Evaluation Results for Generated Responses

Table 13 shows automatic evaluation results for generated responses in our experiment (Section 7). To calculate these scores, we used publicly available tools.[27],[28]

F Experimental Results on Japanese

F.1 Distributions between Human and Automatic Scoring

Figure 6 shows that, for all the models including ablations, the distributions between human scores and automatically computed scores.

F.2 The Distributions of Proposed Scores

Figure 7 shows that the score distributions of our $S_{\mathbf{C}}$, $S_{\mathbf{R}}$, $S_{\mathbf{C+R}}$ across our training data. Note that, for computing $S_{\mathbf{C+R}}$, $S_{\mathbf{R}}$ that less than 0 (pale-colored part in (c)) are treated as 0 (Equation 2).

F.3 Comparison of Top versus Worst Data

Table 14 shows that the comparison of utterance pairs with a high score and a low score in our $S_{\mathbf{C+R}}$. We confirmed there is almost no difference in diversity between the top and the worst ones in terms of pairs, their utterances, and their responses, respectively.

F.4 Automatic Evaluation Results for Generated Responses

Table 15 shows automatic evaluation results for generated responses in our experiment (Section 8.2). To calculate these scores, we used publicly available tools.[29]

Latent Geographical Factors for Analyzing the Evolution of Dialects in Contact

Abstract

Analyzing the evolution of dialects remains a challenging problem because contact phenomena hinder the application of the standard tree model. Previous statistical approaches to this problem resort to admixture analysis, where each dialect is seen as a mixture of latent ancestral populations. However, such ancestral populations are hardly interpretable in the context of the tree model. In this paper, we propose a probabilistic generative model that represents latent factors as geographical distributions. We argue that the proposed model has higher affinity with the tree model because a tree can alternatively be represented as a set of geographical distributions. Experiments involving synthetic and real data suggest that the proposed method is both quantitatively and qualitatively superior to the admixture model.

1 Introduction

How languages have changed over time is a question that has attracted a lasting interest. Observing the present state of a language, we typically want to trace it back to the past. Historical–comparative linguists have done this by systematically comparing related languages and representing them as a tree. The success of this approach led to the establishment of language families such as Indo-European and Austronesian (Campbell, 2004). The recent adoption of computer-intensive statistical methods offer additional insights (Gray and Atkinson, 2003; Bouckaert et al., 2012; Chang et al., 2015).

When it comes to dialects, or closely-related languages,[1] the situation is very different. When we draw an *isogloss*, or the geographical boundary of a linguistic feature, and collect such isoglosses, it often happens that they conflict with each other (Kalyan and François, 2018). Conflicting isoglosses violate the assumption of the tree model, where after a branching event, two daughter languages evolve without any contact.

Nevertheless, some historical–comparative linguists have recently tried to apply the tree model to dialects in intense contact, with the assumption that at least some portion of observed data reflects tree-like vertical inheritance while the rest may result from horizontal contact (Lawrence, 2006; Pellard, 2009; Igarashi, 2017). While these efforts have been met with some success, it seems to us that the inherent difficulty in disentangling the two modes of transmission remains unresolved. This motivates us to turn to statistical modeling because computers are better at handling uncertainty than humans.

As a statistical model to analyze the evolution of dialects, admixture analysis has received attention in recent years (Bowern, 2012; Syrjänen et al., 2016; Cathcart, 2020). It assumes that each dialect is generated from a mixture of latent ancestral populations. Unfortunately, such ancestral populations can hardly be used for humans to infer a tree. Covering all the dialects with varying degrees of membership, an ancestral population only offers vague information about subgrouping if it does.

In this paper, we propose a probabilistic generative model that represents latent factors as geographical distributions (Figure 1). The geographical distribution of an observed feature is assumed to be stochastically generated from a weighted combination of the latent geographical factors. These factors are much more easier to interpret in the context of the tree model than latent ancestral population of the admixture model because an internal node of a tree can be geographically represented as the set of its descendant leaves. Some latent factors may be associated with vertical inheritance while others reflect horizontal transfer. We revisit this point in Section 5.3.

To evaluate the proposed method, we begin by

---

[1] The language/dialect distinction is not clear-cut. In this paper, the two terms are used interchangeably.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 959–976,
November 16–20, 2020.

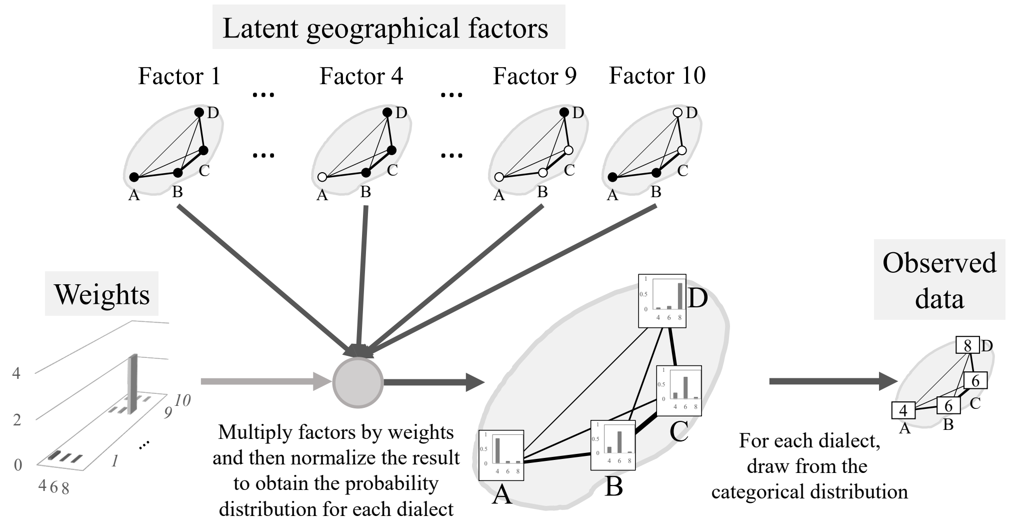

Figure 1: An overview of the proposed method. There are $L = 4$ dialects, A, B, C, and D, on the island. The figure focuses on one of N features, for which each dialect takes the value 4, 6, or 8 (bottom right). The proposed method decomposes the observed data into $K = 10$ latent factors and the corresponding weights. Each latent factor has its own geographical distribution (top). Filled circles indicates the dialects are covered by the latent factor, while the dialects represented by hollow circles are not. Each feature value is tied to K weights (bottom left). Multiplying the binary factors by the weights and normalizing the resultant scores, we obtain a probability distribution for each dialect (bottom center). The value of each dialect is assumed to be drawn from the categorical distribution.

simulation experiments, where we know the ground truth. We demonstrate that the proposed method recovers tree-based and geographical clusters better than the admixture model. We then switch to a basic vocabulary database of Fijian dialects, whose evolutionary history is yet to be uncovered. We confirm that the proposed method detects major dialect groups. Although the proposed method in its current form focuses on spatial inference, the quantification it offers shows the potential of making temporal reasoning. The code is available at `https://github.com/murawaki/dialect-latgeo`.

2 Background

2.1 Dialectology

It is important to note that although we work on dialects, we methodologically lean toward historical–comparative linguistics. While historical–comparative linguistics is known for the Neogrammarian doctrine of *exceptionless* sound laws, dialectology is dominated by the dictum, "every word has its own history." In fact, the *Atlas linguistique de la France* (Gilliéron and Edmont, 1902–1910) and subsequent linguistic atlases that have been produced by dialectologists elaborate "the geography not of dialects but of linguistic traits" (Goebl, 2018).

Nevertheless, there have been several attempts in dialectology to aggregate over a large set of features (see Nerbonne and Wieling (2018) for an overview). Among the most popular ones are dimensionality reduction techniques such as principal component analysis (PCA) and multidimensional scaling (MDS). PCA is also routinely employed in population genetics to infer population structure from recombining genetic markers (Menozzi et al., 1978; Patterson et al., 2006). For visualization, each language is colored according to the value of a selected principal component (PC). In typical applications, at most the first three PCs are examined because subsequent PCs are hardly interpretable.

Recent applications of NLP techniques to dialectology and sociolinguistics (Eisenstein et al., 2010, 2014) make use of geotagged social media. While the big data allow us to analyze language variation and language change to the fine details, our interest lies in (1) applicability to unwritten languages and (2) language change on the order of hundred years or more. For these reasons, we work on data manually complied by field linguists.

2.2 Historical–Comparative Linguistics

Historical–comparative linguistics is characterized by careful manual selection of features (Sagart et al.

(2019) is a recent example). If two languages are phylogenetically closely related, they must be similar to each other, but not vice versa. It is because there are at least four ways to explain the fact that two languages share the same feature value: (1) inherited from a common ancestor (*vertical inheritance*), (2) borrowed from one language into another (*horizontal transfer*), (3) reflecting universal tendencies, and (4) coincidence. Only the first factor is a genuine phylogenetic signal. In order to establish phylogenetic relationships, linguists carefully count out features that have potential connections to the remaining three factors.

When three or more languages are involved, their subgroups need to be determined. To do so, linguists focus on *shared innovations* (Hoenigswald, 1966). A shared innovation is a change that occurred in an intermediate descendant from which a subset of modern languages have descended and that is not shared by the remaining languages. In other words, *shared retentions*, or feature values inherited from the common ancestor, are disregarded because they cannot be used as a criterion for subgrouping.

When the above-mentioned principle is applied to dialects in intense contact, an even more stringent feature selection is performed.[2] For example, Lawrence (2006) and Pellard (2009) discard a set of regular sound changes in favor of a conflicting *irregular* sound change, arguing that the former is more likely to occur in parallel (i.e., universal tendencies). However, they appear to have so much trouble distinguishing vertical inheritance from horizontal transfer. In addition, a large number of discarded features must constitute an important aspect of evolutionary history that awaits description. For these reasons, we choose a setting where no manual feature selection is performed. At this stage of research, our model is agnostic as to which factor has led to the current distribution of a given feature although we are much interested in tying some of the latent factors to the tree model.

Igarashi (2017) manually searched for *matryoshka*-like geographical distributions of shared innovations to construct a phylogenetic tree of dialects, with the assumption that if the distribution of one innovation is nested inside that of another, it reflects a branching event within the tree. We concur with his idea that spatial inference forms the basis for temporal reasoning. We note that an innovation that occurred in the past is not necessarily directly observable because it can be overshadowed by subsequent changes. As a probabilistic model, the proposed method has the potential to recover the original pattern given that it is supported by other observed features.

2.3 Admixture Analysis

Originally borrowed from population genetics (Pritchard et al., 2000; Alexander et al., 2009), what we collectively refer to as admixture analysis has been employed in recent studies on dialects (Bowern, 2012; Syrjänen et al., 2016; Cathcart, 2020). The same technique was also used to analyze typological features (Reesink et al., 2009; Longobardi et al., 2013).

Like the more familiar latent Dirichlet allocation (LDA) (Blei et al., 2003), an admixture model assumes that each individual (document) is stochastically generated from a mixture of K ancestral populations (topics). A major difference is that while LDA ties a single vocabulary distribution to each topic, each ancestral population has N discrete distributions, one per feature type.

We argue that this is not a natural assumption for languages although it is for genetic data. A population (a collection of individuals) normally maintains multiple values for a genetic marker. In contrast, a speech community would have trouble communicating if it uses multiple values for a single feature (e.g., multiple words for a given concept). To guarantee efficient communication, a language must take a single value for each feature, except for transitional periods. To address this problem, Cathcart (2020) explicitly imposes sparsity on his model.

2.4 Phylogenetic Networks

When horizontal transfer is non-negligible, a network model is often used as an alternative to the tree. NeighborNet (Bryant and Moulton, 2004) is arguably the most famous implementation of the idea and has been applied to dialect data (Lee and Hasegawa, 2011; Saitou and Jinam, 2017).

However, it must be noted that NeighborNet does not explicitly indicate any single evolutionary scenario but simply visualizes multiple conflicting trees as a single network. Nichols and Warnow

---

[2] Ignoring the methodology of historical–comparative linguistics, Lee and Hasegawa (2011) applied a computer-intensive phylogenetic method to a lexical dataset of dialects. Not surprisingly, the resulting phylogenetic tree is judged totally unreliable by an expert linguist (Pellard, 2018).

(2008) give warning against applying the model to dialects under intense contact.

3 Proposed Method

3.1 Basic Idea

The key insight behind the proposed method is that both vertical and horizontal signals can be represented as geographical distributions. If horizontal contact occurs in a certain area, leading to multiple feature values being shared by the dialects there, we can identify the corresponding geographical cluster. Similarly, a group of dialects that exclusively share the same ancestor usually occupies a continuum geographical space. Because their shared evolutionary history results in many shared feature values, the corresponding geographical subspace can be identified. Note, however, that we do not necessarily observe geographical distributions in their original forms because a state in the past can be overshadowed by subsequent changes. Therefore, our goal is to induct latent, typically clearer geographical factors from observed geographical distributions, as illustrated in Figure 1.

Each latent geographical factor is responsible for spreading certain feature values. Ideally, a binary variable should indicate the presence or absence of a feature value in the latent geographical factor. However, observed data are too complex and noisy to be explained by a deterministic generative process, and we want to reserve clear-cutness for latent geographical distributions. For these reasons, we introduce soft membership to feature values: A non-negative continuous weight indicates how strong the feature value is associated with the latent geographical factors.

3.2 Bayesian Generative Model

The proposed method is a Bayesian generative model that is based on the model of Murawaki (2019) even though at first glance, our task has little in common with that of Murawaki (2019). The differences between the two are summarized in Appendix A.

Formally, the observed data[3] are an $L \times N$ matrix X, where L is the number of languages and N is the number of features. Its element $x_{l,n}$ represents language l's n-th feature. Features are categorical and feature n takes one of F_n values.

We assume that X can be reorganized into an $L \times K$ binary matrix Z, where K is the number of latent factors and is specified a priori. The latent factor k is represented by the vector $\mathrm{z}_{*,k} = (z_{1,k}, \cdots, z_{L,k})$, in which $z_{l,k} \in \{0, 1\}$ indicates whether the latent factor k is active for language l.

Each latent factor has a geographical interpretation. Filled and hollow circles in the top of Figure 1 indicate one- and zero-valued $z_{l,k}$'s, respectively.

To incorporate our prior expectation that nearby languages are likely to take the same value for each k, we use an autologistic model (Besag, 1974; Towner et al., 2012). Relationships between languages are represented as a *neighbor graph*, which is indicated by edges between dialects in Figure 1.

We use a weighted variant of the graph. The probability of language l taking the value $b \in \{0, 1\}$, conditioned on the rest of the languages, $\mathrm{z}_{-l,k} = (z_{1,k}, \cdots, z_{l-1,k}, z_{l+1,k}, \cdots, z_{L,k})$, is

$$P(z_{l,k} = b \mid \mathrm{z}_{-l,k}, h_k, u_k) \propto \exp\left(h_k \sum_{l' \in \mathcal{G}(l)} \omega_{l,l'} I(z_{l',k} = b) + u_k b \right). \quad (1)$$

The parameter $h_k > 0$ controls the degree of influence from neighboring languages while $u_k \in (-\infty, +\infty)$ serves as a bias term. Their prior distributions are: $h_k \sim \mathrm{Gamma}(\kappa, \theta)$ and $u_k \sim \mathcal{N}(0, \sigma^2)$. $\mathcal{G}(l)$ returns a set of l's neighbors and $\omega_{l,l'} > 0$ indicates how strongly the pair is connected. Both $\mathcal{G}(l)$ and $\omega_{l,l'}$ are given a priori. Eq. (1) encodes our assumption that the more neighboring languages take the value b, the more likely language l also takes the value b.

This model is called an *auto*logistic model because the target variable $z_{l,k}$ depends on explanatory variables of the same kind, $z_{l',k}$'s. To solve the chicken-and-egg problem, we define a joint distribution, $P(\mathrm{z}_{*,k} \mid h_k, u_k)$ (Besag, 1974).

The generation of Z is followed by that of the weight matrix $W \in \mathbb{R}_{>0}^{K \times M}$, where $M = \sum_{n=1}^{N} F_n$. Suppose that feature n's i-th value corresponds to the m-th weight. We map the two indexes using $f(n, i) = m$. An element of W, $w_{k,m}$, is drawn from $\mathrm{Gamma}(1, 1)$.

Next, we compute $\tilde{\Theta} = ZW \in \mathbb{R}_{\geq 0}^{L \times M}$ and then normalize $\tilde{\Theta}$ for each feature n using the softmax function:

$$\begin{aligned} \theta_{l,f(n,i)} &= \mathrm{softmax}_i(\tilde{\theta}_{l,f(n,1)}, \cdots, \tilde{\theta}_{l,f(n,F_n)}) \\ &= \frac{\exp(\tilde{\theta}_{l,f(n,i)})}{\sum_{i'=1}^{F_n} \exp(\tilde{\theta}_{l,f(n,i')})}. \end{aligned} \quad (2)$$

---

[3] To be precise, a language can have missing features.

Finally, $x_{l,n}$ is drawn from the corresponding categorical distribution:

$$x_{l,n} \sim \text{Categorical}(\theta_{l,f(n,1)}, \cdots, \theta_{l,f(n,F_n)}). \tag{3}$$

To see how Z and W affect the generation of X, we should note that $\theta_{l,f(n,i)}$ indicates how likely language l takes the value i for feature n. Recall that $\tilde{\theta}_{l,f(n,i)}$, the unnormalized counterpart of $\theta_{l,f(n,i)}$, is calculated as

$$\tilde{\theta}_{l,f(n,i)} = \sum_{k=1}^{K} z_{l,k} w_{k,f(n,i)}. \tag{4}$$

If $z_{l,k} = 0$, the latent factor k has no effect on $\theta_{l,f(n,i)}$; otherwise $w_{k,f(n,i)}$ raises the probability of language l's taking the value i for feature n. Let $\tilde{\theta}_{*,f(n,i)} = (\tilde{\theta}_{1,f(n,i)}, \cdots \tilde{\theta}_{L,f(n,i)})$. For each latent factor k, $w_{k,f(n,i)}$ is added to the vector $\tilde{\theta}_{*,f(n,i)}$, but zero-valued $z_{l,k}$'s mask the operation.

To complete the generative story, we define the joint distribution (hyperparameters are omitted for brevity):

$$P(A, Z, W, X) = P(A)P(Z|A)P(W)P(X|Z, W), \tag{5}$$

where $A = (H, U)$, $H = (h_1, \cdots, h_K)$ and $U = (u_1, \cdots, u_K)$.

3.3 Inference

Following Murawaki (2019), we use Gibbs sampling to perform posterior inference. Given observed values $x_{l,n}$, we iteratively update $z_{l,k}$, h_k, u_k, and $\mathrm{w}_{k,*} = (w_{k,1}, \cdots, w_{k,M})$, and missing values $x_{l,n}$.

Update $x_{l,n}$ $x_{l,n}$ is sampled from Eq. (3).

Update $z_{l,k}$ and $\mathrm{x}^{\mathrm{mis}}_{l,*}$ We use the Metropolis-Hastings algorithm to update $z_{l,k}$ and $\mathrm{x}^{\mathrm{mis}}_{l,*}$, the missing portion of $\mathrm{x}_{l,*} = (x_{l,1}, \cdots, x_{l,N})$. We find that jointly updating $\mathrm{x}^{\mathrm{mis}}_{l,*}$ drastically improves the mobility of $z_{l,k}$.

Update h_k and u_k We want to sample h_k (and u_k) from $P(h_k \mid -) \propto P(h_k)P(\mathrm{z}_{*,k} \mid h_k, u_k)$. Since this belongs to a class of problems known as sampling from doubly-intractable distributions (Møller et al., 2006; Murray et al., 2006), we adopt an approximate sampler (Liang, 2010).

Update $\mathrm{w}_{k,*}$ We block-sample $\mathrm{w}_{k,*} = (w_{k,1}, \cdots, w_{k,M})$ using Hamiltonian Monte Carlo (HMC) (Neal, 2011).

4 Simulation Experiments

4.1 Synthetic Data

Evaluating the proposed method is a tough challenge. Here we turn to synthetic data. While rare in NLP, simulation is an established practice in evolutionary biology as a means of quantitatively evaluating statistical models.

Specifically, we consider a general scenario where dialects follow tree-shaped evolutionary paths but a high degree of borrowing obscures the phylogenetic signal. The resultant leaf nodes (modern dialects) are given to the proposed model to perform inference while the tree is used for evaluation. Our simulator is similar in spirit to the TraitLab software package extended with lateral transfer,[4] which is used extensively to test the robustness of the tree model with respect to contact phenomena (Greenhill et al., 2009; Kelly and Nicholls, 2017). There are, however, two important differences that make our simulation more realistic:

1. Instead of independently simulating the birth and death of each trait along branches, we group traits into features. Having a new trait born at a branch, we randomly choose a feature type and update the feature value of the dialect in question to the new one (i.e., the old value dies there).

2. We simulate spatial diffusion using a 2D Brownian random walk process. While the local borrowing variant of the TraitLab model makes dialects borrow traits from phylogenetically close dialects, we control the degree of borrowing according to spatial proximity.

We set the number of observed dialects to 50, the number of features to 100, and the root date to 1,000 BP (before present). The simulation was repeated 5 times using different random seeds. We removed features that had only one value (i.e., no variation) and merged dialects that were too similar to each other to be documented separately.

To make simulation experiments realistic, we tuned hyperparameters by manually checking neighbor-joining trees (Saitou and Nei, 1987) and NeighborNets (Bryant and Moulton, 2004) drawn from generated data, in addition to monitoring several statistics. We found that only a small subspace in the hyperparameter space led to realistic-looking data. As a result, we obtained 44.4 ± 2.6 languages

---

[4] `https://github.com/lukejkelly/TraitLabSDLT`

and 92.4 ± 3.0 features with 524.6 ± 86.8 unique values.

To assess how realistic the synthetic data were, we checked the δ score (Holland et al., 2002). Ranging from 0 to 1, the δ score indicates how tree-like the data are (lower is more tree-like). We obtained the score of 0.246 ± 0.057, which was roughly comparable to those calculated from real datasets known for non-tree-like evolution (Murawaki, 2015).

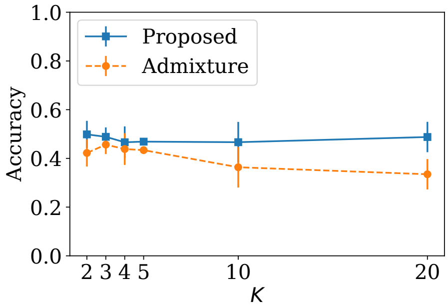
4.2 Model Settings and Evaluation Metric

We compared the proposed method with an admixture model. The settings for the proposed method is described in detail in Appendix B. We implemented a simple, fully Bayesian variant of admixture analysis, which is explained in Appendix C. For both models, we varied the number of latent factors, K, to be 2, 3, 4, 5, 10, and 20.

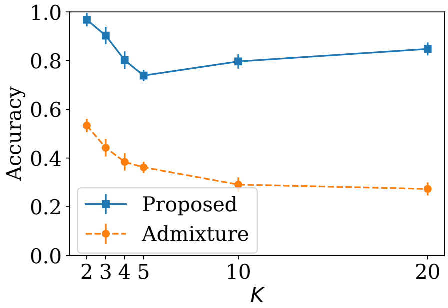
As the evaluation metric, we used a variant of many-to-one mapping accuracy. The induced latent factors were compared against gold standard clusters, and more than one latent factor may be mapped to the same gold standard cluster. Each latent factor was first mapped to the gold standard cluster that had the highest similarity score. We used the Jaccard index as the similarity score. The accuracy was then obtained by averaging each latent factor's score.

We considered two types of gold standard clusters: (1) phylogenetic tree and (2) spatial hierarchical clustering. For the ground-truth phylogenetic tree, each node was mapped to the set of its descendant leaves, and it was used as a gold standard cluster if it covered at least 10% of the leaves. We also conducted spatial hierarchical clustering using the UPGMA algorithm with the Euclidean distance, and generated clusters in the same manner.

Although the proposed method assumes clear-cut latent geographical distributions, posterior inference entails uncertainty about membership. To determine hard membership, we applied the threshold of 0.5 to the posterior probability $P(z_{l,k} \mid -)$. Obtaining clusters with hard membership from the admixture model is non-straightforward because it assumes soft membership by design. For each l, we averaged the ancestral population assignment $z_{l,n}$ over N and over posterior samples, and applied the threshold of 0.2. We confirmed that changing the threshold did not have much impact on accuracy.



(a) Phylogenetic tree.



(b) Spatial hierarchical clustering.

Figure 2: Many-to-one mapping accuracy of the induced latent factors, with varying K.

4.3 Results

The results are shown in Figure 2. We can confirm that the proposed method consistently outperformed the admixture model. The proposed method was particularly better at recognizing spatial patterns. It is understandable given that the geography is explicitly encoded to the proposed method while it is ignored by the admixture model.

For the admixture model, the accuracy dropped more noticeably as K increased. In contrast, the proposed method retained a relatively high accuracy even with $K = 20$. It used additional latent factors to capture minor but genuine patterns.

5 Analysis of Real Data

5.1 Fijian Basic Vocabulary Database

Next, we analyzed a dataset of Fijian dialects, which was originally collected by Paul Geraghty and is in process of digitization by the Fijian Language GIS Project.[5] The details of the dataset will be published in the near future. We combined a lexical dataset with coordinate data. For each dialect, the dataset contains word form(s) that describe each of 100 basic concepts. Coordinate data were based on the Fiji Map Grid system, where the

---

(a) (b)

Figure 3: Linguistic maps of Fiji. (a) Locations of Fijian dialects, with an approximate boundary between Eastern and Western Fijian. (b) An example of features (seven more are shown in Figure A.1). The shape and color of a language indicates the value it takes. We can see that the feature value indicated by cyan down-pointing triangles (word form *ka*) transgresses the east–west boundary.

x- and y-axes correspond to local horizontal, and local vertical coordinates, respectively. As a result of preprocessing described in Appendix D.1, we obtained data with $L = 106$ and $N = 97$. The δ score was 0.286.

Figure 3(a) shows the locations of Fijian dialects in the dataset. It is well known that two major dialect groups, Eastern and Western Fijian, are demarcated by a boundary crossing the largest island of Viti Levu (Geraghty, 1983). As exemplified by Figure 3(b), however, features do not necessarily align with the boundary. Although Geraghty (1983) proposed multiple subgroups of Fijian by identifying shared innovations, he refrained from constructing a phylogenetic tree, arguing that they were likely to have resulted from intense contact. In short, no ground-truth is known for Fijian language history.

5.2 Qualitative Analysis

Due to lack of gold standard for the Fijian data, we chose to perform qualitative analysis. To do this, we first identify several desiderata for a model: (d1) intuitive geographical visualization of patterns, (d2) identification of Eastern and Western Fijian, (d3) identification of many more common patterns, and (d4) identification of conflicting patterns.

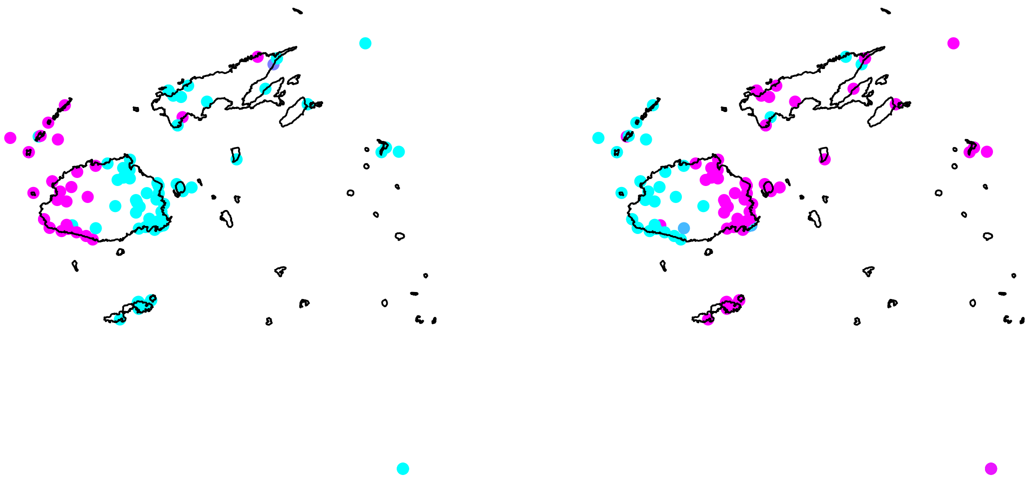
We performed posterior inference in the same manner as in Section 4. Figures 4 and A.3 visualize latent factors induced by the proposed method ($K = 20$). The visualization is intuitive (d1) and latent factors 20 and 6 (Figures 4(a–b)) correctly identified Western and Eastern Fijian, respectively (d2). At the same time, latent factor 2 (Figures 4(c)) covers Western Fijian and Kadavu in the southwest, transgressing the the east–west boundary (d4).

Impressionistically, other latent factors also appear to capture genuine patterns (d3), but the proposed model's superior performance with respect to desideratum 3 becomes more apparent when it is compared against other methods (Appendix D.2). Most importantly, admixture analysis was interpretable only with $K \leq 4$. Indeed, it is a standard practice in admixture analysis that K is carefully incremented from 2 until the output becomes uninterpretable. Confirming the result of the quantitative evaluation, the proposed method had no problem with $K = 20$. Although how to determine the optimal number of latent factors is an unresolved question, the proposed method safely allows us to try a large K. It is also worth noting that in admixture analysis, ancestral populations obtained with different Ks are routinely compared although they cannot necessarily be aligned in a consistent manner. In contrast, the proposed method does not necessitate incremental exploration.

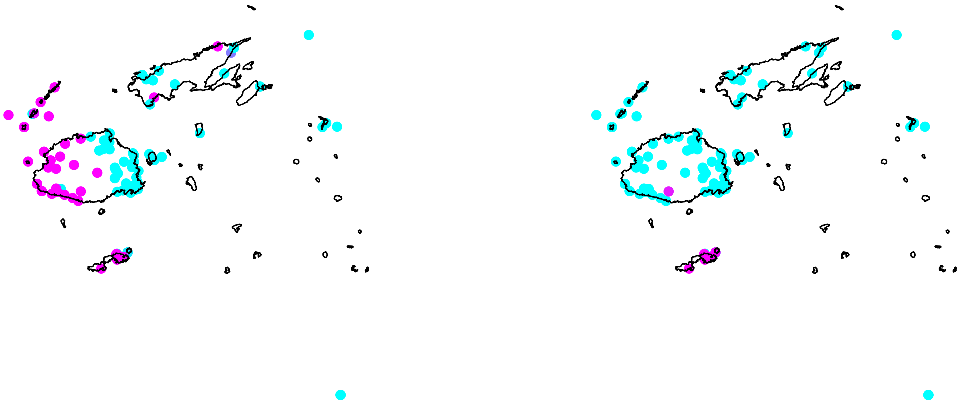
In summary, only the proposed method satisfied the four desiderata at the same time. Although this does not necessarily guarantee the correctness of the model, we believe that the proposed method is worth further exploration.

5.3 Discussion

Our ultimate goal is to uncover spatio-temporal dynamics of languages although in this paper we



(a) Latent factor 20. (b) Latent factor 6.



(c) Latent factor 2. (d) Latent factor 19.

Figure 4: The visualization of four latent factors induced by the proposed method ($K = 20$). Other eight latent factors are shown in Figure A.3. The warmest color indicates that the latent factor k is active for language l ($z_{l,k} = 1$) while the coolest color corresponds to the opposite ($z_{l,k} = 0$). Intermediate colors indicate uncertainty.

concentrate on spatial inference. How does the proposed method provide a basis for temporal reasoning? To gain a toehold on this question, recall that the proposed method piles up multiple, potentially conflicting geographical clusters for each feature n. Since their relative strengths are controlled by $w_{k,f(n,i)}$'s, we expect that in case of conflict, a newer feature value gets a larger weight to supersede an older one.

Figure 6 shows a portion of the weight matrix W corresponding to feature 4 in Figure 3(b). We can see that although we did not explicitly impose sparsity on W, the overwhelming majority of elements in it were close to zero.

The feature value indicated by gray diamonds (word form *i*) was used by many, but not all, dialects on the southwestern island of Kadavu. Not surprisingly, this group gave the largest weight to latent factor 19, which also concentrated on Kadavu (Figures 4(d)). Interestingly, this conflicted with the feature value indicated by red circles (word form *e*) because it assigned a relatively large weight to latent factor 18, which covered Kadavu in addition to southeastern Viti Levu, Vanua Levu and some other small islands (Figure A.3(b)). However, latent factor 19 for *i* had a much larger weight than latent factor 18 for *e*, and as a result, the former overwhelmed the latter.

This seems to suggest that *e* was once widely used in Kadavu but was later replaced by *i*. Needless to say, however, a different run of the model may provide a different interpretation. We need to devise a statistical measure to quantify how likely the hypothesis is.

At this stage of research, temporal reasoning is left to human interpretation. Can we directly incor-

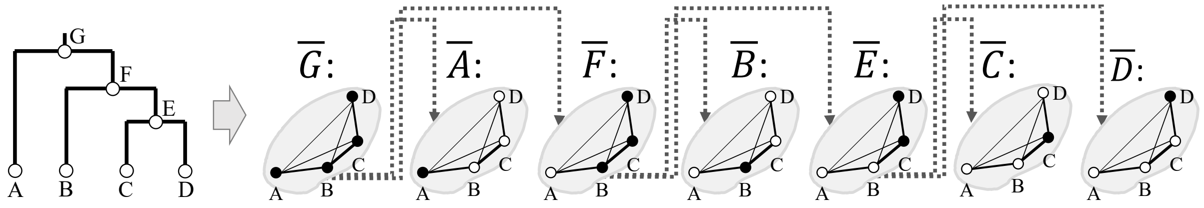


Figure 5: A geographical representation of a phylogenetic tree. We assume that the four modern dialects in Figure 1 have followed evolutionary paths shown on the left. We label internal nodes as E, F, and G. Each node X in the tree can be uniquely mapped to the set of its descendant leaves, which we denote as $\bar{X}$. A dotted arrow corresponds to a branch in the tree.

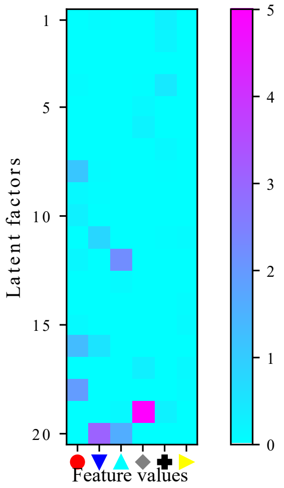

Figure 6: A portion of the weight matrix W corresponding to feature 4 in Figure 3(b).

porate it to the model? A hint is given in Figure 5. A node in a tree can be reinterpreted as a latent factor of the proposed method because it can be mapped to the set of its descendant leaves. All we have to do is to force the set of latent factors to satisfy the tree constraint: The two sets of active dialects in the children are a partition of the set of active dialects in their parent. As such, the proposed model has the potential of incorporating the tree model. With additional latent factors that are outside of the tree, the extended model can straightforwardly capture contact phenomena.[6]

Incorporating the tree constraint into the proposed method, especially as a hard constraint, is highly challenging. It is because each latent factor alone forms so complex a network that we resort to approximate sampling (Møller et al., 2006; Murray et al., 2006). However, this extension deserves further investigation. If a trait is observed in geographically fragmented regions and the possibility of parallel innovation is ruled out, linguists assume that it once had a wider geographical distribution connecting them. The proposed method in its present form has no mechanism to favor such a scenario, but the tree constraint does.

A caveat is that the proposed model does not keep track of the birth and death (or replacement by a new trait) of traits but lets multiple layers of historical changes simply pile up. This means that the state of an ancestral node cannot be reconstructed. This limitation appears inevitable especially if we want to model both vertical inheritance and horizontal contact, because it is hard to date contact events relative to an ancestral node.

6 Conclusions

In this paper, we proposed a Bayesian generative model to analyze dialectal variation. With this model, we successfully induced a large number of latent factors from a set of noisy surface features. Each latent factor is associated with an intuitively appealing geographical interpretation.

In the experiments, we used synthetic data and Fijian lexical data. Future directions include the incorporation of phonological and morphosyntactic features, application to other languages, and most importantly, a model extension to infer temporal ordering.

Acknowledgments

We thank Paul Geraghty, John Lowry, Ritsuko Kikusawa, Susumu Okamoto, Fumiya Sano, and the *itaukei ni vosa* (owners of the language) for providing the Fijian lexical/GIS data. We also thank Chundra A. Cathcart for valuable comments and suggestions on an earlier draft of this paper. This work was partly supported by JSPS KAKENHI Grant Numbers 18K18104 and 18KK0012.

[6] To analyze typological data, Daumé III (2009) presented a mixture model of a phylogenetic tree and a set of areal clusters. Although we share similar motivations with Daumé III (2009), our key idea is to represent vertical and horizontal signals in a unified manner, rather than given them completely different representations.

Appendix A A Comparison between the Model of Murawaki (2019) and the Proposed Method

The proposed method is a Bayesian generative model that is based on the model proposed by Murawaki (2019) even though at first glance, our task has little in common with that of Murawaki (2019). Table A.1 summarizes key differences between the two models. The most obvious difference is scale. While Murawaki (2019) worked on languages around the world, our target is a group of closely related dialects that usually occupies a relatively small area of the globe.

The difference in scale leads to the difference in the choice of features. In order to compare any pair of languages, which may have no known phylogenetic relationships, one has a limited choice. For this reason, Murawaki (2019) used features of linguistic typology (Haspelmath et al., 2005; Bickel et al., 2017). In contrast, we have a wide range of options for comparing dialects. While we used lexical features in the experiments, phonological and morphosyntactic features can readily be incorporated into the model although these features may be more prone to parallel innovation.

Both models encode our assumption that languages related to each other in some way tend to take the same feature value. However, whereas Murawaki (2019) used two neighbor graphs, one for phylogenetic relations and the other for spatial relations, we only use a spatial neighbor graph. It is because we are interested in cases where no ground truth is available for the internal phylogenetic classification of the languages in question.

The weight matrix W, which connects latent and surface representations, also differs slightly. We constrain $w_{k,m}$ to be positive whereas in Murawaki (2019), $w_{k,m}$ can be negative. Negative weights are hard to interpret in our task because we assume that multiple layers of historical changes simply pile up.

Finally, we look at $\tilde{\Theta}$ from a different angle. Murawaki (2019) interpreted $\tilde{\Theta}$ row-wise (fixing language l and discussing how the feature values (n_1, i_1) and (n_2, i_2) depend on each other). On the other hand, we present a column-wise interpretation (fixing the feature value (n, i) and discussing how l's get their probabilities).

Appendix B Settings of the Proposed Method

We constructed the neighbor graph as follows. First, we connected any pair of languages that are within the distance of 300 km. The edge weight ω_{l_1,l_2} for the pair of languages l_1 and l_2 was then given as

$$\max(d_{l_1,l_2}/3, 1)^{-1/2}.$$

σ^2, the hyperparameter for u_k, was set to 5. Recall that h_k is drawn from $\mathrm{Gamma}(\kappa, \theta)$. We set $\kappa = \hat{h}/5$ and $\theta = 5$. This means that the gamma distribution had mean $\hat{h}$ and variance $5\hat{h}$. Using the Fijian data, we estimated $\hat{h}$ using the autologistic models for N surface features (Murawaki and Yamauchi, 2018), with the assumption that the range of the parameter for latent factors should not deviate too much from the range for surface features. Specifically, we tied a single single parameter h to N autologistic models, sampled h's using an MCMC algorithm, and calculated their geometric mean. As a result, we obtained $\hat{h} \approx 0.009$.

Before collecting posterior samples, we ran 1,000 burn-in iterations. Following Murawaki (2019), we applied simulated annealing to the sampling of $z_{l,k}$ and $\mathrm{x}^{\mathrm{mis}}_{l,*}$. For the first 100 iterations, the inverse temperature was increased from 0.1 to 1.0. After the burn-in iterations, we collected 100 samples, one per iteration.

Appendix C Admixture Model

We implemented a simpler version of admixture analysis (Pritchard et al., 2000; Alexander et al., 2009). While population geneticists have devoted much effort to make inference scale to large genetic data, linguistic data are so small that a naïve Markov chain Monte Carlo algorithm suffices.

The generative story of the admixture model is as follows:

1. For each ancestral population $k \in \{1, \cdots, K\}$:
   (a) For each feature type $n \in \{1, \cdots, N\}$:
      i. Draw a categorical distribution from a symmetric Dirichlet distribution $\phi_{k,n} \sim \mathrm{Dir}(\beta_n)$.
2. For each language $l \in \{1, \cdots, L\}$:
   (a) Draw a mixing proportion from a symmetric Dirichlet distribution $\theta_l \sim \mathrm{Dir}(\alpha)$.

	Murawaki (2019)	Proposed method
Target	Worldwide	Dialects
Linguistic domain	Typology	Lexicon
Neighbor graphs	2	1
Weight range	$(-\infty, +\infty)$	$(0, +\infty)$
Interpretation of $\tilde{\Theta}$	Row-wise	Column-wise

Table A.1: A summary of key differences between the model of Murawaki (2019) and the proposed method.

(b) Then for each feature type $n \in \{1, \cdots, N\}$:
  i. Draw an ancestral population assignment $z_{l,n} \sim \text{Categorical}(\theta_l)$.
  ii. Draw a feature $x_{l,n} \sim \text{Categorical}(\phi_{z_{l,n}})$.

We marginalize out $\phi_{k,n}$ and θ_l and run a collapsed Gibbs sampler (Griffiths and Steyvers, 2004) to draw posterior samples. In the experiments, we ran 1,000 burn-in iterations and after that, collected 500 samples, one per iteration. As routinely done in population genetics (Jones et al., 2015), we increased the number of ancestral populations, K, one by one, starting from 2.

Appendix D Fijian Dataset

D.1 Details of Preprocessing

The lexical data of Fijian dialects[7] covered 100 basic concepts. The list was inspired by but is not identical with Swadesh's famous list (Swadesh, 1952) since it was tailored to Fijian.

We converted word forms into categorical features. To do this, we adopted a sequence comparison tool named LingPy (List et al., 2018). For each concept, it automatically clustered word forms into cognate groups, to which we assigned unique numbers. We discarded 3 concepts that were covered by single cognate groups. This means that each language was represented as a sequence of 97 lexical features. Note that since the proposed method only requires features to be discrete, it can also deal with phonological and morphosyntactic features.

Finally, we removed languages for which we were unable to determine coordinates. As a result, we chose 106 languages for further analysis. The ratio of missing features was 17.4%.

The Fijian dataset is still a work in progress, and a finished version is expected to be published in the near future. Needless to say, automatic cognate detection was not without errors, and the alignment between lexical and coordinate data was a source of additional complications. Nevertheless, we believe that the result of preprocessing was good enough to evaluate the proposed method, even if it may be too early to draw Fijian-specific linguistic insights.

Figure A.1 visualizes the dataset. A high degree of contact is evident from the NeighborNet analysis (Bryant and Moulton, 2004).

D.2 Additional Analysis with Baseline Methods

In addition to NeighborNet, several baseline methods were used to analyze the Fijian dataset.

Isogloss bundles The map is partitioned using a Voronoi diagram. An edge is drawn between two nearby languages, and its width is proportional to the number of features over which they disagree. Thus, thick lines indicate major dialect boundaries.

PCA Principal component analysis maps languages into lower dimensions (Nerbonne and Wieling, 2018). We visualize the first two principal components (PCs).

Admixture The admixture model used in simulation experiments in Section 4.

In NeighborNet (Figure A.1(a)), we can recognize Eastern Fijian (right) and Western Fijian (left), and also some of their subgroups. However, it is not easy to draw insights from reticulations, except for the obvious fact that the tree model does not fit well. Also, since NeighborNet visualizes clusters without reference to location, it does not provide any intuitive geographical interpretation.

Isogloss bundles in Figure A.2(a) illuminated so many dialect boundaries that even the most important east–west boundary got buried. The result partly explains why dialectologists are reluctant to generalize.

As for PCA, the first PC shown in Figure A.2(b) clearly identified the east–west boundary. The in-

Detect conflicts	✓	? ∼ ✓	✗	✗	✓

Table A.2: A summary of the comparison of various methods.

termediate colors found in the middle of Viti Levu suggest that the two groups are in contact. They explain why isoglosses were not clearly bundled together. It turns out, however, that PCA uncovered only one factor since the second PC, visualized in Figure A.2(c), discouraged any geographical interpretation.

In admixture analysis (Figure A.2(d–f)), each language is given a pie chart indicating the mixing proportion of ancestral populations. At first glance, admixture analysis generated a beautiful high-level picture of the dataset although the outputs with $K \geq 5$ were hard to interpret. With $K = 2$, it identified Eastern and Western Fijian, again with traces of contact in the middle of Viti Levu. With $K = 3$, Eastern Viti Levu was separated from the rest of Eastern Fijian, and with $K = 4$, Eastern Viti Levu was further divided into the northeast and the southeast.

However, a close examination reveals that admixture analysis went against our intuition. As Figure A.1 demonstrates, non-overlapping isoglosses were the norm in the dataset, but admixture analysis far too often assigned a single ancestral population to a language. We conjecture that most conflicts were absorbed by over-expressive ancestral populations and escaped detection.

Recall that in Section 5.2, we enumerated several desiderata: (d1) intuitive geographical visualization of patterns, (d2) identification of Eastern and Western Fijian, (d3) identification of many more common patterns, and (d4) identification of conflicting patterns. Based on the discussion above, we summarize the comparison of various methods in Table A.2. Now we can see that only the proposed method satisfies all of the four desiderata.

Abstract

Whereas there is a growing literature that probes neural language models to assess the degree to which they have latently acquired grammatical knowledge, little if any research has investigated their acquisition of discourse modeling ability. We address this question by drawing on a rich psycholinguistic literature that has established how different contexts affect referential biases concerning who is likely to be referred to next. The results reveal that, for the most part, the prediction behavior of neural language models does not resemble that of human language users.

1 Introduction

The impressive power of deep learning based language models has inspired a new line of computational psycholinguistics research that examines the extent to which linguistic knowledge lies latent within their distributed networks. This work has primarily focused on linguistic phenomena that syntactic theory tells us requires syntactic knowledge to capture, with mixed results (Linzen et al. 2016; Lau et al. 2017; Goldberg 2019; Warstadt et al. 2019; inter alia). This paper asks a new question: to what extent do these language models capture the linguistic knowledge required to perform *discourse* modeling?

We are unaware of any work that has addressed this question directly. Perhaps the closest research has centered on the Winograd Schema Challenge (WSC) (Levesque et al., 2012), which evaluates the ability of systems to employ world knowledge to interpret ambiguous pronouns in minimal pairs that resemble Winograd's famous example (1).

(1) The city councilmen refused the demonstrators a permit because
   a. they feared violence. [they = city council]
   b. they advocated violence. [they = demonstrators]

However, WSC is essentially a 'fill in the blank' problem-solving task, and doesn't evaluate the extent to which systems display humanlike ability to model discourse in an online, incremental fashion. We instead take our inspiration from psycholinguistic work that has focused on this question. For instance, the Bayesian Model of pronoun interpretation (Kehler et al., 2008; Kehler and Rohde, 2013) posits that comprehenders resolve the meaning of a pronoun via Bayesian principles by combining their estimates of the speaker's production biases (the LIKELIHOOD term) with their top-down expectations about which entities are likely to be mentioned next (the PRIOR term, which we refer to as the NEXT-MENTION BIAS). Kehler and Rohde (2013) demonstrate that an array of semantic biases (e.g., verb semantics) and pragmatic biases (e.g., coherence relations) that have been claimed to influence pronoun interpretation directly actually do so only indirectly, by conditioning the prior.

The role of the prior in the Bayesian Model is directly analogous to its role in Bayesian approaches to tasks such as speech recognition and machine translation, where a language model provides the prior probabilities. We argue that the ability to capture the influence of context on next-mention biases is thus a particularly appropriate task for evaluating the extent to which language models capture discourse modeling knowledge. Our focus will be on effects of verb semantics that the psycholinguistic literature has shown to influence next-mention biases. These studies have used a PASSAGE COMPLETION paradigm, in which experimental participants are presented with context clauses followed by either a full stop (2a) or a conjunction (2b-c), and asked to complete the passage with the first follow-on sentence that comes to mind.

November 16–20, 2020. ©2020 Association for Computational Linguistics

(2) a. John impresses Mary. _______________

b. John impresses Mary because _________

c. John impresses Mary, and as a result ___

Analysis of the completions yields estimates of next-mention biases and of referential form production. In the task described in §3, we will probe the next-mention biases produced by two language models in different contexts that we describe now.

2 Comparisons and Predictions

If neural language models latently acquire discourse modeling knowledge, they should be able to distinguish between contexts that are superficially similar but which are known from psychological research to yield significant effects on next-mention biases. We focus on three such contrasts.

Implicit Causality Verbs The first comparison is between two kinds of so-called IMPLICIT CAUSALITY (IC) verb, exemplified in (3a-b).

(3) a. John aggravated Mary. [IC1]

b. John praised Mary. [IC2]

Sentences with IC verbs generate an expectation that the follow-on sentence will participate in an Explanation coherence relation, in which the second sentence provides a cause or reason for the eventuality described by the first (Kehler et al., 2008). However, the two types differ in which event participant causality is attributed to. IC1 verbs (3a) have been experimentally shown to generate a strong expectation that the preceding subject will be mentioned next in the follow-on sentence—we heard that John is aggravating, and we now expect to hear why (Garvey and Caramazza 1974; Caramazza et al. 1977; Brown and Fish 1983; Terry Kit-fong Au 1986; McKoon et al. 1993; Koornneef and van Berkum 2006; Kehler et al. 2008; inter alia). IC2 verbs (3b), on the other hand, have been shown to generate a strong expectation that the preceding object will be mentioned next in the follow-on sentence—we heard that Mary received praise, and we now expect to hear why. We can then ask: do IC1 and IC2 verbs generate different expectations in language models for next mention in otherwise identical contexts?

There are also subsidiary predictions regarding the use of connective prompts as in (2b-c). For both types of IC verbs, *because* prompts strengthen their biases, since virtually 100% of the continuations will now be Explanations rather than 60% as found in full stop prompt conditions (Kehler et al., 2008). So we expect to see a higher probability of next-mention of the subject with *because* prompts for IC1 verbs, and likewise for objects for IC2 verbs. Both types of IC verb, however, are known to have a strong bias to the object in Result coherence relations (Stewart et al., 1998; Kehler et al., 2008)—in which the follow-on describes an effect rather than a cause—which are enforced by the *and as a result* prompt. For IC1 verbs, therefore, we should see a strong shift toward the object with *and as a result* prompts compared to full stop prompts. To summarize the predictions:

1a. IC1 contexts with full stop prompts should display a stronger next-mention bias to the subject compared to IC2 contexts.

1b. Contexts with *because* prompts should strengthen the next-mention bias associated with each type of verb compared to full stops.

1c. *And as a result* prompts in IC1 contexts should result in a greater next-mention bias toward the object compared to full stops.

Motion vs. Transfer of Possession Verbs The second comparison is between Motion (4a) and Transfer-of-Possession (ToP) verbs (4b).

(4) a. The man jogged to the woman. [Motion]

b. The man handed a gift to the woman. [ToP]

These sentence types are superficially similar: they each have a grammatical subject that functions as a thematic Agent/Source, and a grammatical object-of-preposition that functions as a thematic Goal. However, they are known to yield very different next-mention biases. Specifically, previous studies have revealed that whereas motion verbs have a strong next-mention bias toward the previous subject (e.g., 84.4% in a study run by Stevenson et al. (1994)), ToP contexts give rise to a distribution that's closer to 50/50 (51.0%). The reason is that the Goal in ToP sentences functions not only as a location but a recipient as well, leading to an expectation that we'll next hear about what the recipient did with the object of transfer, which counteracts the typical subject bias. We thus expect to see a much stronger next-mention bias toward the subject for Motion contexts as compared to ToP contexts, despite their superficially similar properties. Further, we expect a large effect of the connective conditions: previous work (Stevenson et al., 1994; Kehler et al., 2008) has shown Explanations to be strongly biased to the Source, and Result continuations to be strongly biased to the Goal for ToP contexts.[1] To summarize the predictions:

2a. Motion contexts with full stop prompts should display a stronger next-mention bias to the subject compared to ToP contexts.

2b. ToP contexts with *because* prompts should yield a stronger bias toward the subject compared to full stop prompts.

2c. ToP contexts with *and as a result* prompts should yield a stronger bias to the object compared to full stop prompts.

Aspectual Marking with Transfer of Possession Verbs The final comparison varies aspectual marking rather than the semantic class of the verb. Kehler et al. (2008) compared ToP contexts in the perfective such as (4b) with otherwise identical sentences in the imperfective (5):

(5) The man was handing a gift to the woman.

Following Stevenson et al. (1994), Kehler et al. conjectured that ToP verbs have a special property in that the prominence of the event participants depends on what component of event structure is being focused on. Specifically, the imperfective focuses the hearer's attention on the ongoing development of the event, where the agent of the event is most prominent. The perfective (4b), on the other hand, focuses the hearer's attention on the end state of the event, where the recipient becomes prominent. Kehler et al. therefore predicted that imperfective contexts would lead to a greater referential bias to the agent than perfective contexts, which is precisely what they found (80% vs. 57%). This gives rise to the following prediction:

3. Imperfective ToP contexts should display a stronger next-mention bias to the subject compared to perfective ToP contexts.

3 Experimental Setup

We evaluated two state-of-the-art, pre-trained autoregressive language models (LMs): GPT-2 large (Radford et al., 2018) and Transformer-XL (Dai et al., 2019).[2] The experiments were conducted in a zero-shot setting, and the task of generating continuations was reformulated to a next-word prediction task. Prior to tokenization, the input stimulus was prepended with a token indicating the beginning of the sentence. Additionally, the inputs for Transformer-XL were prepended with a padding text to account for the shorter stimulus length.[3]

Miss Smith ___ Mr. Smith	Mary ___ John
The woman ___ the man	Alice ___ Bob
The actress ___ the actor	The girl ___ the boy
Mrs. Taylor ___ Mr. Williams	Emma ___ David
The princess ___ the prince	Sarah ___ Robert
Mrs. Williams ___ Mr. Taylor	Emily ___ Paul

Table 1: Context Sentence Frames

To capture the diversity of ways in which event participants can be mentioned in the context sentence, the twelve frames shown in Table 1 were used. In order to balance for the effects of gender (Zhao et al., 2018; Bordia and Bowman, 2019), each frame was used again with the order of the event participants reversed, for a total of 24 frames. 20 IC1 verbs, 20 IC2 verbs, 18 Motion verbs, and 18 ToP verbal complexes (in both perfective and imperfective variants) were each run in the full stop prompt, *because* prompt, and *and as a result* prompt conditions, in each of the 24 frames.[4]

After presenting a pairing of a context sentence and prompt, we compute the (normalized) conditional probabilities of *He* and *She* in the full stop prompt condition and their lowercase equivalents for the connective prompt conditions. The average biases to the subject are computed for each verb over the sentence frames, which are in turn averaged to compute the overall subject bias for each context type. The latter averages are reported with 95% confidence intervals in the tables below.

4 Results

Implicit Causality Comparison The next-mention biases toward the subject produced by each system in the IC verb conditions are shown in Tables 2 and 3.

---

[1] Unfortunately, Stevenson et al. (1994) left Motion contexts out of their experiment that examined the role of connectives. We thus have no data to compare to for these conditions.

[2] We considered also evaluating BERT on this task but decided that it was unsuitable. BERT performs masked language modeling, conditioned on both left and right contexts. The current experiments use only the left context, and hence BERT would need to be queried in a non-natural setting.

[4] The actual verbs used and other information necessary for reproducibility of results has been placed at https://github.com/shiva-upadhye/predicting-reference.

Prompt	Transformer-XL	GPT-2
full stop	.51 ± .01	.59 ± .02
because	.61 ± .03	.63 ± .02
and as a result	.43 ± .02	.31 ± .02

Table 2: Subject next-mention bias for IC1 contexts

Prompt	Transformer-XL	GPT-2
full stop	.51 ± .02	.66 ± .02
because	.45 ± .02	.42 ± .05
and as a result	.50 ± .05	.47 ± .07

Table 3: Subject next-mention bias for IC2 contexts

Our first question (Prediction 1a) is whether the LMs would display a greater next-mention bias toward the preceding subject in IC1 contexts than IC2 contexts. The answer is no: As can be seen in the first rows of Tables 2 and 3, the biases across conditions for Transformer-XL are identical (.51) and the difference witnessed for GPT-2 goes in the wrong direction (.59 vs. .66). These results therefore do not align with the more polar biases for IC contexts that the psycholinguistic literature has revealed in human studies.

The second question (Prediction 1b) is whether the occurrence of *because* at the end of the prompt—which for human language users shifts discourse coherence expectations toward Explanation continuations—strengthens the respective IC biases. This prediction receives only limited support: The results in Table 2 reveal increased biases toward the subject compared to the full stop condition for IC1 verbs, and those in Table 3 reveal similar decreases for IC2 verbs. However, only GPT-2 in the IC2 condition yielded an effect of the magnitude that human language studies might lead us to expect.[5]

The final question (Prediction 1c) is whether the occurrence of *and as a result* at the end of the prompt—which for human language users shifts discourse coherence expectations toward Result continuations—generates a stronger bias toward the preceding object compared to the free prompt baseline in IC1 contexts. This prediction was confirmed for GPT-2, where the connective prompt reduced the bias to the subject by .28. Whereas Transformer-XL witnessed a lower bias in this condition as well, the effect was smaller (.08).

To sum, both models failed to yield the hypothesized effect of verb type in the full stop condition. However, there was some degree of sensitivity to the occurrence of a connective, with GPT-2 in particular displaying a strong numerical difference compared to the free prompt baseline in all but the IC1/*because* condition.

Motion vs. ToP Verb Comparison The next-mention biases toward the subject produced by each system in the Motion and ToP context conditions are shown in Tables 4 and 5.

Prompt	Transformer-XL	GPT-2
full stop	.57 ± .01	.63 ± .01
because	.61 ± .02	.65 ± .01
and as a result	.54 ± .02	.47 ± .02

Table 4: Subject next-mention bias for Motion verbs

Prompt	Transformer-XL	GPT-2
full stop	.52 ± .01	.54 ± .03
because	.53 ± .03	.53 ± .03
and as a result	.47 ± .04	.26 ± .03

Table 5: Subject next-mention bias for ToP verbs (perfective)

Our first question (Prediction 2a) asked whether the LMs would display a greater next-mention bias toward the preceding subject in Motion contexts than ToP contexts in the full stop condition. The answer is mostly no: Whereas there is a small numerical difference for each system in the right direction, it is far from what the results of experimental studies would predict. In particular, whereas the bias found for ToP verbs is aligned with established experimental results, the expected strong subject bias for Motion verbs did not materialize.

The second and third questions (Predictions 2b and 2c) asked about the effect of connectives in the ToP condition, whereby *because* and *and as a result* prompts should pull expectations toward the subject and object compared to the full stop prompt baselines respectively. As with IC verbs, no strong effect was witnessed for Transformer-XL, whereas GPT-2 did show a strong shift in the predicted direction for *and as a result* prompts. However, no appreciable effect was seen for GPT-2 in the *because* prompt condition.

Aspectual Marking in ToP Verbs Comparison Our final question (Prediction 3) probes the poten-

---

[5] For instance, Kehler et al. (2008) found subject biases of 85% and 60% for IC1 verbs in the *because* and full stop prompt conditions respectively.

tial effects of aspectual marking on next-mention biases, in particular whether imperfective ToP contexts will yield a stronger next-mention bias to the subject compared to perfective ToP contexts. The results for perfective and imperfective ToP contexts are shown in Tables 5 and 6 respectively.

Prompt	**Transformer-XL**	**GPT-2**
full stop	.57 ± .01	.62 ± .02
because	.56 ± .03	.57 ± .02
and as a result	.63 ± .03	.45 ± .03

Table 6: Subject next-mention bias for ToP verbs (imperfective)

Prediction 3 was mostly disconfirmed: There is only a modest difference between ToP contexts using the perfective and imperfective aspect in the full stop prompt condition. Interestingly, however, the predicted effect did exist for both systems in the *and as a result* condition. It is not clear to us why the effect would be limited to only this condition.

5 Conclusions

We set out to evaluate the extent to which neural LMs latently acquire the discourse modeling capability necessary to perform a particular type of incremental processing that human language users do: The ability to predict what entities are most likely to be mentioned next. We examined three context pairs with superficially similar linguistic properties that the experimental literature has shown to result in divergent next-mention biases, both with and without connectives.

The results were mostly, but not entirely, negative. On the one hand, we found no compelling evidence that the LMs are sensitive to any of the three manipulations within the verbal complex in the context sentence. On the other hand, one could argue for preliminary support for the claim that one of the LMs—GPT-2—is sensitive to the occurence of the two connectives examined here. Future work will be required to assess the extent to which these effects do in fact reflect the acquisition of a latent form of discourse modeling ability.

Our conclusions, of course, remain preliminary in a number of respects. First, we have analyzed the behavior of only two systems. Since each system can be said to stand proxy for a single experimental participant, these results could be argued to be less robust than human language studies, which typically utilize several dozen participants. Whereas this limitation is shared with previous work that probes LMs for inherently acquired syntactic knowledge, the robustness of the findings would be enhanced by examining a broader range of systems and/or system configurations so as to better capture the kinds of variation found among groups of human participants.

Second, we have focused here on broad contrasts between context types that have been studied in the psycholinguistic literature. Although the stimuli employed were modeled after those used in experimental studies, to improve the robustness of the findings we felt it necessary to compute means over a variety of sentence frames (Table 1), so that any idiosyncrasies of particular frames that are independent of the manipulation under scrutiny wouldn't unduly (and undetectably) drive the results. This improves the robustness of our results in terms of items—whereas participants in psycholinguistic studies typically see only one example sentence for each verb, the LMs here saw 24—it also means that no lab data exists for the exact stimuli used here. Since an experiment that collects data on this scale would require a substantial annotation effort, a more careful comparison of this sort must be left for future work.

Third, there are many variations of the studies presented here that could be attempted. Examples would include variants that employ longer and more realistic contexts. In this initial investigation we focused on single-sentence contexts so as to hew as closely as possible to previous experimental work. We hope that this short paper will inspire further research that takes next steps in this and a variety of other directions.

Finally, we want to be clear that we do not claim that the two LMs examined have in any sense 'failed' at this task—they were obviously not trained for this purpose. Our goal instead was to pose the novel question of to what extent discourse knowledge of the sort examined here may exist latently in the models. That having been said, we consider the identification of alternative language model architectures that are capable of capturing the requisite discourse modeling capability for this task to be an interesting challenge problem for future work.

Abstract

Word class flexibility refers to the phenomenon whereby a single word form is used across different grammatical categories. Extensive work in linguistic typology has sought to characterize word class flexibility across languages, but quantifying this phenomenon accurately and at scale has been fraught with difficulties. We propose a principled methodology to explore regularity in word class flexibility. Our method builds on recent work in contextualized word embeddings to quantify semantic shift between word classes (e.g., noun-to-verb, verb-to-noun), and we apply this method to 37 languages[1]. We find that contextualized embeddings not only capture human judgment of class variation within words in English, but also uncover shared tendencies in class flexibility across languages. Specifically, we find greater semantic variation when flexible lemmas are used in their dominant word class, supporting the view that word class flexibility is a directional process. Our work highlights the utility of deep contextualized models in linguistic typology.

1 Introduction

In natural languages, lexical items can often be used in multiple word classes without overt changes in word form. For instance, the word *buru* in Mundari can be used as a noun to denote 'mountain', or as a verb to denote 'to heap up' (Evans and Osada, 2005). Known as word class flexibility, this phenomenon is considered one of the most challenging topics in linguistic typology (Evans and Levinson, 2009). We present a computational methodology to quantify the regularity in word class flexibility across languages.

There is an extensive literature on how languages vary in word class flexibility, either directly (Hengeveld, 1992; Vogel and Comrie, 2000; Van Lier and Rijkhoff, 2013) or through related notions such as word class conversion (with zero-derivation) (Vonen, 1994; Don, 2003; Bauer and Valera, 2005a; Manova, 2011; Ştekauer et al., 2012). However, existing studies tend to rely on analyses of small sets of lexical items that may not be representative of word class flexibility in the broad lexicon. Critically lacking are systematic analyses of word class flexibility across many languages, and existing typological studies have only focused on qualitative comparisons of word class systems.

We take to our knowledge the first step towards computational quantification of word class flexibility in 37 languages, taken from the Universal Dependencies project (Zeman et al., 2019). We focus on lexical items that can be used both as nouns and as verbs, i.e., noun-verb flexibility. This choice is motivated by the fact that the distinction between nouns and verbs is the most stable in word class systems across languages: if a language makes any distinction between word classes at all, it will likely be a distinction between nouns and verbs (Hengeveld, 1992; Evans, 2000; Croft, 2003). However, our understanding of cross-linguistic regularity in noun-verb flexibility is impoverished.

We operationalize word class flexibility as a property of lemmas. We define a lemma as flexible if some of its occurrences are tagged as nouns and others as verbs. Flexible lemmas are sorted into noun dominant lemmas, which occur more frequently as nouns, and verb dominant lemmas that occur more frequently as verbs. Our methodology builds on contextualized word embedding models (e.g., ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019)) to quantify semantic shift be-

---

tween grammatical classes of a lemma, within a single language. This methodology can also help quantify metrics of flexibility in the lexicon across languages.

We use our methodology to address one of the most fundamental questions in the study of word class flexibility: should this phenomenon be analyzed as a directional word-formation process similar to derivation, or as a form of underspecification? Derived words are commonly argued to have a lower frequency of use and a narrower range in meaning compared to their base (Marchand, 1964; Iacobini, 2000). If word class flexibility is a directional process, we should expect that flexible lemmas are subject to more semantic variation in their dominant word class than in their less frequent class. We also test the claim that noun-to-verb flexibility involves more semantic shift than verb-to-noun flexibility. While previous work has explored these questions, it remains challenging to quantify semantic shift and semantic variation, particularly across different languages.

We present a novel probing task that reveals the ability of deep contextualized models to capture semantic information across word classes. Our utilization of deep contextual models predicts human judgment on the spectrum of noun-verb flexible usages including homonymy (unrelated senses), polysemy (different but related senses), and word class flexibility. We find that BERT outperforms ELMo and non-contextual word embeddings, and that the upper layers of BERT capture the most semantic information, which resonates with existing probing studies (Tenney et al., 2019).

2 Related work and assumptions

2.1 Types of flexibility

The phenomenon of word class flexibility has been analyzed in different ways. One way is to assume the existence of underspecified word classes. For instance, Hengeveld (2013) claims that basic lexical items in Mundari belong to a single class of *contentives* that can be used to perform all the functions associated with nouns, verbs, adjectives or adverbs in a language like English. Alternatively, word class flexibility can be analyzed as a form of conversion, i.e., as a relation between words that have the same form and closely related senses but different word classes, such as *a fish* and *to fish* in English (Adams, 1973). Conversion has been analyzed as a derivational process that relates different lexemes (Jespersen, 1924; Marchand, 1969; Quirk et al., 1985), or as a property of lexemes whose word class is underspecified (Farell, 2001; Barner and Bale, 2002). We use word class flexibility as a general term that subsumes these different notions. This allows us to assess whether there is evidence that word class flexibility should be characterized as a directional word formation process, rather than as a form of underspecification.

2.2 Homonymy and polysemy

Word class flexibility has often been analyzed in terms of homonomy and polysemy (Valera and Ruz, 2020). Homonymy is a relation between lexemes that share the same word form but are not semantically related (Cruse, 1986, p.80). Homonyms may differ in word class, such as *ring* 'a small circular band' and *ring* 'make a clear resonant or vibrating sound.' Polysemy is defined as a relation between different senses of a single lexeme (*ibid.*). Insofar as the nominal and verbal uses of flexible lexical items are semantically related, one may argue that word class flexibility is similar to polysemy, and must be distinguished from homonymy. In practice, homonymy and polysemy exist on a continuum, so it is difficult to apply a consistent criterion to differentiate them (Tuggy, 1993). As a consequence, we will not attempt to tease homonymy apart from word class flexibility.

Regarding morphology, word class flexibility excludes pairs of lexical items that are related by overt derivational affixes, such as *to act*/*an actor*. In such cases, word class alternations can be attributed to the presence of a derivational affix, and are therefore part of regular morphology. In contrast, we allow tokens of flexible lexical items to differ in inflectional morphology.

2.3 Directionality of class conversion

Word class flexibility can be analyzed either as a static relation between nominal and verbal uses of a single lexeme, or as a word formation process related to derivation. The merits of each analysis have been extensively debated in the literature on conversion (see e.g., Farell, 2001; Don, 2005). One of the objectives of our study is to show that deep contextualized language models can be used to help resolve this debate. A hallmark of derivational processes is their directionality. Direction of derivation can be established using several synchronic criteria, among which are the principles that a derived form tends to have a lower frequency of use and a smaller range of senses than its base (Marchand, 1964; Iacobini, 2000). In languages where word class flexibility is a derivational process, one should therefore expect greater semantic variation when flexible lemmas are used in their dominant word class—an important issue that we verify with our methodology.

Semantic variation has been operationalized in several ways. Kisselew et al. (2016) uses an entropy-based metric, while Balteiro (2007) and Bram (2011) measure semantic variation by counting the number of different noun and verb senses in a dictionary. The latter study found that the more frequent word class has greater semantic variation at a rate above random chance. Here we propose a novel metric based on contextual word embeddings to compare the amount of semantic variation of flexible lemmas in their dominant and non-dominant grammatical classes. Differing from existing methods, our metric is validated explicitly on human judgements of semantic similarity, and can be applied to many languages without the need for dictionary resources.

2.4 Asymmetry in semantic shift

If word class flexibility is a directional process, a natural question is whether derived verbs stand in the same semantic relation to their base as derived nouns. The literature on conversion suggests that there might be significant differences between these two directions of derivation. In English, verbs that are derived from nouns by conversion have been argued to describe events that include the noun's denotation as a participant (e.g. *hammer*, 'to hit something with a hammer') or as a spatio-temporal circumstance (*winter* 'to spend the winter somewhere'). Clark and Clark (1979) argue that the semantic relations between denominal verbs and their base are so varied that they cannot be given a unified description. In comparison, when the base of conversion is a verb, the derived noun most frequently denotes an event of the sort described by the verb (e.g. *throw* 'the act of throwing something'), or the result of such an act (e.g. *release* 'state of being set free') (Jespersen, 1942; Marchand, 1969; Cetnarowska, 1993). This has led some authors to suggest that verb to noun conversion in English involves less semantic shift than noun to verb conversion (Bauer, 2005, p.22). Here we consider a new metric of semantic shift based on contextual embeddings, and we use this metric to test the hypothesis that the expected semantic shift involved in word class flexibility is greater for noun dominant lexical items (as compared to verb dominant lexical items) in our sample of languages. As we will show, this proposal is consistent with the empirical observation that verb-to-noun conversion is statistically more salient than noun-to-verb conversion.

2.5 Contextualized language models

Deep contextualized language models take a sequence of natural language tokens and produce a sequence of context-sensitive embeddings for each token. These embeddings can be used in a variety of downstream tasks and have achieved state-of-the-art performance in many of them. There are many models that generate contextual embeddings, generally trained with unsupervised learning using a large corpus. In particular, ELMo (Peters et al., 2018) uses a left-to-right and a right-to-left LSTM trained to minimize perplexity across a large corpus. To generate contextual embeddings, it feeds the sentence through both LSTMs and concatenates the left-to-right and right-to-left LSTM states. BERT (Devlin et al., 2019) uses 12 layers of the Transformer module (Vaswani et al., 2017) and is pre-trained on a large corpus using two tasks: masked language modeling to predict randomly masked tokens from context, and next sentence prediction to predict whether two sentences are contiguous in the original text.

Both ELMo and BERT can be adapted to non-English languages without modification. The authors of BERT trained multilingual BERT (mBERT) by concatenating Wikipedia for 104 languages. There are models designed specifically for multilingual situations: XLM (Conneau and Lample, 2019) and XLM-R (Conneau et al., 2020) are similar to BERT, but include an additional pre-training objective that leverages parallel text.

Typically, BERT is used in combination with task-specific modules and the parameters fine-tuned using domain data. Here we use contextual embeddings without fine-tuning. Probing experiments revealed that BERT embeddings contain semantic information beyond static embeddings, especially in the upper layers (Tenney et al., 2019), and this information is demonstrably useful for word sense disambiguation (Wiedemann et al., 2019; Hadiwinoto et al., 2019).

3 Identification of word class flexibility

3.1 Definitions

A lemma is *flexible* if it can be used both as a noun and as a verb. To reduce noise, we require each lemma to appear at least 10 times and at least 5% of the time as the minority class to be considered flexible. The *inflectional paradigm* of a lemma is the set of words that have the lemma.

A flexible lemma is *noun (verb) dominant* if it occurs more often as a noun (verb) than as a verb (noun). This is merely an empirical property of a lemma: we do not claim that the base POS should be determined by frequency. The *noun (verb) flexibility* of a language is the proportion of noun (verb) dominant lemmas that are flexible.

3.2 Datasets and preprocessing

Our experiments require corpora containing part-of-speech annotations. For English, we use the British National Corpus (BNC), consisting of 100M words of written and spoken English from a variety of sources (Leech, 1992). Root lemmas and POS tags are provided, and were generated automatically using the CLAWS4 tagger (Leech et al., 1994). For our experiments, we use BNC-baby, a subset of BNC containing 4M words.

For other languages, we use the Universal Dependencies (UD) treebanks of over 70 languages, annotated with lemmatizations, POS tags, and dependency information (Zeman et al., 2019). We concatenate the treebanks for each language and use the languages that have at least 100k tokens.

The UD treebanks are too small for our contextualized experiments and are not matched for content and style, so we supplement them with Wikipedia text[2]. For each language, we randomly sample 10M tokens from Wikipedia; we then use UDPipe 1.2 (Straka and Straková, 2017) to tokenize the text and generate POS tags for every token. We do not use the lemmas provided by UDPipe, but instead use the lemma merging algorithm to group lemmas.

3.3 Lemma merging algorithm

The UD corpus provides lemma annotations for each word, but these lemmas are insufficient for our purposes because they do not always capture instances of flexibility. In some languages, nouns and verbs are lemmatized to different forms by convention. For example, in French, the word *voyage* can be used as a verb (*il voyage* 'he travels') or as a noun (*un voyage* 'a trip'). However, verbs are lemmatized to the infinitive *voyager*, whereas nouns are lemmatized to the singular form *voyage*. Since the noun and verb lemmas are different, it is not easy to identify them as having the same stem.

Table 1: Noun and verb flexibility for 37 languages with at least 100k tokens in the UD corpus. We include the 27 languages with over 2.5% noun and verb flexibility; 10 languages are excluded from further analysis.

The different lemmatization conventions of French and English reflect a more substantial linguistic difference. French has a stem-based morphology, in which stems tend to occur with an inflectional ending. By contrast, English has a word-based morphology, where stems are commonly used as free forms (Kastovsky, 2006). This dif-

---

[2] We use Wikiextractor to extract text from Wikimedia dumps: `https://github.com/attardi/wikiextractor`.

ference is relevant to the definition of word class flexibility: in stem-based systems, flexible items are stems that may not be attested as free forms (Bauer and Valera, 2005b, p.14).

We propose a heuristic algorithm to capture stem-based flexibility as well as word-based flexibility. The key observation is that the inflectional paradigms of the noun and verb forms often have some words in common (such is the case for *voyager*). Thus, we merge any two lemmas whose inflectional paradigms have a nonempty intersection. This is implemented with a single pass through the corpus, using the union-find data structure: for every word, we call UNION on the inflected form and the lemmatized form.

Using this heuristic, we can identify cases of flexibility that do not share the same lemma in the UD corpus (Table 1). This method is not perfect, and is unable to identify cases of stem-based flexibility where the inflectional paradigms don't intersect, for example in French, *chant* 'song' and *chants* 'songs' are not valid inflections of the verb *chanter* 'to sing'. There are also false positives that cause two unrelated lemmas to be merged if their inflectional paradigms intersect, for example, *avions* (plural form of *avion* 'airplane') happens to have the same form as *avions* (first person plural imperfect form of *avoir* 'to have').

4 Methodology and evaluation

4.1 Probing test of contextualized model

Deep contextual embeddings can capture a variety of information other than semantics, which can introduce noise into our results, for example: the lexicographic form of a word, syntactic position, etc. In order to compare different contextual language models on how well they capture semantic information, we perform a probing test of how accurate the models can capture human judgements of word sense similarity.

We begin with a list of the 138 most frequent flexible words in the BNC corpus. Some of these words are flexible (e.g., *work*), while others are homonyms (e.g., *bear*). For each lemma, we get five human annotators from Mechanical Turk to make a sentence using the word as a noun, then make a sentence using the word as a verb, then rate the similarity of the noun and verb senses on a scale from 0 to 2. The sentences are used for quality assurance, so that ratings are removed if the sentences are nonsensical. We will call the average human rating for each word the *human similarity score*.

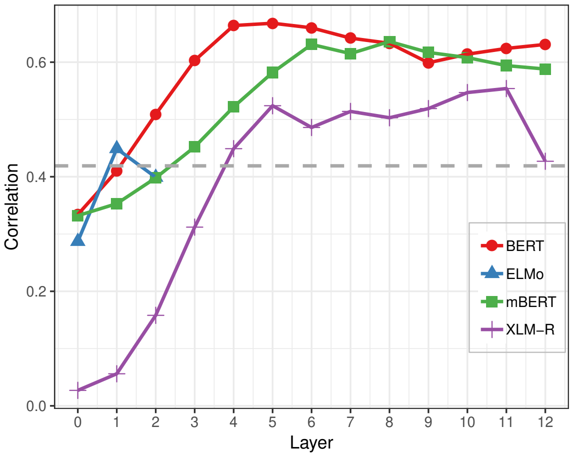

Figure 1: Spearman correlations between human and model similarity scores for ELMo, BERT, mBERT, and XLM-R. The dashed line is the baseline using static GloVe embeddings.

Next, we evaluate each layer of ELMo, BERT, mBERT, and XLM-R[3] on correlation with the human similarity score. That is, we compute the mean of the contextual vectors for all noun instances of the given word in the BNC corpus, the mean across all verb instances, then compute the cosine distance between the two mean vectors as the model's similarity score. Finally, we evaluate the Spearman correlation of the human and model's similarity scores for 138 words: this score measures the model's ability to gauge the level of semantic similarity between noun and verb senses, compared to human judgements.

For a baseline, we do the same procedure using non-contextual GloVe embeddings (Pennington et al., 2014). Note that while all instances of the same word have a static embedding, different words that share the same lemma still have different embeddings (e.g., *work* and *works*), so that the baseline is not trivial.

The correlations are shown in Figure 1. BERT and mBERT are better than ELMo and XLM-R at capturing semantic information, in all transformer models, the correlation increases for each layer up until layer 4 or so, and after this point, adding more layers neither improves nor degrades the performance. Thus, unless otherwise noted, we use the final layers of each model for down-

---

[3] We use the models 'bert-base-uncased', 'bert-base-multilingual-cased', and 'xlm-roberta-base' from Wolf et al. (2019).

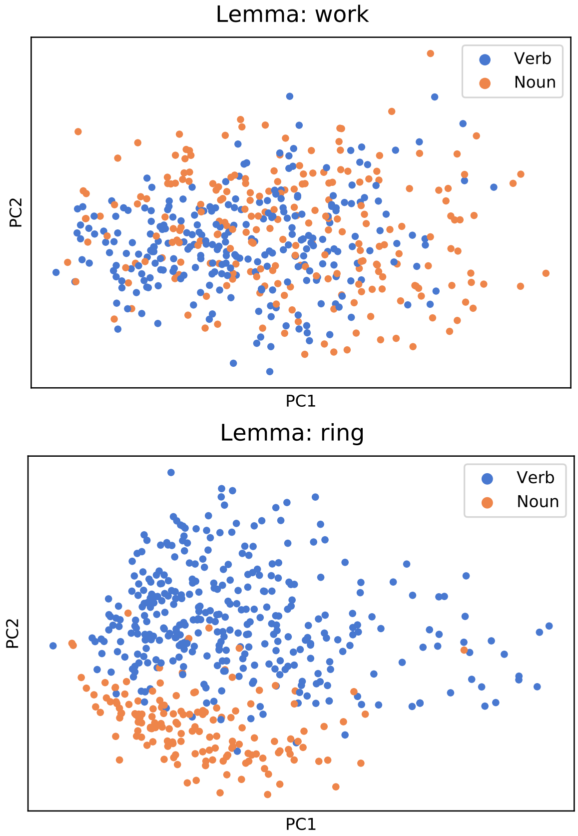

Figure 2: PCA plot of BERT embeddings for the lemmas “work” (high similarity between noun and verb senses) and “ring” (low similarity).

stream tasks.

Figure 2 illustrates the contextual distributions for two lemmas on the opposite ends of the noun-verb similarity spectrum: *work* (human similarity score: 2) and *ring* (human similarity score: 0). We apply PCA to the BERT embeddings of all instances of each lemma in the BNC corpus. For *work*, the noun and verb senses are very similar and the distributions have high overlap. In contrast, for *ring*, the most common noun sense (‘a circular object’) is etymologically and semantically unrelated to the most common verb sense (‘to produce a resonant sound’), and accordingly, their distributions have very little overlap.

4.2 Three contextual metrics

We define three metrics based on contextual embeddings to measure various semantic aspects of word class flexibility. We start by generating contextual embeddings for each occurrence of every flexible lemma. For each lemma l, let $E_{n,l}$ and $E_{v,l}$ be the set of contextual embeddings for noun and verb instances of l. We define the *prototype noun vector* $\mathbf{p}_{n,l}$ of a lemma l as the mean of embeddings across noun instances, and the *noun variation* $V_{n,l}$ as the mean Euclidean distance from each noun instance to the noun vector:

$$\mathbf{p}_{n,l} = \frac{1}{|E_{n,l}|} \sum_{\mathbf{x} \in E_{n,l}} \mathbf{x} \tag{1}$$

$$V_{n,l} = \frac{1}{|E_{n,l}|} \sum_{\mathbf{x} \in E_{n,l}} ||\mathbf{x} - \mathbf{p}_{n,l}|| \tag{2}$$

The *prototype verb vector* $\mathbf{p}_{v,l}$ and *verb variation* $V_{v,l}$ for a lemma l are defined similarly:

$$\mathbf{p}_{v,l} = \frac{1}{|E_{v,l}|} \sum_{\mathbf{x} \in E_{v,l}} \mathbf{x} \tag{3}$$

$$V_{v,l} = \frac{1}{|E_{v,l}|} \sum_{\mathbf{x} \in E_{v,l}} ||\mathbf{x} - \mathbf{p}_{v,l}|| \tag{4}$$

Lemmas are included if they appear at least 30 times as nouns and 30 times as verbs. To avoid biasing the variation metric towards the majority class, we downsample the majority class to be of equal size as the minority class before computing the variation. The method does not filter out pairs of lemmas that are arguably homonyms rather than flexible (section 2.2); we choose to include all of these instances rather than set an arbitrary cutoff threshold.

We now define language-level metrics to measure the asymmetries hypothesized in sections 2.3 and 2.4. The *noun-to-verb shift (NVS)* is the average cosine distance between the prototype noun and verb vectors for noun dominant lemmas, and the *verb-to-noun shift (VNS)* likewise for verb dominant lemmas:

$$NVS = 1 - \mathbb{E}_{l \text{ noun-dominant}}[\cos(\mathbf{p}_{n,l}, \mathbf{p}_{v,l})] \tag{5}$$

$$VNS = 1 - \mathbb{E}_{l \text{ verb-dominant}}[\cos(\mathbf{p}_{n,l}, \mathbf{p}_{v,l})] \tag{6}$$

We define the *noun (verb) variation* of a language as the average of noun (verb) variations across all lemmas. Finally, define the *majority variation* of a language as the average of the variation of the dominant POS class, and the *minority variation* as the average variation of the smaller POS class, across all lemmas.

5 Results

5.1 Identifying flexible lemmas

Of the 37 languages in UD with at least 100k tokens; in 27 of them, at least 2.5% of verb and noun lemmas are flexible, which we take to indicate that

Language	**N→V shift**	**V→N shift**	**Noun variation**	**Verb variation**	**Majority variation**	**Minority variation**

Table 2: Semantic metrics for 25 languages, computed using mBERT and 10M tokens of Wikipedia text for each language. Asterisks denote significance at $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$. For the "Overall" row, we count the languages with a significant tendency towards one direction, out of the number of languages with statistical significance towards either direction (with $p < 0.05$ treated as significant).

word class flexibility exists in the language (Table 1). The lemma merging algorithm is crucial for identifying word class flexibility: only 6 of the 37 languages pass the 2.5% flexibility threshold using the default lemma annotations provided in UD[4]. Languages differ in their prevalence of word class flexibility, but every language in our sample has higher verb flexibility than noun flexibility.

5.2 Asymmetry in semantic metrics

Table 2 shows the values of the three metrics, computed using mBERT and Wikipedia data for 25 languages[5]. For testing significance, we use the unpaired Student's t-test to compare N-V versus V-N shift, and the paired Student's t-test for the other two metrics[6]. The key findings are as follows:

1. **Asymmetry in semantic shift.** In English, N-V shift is greater than V-N shift, in agreement with Bauer (2005). However, this pattern does not hold in general: there is no significant difference in either direction in most languages, and two languages exhibit a difference in the opposite direction as English.

---

[4] Chinese, Danish, English, Hebrew, Indonesian, and Japanese pass the flexibility threshold without the lemma merging algorithm.

[5] We exclude 2 of the 27 languages that we identify word class flexibility. Old Russian was excluded because it is not supported by mBERT; Korean is excluded because the lemma annotations deviate from the standard UD format.

[6] We do not apply the Bonferroni correction for multiple comparisons, because we make claims for trends across all languages, and not for any specific languages.

Dataset	Model	N→V shift	V→N shift	Noun variation	Verb variation	Majority variation	Minority variation
BNC	ELMo	0.389*	0.357	20.261	20.455	20.329	20.388
	BERT	0.122*	0.112	9.015	9.074	9.100***	8.989
	mBERT	0.189*	0.169	7.211	8.401***	7.875**	7.717
	XLM-R	0.004	0.005	2.058	2.374***	2.262	2.170
Wikipedia	ELMo	0.339***	0.330	22.556	22.521	22.463	22.614*
	BERT	0.120***	0.100	9.218***	8.944	9.118**	9.044
	mBERT	0.175*	0.160	8.035	8.624***	8.390***	8.268
	XLM-R	0.004**	0.003	1.966	1.954	1.946	1.974

Table 3: Comparison of semantic models on BNC and Wikipedia datasets (English), computed using several different language models. Asterisks denote significance at $^*p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$.

2. **Asymmetry in semantic variation between noun and verb usages.** Of the 17 languages with a statistically significant difference in noun versus verb variation, 14 of them have greater verb variation than noun variation.

3. **Asymmetry in semantic variation between majority and minority classes.** All of the 20 languages with a statistically significant difference in majority and minority variation have greater majority variation.

5.3 Model robustness

Next, we assess the robustness of our metrics with respect to choices of corpus and language model. Robustness is desirable because it gives confidence that our models capture true linguistic tendencies, rather than artifacts of our datasets or the models themselves. We compute the three semantic metrics on the BNC and Wikipedia datasets, using all 4 contextual language models: ELMo, BERT, mBERT, and XLM-R. Table 3 summarizes the results from this experiment.

We find that in almost every case where there is a statistically significant difference, all models agree on the direction of the difference. One exception is that noun variation is greater when computed using Wikipedia data than when using the BNC corpus. Wikipedia has many instances of nouns used in technical senses (e.g., *ring* is a technical term in mathematics and chemistry), whereas similar nonfiction text is less common in the BNC corpus.

6 Discussion

6.1 Frequency asymmetry

Every language in our sample has verb flexibility greater than noun flexibility. The reasons for this asymmetry are unclear, but may be due to semantic differences between nouns and verbs. We note that every language in our sample has more noun lemmas than verb lemmas, a pattern that was also attested by Polinsky (2012), although this does not provide an explanation of the observed phenomenon. We leave further exploration of the flexibility asymmetry to future work.

6.2 Implications for theories of flexibility

There is a strong cross-linguistic tendency for the majority word class of a flexible lemma to exhibit more semantic variation than the minority class. In other words, the frequency and semantic variation criteria of determining the base of a conversion pair agree more than at chance. This supports the analysis of word class flexibility as a directional process of conversion, as opposed to underspecification (section 2.3)[7]. Within a flexible lemma, verbs exhibit more semantic variation than nouns. It is attested across many languages that nouns are more physically salient, while verbs have more complex event and argument structure, and are harder for children to acquire than nouns (Gentner, 1982; Imai et al., 2008). Thus, verbs are expected to have greater semantic variation than nouns, which our results confirm. More importantly, for our purposes, this metric serves as a control for the previous metric. Flexible lemmas are more likely to be noun-dominant than verb-dominant, so could the majority and minority variation simply be proxies for noun and verb variation, respectively? In fact, we observe greater verb than noun variation, so this cannot be the case.

---

[7] Since 18 of the 25 languages for which semantic metrics were calculated are Indo-European, it is unclear whether these results generalize to non-Indo-European languages.

Finally, as suggested by Bauer (2005), we find evidence in English that N-V flexibility involves more semantic shift than V-N flexibility, and the pattern is consistent across multiple models and datasets (Table 3). However, this pattern is idiosyncratic to English and not a cross-linguistic tendency. It is thus instructive to analyze multiple languages in studying word class flexibility, as one can easily be misled by English-based analyses.

7 Conclusion

We use contextual language models to examine shared tendencies in word class flexibility across languages. We find that the majority class often exhibits more semantic variation than the minority class, supporting the view that word class flexibility is a directional process. We also find that in English, noun-to-verb flexibility is associated with more semantic shift than verb-to-noun flexibility, but this is not the case for most languages.

Our probing task reveals that the upper layers of BERT contextual embeddings best reflect human judgment of semantic similarity. We obtain similar results in different datasets and language models in English that support the robustness of our method. This work demonstrates the utility of deep contextualized models in linguistic typology, especially for characterizing cross-linguistic semantic phenomena that are otherwise difficult to quantify.

Abstract

Deep encoders have been proven to be effective in improving neural machine translation (NMT) systems, but training an extremely deep encoder is time consuming. Moreover, why deep models help NMT is an open question. In this paper, we investigate the behavior of a well-tuned deep Transformer system. We find that stacking layers is helpful in improving the representation ability of NMT models and adjacent layers perform similarly. This inspires us to develop a shallow-to-deep training method that learns deep models by stacking shallow models. In this way, we successfully train a Transformer system with a 54-layer encoder. Experimental results on WMT'16 English-German and WMT'14 English-French translation tasks show that it is $1.4\times$ faster than training from scratch, and achieves a BLEU score of 30.33 and 43.29 on two tasks. The code is publicly available at `https://github.com/libeineu/SDT-Training`.

1 Introduction

In recent years, neural models have led to state-of-the-art results in machine translation (MT) (Bahdanau et al., 2015; Sutskever et al., 2014). Many of these systems can broadly be characterized as following a multi-layer encoder-decoder neural network design: both the encoder and decoder learn representations of word sequences by a stack of layers (Vaswani et al., 2017; Wu et al., 2016; Gehring et al., 2017), building on an interesting line of work in improving such models. The simplest of these increases the model capacity by widening the network, whereas more recent work shows benefits from stacking more layers on the encoder side. For example, for the popular Transformer model (Vaswani et al., 2017), deep systems have shown promising BLEU improvements by either easing the information flow through the network (Bapna et al., 2018) or constraining the gradient norm across layers (Zhang et al., 2019; Xu et al., 2020; Liu et al., 2020). An improved system can even learn a 35-layer encoder, which is $5\times$ deeper than that of vanilla Transformer (Wang et al., 2019).

Although these methods have enabled training deep neural MT (NMT) models, questions remain as to the nature of the problem. The main question here is: *why and how deep networks help in NMT*. Note that previous work evaluates these systems in a black-box manner (i.e., BLEU score). It is thus natural to study how much a deep NMT system is able to learn that is different from the shallow counterpart. Beyond this, training an extremely deep model is expensive although a narrow-and-deep network can speed up training (Wang et al., 2019). For example, it takes us $3\times$ longer time to train the model when we deepen the network from 6 layers to 48 layers. This might prevent us from exploiting deeper models in large-scale systems.

In this paper, we explore why deep architectures work to render learning NMT models more effectively. By investigating the change of the hidden states in different layers, we find that new representations are learned by continually stacking layers on top of the base model. More stacked layers lead to a stronger model of representing the sentence. This particularly makes sense in the deep NMT scenario because it has been proven that deep models can benefit from an enriched representation (Wang et al., 2019; Wu et al., 2019b; Wei et al., 2020).

In addition, the finding here inspires us to develop a simple yet efficient method to train a deep NMT encoder: we train model parameters from shallow to deep, rather than training the entire model from scratch. To stabilize training, we design a sparse linear combination method of connecting lower-level layers to the top. It makes efficient pass

of information through the deep network but does not require large memory footprint as in dense networks. We experiment with the method in a state-of-the-art deep Transformer system. Our encoder consists of 48-54 layers, which is almost the deepest Transformer model used in NMT. On WMT En-De and En-Fr tasks, it yields a 1.4× speedup of training, matching the state-of-the-art on the WMT'16 En-De task.

2 Background

We start with a description of deep Transformer. In Transformer (Vaswani et al., 2017), the encoder takes a sequence of words $\{x_1, ..., x_n\}$ as input. The input is first transformed into a sequence of embeddings $\{w_1 + p_1, ..., w_n + p_n\}$, where w_k is a word embedding and p_k is a positional embedding. Then, the embedding sequence is fed into a stack of N identical layers. Each layer consists of two stacked sub-layers: a multi-head self-attention sub-layer and a feed-forward sub-layer. The decoder shares a similar architecture as the encoder but possesses an encoder-decoder attention sub-layer to capture the mapping between two languages.

For a deep model, layer normalization networks and layer-wise connections are needed, following the previous work of Bapna et al. (2018) and Wang et al. (2019).

- **Pre-Norm Residual Networks**. We make a residual connection (He et al., 2016) and a layer normalization unit (Lei Ba et al., 2016) at the input of each sub-layer. The output of the sub-layer is defined to be:

$$s_{i+1} = s_i + \text{SubLayer}(\text{LayerNorm}(s_i))$$

  where s_i and s_{i+1} are the output of sub-layers i and $i+1$. See Figure 1 (a) for the architecture of a pre-norm sub-layer. Pre-norm residual network has been found to be more efficient for back-propagation over a large number of layers than the post-norm architecture (Wang et al., 2019; Li et al., 2019).

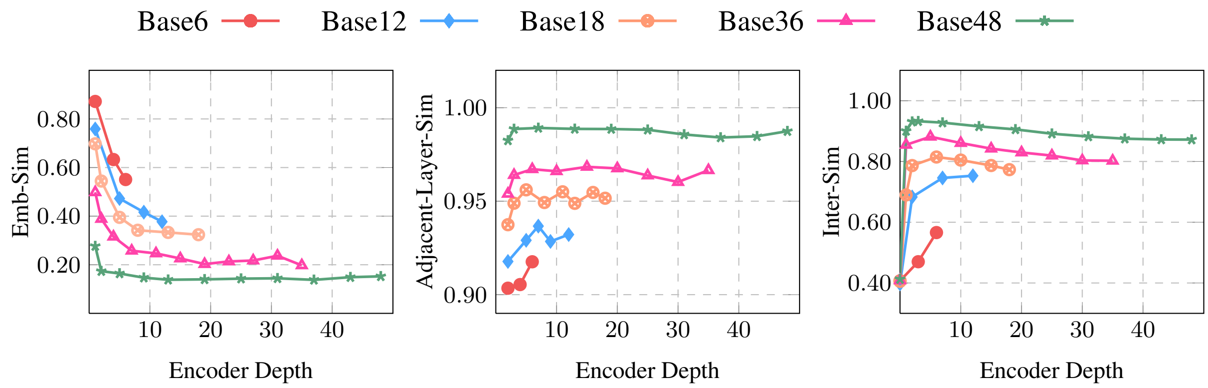
- **Dense Connections**. Direct layer connections can make easy access to distant layers in the stack (Wang et al., 2018; Bapna et al., 2018). Let $\{y_1, ..., y_N\}$ be the output of the stacked layers. We define a network $G(y_1, ..., y_{j-1})$ that reads all layer output vectors prior to layer j and generates a new vector. Then, $G(y_1, ..., y_{j-1})$ is regarded as a part of the input of layer j. In this way, we create direct connections from layers $\{1, ..., j-1\}$ to layer j. For $G(\cdot)$, we choose a linear model as in (Wang et al., 2019).

3 Why do Deep Models Help?

The Transformer encoder (or decoder) is essentially a representation model (Vaswani et al., 2017). Given a word sequence, a layer generates a distributed representation (i.e., y_j) for each position of the sequence. The representation is a mixture of word+position embedding and context embedding. For a simple implementation, only the top-most representation (i.e., y_N) is used for downstream components of the system. Nevertheless, the dense connections can make the lower-level representations directly accessible to the top layers. Hence, the representation model is actually encoded by the set of layer outputs $\{y_1, ..., y_N\}$.

For a stronger model, enlarging the size of each layer can fit the objective function with enough capacity. For example, Transformer-Big doubles the layer size of the base model and shows consistent improvements on several MT tasks. But the number of parameters increases quadratically with network width, which poses new difficulties in training such systems and the risk of overfitting. Alternatively, one can stack layers to strengthen the model because more layers offer more representations for the input sentence. Moreover, top-level layers can generate refined representations (Greff et al., 2017) by passing the input vectors through more linear and non-linear transformations in different layers.

To study how each layer behaves, we evaluate the change of the representation vector in the stack.



(a) Emb-Similarity (b) Adjacent-Layer-Similarity (c) Inter-Similarity

Figure 2: (a) Similarity of layer i and the input embedding, (b) Similarity of layer i and layer $i-1$, and (c) Inter-Similarity over the validation sequences. Note that 0 represents the embedding layer.

To do this, we compute the similarity between the outputs of two layers, as below,

$$\mathrm{sim}(i,j) = \frac{1}{n}\sum_{l=1}^{n}\mathrm{cosine}(y_i(l), y_j(l))$$

where $y_i(l)$ (or $y_j(l)$) is the output of layer i (or j) for position l of the sequence. $\mathrm{sim}(i,j)$ measures the degree of how close the representation vector of layer i is to that of layer j.

Figure 2(a) plots $\mathrm{sim}(i,0)$ curves for WMT En-De systems of different encoder depths. Here $\mathrm{sim}(i,0)$ measures how similar the output of layer j is to the input embedding of the encoder. We see that the similarity keeps going down when we stack more layers. It indicates that the model can learn new representations by using more stacked layers. But the similarity does not converge for shallow models (e.g., 6-layer and 12-layer encoders). It somehow reflects the fact that the shallow models "want" more layers to learn something new. More interestingly, deeper models (e.g., encoders of 18 layers or more) make the similarity converge as the depth increases, showing the effect of rendering the need of representation learning fulfilled.

Also, we investigate the similarity between adjacent layers for different systems. Figure 2(b) plots $\mathrm{sim}(i, i-1)$ as a function of layer number, which begins with $\mathrm{sim}(2,1)$ rather than $\mathrm{sim}(1,0)$[1] for better visualization. The results show that adjacent layers in converged systems have a high similarity. This agrees with previous work on the similarity of attention weights among layers (Xiao et al., 2019) though we study a different issue here. The deeper the models, the higher the similarity between adjacent layers. A natural question is whether we can initialize the higher layers by reusing the parameters of previous layers during training procedure?

Note that the Transformer model is doing something like encoding both contextual information and word information for each position of the sequence. Here, we design the Inter-Sim over the sequence to see how much the representation of a position holds to encode the sequence. For layer i, we have

$$\begin{aligned}\mathrm{sim}_{\mathrm{in}}(i) &= \frac{1}{n}\sum_{l=1}^{n}\mathrm{cosine}(y_i(l), \bar{y}_i)\\ \bar{y}_i &= \frac{1}{n}\sum_{l=1}^{n} y_i(l)\end{aligned}$$

where $\bar{y}_i$ is the mean vector of sequence $\{y_i(1), ..., y_i(n)\}$ and can be seen as the global representation of the entire sequence. $\mathrm{sim}_{\mathrm{in}}(i)$ is an indicator of the distance between an individual representation and the global representation. Figure 2(c) shows that the representation of a position tends to be close to the global representation for higher-level layers. This can be seen as smoothing the representations over different positions. A smoothed representation makes the model more robust and is less sensitive to noisy input. This result constitutes evidence that deep models share more global information over different positions of the encoder. Hence, it is easier to access the global representation of the source sequence for decoder and to generate the translation using a global context.

---

[1] Note that $(\mathrm{sim}(1,0))$ of Figure 2(b) are the same with those in Figure 2(a).

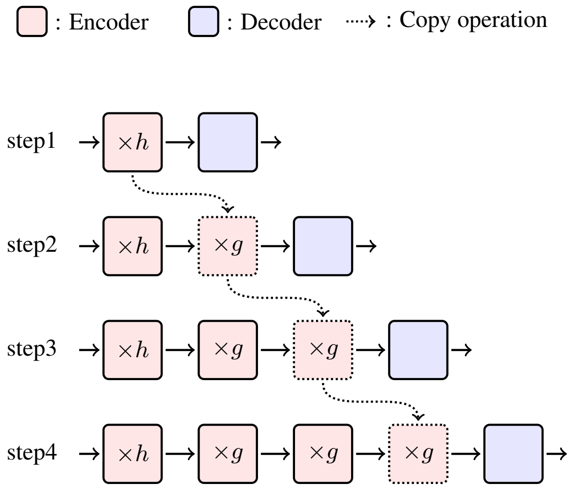


Figure 3: Shallow-to-deep training process.

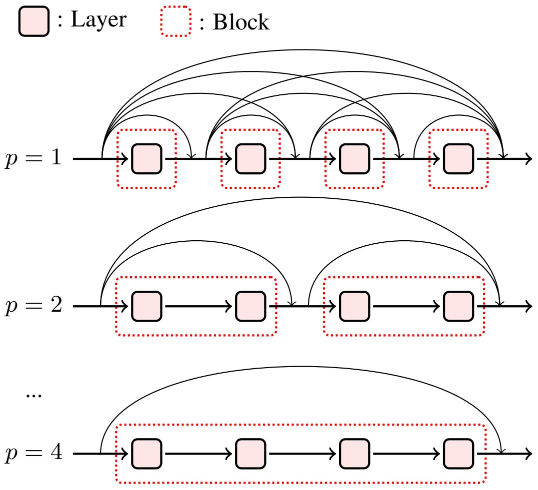

Figure 4: Sparse connections between layers.

4 Shallow-to-Deep Training

Although we are able to train deep models with the standard methods (Wang et al., 2019), it is obviously a time consuming task to learn a model with too many layers. For example, training a 48-layer system takes us $3\times$ longer time than the 6-layer baseline. As stated in Section 3, adjacent layers in a deep network are likely to behave in a similar fashion. This observation inspires us to train upper-level layers by reusing the learned parameters of lower-level layers. We call this method shallow-to-deep training (SDT) because we start with training a shallow model and then train a deeper model on top of it.

4.1 The Method

Assume that we have an initial model A with h layers that have already been trained. Now we need to train a new model B with $h + g$ layers ($h \geq g$). Unlike previous work, we do not train all $h + g$ layers from scratch. Instead,

- We copy the parameters of the first h layers from A to B.
- We then copy the parameters of the g top-most layers from A to B.

Model A can be seen as a good starting point of model B. After initializing of the model, we continue training model B as usual. The training can converge faster because the model initialization tends to place the parameters in regions of the parameter space that generalize well. See Figure 3 for an illustration of the method. In this work, we use the same step to learn from shallow to deep. For example, we train a 6-layer model, and then a 12-layer model, and then a 18-layer model, and so on.

4.2 Sparse Connections between Layers

The efficient pass of information plays an important role in training deep models. To this end, one can create direct connections between layers by dense networks. They are found to be necessary to learn strong Transformer systems (Bapna et al., 2018; Wang et al., 2019; Wu et al., 2019b). However, an extremely deep model in general results in a large number of such connections and of course a heavy system. For example, a 48-layer system runs $1.87\times$ slower than the system with no use of dense connections. We cannot even train it using a batch of 2048 tokens on TITAN V GPUs due to large memory footprint. Instead, we develop a method that resembles the merits of layer-wise connections but is lighter. The idea is pretty simple: we group every p layers to form a layer block and make connections between layer blocks. The connections between blocks are created in the standard way as used in dense networks (see Section 2). Here p is a parameter to control the connection density. For example, $p = 1$ means dense networks, and $p = \infty$ means networks with no layer-wise connections [2]. See Figure 4 for example networks with block/layer-wise connections.

4.3 Learning Rate Restart

The design of the learning rate schema is one of the keys to the success of Transformer. For example, Vaswani et al. (2017) designed a method to warm

---

[2] Residual connections are used by default in this work.

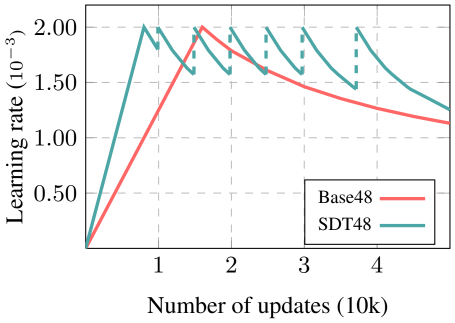

Figure 5: The learning rate schedule of each stacking.

up training for a number of training steps and then decrease the learning rate. In this work, shallow-to-deep training breaks the training process because we need to switch to a deeper model with initialization at some training steps. We found in our experiments that deep models could not be trained efficiently in the standard way because we had a small learning rate for a newly stacked model in late training steps.

We develop a new method to ensure that the model can be trained using a proper learning rate at every point of switching to a deeper model. We divide the training into a number of stages. Each of them is associated with a deeper model.

- For the first ω stages, the model is trained with a linear-warmup learning rate (lr) as described in (Vaswani et al., 2017).

  $$lr = d_{\text{model}}^{-0.5} \cdot step\_num \cdot warmup\_steps^{-1.5}$$

- For each of the following stages, the learning rate of a newly stacked model declines from the max-point with an inverse squared root of the current step.

  $$lr = d_{\text{model}}^{-0.5} \cdot step\_num^{-0.5}$$

  At the beginning of the stage, we reset the number of training steps.

Here $step\_num$ and $warmup\_steps$ are the current training step number and the warmup-step number. d_{model} is the size of the layer output. See Figure 5 for a comparison of different learning schemas.

5 Experiments

We report the experimental results on two widely used benchmarks - WMT'16 English-German (En-De) and WMT'14 English-French (En-Fr).

5.1 Data

For the En-De task, we used the same preprocessed data with (Vaswani et al., 2017; Ott et al., 2019; Wang et al., 2019), consisting of approximate 4.5M tokenized sentence pairs. All sentences were segmented into sequences of sub-word units (Sennrich et al., 2016) with 32K merge operations using a vocabulary shared by source and target sides. We selected *newstest2012+newstest2013* as validation data and *newstest2014* as test data.

For the En-Fr task, we replicated the setup of Vaswani et al. (2017) with 36M training sentence pairs from WMT14. We validated the En-Fr system on the union set of *newstest2012* and *newstest2013*, and tested it on *newstest2014*. We filtered out sentences of more than 200 words and generated a shared vocabulary with 40K merge operations on both source and target side.

We re-merged sub-word units to form complete words in the final output. For comparable results with previous work (Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017), we also adopted compound split for En→De. We reported case-sensitive tokenized BLEU scores for both En-De and En-Fr tasks, and sacrebleu[3] scores for both En-De and En-Fr tasks. The results were the mean of three times run with different random seeds.

5.2 Model Settings

Our implementation was based on Fairseq (Ott et al., 2019). For training, we used Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.997$, and $\epsilon = 10^{-8}$. We adopted the same learning rate schedule as the latest implementation of Tensor2Tensor[4]. For deep models, the learning rate (lr) first increased linearly for $warmup = 8,000$ steps from $1e^{-7}$ to $2e^{-3}$. After warmup, the learning rate decayed proportionally to the inverse square root of the current step. For our SDT method presented in Section 4, we set $h = g = p = 6$ on both the WMT En-De and En-Fr tasks. For a stronger system, we employed relative position representation (RPR) to strengthen the position embedding model (Shaw et al., 2018). We only used the relative key in each layer.

We batched sentence pairs by approximate length, and limited input/output tokens per batch to $4,096$/GPU. Following the method of (Wang et al.,

Table 1: Results of deep models on WMT14 En-De and WMT14 En-Fr tasks by the model parameters [million], training costs [hours], acceleration rates [%], BLEU scores [%], $\triangle$ BLEU [%] and Sacrebleu scores [%].

2019), we accumulated every two steps for a better batching. This resulted in approximately $56,000$ source and $56,000$ target tokens per training batch. The deep models were updated for 50k steps on the En-De task and 150k steps on the En-Fr task. All models were trained on 8 NVIDIA TITAN V GPUs with mix-precision accelerating. For fair comparison, we trained the deep Pre-Norm Transformer with the same settings reported in Wang et al. (2019). And all results are the average of three times running with different random seeds. We chose different hyper-parameter settings for the models.

- Base/Deep Model. The hidden layer size of self-attention was 512, and the size of feed forward inner-layer was $2,048$. Also, we used 8 heads for attention. For training, we set all dropout to 0.1, including residual dropout, attention dropout, relu dropout. Label smoothing $\epsilon_{ls} = 0.1$ was applied to enhance the generation ability of the model.
- Big Model. We used the same architecture as Transformer-Base but with a larger hidden layer size $1,024$, more attention heads (16), and a larger feed forward inner-layer ($4,096$ dimensions). The residual dropout was set to 0.3 for the En-De task and 0.1 for the En-Fr task. Additionally, the same depth (6) on both encoder and decoder side with Base model. For deeper Big model, we only change the encoder depth.

For evaluation, we averaged the last 5 consecutive checkpoints which were saved per training epoch on all WMT models. For all datasets, the length penalty was set to 0.6 and the beam size was set to 4.

5.3 Results

Table 1 summarizes the training cost and the translation quality on the WMT En-De and En-Fr tasks. First, we compare deep Transformer systems (Pre-Norm) with previously reported systems. Deep Transformer brings substantial improvements than big counterparts within the same experiment settings[5]. In addition, our SDT method enables efficient training for deeper networks with no loss in BLEU. As we can see from Table 1, the systems trained with the SDT method achieve comparable or even higher BLEU scores with their baselines, and the training costs are much less.

Another finding is that systems encoding relative position representation in the same encoder depth outperform their baselines by $0.44 - 0.59$ BLEU points on the En-De task, indicating that relative

Table 5: Comparison of DLCL and our work.

position representation can further strengthen deep Transformer. Similarly, it is observed that SDT can also speed up the RPR enhanced systems with no loss of translation quality. The speedup is larger for deeper models that the SDT method speeds up the training of 48-layer systems by $35.02\% - 39.98\%$. Surprisingly, both SDT-48L and SDT-RPR-48L achieve modest BLEU improvements compared with the baseline. This indicates that the benefit from enlarging encoder depth gradually decreases and our method alleviates the overfitting problem when the model is extremely deep.

To further validate the effectiveness of SDT method, we experimented on 24-layer Big models. Through Table 1 we see that, it achieves up to 52.30% speedup and match the performance with learning from scratch. Note that the training time of Deep-24L (Big) and Deep-RPR-24L (Big) are 37.41 and 38.80 hours respectively because the models were only optimized by 50k steps and they converged on the validation set. The finding here is similar with Wang et al. (2019)'s work that deep encoders can speed up the training process with a large learning rate. In addition, the BLEU score of SDT-RPR-24L (Big) is 30.46, which matches with the state-of-the-art within less parameters and training cost. Another finding here is the speedup of SDT training may gets larger when the model architecture gets more complex.

The similar phenomenon is observed in the WMT En-Fr task, a much larger dataset than that of the En-De task. The results in Table 1 show the effectiveness of our SDT method. It accelerates the training procedure by 44.90% with nearly 0.2 BLEU improvement on a 48-layer RPR system. The larger the dataset is, the greater the speedup will be. Note that our 48-layer deep system matches the state-of-the-art reported in (Ott et al., 2018; Wu et al., 2019a,b) within 8 GPUs training. We will furthermore verify whether there is an another improvement when we switch to a much larger batching schema. However, due to the large size of En-Fr dataset, optimizing a 24-layer Big model is quite time consuming, thus we have not finished the training yet. The experimental results can be found in our codebase soon. In addition, another benifit brought by SDT is that we can efficiently build the ensemble system given an already optimized model, we will show more details in our codebase.

6 Analysis

6.1 Ablation Study

In Table 2, we summarize the effect of resetting the learning rate and copy-initialization strategy in our SDT method. We choose SDT-RPR-48L as our baseline due to its strong performance. We see, first of all, that the copy-initialization plays an important role in our shallow-to-deep training process. For example, the BLEU score decreases dramatically if we stack the model from 6 layers to 12 layers and initialize the new block by a uniform distribution. This can be explained by the fact that every top-most layers are not sufficiently converged in stacking. Another observation is that the reset learning rate can also facilitate the training, enabling the model to learn fast and bringing nearly a +0.3 BLEU improvement. Moreover, we

compare different copy-initialization strategies, including initializing the new group by copying the g top-most layers, copying the top-most layer for g times and inserting the layer right after each existing layer in the group. From Table 3, we observe that our copying g top-most strategy achieves best performance.

Also, we investigate the impact of different stacking strategies on translation quality and speedup. Table 4 shows results of the models trained with different settings of g and training intervals[6]. Row 4 denotes the case that we stack the shallow model in an incremental way. We find that the stacking strategy and its training interval make great impacts on both translation quality and speedup. We need a trade-off to select the "best" system in different situations. For example, our default strategy (line 2) obtains the best performance, and the incremental stacking achieves the biggest speedup.

6.2 Comparison with Previous Work

Next, we compare the system Transformer-DLCL (Wang et al., 2019) with our SDT system. Table 5 shows the BLEU scores of the models trained with DLCL, sparse connection and SDT based on RPR, respectively. We see that Sparse-RPR-30L can achieve comparable performance with DLCL-RPR-30L using much fewer connections across encoder layers. More interestingly, our SDT-RPR-30L has a comparable BLEU score with DLCL-RPR-30L, but is 42.1% faster. In addition, we find that SDT-RPR-54L outperforms SDT-RPR-30L by 0.38 BLEU scores, but much deeper models cannot gain more benefits. This result indicates that deeper representation models might suffer from the overfitting problem.

Another benefit brought by SDT method is that we can train a deep Transformer model from a pre-trained model instead of training from scratch. For example, we can begin training from a pre-trained 24-layer system to progressively obtain a 48-layer system. The experimental results in Figure 6 verify our conjecture. Except the advantage of accelerating the training, the models trained through the SDT method can even slightly outperform those training from scratch at almost all encoder depths. This enables us to quickly obtain single systems in different depth from an already trained system, which is efficient to build ensemble systems, especially when the training data is extremely large.

6.3 Similarity of Layers

We show that the inter-similarity and emb-similarity of shallow models fail to converge in Section 3. Here, we further study the model behavior for different systems. We fix the parameters of a well-trained Pre-Norm-6L baseline and stack it into a 12-layer system by copying the top-6 layers. The dash lines in Figure 7 denote the new stacked system Stack-12L. We observe that

---

[6] Training interval means the training epoch of each newly stacking model

both inter-similarity and emb-similarity continue to rise and decline respectively, which exhibit similar phenomenon with Pre-Norm-12L which is trained from scratch. And it also outperforms the baseline by 0.99 BLEU points and is slightly inferior to Pre-Norm-12L (Table 6). Motivated by this, we design a regularization (according to Inter-sim) to constrain each layer to learn more global information on Pre-Norm-6L. Experimental results show that Reg-6L outperforms the baseline by 0.4 BLEU scores, indicating that a stronger global representation substantially improves the NMT model. This confirms our hypothesis in Section 3.

Figure 8 plots the emb-similarity of Base48 and SDT-48L. The model trained from shallow to deep behaves similarly with learning from scratch. The emb-similarity shows the same trend of decreasing in terms of similarity, and tends to coverage after layer 48. The results also indicate that our method can enbale the deep models to learn efficiently.

7 Related Work

In this section, we discuss the related work from two aspects as follows:

7.1 Deep Network Modeling

In recent years, researchers gradually concentrate on building deep networks for Transformer (Vaswani et al., 2017). Pham et al. (2019) developed a 48-layer Transformer for speech recognition and adopted the stochastic residual connection to alleviate gradient vanishing/exploding problem. Bapna et al. (2018) demonstrated the challenge when training deep encoder models with vanilla Transformer on NMT task, due to the gradient vanishing or exploding. They also proposed a transparent attention mechanism to alleviate the problem. Wang et al. (2019) demonstrated the essential of layer-normalization in each layer and proposed the dynamic linear combination method to ease the information flow. Homochronously, (Wu et al., 2019b) trained a 8-layer Transformer-Big with three specially designed components. More recently, Wei et al. (2020) further enhanced the Transformer-Big up to 18 layers through a multiscale collaborative framework. In general, shortening the path from bottom to top can obtain consistent improvements in the aforementioned studies. On the other hand, researchers observed that proper initialization strategies without any structure adjustment can also ease the optimization of Post-Norm Transformer, which highlighted the importance of careful parameter-initialization (Zhang et al., 2019; Xu et al., 2020; Huang et al., 2020).

7.2 Efficient Training Methods

When the model goes deeper, a challenge is the long training time for model convergence and the huge GPU cost. To alleviate this issue, several attempts have been made. Chang et al. (2018) proposed a multi-level training method by interpolating a residual block right after each existing block to accelerate the training of ResNets in computer version. Similarly, Gong et al. (2019) adopted a progressive stacking strategy to transfer the knowledge from a shallow model to a deep model, thus successfully trained a large-scale pre-training model BERT (Devlin et al., 2019) at a faster rate with comparable performance on downstream tasks. Unlike previous work, we only copy parameters of the g top-most layers and employ sparse connections across each stacking block in our shallow to deep training method, which has not been discussed yet in learning deep MT models.

8 Conclusions

We have investigated the behaviour of the well-trained deep Transformer models and found that stacking more layers could improve the representation ability of NMT systems. Higher layers share more global information over different positions and adjacent layers behave similarly. Also, we have developed a shallow-to-deep training strategy and employ sparse connections across blocks to ease the optimization. With the help of learning rate restart and appropriate initialization we successfully train a 48-layer RPR model by progressive stacking and achieve a 40% speedup on both WMT'16 English-German and WMT'14 English-French tasks. Furthermore, our SDT-RPR-24L (Big) achieves a BLEU score of 30.46 on WMT'16 English-German task, and speeds up the training by $1.5\times$.

Abstract

We propose an efficient inference procedure for non-autoregressive machine translation that iteratively refines translation purely in the continuous space. Given a continuous latent variable model for machine translation (Shu et al., 2020), we train an inference network to approximate the gradient of the marginal log probability of the target sentence, using only the latent variable as input. This allows us to use gradient-based optimization to find the target sentence at inference time that approximately maximizes its marginal probability. As each refinement step only involves computation in the latent space of low dimensionality (we use 8 in our experiments), we avoid computational overhead incurred by existing non-autoregressive inference procedures that often refine in token space. We compare our approach to a recently proposed EM-like inference procedure (Shu et al., 2020) that optimizes in a hybrid space, consisting of both discrete and continuous variables. We evaluate our approach on WMT'14 En→De, WMT'16 Ro→En and IWSLT'16 De→En, and observe two advantages over the EM-like inference: (1) it is computationally efficient, i.e. each refinement step is twice as fast, and (2) it is more effective, resulting in higher marginal probabilities and BLEU scores with the same number of refinement steps. On WMT'14 En→De, for instance, our approach is able to decode 6.2 times faster than the autoregressive model with minimal degradation to translation quality (0.9 BLEU).

1 Introduction

Most neural machine translation systems are autoregressive, hence decoding latency grows linearly with respect to the length of the target sentence. For faster generation, several work proposed non-autoregressive models with sub-linear decoding latency given sufficient parallel computation (Gu et al., 2018a; Lee et al., 2018; Kaiser et al., 2018).

As it is challenging to precisely model the dependencies among the tokens without autoregression, many existing non-autoregressive models first generate an initial translation which is then iteratively refined to yield better output (Lee et al., 2018; Gu et al., 2019; Ghazvininejad et al., 2019). While various training objectives are used to admit refinement (e.g. denoising, evidence lowerbound maximization and mask language modeling), the generation process of these models is similar in that the refinement process happens in the *discrete* space of sentences.

Meanwhile, another line of work proposed to use *continuous* latent variables for non-autoregressive translation, such that the distribution of the target sentences can be factorized over time given the latent variables (Ma et al., 2019; Shu et al., 2020). Unlike the models discussed above, finding the most likely target sentence under these models requires searching over continuous latent variables. To this end, Shu et al. (2020) proposed an EM-like inference procedure that optimizes over a hybrid space consisting of both continuous and discrete variables. By introducing a deterministic delta posterior, it maximizes a proxy lowerbound by alternating between matching the delta posterior to the original approximate posterior (continuous optimization), and finding a target sentence that maximizes the proxy lowerbound (discrete search).

In this work, we propose an iterative inference procedure for latent variable non-autoregressive models that purely operates in the continuous space.[1] Given a latent variable model, we train an inference network to estimate the gradient of the marginal log probability of the target sentence, using only the latent variable as input. At inference time, we find the target sentence that approximately

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1006–1015,
November 16–20, 2020.

maximizes the log probability by (1) initializing the latent variable e.g. as the mean of the prior, and (2) following the gradients estimated by the inference network.

We compare the proposed approach with the EM-like inference (Shu et al., 2020) on three machine translation datasets: WMT'14 En→De, WMT'16 Ro→En and IWSLT'16 De→En. The advantages of our approach are twofold: (1) each refinement step is twice as fast, as it avoids discrete search over a large vocabulary, and (2) it is more effective, giving higher marginal probabilities and BLEU scores with the same number of refinement steps. Our procedure results in significantly faster inference, for instance giving 6.2× speedup over the autoregressive baseline on WMT'14 En→De at the expense of 0.9 BLEU score.

2 Background: Iterative Refinement for Non-Autoregressive Translation

We motivate our approach by reviewing existing refinement-based non-autoregressive models for machine translation in terms of their inference procedure. Let us use V, D, T and L to denote vocabulary size, latent dimensionality, target sentence length and the number of refinement steps, respectively.

Most machine translation models are trained to maximize the conditional log probability $\log p(\mathbf{y}|\mathbf{x})$ of the target sentence $\mathbf{y}$ given the source sentence $\mathbf{x}$, averaged over the training data consisting of sentence pairs $\{(\mathbf{x}_n, \mathbf{y}_n)\}_{n=1}^N$. To find the most likely target sentence at test time, one performs maximum-a-posteriori inference by solving a search problem $\hat{\mathbf{y}} = \text{argmax}_{\mathbf{y}} \log p(\mathbf{y}|\mathbf{x})$.

2.1 Refinement in a Discrete Space

As the lack of autoregression makes it challenging to model the dependencies among the target tokens, most of the existing non-autoregressive translation models use iterative refinement to impose dependencies in the generation process. Various training objectives are used to incorporate refinement, e.g. denoising (Lee et al., 2018), mask language modeling (Ghazvininejad et al., 2019) and evidence lowerbound maximization (Chan et al., 2019; Gu et al., 2019). However, inference procedures employed by these models are similar in that an initial hypothesis is generated and then successively refined. We refer the readers to (Mansimov et al., 2019) for a formal definition of a sequence generation framework that unifies these models, and briefly discuss the inference procedure below.

By viewing each refinement step as introducing a discrete random variable $\mathbf{z}_i$ (a $T \times V$-dimensional matrix, where each row is one-hot), inference with L refinement steps requires finding $\mathbf{y}$ that maximizes the log probability $\log p(\mathbf{y}|\mathbf{x})$.

$$\begin{aligned}
&\log p_\theta(\mathbf{y}|\mathbf{x}) = \log \sum_{\mathbf{z}_{1:L}} p_\theta(\mathbf{y}, \mathbf{z}_{1:L}|\mathbf{x}) \\
&= \log \sum_{\mathbf{z}_{1:L}} \Big(p_\theta(\mathbf{y}|\mathbf{z}_{1:L}, \mathbf{x}) \cdot \prod_{i=1}^{L} p_\theta(\mathbf{z}_i|\mathbf{z}_{<i}, \mathbf{x}) \Big) \\
&\geq \sum_{\mathbf{z}_{1:L}} \Big(\log p_\theta(\mathbf{y}|\mathbf{z}_{1:L}, \mathbf{x}) + \sum_{i=1}^{L} \log p_\theta(\mathbf{z}_i|\mathbf{z}_{<i}, \mathbf{x}) \Big).
\end{aligned} \tag{1}$$

As the marginalization over $\mathbf{z}_{1:L}$ is intractable, inference for these models instead maximize the log joint probability with respect to $\hat{\mathbf{z}}_{1:L}$ and $\mathbf{y}$:

$$\log p_\theta(\mathbf{y}|\hat{\mathbf{z}}_{1:L}, \mathbf{x}) + \sum_{i=1}^{L} \log p_\theta(\hat{\mathbf{z}}_i|\hat{\mathbf{z}}_{<i}, \mathbf{x}).$$

Approximate search methods are used to find $\hat{\mathbf{z}}_{1:L}$ as $\hat{\mathbf{z}}_i = \text{argmax}_{\mathbf{z}_i} \log p_\theta(\mathbf{z}_i|\hat{\mathbf{z}}_{<i}, \mathbf{x})$.

2.2 Refinement in a Hybrid Space

Learning On the other hand, Ma et al. (2019); Shu et al. (2020) proposed to use *continuous* latent variables for non-autoregressive translation. By letting the latent variables $\mathbf{z}$ (of dimensionality $T \times D$) capture the dependencies between the target tokens, the decoder $p_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})$ can be factorized over time. As exact posterior inference and learning is intractable for most deep parameterized prior and decoder distributions, these models are trained to maximize the evidence lowerbound (ELBO) (Kingma and Welling, 2014; Wainwright and Jordan, 2008).

$$\log p_\theta(\mathbf{y}|\mathbf{x}) \geq \mathop{\mathbb{E}}_{\mathbf{z} \sim q_\phi} \left[\log \frac{p_\theta(\mathbf{y}, \mathbf{z}|\mathbf{x})}{q_\phi(\mathbf{z}|\mathbf{y}, \mathbf{x})} \right]$$

Inference Exact maximization of ELBO with respect to $\mathbf{y}$ is challenging due to the expectation over $\mathbf{z} \sim q_\phi$. To approximately maximize the ELBO, Shu et al. (2020) proposed to optimize a deterministic proxy lowerbound using a Dirac delta posterior:

$$\delta(\mathbf{z}|\boldsymbol{\mu}) = \mathbb{1}_{\boldsymbol{\mu}}(\mathbf{z})$$

Then, the ELBO reduces to the following proxy lowerbound:

$$\mathbb{E}_{\mathbf{z}\sim\delta(\mathbf{z}|\boldsymbol{\mu})}\Big[p_\theta(\mathbf{y}|\mathbf{z},\mathbf{x}) + p_\theta(\mathbf{z}|\mathbf{x})\Big] + \overbrace{\mathcal{H}(\delta)}^{=0},$$
$$= \log p_\theta(\mathbf{y}|\boldsymbol{\mu},\mathbf{x}) + \log p_\theta(\boldsymbol{\mu}|\mathbf{x}).$$

Shu et al. (2020) proposed to approximately maximize the ELBO with an EM-like inference procedure, to which we refer as *delta inference*. It alternates between continuous and discrete optimization: (1) E-step matches the delta posterior with the approximate posterior by minimizing their KL divergence: $\boldsymbol{\mu}_i = \text{argmin}_{\boldsymbol{\mu}} \text{KL}\big[\,\delta(\mathbf{z}|\boldsymbol{\mu})\,\big\|\,q_\phi(\mathbf{z}|\hat{\mathbf{y}}_{i-1},\mathbf{x})\,\big]$, and (2) M-step maximizes the proxy lowerbound with respect to $\mathbf{y}$: $\hat{\mathbf{y}}_i = \text{argmax}_{\mathbf{y}} \log p_\theta(\mathbf{y}|\boldsymbol{\mu}_i,\mathbf{x})$. Overall, delta inference finds $\mathbf{y}$ and $\boldsymbol{\mu}$ that maximizes $\log p_\theta(\mathbf{y}|\boldsymbol{\mu},\mathbf{x}) + \log q_\phi(\boldsymbol{\mu}|\mathbf{y},\mathbf{x})$. This iterative inference procedure in hybrid space was empirically shown to result in improved BLEU scores and ELBO on each refinement step (Shu et al., 2020).

3 Iterative Refinement in a Continuous Space

While the delta inference procedure is an effective inference algorithm for machine translation models with continuous latent variables, it is unsatisfactory as the M-step requires searching over V tokens T times for each refinement step. As V is large for most machine translation models, this is an expensive operation, even when the T searches can be parallelized. We thus propose to replace the delta inference with continuous optimization in the latent space only, given the underlying latent variable model.

3.1 Learning

Let us define $\tau_\theta(\mathbf{z};\mathbf{x})$ as the marginal log probability of the most likely target sentence under the latent variable model given $\mathbf{z}$.

$$\tau_\theta(\mathbf{z};\mathbf{x}) = \log p_\theta(\hat{\mathbf{y}}|\mathbf{x}), \tag{2}$$

where $\hat{\mathbf{y}} = \text{argmax}_{\mathbf{y}} \log p_\theta(\mathbf{y}|\mathbf{z},\mathbf{x})$. Our goal is to find a function $-E_\psi(\mathbf{z};\mathbf{x})$ that approximates $\tau_\theta(\mathbf{z};\mathbf{x})$ up to an additive constant and a positive multiplicative factor, such that

$$\text{argmin}_{\mathbf{z}}\big(E_\psi(\mathbf{z};\mathbf{x})\big) \approx \text{argmax}_{\mathbf{z}}\big(\tau_\theta(\mathbf{z};\mathbf{x})\big).$$

In this work, instead of directly approximating τ_θ, we train $-E_\psi$ to learn the difference of τ_θ between a pair of configurations of latent variables. Omitting the source sentence $\mathbf{x}$ and the model parameters θ for notational simplicity, we solve the following problem for $\mathbf{z} \neq \overline{\mathbf{z}}$:

$$\begin{aligned}&\min_\psi \Big\| \Big(-E_\psi(\overline{\mathbf{z}}) + E_\psi(\mathbf{z})\Big) - \Big(\tau(\overline{\mathbf{z}}) - \tau(\mathbf{z})\Big)\Big\|^2 \\ &\approx \min_\psi \Big\|\nabla_{\mathbf{z}} E_\psi(\mathbf{z})\Big\|^2 + 2\Big(\big(\nabla_{\mathbf{z}} E_\psi(\mathbf{z})\big)^\intercal \cdot \nabla_{\mathbf{z}}\tau(\mathbf{z})\Big).\end{aligned} \tag{3}$$

See Appendix A for a full derivation. Intuitively, $\nabla_{\mathbf{z}}\big(-E_\psi(\mathbf{z};\mathbf{x})\big)$ is trained to approximate $\nabla_{\mathbf{z}}\,\tau_\theta(\mathbf{z};\mathbf{x})$, as Eq. 3 maximizes their dot product while minimizing its squared norm.

As $\tau_\theta(\mathbf{z};\mathbf{x})$ is not differentiable with respect to $\mathbf{z}$ due to the argmax operation in Eq. 2, $\nabla_{\mathbf{z}}\,\tau_\theta(\mathbf{z};\mathbf{x})$ is not defined. We thus use a proxy gradient from delta inference. Furthermore, we weigh the latent configuration $\mathbf{z}$ according to the prior. Our final training objective for E_ψ is then as follows:

$$\begin{aligned}&\mathbb{E}_{\mathbf{z}\sim p_\theta(\mathbf{z}|\mathbf{x})}\Big[\Big\|\nabla_{\mathbf{z}} E_\psi(\mathbf{z};\mathbf{x})\Big\|^2 + \\ &\qquad 2\Big(\big(\nabla_{\mathbf{z}} E_\psi(\mathbf{z};\mathbf{x})\big)^\intercal \cdot (\widetilde{\mathbf{z}} - \mathbf{z})\Big)\Big],\end{aligned} \tag{4}$$

where $\widetilde{\mathbf{z}}$ is the output of applying k steps of delta inference on $\mathbf{z}$. If delta inference improves the log probability at each iteration, we hypothesize that $(\widetilde{\mathbf{z}} - \mathbf{z})$ is a reasonable approximation to the true gradient $\nabla_{\mathbf{z}}\,\tau_\theta(\mathbf{z};\mathbf{x})$. We empirically show that this is indeed the case in Sec. 5.2.

3.2 Parameterization

We have two options for parameterizing $\nabla_{\mathbf{z}} E_\psi(\mathbf{z};\mathbf{x})$ when minimizing Eq. 4. First, we can parameterize it as the gradient of a scalar-valued function E, to which earlier work have referred as an *energy* function (Teh et al., 2003; LeCun et al., 2006). Second, we can parameterize it as a function $S_\psi(\mathbf{z};\mathbf{x})$ that directly outputs the gradient of the log probability with respect to $\mathbf{z}$ (which is often referred to as a *score* function (Hyvärinen, 2005)), without estimating the energy directly.

While previous work found direct score estimation that bypasses energy estimation unstable (Alain and Bengio, 2014; Saremi et al., 2018), it leads to faster inference by avoiding backpropagation in each refinement step. We compare the two approaches in our experiments.

Algorithm 1: Inference for Latent Variable Models using Learned Gradients

```
Input  : $\mathbf{x}$, $\alpha$, $\theta$, $\psi$
Output : $\hat{\mathbf{y}}$
let $\mathbf{z} = \mathbb{E}_{\mathbf{z} \sim p_\theta(\mathbf{z}|\mathbf{x})}[\mathbf{z}]$
while termination condition not met, do
    $\mathbf{z} = \mathbf{z} - \alpha \cdot (\nabla_\mathbf{z} E_\psi(\mathbf{z}; \mathbf{x}))$
end
$\hat{\mathbf{y}} = \text{argmax}_\mathbf{y} \log p_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})$
```

3.3 Inference

At inference time, we initialize the latent variable (e.g. using either a sample from the prior or its mean) and iteratively update the latent variable using the estimated gradients (see Alg. 1). As our inference procedure only involves optimization in the continuous space each step, we avoid having to search over a large vocabulary. We can either perform iterative refinement for a fixed number of steps, or until some convergence condition is satisfied.

4 Experimental Setup

4.1 Datasets and Preprocessing

We evaluate our approach on three widely used machine translation datasets: IWSLT'16 De→En[2] (containing 197K training, 2K development and 2K test sentence pairs), WMT'16 Ro→En[3] (612K, 2K, 2K pairs) and WMT'14 En→De[4] (4.5M, 3K, 3K pairs).

We use sentencepiece tokenization (Kudo and Richardson, 2018) with 32K sentencepieces on all datasets. For WMT'16 Ro→En, we follow Sennrich et al. (2016) and normalize Romanian and remove diacritics before applying tokenization. For training, we discard sentence pairs if either the source or the target length exceeds 64 tokens.

Following Lee et al. (2018), we remove repetitions from the translations with a simple post-processing step before computing BLEU scores. We use detokenized BLEU with Sacrebleu (Post, 2018).

Distillation Following previous work on non-autoregressive translation, we train non-autoregressive models on the target sentences generated by an autoregressive model (Kim and Rush, 2016; Gu et al., 2018a) trained using the FairSeq framework (Ott et al., 2019).

4.2 Models and Baselines

Autoregressive baselines We use Transformers (Vaswani et al., 2017) with the following hyperparameters. For WMT'16 Ro→En and WMT'14 En→De, we use Transformer-base. For IWSLT'16 De→En, we use a smaller model with $(d_{\text{model}}, d_{\text{filter}}, n_{\text{layers}}, n_{\text{heads}}) = (256, 1024, 5, 2)$.

Non-autoregressive latent variable models We closely follow the implementation details from (Shu et al., 2020). The prior and the approximate posterior distributions are spherical Gaussian distributions with learned mean and variance, and the decoder is factorized over time. The only difference is at inference time, the target sentence length is predicted once and fixed throughout the refinement procedure. Therefore, the latent variable dimensionality $\mathbb{R}^{T \times D}$ does not change.

The decoder, prior and approximate posterior distributions are all parameterized using n_{layers} Transformer decoder layers (the last two also have a final linear layer that outputs mean and variance). For IWSLT'16 De→En, we use $(d_{\text{model}}, d_{\text{filter}}, n_{\text{layers}}, n_{\text{heads}}) = (256, 1024, 3, 4)$. For WMT'14 En→De and WMT'16 Ro→En, we use $(512, 2048, 6, 8)$. The latent dimensionality d_{latent} is set to 8 across all datasets. The source sentence encoder is implemented with a standard Transformer encoder. Given the hidden states of the source sentence, the length predictor (a 2-layer MLP) predicts the length difference between the source and target sentences as a categorical distribution in $[-50, 50]$.

Energy function $E_\psi(\mathbf{z}; \mathbf{x})$ is parameterized with n_{layers} Transformer decoder layers and a final linear layer with the output dimensionality of 1. We average the last Transformer hidden states across time and feed it to a linear layer to yield a scalar energy value.

Score function When directly estimating the gradient of the log probability with respect to $\mathbf{z}$, $S_\psi(\mathbf{z}; \mathbf{x})$ is parameterized with n_{layers} Transformer decoder layers and a final linear layer with the output dimensionality of d_{latent}.

Table 1: Translation quality and inference speed of autoregressive baseline (AR) and several inference procedures for non-autoregressive latent variable model (NAR LVM): Delta inference (*Delta*) (Shu et al., 2020), the proposed inference procedure with estimated energy (*Energy*) or score (*Score*). *Speed*: inference speedup compared to the autoregressive model with beam width 4. *Time*: Average wall clock time per example in milliseconds on a Tesla V100 GPU (with standard deviations). b: beam width, L: the number of refinement steps. *Search*: parallel decoding with 5 length candidates and 5 samples from the prior, with 1 refinement step. Results above *Search* are obtained by initializing the latent variable as the mean of the prior. We boldface the highest BLEU among the latent variable models.

4.3 Training and Optimization

We use the Adam optimizer (Kingma and Ba, 2015) with batch size of 8192 tokens and the learning rate schedule used by Vaswani et al. (2017) with warmup of 8K steps. When training our inference networks, we fix the underlying latent variable model. Our inference networks are trained for 1M steps to minimize Eq. 4, where $\widetilde{\mathbf{z}}$ is obtained by applying $k(=4)$ iterations of delta inference on $\mathbf{z}$ sampled from the prior. We also find that stochastically applying one gradient update (using the estimated gradients) to $\mathbf{z}$ before computing $\widetilde{\mathbf{z}}$ leads to better performance.

4.4 Inference

Step size For the proposed inference procedure, we use the step size $\alpha = 1.0$ as it performed well on the development set.

Length prediction Given a distribution of target sentence length, we can either (1) take the argmax, or (2) select the top l candidates and decode them in parallel (Ghazvininejad et al., 2019). In the second case, we select the output candidate with the highest log probability under an autoregressive model, normalized by its length.

Latent search In Alg. 1, we can either initialize the latent variable with a sample from the prior, or its mean. We use n_w samples from the prior and perform iterative refinement (e.g. delta inference or the proposed inference procedures) in parallel. Similarly to length prediction, we select the output with the highest log probability. To avoid stochasticity, we fix the random seed during sampling.

5 Quantitative Results

5.1 Translation Quality and Speed

Table 1 presents translation performance and inference speed of several inference procedures for the non-autoregressive latent variable models, along with the autoregressive baselines. We emphasize that the same underlying latent variable model is used across three different inference procedures (Delta, Energy, Score), to compare their efficiency and effectiveness.

Translation quality We observe that both of the proposed inference procedures result in improvements in translation quality with more refinement steps. For instance, 4 refinement steps using the learned score function improves BLEU by 2.1 on IWSLT'16 De→En. Among the proposed infer-

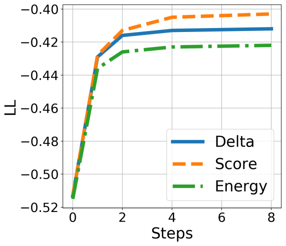

Figure 1: Marginal log probability $\log p_\theta(\hat{\mathbf{y}}|\mathbf{x})$ of output $\hat{\mathbf{y}}$ from each refinement step.

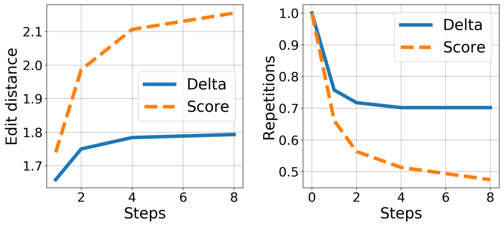

Figure 2: Edit distance from the first output (left) and the number of repetitions in the output (right) for $L = \{1, 2, 4, 8\}$ refinement steps for delta inference and inference using a learned score function.

ence procedures, we find it more effective to use a learned score function, as it gives comparable or better performance to delta inference on all datasets. A learned energy function results in comparable performance to delta inference. Parallel decoding over multiple target length candidates and sampled latent variables leads to significant improvements in BLEU, resulting in 1 BLEU increase or more on all datasets. Similarly to delta inference, we find that the proposed iterative inference procedures converge quite quickly, and often 1 refinement step gives comparable translation quality to running 4 refinement steps.

Inference speed We observe that using a learned score function is significantly faster than delta inference: twice as fast on IWSLT'16 De→En and WMT'16 Ro→En and almost four times as fast on WMT'14 En→De. On WMT'14 En→De, the decoding latency for 4 steps using the score is close to (within one standard deviation of) running 1 refinement step of delta inference. On the other hand, we find that using the learned energy function is slower, presumably due to the overhead from backpropagation. We find its wall clock time to be similar to delta inference. As the entire inference process can be parallelized, we find that parallel decoding with multiple length candidates and latent variable samples only incurs minimal overhead. Finally, we confirm that decoding latency for non-autoregressive models is indeed constant with respect to the sequence length (given parallel computation), as the standard deviation is small (< 10 ms) across test examples.

Overall result Overall, we find the proposed inference procedure using the learned score function highly effective and efficient. On WMT'14 En→De, using 1 refinement step and parallel search leads to 6.2× speedup over the autoregressive baseline with minimal degradation to translation quality (0.9 BLEU score).

5.2 Log Probability Comparison

In Fig 1, we report the marginal log probability $\log p_\theta(\hat{\mathbf{y}}|\mathbf{x})$ of $\hat{\mathbf{y}}$ found after L steps of each iterative inference procedure on IWSLT'16 De→En. We estimate the marginal log probability by importance sampling with 500 samples from the approximate posterior. We observe that the log probability improves with more refinement steps for all inference procedures (delta inference and the proposed procedures). We draw two conclusions from this. First, delta inference indeed increases log probability at each iteration. Second, the proposed optimization scheme increases the target objective function it was trained on (log probability).

5.3 Token Statistics

We compare delta inference and the proposed inference with a learned score function in terms of token statistics in the output translations on IWSLT'16 De→En. In Figure 2 (left), we compute the average edit distance (in sentencepieces) per test example from the initial output (mean of the prior). It is clear that each refinement step using a learned score function results in more changes in terms of edit distance than delta inference. In Figure 2 (right), we compute the number of token repetitions in the output translations (before removing them in a post-processing step), relative to the initial output. We observe that refining with a learned score function results in less repetitive output compared to delta inference.

6 Qualitative Results

6.1 Visualization of learned gradients

We visualize the learned gradients and the optimization trajectory in Figure 3, from a score inference network trained on a two-dimensional latent variable model on IWSLT'16 De→En. The example used to generate the visualization is shown below.

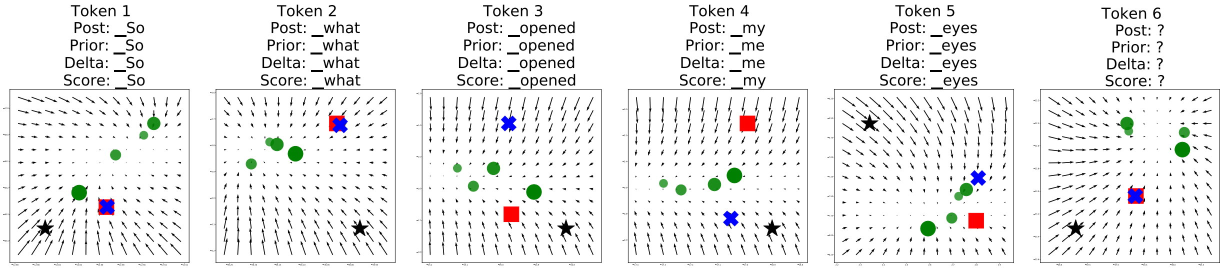

Figure 3: Visualization of estimated gradients and optimization trajectory. Above each plot are tokens predicted from the following latent variables: (1) approximate posterior mean, (2) prior mean, (3) delta inference and (4) inference with the learned score. **Black star**: latent variable before refinement (prior mean). **Blue cross**: latent variables after $L = \{1, 2, 3, 4\}$ steps of delta inference (collapsed into a single point). **Green circle**: latent variables after L steps of inference with a learned score function. Marker size decreases with successive refinement steps. **Red square**: approximate posterior mean.

Source	Was öffnete mir also die Augen?
Reference	So what opened my eyes ?
Posterior	So what opened my eyes ?
Prior	So what opened me eyes ?
Delta	So what opened me eyes ?
Score	So what opened my eyes ?

We observe that for tokens 1, 2 and 6, delta inference converges quickly to the approximate posterior mean. We also find that the local optima estimated by the score function do not necessarily coincide with the approximate posterior mean. For Token 4, while the local optima estimated by the score function (green circle) is far from the posterior mean (red square), they both map to the reference translation ("my"), indicating that there exist multiple latent variables that map to the reference output.

6.2 Sample translations

We demonstrate that refining in the continuous space results in non-local, non-trivial revisions to the original sentence. For each example in Table 2, we show the English source sentence, German reference sentence, original translation decoded from a sample from the prior, and the revised translation with one gradient update using the estimated score function.

In Example 1, the positions of the main clause ("Es gibt nicht viele Ärzte") and the prepositional phrase ("im westafrikanischen Land") are reversed in the continuous refinement process. Inside the main clause, "es gibt" is revised to "gibt es", a correct grammatical form in German when the prepositional phrase comes before the main clause.

In Example 2, the two numbers are exchanged (" 1,2 Milliarden Dollar" and " 6,9 Milliarden Dollar") in the revised translation. Also, the phrase "aus den" (out of the) is correctly inserted between the two.

In Example 3, the noun phrase "Weisheit in Bedouin" is combined into a single German compound noun "Bedouin-Weisheit". Also, the phrases "Der erste ..." and "mit dieser ..." are swapped in the refinement process, to better resemble the reference sentence.

7 Related Work

Learning Our training objective is closely related to the score matching objective (Hyvärinen, 2005), with the following differences. First, we approximate the gradient of the data log density using a proxy gradient, whereas this term is replaced by the Hessian of the energy in the original score matching objective. Second, we only consider samples from the prior. Saremi et al. (2018) proposed a denoising interpretation of the Parzen score objective (Vincent, 2011) that avoids estimating the Hessian. Although score function estimation that bypasses energy estimation was found to be unstable (Alain and Bengio, 2014; Saremi et al., 2018), it has been successfully applied to generative modeling of images (Song and Ermon, 2019).

Inference While we categorize inference methods for machine translation as (1) discrete search, (2) hybrid optimization (Shu et al., 2020) and (3) continuous optimization (this work) in Section 2, another line of work relaxes discrete search into continuous optimization (Hoang et al., 2017; Gu et al., 2018b; Tu et al., 2020). By using Gumbel-softmax relaxation (Maddison et al., 2017; Jang et al., 2017), they train an inference network to generate target tokens that maximize the log probability under a pretrained model.

Table 2: Sample translations on WMT’14 En→De. We show the translation from a latent variable sampled from the prior (*Original*) and the translation after one refinement step in the continuous space with the learned score function (*Refined*). We emphasize phrases whose positions are swapped in the refinement process in red and blue.

Gradient-based Inference Performing gradient descent over structured outputs was mentioned in LeCun et al. (2006), and has been successfully applied to many structured prediction tasks (Belanger and McCallum, 2016; Wang et al., 2016; Belanger et al., 2017). Other work performed gradient descent over the latent variables to optimize objectives for a wide variety of tasks, including chemical design (Gómez-Bombarelli et al., 2018) and text generation (Mueller et al., 2017)

Generation by Refinement Refinement has a long history in text generation. The retrieve-and-refine framework retrieves an (input, output) pair from the training set that is similar to the test example, and performs edit operations on the corresponding output (Sumita and Iida, 1991; Song et al., 2016; Hashimoto et al., 2018; Weston et al., 2018; Gu et al., 2018c). The idea of refinement has also been applied in automatic post-editing (Novak et al., 2016; Grangier and Auli, 2017).

8 Conclusion

We propose an efficient inference procedure for non-autoregressive machine translation that refines translations purely in the continuous space. Given a latent variable model for machine translation, we train an inference network to approximate the gradient of the marginal log probability with respect to the target sentence, using only the latent variable. This allows us to use gradient based optimization to find a target sentence at inference time that approximately maximizes the marginal log probability. As we avoid discrete search over a large vocabulary, our inference procedure is more efficient than previous inference procedures that refine in the token space.

We compare our approach with a recently proposed delta inference procedure that optimizes jointly in discrete and continuous space on three machine translation datasets: WMT’14 En→De, WMT’16 Ro→En and IWSLT’16 De→En. With the same underlying latent variable model, the proposed inference procedure using a learned score function has following advantages: (1) it is twice as fast as delta inference, and (2) it is able to find target sentences resulting in higher marginal probabilities and BLEU scores.

While we showed that iterative inference with a learned score function is effective for spherical Gaussian priors, more work is required to investigate if such an approach will also be successful for more sophisticated priors, such as Gaussian mixtures or normalizing flows. This will be particularly interesting, as recent study showed latent variable models with a flexible prior give high test log-likelihoods, but suffer from poor generation quality as inference is challenging (Lee et al., 2020).

Why Skip If You Can Combine: A Simple Knowledge Distillation Technique for Intermediate Layers

Abstract

With the growth of computing power neural machine translation (NMT) models also grow accordingly and become better. However, they also become harder to deploy on edge devices due to memory constraints. To cope with this problem, a common practice is to distill knowledge from a large and accurately-trained teacher network ($\mathcal{T}$) into a compact student network ($\mathcal{S}$). Although knowledge distillation (KD) is useful in most cases, our study shows that existing KD techniques might not be suitable enough for deep NMT engines, so we propose a novel alternative. In our model, besides matching $\mathcal{T}$ and $\mathcal{S}$ predictions we have a combinatorial mechanism to inject layer-level supervision from $\mathcal{T}$ to $\mathcal{S}$. In this paper, we target low-resource settings and evaluate our translation engines for Portuguese→English, Turkish→English, and English→German directions. Students trained using our technique have 50% fewer parameters and can still deliver comparable results to those of 12-layer teachers.

1 Introduction

Almost in all deep learning tasks, including neural machine translation (NMT), an ensemble of models outperforms a single model. In fact, ensemble modelling (training multiple models and ensemble decoding) is supported by most publicly available NMT frameworks (Klein et al., 2017; Junczys-Dowmunt et al., 2018; Vaswani et al., 2018; Ott et al., 2019). However, we know that dealing with multiple models could be challenging, especially in deep learning scenarios. To tackle the issue, one effective solution is to compress the knowledge in an ensemble into a single model through distillation (Buciluă et al., 2006; Hinton et al., 2015).

The core part of any knowledge distillation (KD) pipeline is a component that matches different models' predictions, which is usually implemented via multiple cost functions (see Section 2). Furthermore, we also need to take care of the architecture mismatch that may exist between student ($\mathcal{S}$) and teacher ($\mathcal{T}$) models. In KD, these two models can have different architectures (Jiao et al., 2019; Sun et al., 2019) and the motivation is to be able to compress a large teacher into a smaller student.

This research focuses on the aforementioned issue. If we distill from intermediate layers of a teacher that has more layers than its student, we have to select a subset of $\mathcal{T}$ layers and skip others as there are no peers for all of them on the $\mathcal{S}$ side. Clearly, we do not benefit from the skipped layers in this scenario. This type of KD introduces a problem of finding an optimal subset of $\mathcal{T}$ layers (to distill from). Although this might, to some extent, be mitigated via a search mechanism, our experimental results show that the problem is severe in NMT and each layer plays a unique role. Therefore, we prefer to keep all layers rather than skip them.

KD has recently become popular in NMT but, to the best of our knowledge, all NMT models (Kim and Rush, 2016; Tan et al., 2019) are still trained using the original idea of KD (Hinton et al., 2015), which is referred to as Regular KD (*RKD*) throughout this paper. *RKD* only matches $\mathcal{S}$ and $\mathcal{T}$ outputs, regardless of their internal architecture. However, there exist techniques such as Patient KD (*PKD*) (Sun et al., 2019) proposed for other tasks that not only match final predictions but also focus on internal components and distill their information too (Sun et al., 2020). In this research, we borrowed those ideas and adapted them to NMT. This is the first contribution of the paper.

PKD and other similar models suffer from the *skip* problem, which happens when $\mathcal{T}$ has more layers than $\mathcal{S}$ and some $\mathcal{T}$ layers have to be skipped in order to carry out layer-to-layer distillation. In this paper, we propose a model to distill from *all* teacher

November 16–20, 2020.

layers so we do not have to skip any of them. This is our second contribution by which we are able to outperform *PKD*. Moreover, for the first time we report experimental results for Transformer-based (Vaswani et al., 2017) models trained with a layer-level KD technique in the context of NMT. This set of results is our third and last contribution in this paper.

The remainder of the paper is organized as follows: In Section 2 we explain the fundamentals of KD. Section 3 discusses the methodology. We describe the advantages of our model and accompany our claims with experimental results in Section 4. Finally, in Section 5, we conclude the paper with our future plan.

2 Background

Usually, in multi-class classification scenarios the training criterion is to minimize the negative log-likelihood of samples, as shown in Equation 1:

$$\mathcal{L}(\theta) = -\sum_{v=1}^{|V|} \mathbb{1}(y = v) \times \log p(y = v|x; \theta) \quad (1)$$

where $\mathbb{1}(.)$ is an indicator function, (x, y) is an input-output training tuple, and θ and $|V|$ are the parameter set of the model and the number of classes, respectively. There is no feedback returned from the network for misclassified examples as $\mathbb{1}(y \neq v) = 0$. This issue is resolved in KD with extending $\mathcal{L}$ with an additive term (Kim and Rush, 2016; Tan et al., 2019), as shown in Equation 2:

$$\mathcal{L}_{KD}(\theta_{\mathcal{T}}, \theta_{\mathcal{S}}) = \\ -\sum_{v=1}^{|V|} q(y = v|x; \theta_{\mathcal{T}}) \times \log p(y = v|x; \theta_{\mathcal{S}}) \quad (2)$$

where there is a student model with the parameter set θ_S whose predictions are penalized with its own loss as well as $\mathcal{T}$ predictions given by $q(y = v|x; \theta_T)$. In KD, the first component of the loss (q) is usually referred to as the *soft* loss and the $\mathcal{S}$ model's loss is known as the *hard* loss. This form of training provides richer feedback compared to the previous one and leads to high(er)-quality results. KD for NMT also follows the same principle where V is a target-language vocabulary set and $\mathcal{L}_{KD}$ is computed for *each* word during decoding.

With the matching strategy proposed in KD, $\mathcal{S}$ learns to mimic its $\mathcal{T}$. A teacher could be a deep model trained on a large dataset but we do not necessarily need to have the same complex architecture for $\mathcal{S}$. We can distill teacher's knowledge into a smaller model and replicate its results with fewer resources.

Kim and Rush (2016) studied this problem and proposed a sequence-level extension of Equation 2 for NMT models. They evaluated their idea on recurrent, LSTM-based models (Hochreiter and Schmidhuber, 1997) and could run the final model on a cellphone. Freitag et al. (2017) extended the original two-class idea (one $\mathcal{S}$ with one $\mathcal{T}$) to distill from multiple teachers. They trained an attention-based recurrent model (Bahdanau et al., 2015) for their experiments.

Tan et al. (2019) proposed a setting to train a multilingual Transformer for different language directions. In order to have a high-quality multilingual model they distill knowledge from separately trained bilingual models. Their work is one of the few papers that reports KD results for NMT on Transformers. However, their results are not directly comparable to ours as they benefit from rich, multilingual corpora.

Wei et al. (2019) introduced a pipeline where a student model learns from different checkpoints. At each validation step, if the current checkpoint is a better model than the best existing checkpoint, $\mathcal{S}$ learns from it, otherwise the best stored checkpoint is considered as the teacher.

In all models discussed so far, *i*) $\mathcal{S}$ usually has the same architecture as its teacher(s) but we know that recent NMT models, particularly Transformers, are deep models which makes them challenging to run on edge devices. Moreover, *ii*) the training criterion in the aforementioned models is to combine final predictions. Transformers have new components (e.g. self-attention) and multiple (sub-)layers that consist of valuable information (Clark et al., 2019) and we need more than an output-level combination to efficiently distill for/from these models. Therefore, a new technique that is capable of addressing *i* and *ii* is required.

Authors of *PKD* spotted the problem and focused on internal layers (Sun et al., 2019). They studied the limitations of *RKD* for BERT (Devlin et al., 2019) models and introduced a layer-to-layer cost function. They select a subset of layers from $\mathcal{T}$ whose values are compared to $\mathcal{S}$ layers. They also showed that different internal components are important and play critical roles in KD.

The layer-level supervision idea was successful for monolingual models but so far, no one has tried it in the context of NMT. In this paper, we investigate if the same idea holds for bilingual models or if NMT requires a different type of KD. Moreover, we address the *skip* problem in *PKD* (shown in Figure 1). It seems in deep teacher models we do not need to skip layers and we can distill from *all layers*.

3 Methodology

In *RKD*, distillation only happens at the output level whereas *PKD* introduces layer-wise supervision. This idea is illustrated in Figure 1.

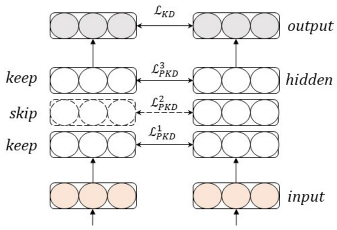

Figure 1: The network on the left-hand side is $\mathcal{S}$ and the other one is $\mathcal{T}$. In this example, $\mathcal{T}$ has 3 hidden layers and KD for intermediate layers can be applied using all layers or a subset of them, e.g. the second layer can be skipped.

In *PKD*, finding a skippable layer is the main challenge. Accordingly, we propose a combinatorial idea, *CKD*, by which we are able to fuse layers and benefit from *all* information stored in *all* layers. Our idea can be formulated as follows:

$$\mathcal{L}_{CKD}(L_s, L_t) = \sum_{l^i_s \in L_s} MSE(l^i_s, f^i_t) \tag{3}$$
$$f^i_t = F(l^j_t); j \in M(i)$$

where L_s and L_t indicate the set of all hidden layers of $\mathcal{S}$ and $\mathcal{T}$, respectively. $MSE()$ is the mean-square error function and l^i_s is the i-th hidden layer of $\mathcal{S}$. In *PKD*, f^i_t is the teacher's i-th layer whereas in our case f^i_t is the result of a fusion applied through the function $F()$ to a particular subset of $\mathcal{T}$ layers. This subset is defined via a mapper function $M()$ which takes an index (pointing to a layer on the student side) and returns a set of indices from the teacher model. Based on these indices, teacher layers are combined and passed to the distillation process, e.g. if $M(2) = \{1, 3\}$ that means F is fed by the first (l^1_t) and third (l^3_t) layers of $\mathcal{T}$ and the distillation happens between l^2_s and f^2_t (result of fusion).

For $F()$, a simple concatenation followed by a linear projection provided the best results in our experiments, so in the previous example:

$$f^2_t = F(l^1_t, l^3_t) = W[l^1_t \bullet l^3_t]^T + b$$

where $\bullet$ indicates concatenation, and $W \in \mathbb{R}^{d \times 2d}$ and $b \in \mathbb{R}^d$ are learnable parameters of KD. All l^1_t, l^3_t, l^2_s, and f^2_t are d-dimensional vectors.

The mapper function $M()$ defines our combination strategy for which we have 4 different variations of regular combination *(RC)*, overlap combination *(OC)*, skip combination *(SC)*, and cross combination *(CC)*. Figure 2 visualizes these variations. As the figure shows, *PKD* is a particular case of our model, but *CKD* gives us more flexibility in terms of distilling from different teacher configurations.

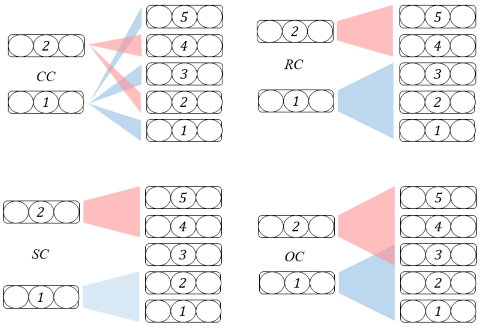

Figure 2: Different variations of *CKD*. $\mathcal{T}$ has 5 and $\mathcal{S}$ has 2 hidden layers. For the *CC* case $M(1) = \{1, 3, 5\}$.

4 Experimental Study

Although our proposed model is a general KD technique and can be applied in different settings, we narrow down the scope of this paper to low-resource, NMT settings. The incentive idea behind our project was to train NMT models for small datasets, so we report experimental results accordingly.

To evaluate *CKD*, we trained multiple models to translate from English (En) into German (De), and from Portuguese (Pt) and Turkish (Tr) into English (En). For the Pt|Tr→En directions we use the `IWSLT-2014` dataset, and the En→De experiment uses the `WMT-2014` dataset.

In Pt→En, we use the original split of datasets from IWSLT[1] with 167K, 7590, and 5388 sentences for training, development, and test sets, respectively. For Tr→En, the split is 142K, 1958,

Table 1: BLEU score comparisons of different KD models. *No-KD* is a model trained with no KD techniques using the the same architecture and dataset as students'.

and 1982 for training, development, and test sets. With this dataset selection our $\mathcal{T}$ models' results are comparable to publicly reported results.[2] On these datasets, our teachers outperform all other existing models so we can ensure that we distill from reliable sources.

For En→De, the dataset is the same as the original Transformer's (Vaswani et al., 2017), namely the training set includes 4.5M sentences, `newstest2013` is used as the validation set and `newstest2014` is our test set with 3000 and 3003 sentences, respectively. We selected this dataset to be comparable to a well-known baseline and make sure our training pipeline yields high-quality engines.

We preprocess datasets with Sentence-Piece (Kudo and Richardson, 2018). For Pt→En, we extracted a shared vocabulary set for both source and target sides with 32K subwords. Both $\mathcal{S}$ and $\mathcal{T}$ are trained using the same training set. Tr→En follows the same setting. For En→De, we conduct two experiments. Since our focus in this paper is to work with low-resource settings, in En→De$_1$, $\mathcal{S}$ and $\mathcal{T}$ are trained on a dataset of 200K sentences randomly sampled from the main dataset (4.5M).[3] For this experiment the vocabulary set size is 15K. In En→De$_2$, we slightly changed the setting where we use the entire set of 4.5M sentences to train $\mathcal{T}$ but $\mathcal{S}$ still uses the same 200K dataset. In this scenario, we assumed that there already exists a high-quality teacher trained on a large dataset but we only have a small in-house dataset to train the student. For this experiment the vocabulary size is 37K.

Table 1 summarizes our results for all experiments. Models are compared based on BLEU (Papineni et al., 2002) scores computed using sacreBLEU (Post, 2018). As the table shows, our students outperform all other students trained with different KD techniques. Moreover, students in Pt|Tr→En and En→De$_1$ settings are even comparable to accurately-trained, deep teachers. All teachers are 12-layer Transformers (6 for encoding and 6 for decoding), whereas students only have 4 layers (2 encoder layers and 2 decoder layers). All settings in our experiments are identical to those of Vaswani et al. (2017), which means hyper-parameters whose values are not clearly declared in this paper use the same values as the original Transformer model.

CKD makes it possible to reduce the number of parameters in our students by 50% and yet deliver the same high-quality translations. Accordingly, this enables us to run these translation engines on edge devices. Table 2 shows the exact number of parameters for each model.

	Pt→En	Tr→En	En→De$_1$	En→De$_2$
$\mathcal{T}$	61M	61M	52M	63M
$\mathcal{S}$	31M	31M	22M	34M

Table 2: The exact number of parameters for different models and settings.

For results reported in Table 1, cross-model layer mappings between teacher and student layers are as follow:

$$\begin{array}{ll} M_{SC}(1) = \{1,2\} & M_{SC}(2) = \{5,6\} \\ M_{CC}(1) = \{1,3\} & M_{CC}(2) = \{4,6\} \\ M_{RC}(1) = \{1,2,3\} & M_{RC}(2) = \{4,5,6\} \\ M_{OC}(1) = \{1,2,3,4\} & M_{OC}(2) = \{3,4,5,6\} \end{array}$$

---

[2] `http://cs.jhu.edu/~kevinduh/a/multitarget-tedtalks/`

[3] Our code and datasets: `https://github.com/yimeng0701/CKD_pytorch`

We tried a simple (and somewhat arbitrary) configuration for layer connections and there is no systematic strategy behind it. However, better results can be achieved with better heuristics or through a search process. Moreover, as the mappings show there is no connection between student and teacher models' decoder layers. In our experiments, we noticed that *any* KD technique applied to the decoder *considerably* decreases performance, so we only use KD on the encoder side. More specifically, each student model has two decoder layers which only receive inputs from the same model's encoder layers and they are not connected to the teacher side.

To train students with different KD techniques we use different loss functions. In $\mathcal{T}$ and *No-KD* we only have a single loss function ($\mathcal{L}$) as described in the original Transformer model (Vaswani et al., 2017). For models trained with *RKD*, an additional loss is involved to match teacher and student predictions ($\mathcal{L}_{KD}$). The final loss in this case is an interpolation of the aforementioned losses: $\big((\beta \times \mathcal{L}) + (\eta \times \mathcal{L}_{KD})\big)$. In our experiments, $\beta = (1 - \eta)$ where $\eta = 0.1$ is obtained through a search process over the set $\{0.1, 0.3, 0.5, 0.7, 0.9\}$.

For students trained using *PKD* and *CKD*, a third loss is also used in addition to $\mathcal{L}$ and $\mathcal{L}_{KD}$. Similar to other losses, the third one is also multiplied by a weight value (λ) to incorporate its impact into the training process. In this new setting, $\beta = (1 - \eta - \lambda)$, $\eta = 0.1$, and $\lambda = 0.7$. The high value of λ compared to other weights shows the importance of intermediate KD for deep models. All these values are learned through an empirical study in order to minimize the final loss of translation engines.

4.1 How Powerful is *CKD*?

In order to study the behaviour of *CKD*, we designed multiple, small experiments in addition to those reported in Table 1. *PKD* proposes a solution to define a loss between internal components of teacher and student models. The original model implemented this idea for intermediate layers. In one of our experiments we extended *PKD* by adding an extra loss function for *self-attention* components. Therefore, this new extension compares final outputs of student and teacher models as well as their intermediate layers and self-attention parameters. In this experiment, BLEU for Pt→En increased from 42.27 to 43.28, but our model is still superior with the BLEU score **43.78**. For this setting, *CKD* outperforms even a very complicated variation of *PKD* that could be an indication of our model's capacity in training high-quality students. For Tr→En and En→De$_1$ we also observed slight improvements by matching teacher and student self-attention components but results were not statistically significant and *CKD* was still better.

We also studied how *CKD* behaves in large experimental settings, for which we used En→De and En→French (Fr) datastes with 4.5M and 36M training samples, respectively, and trained 12-layer teachers and 4-layer students. For this experiment, we used the same settings, and test and development sets suggested in Vaswani et al. (2017). Table 3 summarizes our results.[4]

	$\mathcal{T}$	*No-KD*	*PKD*	*RC*	*OC*
En→Fr	38.41	35.45	34.97	36.10	35.85
En→De	27.03	24.31	23.38	24.14	23.97

Table 3: BLEU scores of different KD models for large datasets.

As the table shows, *CKD* is better than *PKD* in large experimental settings too. However, in order to have a better understanding of the large-dataset scenario we need to explore more configurations. We emphasize that for this paper our focus was to work with small students and datasets.

5 Conclusion and Future Work

In this paper, we proposed a novel model to distill from intermediate layers as well as final predictions. Moreover, we addressed the *skip* problem of *PKD*. We applied our technique in NMT and showed its potential in training high-quality and compact models. In our future work, *i*) we are interested in distilling from deep NMT models into extremely small students with *CKD*, in the hope of achieving the same results of large models with much smaller counterparts. *ii*) We also try to improve the combination module and find a better alternative than concatenation. *iii*) Finally, we plan to evaluate *CKD* in other tasks such as language modeling.

Abstract

While monolingual data has been shown to be useful in improving bilingual neural machine translation (NMT), effectively and efficiently leveraging monolingual data for Multilingual NMT (MNMT) systems is a less explored area. In this work, we propose a multi-task learning (MTL) framework that jointly trains the model with the translation task on bitext data and two denoising tasks on the monolingual data. We conduct extensive empirical studies on MNMT systems with 10 language pairs from WMT datasets. We show that the proposed approach can effectively improve the translation quality for both high-resource and low-resource languages with large margin, achieving significantly better results than the individual bilingual models. We also demonstrate the efficacy of the proposed approach in the zero-shot setup for language pairs without bitext training data. Furthermore, we show the effectiveness of MTL over pre-training approaches for both NMT and cross-lingual transfer learning NLU tasks; the proposed approach outperforms massive scale models trained on single task.

1 Introduction

Multilingual Neural Machine Translation (MNMT), which leverages a single NMT model to handle the translation of multiple languages, has drawn research attention in recent years (Dong et al., 2015; Firat et al., 2016a; Ha et al., 2016; Johnson et al., 2017; Arivazhagan et al., 2019). MNMT is appealing since it greatly reduces the cost of training and serving separate models for different language pairs (Johnson et al., 2017). It has shown great potential in knowledge transfer among languages, improving the translation quality for low-resource and zero-shot language pairs (Zoph et al., 2016; Firat et al., 2016b; Arivazhagan et al., 2019).

Previous works on MNMT has mostly focused on model architecture design with different strategies of parameter sharing (Firat et al., 2016a; Blackwood et al., 2018; Sen et al., 2019) or representation sharing (Gu et al., 2018). Existing MNMT systems mainly rely on bitext training data, which is limited and costly to collect. Therefore, effective utilization of monolingual data for different languages is an important research question yet is less studied for MNMT.

Utilizing monolingual data (more generally, the unlabeled data) has been widely explored in various NMT and natural language processing (NLP) applications. Back translation (BT) (Sennrich et al., 2016), which leverages a target-to-source model to translate the target-side monolingual data into source language and generate pseudo bitext, has been one of the most effective approaches in NMT. However, well trained NMT models are required to generate back translations for each language pair, it is computationally expensive to scale in the multilingual setup. Moreover, it is less applicable to low-resource language pairs without adequate bitext data. Self-supervised pre-training approaches (Radford et al., 2018; Devlin et al., 2019; Conneau and Lample, 2019; Lewis et al., 2019; Liu et al., 2020), which train the model with denoising learning objectives on the large-scale monolingual data, have achieved remarkable performances in many NLP applications. However, catastrophic forgetting effect (Thompson et al., 2019), where finetuning on a task leads to degradation on the main task, limits the success of continuing training NMT on models pre-trained with monolingual data. Furthermore, the separated pre-training and finetuning stages make the framework less flexible to introducing additional monolingual data or new languages into the MNMT system.

In this paper, we propose a multi-task learning (MTL) framework to effectively utilize monolin-

November 16–20, 2020.

gual data for MNMT. Specifically, the model is jointly trained with translation task on multilingual parallel data and two auxiliary tasks: masked language modeling (MLM) and denoising autoencoding (DAE) on the source-side and target-side monolingual data respectively. We further present two simple yet effective scheduling strategies for the multilingual and multi-task framework. In particular, we introduce a dynamic temperature-based sampling strategy for the multilingual data. To encourage the model to keep learning from the large-scale monolingual data, we adopt dynamic noising ratio for the denoising objectives to gradually increase the difficulty level of the tasks.

We evaluate the proposed approach on a large-scale multilingual setup with 10 language pairs from the WMT datasets. We study three English-centric multilingual systems, including many-to-English, English-to-many, and many-to-many. We show that the proposed MTL approach significantly boosts the translation quality for both high-resource and low-resource languages. Furthermore, we demonstrate that MTL can effectively improve the translation quality on zero-shot language pairs with no bitext training data. In particular, MTL achieves even better performance than the pivoting approach for multiple low-resource language pairs. We further show that MTL outperforms pre-training approaches on both NMT tasks as well as cross-lingual transfer learning for NLU tasks, despite being trained on very small amount of data in comparison to pre-training approaches.

The contributions of this paper are as follows. First, we propose a new MTL approach to effectively utilize monolingual data for MNMT. Second, we introduce two simple yet effective scheduling strategies, namely the dynamic temperature-based sampling and dynamic noising ratio strategy. Third, we present detailed ablation studies to analyze various aspects of the proposed approach. Finally, we demonstrate for the first time that MNMT with MTL models can be effectively used for cross-lingual transfer learning for NLU tasks with similar or better performance than the state-of-the-art massive scale pre-trained models using single task.

2 Background

Neural Machine Translation NMT adopts the sequence-to-sequence framework, which consists of an encoder and a decoder network built upon deep neural networks (Sutskever et al., 2014; Bahdanau et al., 2014; Gehring et al., 2017; Vaswani et al., 2017). The input source sentence is mapped into context representations in a continuous representation space by the encoder, which are then fed into the decoder to generate the output sentence. Given a language pair (x, y), the objective of the NMT model training is to maximize the conditional probability $P(y|x;\theta)$ of the target sentence given the source sentence.

NMT heavily relies on high-quality and large-scale bitext data. Various strategies have been proposed to augment the limited bitext by leveraging the monolingual data. Back translation (Sennrich et al., 2016) utilizes the target-side monolingual data. Self learning (Zhang and Zong, 2016) leverages the source-side monolingual data. Dual learning paradigms utilize monolingual data in both source and target language (He et al., 2016; Wang et al., 2019; Wu et al., 2019). While these approaches can effectively improve the NMT performance, they have two limitations. First, they introduce additional cost in model training and translation generation, and therefore are less efficient when scaling to the multilingual setting. Second, back translation requires a good baseline model with adequate bitext data to start from, which limits its efficiency on low-resource settings.

Multilingual NMT MNMT aims to train a single translation model that translates between multiple language pairs (Firat et al., 2016a; Johnson et al., 2017). Previous works explored the model architecture design with different parameter sharing strategies, such as partial sharing with shared encoder (Dong et al., 2015; Sen et al., 2019), shared attention (Firat et al., 2016a), task-specific attention (Blackwood et al., 2018), and full model sharing with language identifier (Johnson et al., 2017; Ha et al., 2016; Arivazhagan et al., 2019). There are also extensive studies on representation sharing that shares lexical, syntactic, or sentence level representations across different languages (Zoph et al., 2016; Nguyen and Chiang, 2017; Gu et al., 2018). The models in these works rely on bitext for training, and the largely available monolingual data has not been effectively leveraged.

Self-supervised Learning This work is motivated by the recent success of self-supervised learning for NLP applications (Radford et al., 2018; Devlin et al., 2019; Lample et al., 2018a,b; Conneau and Lample, 2019; Lewis et al., 2019; Liu et al., 2020). Different denoising objectives have been designed to train the neural networks on large-scale unlabeled text. In contrast to previous work in pre-training with separated self-supervised pre-training and supervised finetuning stages, we focus on a multi-task setting to *jointly* train the MNMT model on both bitext and monolingual data.

Multi-task Learning Multi-task learning (MTL) (Caruana, 1997), which trains the model on several related tasks to encourage representation sharing and improve generalization performance, has been successfully used in many different machine learning applications (Collobert and Weston, 2008; Deng et al., 2013; Ruder, 2017). In the context of NMT, MTL has been explored mainly to inject linguistic knowledge (Luong et al., 2015; Niehues and Cho, 2017; Eriguchi et al., 2017; Zaremoodi and Haffari, 2018; Kiperwasser and Ballesteros, 2018) with tasks such as part-of-speech tagging, dependency parsing, semantic parsing, etc. In this work, we instead focus on auxiliary self-supervised learning tasks to leverage the monolingual data.

3 Approach

3.1 Multi-task Learning

The main task in the MTL framework is the translation task trained on bitext corpora D_B of sentence pairs (x, y) with the cross-entropy loss:

$$\mathcal{L}_{MT} = \mathbb{E}_{(x,y)\sim D_B}[-\log P(y|x)] \tag{1}$$

With the large amount of monolingual data in different languages, we can train language models on both source-side [1] and target-side languages. We introduce two denoising language modeling tasks to help improve the quality of the translation model: the masked language model (MLM) task and the denoising auto-encoding (DAE) task.

Masked Language Model In the masked language model (MLM) task (Devlin et al., 2019), sentences with tokens randomly masked are fed into the model and the model attempts to predict the masked tokens based on their context. MLM is beneficial for learning deep bidirectional representations. We introduce MLM as an auxiliary task to improve the quality of the encoder representations especially for the low-resource languages. As is illustrated in Figure 1(a), we add an additional output layer to the encoder of the translation model and train the encoder with MLM on source-side monolingual data. The output layer is dropped during inference. The cross entropy loss for predicting the masked tokens is denoted as $\mathcal{L}_{MLM}$.

Following BERT (Devlin et al., 2019), we randomly sample $R_M\%$ units in the input sentences and replace them with a special `[MASK]` token. A unit can either be a subword token, or a word consists of one or multiple subword tokens. We refer to them as token-level and word-level MLM.

Denoising Auto-Encoding (DAE) Denoising auto-encoding (DAE) (Vincent et al., 2008) has been demonstrated to be an effective strategy for unsupervised NMT (Lample et al., 2018a,b). Given a monolingual corpus D_M and a stochastic noising model C, DAE minimizes the reconstruction loss as shown in Eqn 2:

$$\mathcal{L}_{DAE} = \mathbb{E}_{x\sim D_M}[-\log P(x|C(x))] \tag{2}$$

As is illustrated in Figure 1(b), we train all model parameters with DAE on the target-side monolingual data. Specifically, we feed the target-side sentence to the noising model C and append the corresponding language ID symbol; the model then attempts to reconstruct the original sentence.

We introduce three types of noises for the noising model C. 1) *Text Infilling* (Lewis et al., 2019): Following (Liu et al., 2020), we randomly sample $R_D\%$ text spans with span lengths drawn from a Poisson distribution ($\lambda = 3.5$). We replace all words in each span with a single blanking token. 2) *Word Drop & Word Blank*: we randomly sample words from each input sentence, which are either removed or replaced with blanking tokens for each token position. 3) *Word Swapping*: we slightly shuffle the order of words in the input sentence. Following (Lample et al., 2018a), we apply a random permutation σ with condition $|\sigma(i) - i| \leq k, \forall i \in \{1, n\}$, where n is the length of the input sentence, and $k = 3$ is the maximum swapping distance.

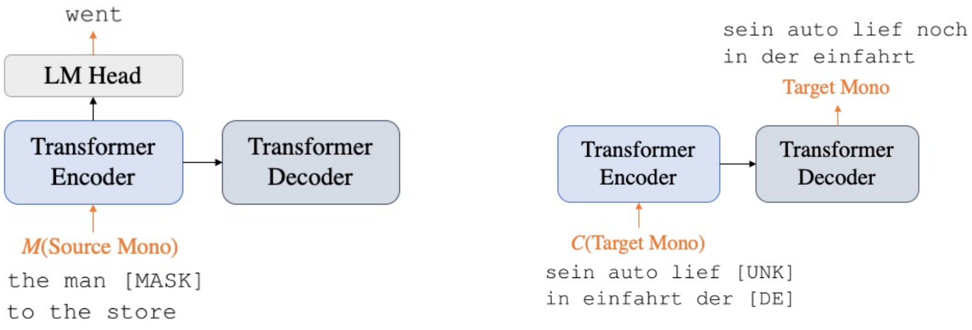
Joint Training In the training process, the two self-learning objectives are combined with the cross-entropy loss for the translation task:

$$\mathcal{L} = \mathcal{L}_{MT} + \mathcal{L}_{MLM} + \mathcal{L}_{DAE} \tag{3}$$

In particular, we use bitext data for the translation objective, source-side monolingual data for MLM,

---

[1] For the English-to-Many translation model, the source-side language is English; for Many-to-English and Many-to-Many, it refers the set of all other languages. Similarly for the target-side language.



(a) Masked Language Model (MLM)

(b) Denoising Auto-Encoding (DAE)

Figure 1: Illustration of the auxiliary tasks with monolingual data

and target-side monolingual data for the DAE objective. A language ID symbol `[LID]` of the target language is appended to the input sentence in the translation and DAE tasks.

3.2 Task Scheduling

The scheduling of tasks and data associated with the task is important for multi-task learning. We further introduce two simple yet effective scheduling strategies in the MTL framework.

Dynamic Data Sampling One serious yet common problem for MNMT is data imbalance across different languages. Training the model with the true data distribution would starve the low-resource language pairs. Temperature-based batch balancing (Arivazhagan et al., 2019) is demonstrated to be an effective heuristic to ease the problem. For language pair l with bitext corpus D_l, we sample instances with probability proportional to $(\frac{|D_l|}{\sum_k |D_k|})^{\frac{1}{T}}$, where T is the sampling temperature.

While MNMT greatly improves translation quality for low-resource languages, performance deterioration is generally observed for high resource languages. One hypothesized reason is that the model might converge before well trained on high-resource data (Bapna and Firat, 2019). To alleviate this problem, we introduce a simple heuristic to feed more high-resource language pairs in the early stage of training and gradually shift more attention to the low-resource languages. To achieve this, we modify the sampling strategy by introducing dynamic sampling temperature $T(k)$ as a function of the number of training epochs k. We use a simple linear functional form for $T(k)$:

$$T(k) = \min\left(T_m, (k-1)\frac{T_m - T_0}{N} + T_0\right) \quad (4)$$

Where T_0 and T_m are the initial and maximum value for sampling temperature respectively. N is the number of warm-up epochs. The sampling temperature starts from a smaller value T_0, resulting in sampling leaning towards true data distribution. $T(k)$ gradually increases in the training process to encourage over-sampling low-resource languages more to avoid them getting starved.

Dynamic Noising Ratio We further schedule the difficulty level of MLM and DAE from easier to more difficult. The main motivation is that training algorithms perform better when starting with easier tasks and gradually move to harder ones as promoted in curriculum learning (Elman, 1993). Furthermore, increasing the learning difficulty can potentially help avoid saturation and encourage the model to keep learning from abundant data.

Given the monolingual data, the difficulty level of MLM and DAE tasks mainly depends on the noising ratio. Therefore, we introduce dynamic noising ratio $R(k)$ as a function of training steps:

$$R(k) = \min\left(R_m, (k-1)\frac{R_m - R_0}{M} + R_0\right) \quad (5)$$

Where R_0 and R_m are the lower and upper bound for noising ratio respectively and M is the number of warm-up epochs. Noising ratio R refers to the masking ratio R_M in MLM and the blanking ratio R_D of the *Text Infilling* task for DAE.

4 Experimental Setup

4.1 Data

We evaluate MTL on a multilingual setting with 10 languages to and from English (En), including French (Fr), Czech (Cs), German (De), Finnish

(Fi), Latvian (Lv), Estonian (Et), Romanian (Ro), Hindi (Hi), Turkish (Tr) and Gujarati (Gu).

Bitext Data The bitext training data comes from the WMT corpus. Detailed desciption and statistics can be found in Appendix A.

Monolingual Data The monolingual data we use is mainly from NewsCrawl[2]. We apply a series of filtration rules to remove the low-quality sentences, including duplicated sentences, sentences with too many punctuation marks or invalid characters, sentences with too many or too few words, etc. We randomly select 5M filtered sentences for each language. For low-resource languages without enough sentences from NewsCrawl, we leverage data from CCNet (Wenzek et al., 2019).

Back Translation We use the target-to-source bilingual models to back translate the target-side monolingual sentences into the source domain for each language pair. The synthetic parallel data from back translation is mixed and shuffled with bitext and used together for the translation objective in training. We use the same monolingual data for back translation as the multi-task learning in all our experiments for fair comparison.

4.2 Model Configuration

We use Transformer for all our experiments using the PyTorch implementation[3] (Ott et al., 2019). We adopt the `transformer_big` setting (Vaswani et al., 2017) with a 6-layer encoder and decoder. The dimensions of word embeddings, hidden states, and non-linear layer are set as 1024, 1024 and 4096 respectively, the number of heads for multi-head attention is set as 16. We use a smaller model setting for the bilingual models on low-resource languages Tr, Hi and Gu (with 3 encoder and decoder layers, 256 embedding and hidden dimension) to avoid overfitting and acquire better performance.

We study three multilingual translation scenarios including many-to-English (X→En), English-to-many (En→X) and many-to-many (X→X). For the multilingual model, we adopt the same Transformer architecture as the bilingual setting, with parameters fully shared across different language pairs. A target language ID token is appended to each input sentence.

4.3 Training and Evaluation

All models are optimized with Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$. We set the learning rate schedule following (Vaswani et al., 2017) with initial learning rate 5×10^{-4}. Label smoothing (Szegedy et al., 2016) is adopted with 0.1. The models are trained on 8 V100 GPUs with a batch size of 4096 and the parameters are updated every 16 batches. During inference, we use beam search with a beam size of 5 and length penalty 1.0. The BLEU score is measured by the de-tokenized case-sensitive SacreBLEU[4] (Post, 2018).

5 Results

5.1 Main Results

We compare the performance of the bilingual models (*Bilingual*), multilingual models trained on bitext only, trained on both bitext and back translation (*+BT*) and trained with the proposed multi-task learning (*+MTL*). Translation results of the 10 languages translated to and from English are presented in Table 1 and 2 respectively. We can see that:

1. *Bilingual vs. Multilingual*: The multilingual baselines perform better on lower-resource languages, but perform worse than individual bilingual models on high-resource languages like Fr, Cs and De. This is in concordance with the previous observations (Arivazhagan et al., 2019) and is consistent across the three multilingual systems (i.e., X→En, En→X and X→X).

2. *Multi-task learning*: Models trained with multi-task learning (+MTL) significantly outperform the multilingual baselines for all the languages pairs in all three multilingual systems, demonstrating the effectiveness of the proposed framework.

3. *Back Translation*: With the same monolingual corpus, MTL achieves better performance on some language pairs (e.g. Fr→En, Gu→En), while getting outperformed on some others, especially on the En→X direction. However, back translation is computationally expensive as it involves the additional procedure of training 10 bilingual models (20 for the X→X system) and generating translations for each monolingual sentence. Combining MTL with BT (+BT+MTL) introduces further improvements for most language pairs without using any additional monolingual data. This suggests

that when there is enough computation budget for BT, MTL can still be leveraged to provide good complementary improvement.

5.2 Zero-shot Translation

We further evaluate the proposed approach on zero-shot translation of non English-centric language pairs. We compare the performances of the pivoting method, the X→X baseline system, X→X with BT, and with MTL. For the pivoting method, the source language is translated into English first, and then translated into the target language (De Gispert and Marino, 2006; Utiyama and Isahara, 2007). We evaluate on a group of high-resource languages with a multi-way parallel test set for De, Cs, Fr and En, constructed by newstest2009 with 3027 sentences and that of a group of low-resource languages Et, Hi, Tr and Hi (995 sentences). The results are shown in Table 3 and 4 respectively.

Utilizing monolingual data with MTL significantly improves the zero-shot translation quality of the X→X system, further demonstrating the effectiveness of the proposed approach. In particular, MTL achieves significantly better results than the pivoting approach on the high-resource pair Cs→De and almost all low-resource pairs. Furthermore, leveraging monolingual data through BT does not perform well for many low-resource language pairs, resulting in comparable and even downgraded performances. We conjecture that this is related to the quality of the back translations. MTL helps overcome such limitations with the auxiliary self-supervised learning tasks.

	De→Fr	Fr→De	Cs→De	De→Cs
Pivoting	22.1	19.1	17.5	15.9
X→X	15.1	11.9	15.5	15.2
+ BT	19.7	7.4	17.0	7.8
+ BT + MTL	20.1	12.2	19.7	12.0

Table 3: Zero-shot translation performances on high-resource language pairs.

5.3 MTL vs. Pre-training

We also compare MTL with mBART (Liu et al., 2020), the state-of-the-art multilingual pre-training method for NMT. We adopt the officially released mBART model pre-trained on CC25 corpus[5] and

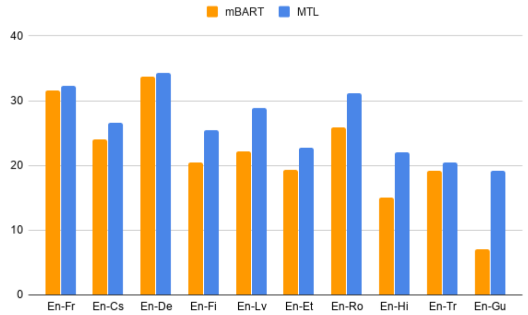

Figure 2: Comparison with mBART on En→X language pairs. BLEU scores are reported on the full individual validation set.

finetune the model on the same bitext training data used in MTL for each language pair. As shown in Figure 2, MTL outperforms mBART on all language pairs. This suggests that in the scenario of NMT, jointly training the model with MT task and self-supervised learning tasks could be a better task design than the separated pre-training and finetuning stages. It is worth noting that mBart is utilizing much more monolingual data; for example, it uses 55B English tokens and 10B French tokens, while our approach is using just 100M tokens each. This indicates that MTL is more data efficient.

5.4 Multi-task Objectives

We present ablation study on the learning objectives of the multi-task learning framework. We compare performance of multilingual baseline model with translation objective only, jointly learning translation with MLM, jointly learning translation with DAE, and the combination of all objectives. Table 5 shows the results on a high-resource pair De↔En and low-resource pair Tr↔En. We can see that introducing MLM or DAE can both effectively improve the performance of multilingual systems, and the combination of both yields the best performance. We also observe that MLM is more beneficial for '→En' compared with 'En→' direction, especially for the low-resource languages. This is in concordance with our intuition that the MLM objective contributes to improving the encoder quality and source-side language modeling for low-resource languages.

	De→En		Tr→En	
Systems	X→En	X→X	X→En	X→X
Multilingual	36.5	36.1	20.0	20.9
+ MLM	36.3	36.6	21.0	21.4
+ DAE	37.7	37.8	21.7	22.6
+ MLM + DAE	38.7	37.6	22.9	23.7

	En→De		En→Tr	
Systems	En→X	X→X	En→X	X→X
Multilingual	33.0	32.0	16.4	17.0
+ MLM	32.9	32.6	16.9	17.2
+ DAE	33.7	33.7	17.3	18.2
+ MLM + DAE	34.2	33.6	18.0	18.3

Table 5: Comparison of different multi-task learning objectives on De-En and Tr-En translation. BLEU scores are reported on the full individual validation set.

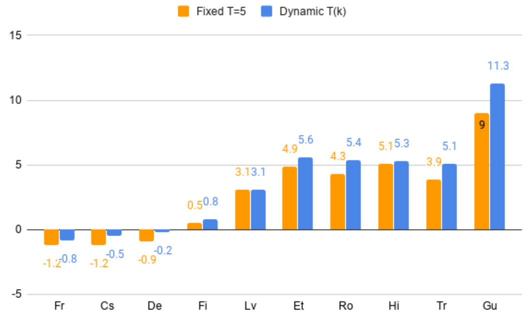

Figure 3: Performance gain of data sampling strategies on the X→En system. Results are reported as ΔBLEU relative to the corresponding bilingual baseline on validation sets. The languages are arranged from high-resource (left) to low-resource (right).

5.5 Dynamic Sampling Temperature

We study the effectiveness of the proposed dynamic sampling strategy. We compare multilingual systems using a fixed sampling temperature $T = 5$ with systems using dynamic temperature $T(k)$ defined in Equation 4. We set $T_0 = 1, T_m = 5, N = 5$, which corresponds to gradually increasing the temperature from 1 to 5 with 5 training epochs and saturate to $T = 5$ afterwards. The results for X→En and En→X systems are presented in Figure 3 and 4 respectively, where we report ΔBLEU relative to their corresponding bilingual baseline

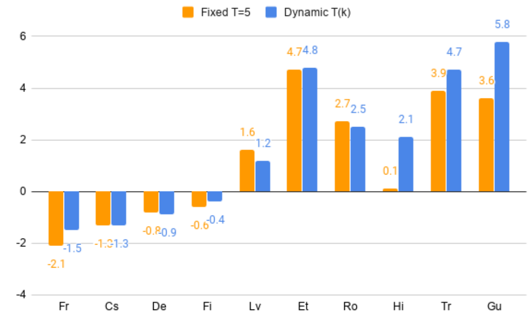

Figure 4: Performance of data sampling strategies on the En→X system.

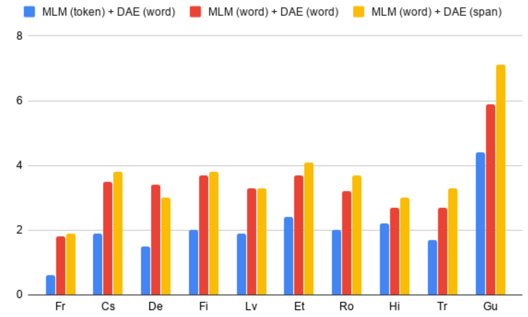

Figure 5: Performance of different noising schemes on the X→En system. Results are reported as ΔBLEU relative to the multilingual X→En baseline on validation sets. The languages are arranged from high-resource (left) to low-resource (right).

	De	Lv	Et	Hi	Tr
Bilingual	32.9	23.4	18.7	12.9	16.1
X→En + BT	35.2	30.1	28.3	18.7	24.7
+ MTL	36.9	31.9	31.4	21.6	27.4
+ Dynamic	37.0	32.4	32.0	21.7	27.5

Table 6: BLEU scores of dynamic noising strategy on X→En translation system with large-scale monolingual data setting on validation sets.

model that was evaluated on the individual validation sets for each language pairs. The dynamic temperature strategy improves the quality for high-resource language pairs (e.g. Fr→En, De→En, En→Fr), while introducing minimum effect for mid-resource languages (Lv). Surprisingly, the proposed strategy also greatly boosts performance for low-resource languages Tr and Gu, with over +1 BLEU gain for both to and from English direction.

5.6 Noising Scheme

We study the effect of different noising schemes in the MLM and DAE objectives. As introduced in Section 3.1, we have token-level and word-level masking scheme for MLM depending on the unit of masking. We also have two noising schemes for DAE, where the *Text Infilling* task blanks a span of words (span-level), and the *Word Blank* task blanks the input sentences at word-level. We compare performance of these different noising schemes on X→En system as shown in Figure 5.

We report ΔBLEU relative to the multilingual X→En baseline on the corresponding language pairs for each noising scheme. As we can see, the model benefits most from the word-level MLM and the span-level *Text Infilling* task for DAE. This is in concordance with the intuition that the *Text Infilling* task teaches the model to predict the length of masked span and the exact tokens at the same time, making it a harder task to learn. We use the word-level MLM and span-level DAE as the best recipe for our MTL framework.

5.7 Noising Ratio Scheduling

In our initial experiments, we found that the dynamic noising ratio strategy does not effectively improve the performance. We suspect that it is due to the limitation of data scale. We experiment with a larger scale setting by increasing the amount of monolingual data from 5M sentences for each language to 20M. For low-resource languages without enough data, we take the full available amount (18M for Lv, 11M for Et, 5.2M for Gu).

Table 6 shows results on X→En MNMT model with large-scale monolingual data setting. We compare the performance of multilingual with back translation baseline, a model with MTL and a model with both MTL and dynamic noising ratio. For the dynamic noising ratio, we set the masking ratio for MLM to increase from 10% to 20% and blanking ratio for DAE to increase from 20% to 40%. As we can see, the dynamic noising strategy helps boost performance for mid-resource languages like Lv and Et, while introducing no negative effect to other languages. For future study, we would like to cast the dynamic noising ratio over different subsets of monolingual datasets to prevent the model from learning to copy and memorize.

5.8 MTL for Cross-Lingual Transfer Learning for NLU

Large scale pre-trained cross-lingual language models such as mBERT (Devlin et al., 2019) and XLM-Roberta (Conneau et al., 2020) are the state-of-the-art for cross-lingual transfer learning on natu-

	EN	ES	DE	FR
XLM-Roberta	84.7	79.4	77.4	79.1
MMTE	79.6	71.6	68.2	69.5
MTL	84.8	80.1	78.3	79.8

Table 7: Evaluation on XNLI task, XLM-Roberta results is our reproduction of the results. Massively Multilingual Translation Encoder (MMTE) is reported from (Siddhant et al., 2020)

ral language understanding (NLU) tasks, such as XNLI (Conneau et al., 2018) and XGLUE (Liang et al., 2020). Such models are trained on massive amount of monolingual data from all language as a masked language model. It has been shown that massive MNMT models are not able to match the performance of pre-trained language models such as XLM-Roberta on NLU downstream tasks (Siddhant et al., 2020). In Siddhant et al. (2020), the MNMT models are massive scale models trained only on the NMT task. They are not able to outperform XLM-Roberta, which is trained with MLM task without any parallel data. In this work, we evaluate the effectiveness of our proposed MTL approach for cross-lingual transfer leaning on NLU application. Intuitively, MTL can bridge this gap since it utilizes NMT, MLM and DAE objectives.

In the experiment, we train a system on 6 languages using both bitext and monolingual data. For the bitext training data, we use 30M parallel sentences per language pair from in-house data crawled from the web. For the monolingual data, we use 40M sentences per language from CCNet (Wenzek et al., 2019). Though this is a relatively large-scale setup, it only leverages a fraction of the data used to train XLM-Roberta for those languages. We train the model with 12 layers encoders and 6 layers decoder. The hidden dimension is 768 and the number of heads is 8. We tokenize all data with the SentencePiece model (Kudo and Richardson, 2018) with the vocabulary size of 64K. We train a many-to-many MNMT system with three tasks described in Section 3.1: NMT, MLM, and DAE. Once the model is trained, we use the encoder only and discard the decoder. We add a feedforward layer for the downstream tasks.

As shown in Table 7, MTL outperform both XLM-Roberta and MMTE (Siddhant et al., 2020) which are trained on massive amount of data in comparison to our system. XLM-Roberta is trained only on MLM task and MMTE is trained only on NMT task. Our MTL system is trained on three tasks. The results clearly highlight the effectiveness of multi-task learning, and demonstrate that it can outperform single-task systems trained on massive amount of data. We observe the same pattern in Table 8 with XGLUE NER task, which outperforms SOTA XLM-Roberta model.

	EN	ES	DE
XLM-Roberta	91.1	76.5	70.3
MTL	91.2	77.0	75.0

Table 8: Evaluation on XGLUE NER task, XLM-Roberta results is our reproduction of the results.

6 Conclusion

In this work, we propose a multi-task learning framework that jointly trains the model with the translation task on bitext data, the masked language modeling task on the source-side monolingual data and the denoising auto-encoding task on the target-side monolingual data. We explore data and noising scheduling approaches and demonstrate their efficacy for the proposed approach. We show that the proposed MTL approach can effectively improve the performance of MNMT on both high-resource and low-resource languages with large margin, and can also significantly improve the translation quality for zero-shot language pairs without bitext training data. We showed that the proposed approach is more effective than pre-training followed by finetuning for NMT. Furthermore, we showed the effectiveness of multitask learning for cross-lingual downstream tasks outperforming SOTA larger models trained on single task.

For future work, we are interested in investigating the proposed approach in a scaled setting with more languages and a larger amount of monolingual data. Scheduling the different tasks and different types of data would be an interesting problem. Furthermore, we would also like to explore the most sample efficient strategy to add a new language to a trained MNMT system.

Acknowledgment

We would like to thank Alex Muzio for helping with zero-shot scoring and useful discussions. We also would like to thank Dongdong Zhang for helping with mBART comparison and Felipe Cruz Salinas for helping with XNLI and XGLUE scoring.

Appendices

A Bitext Training Data

We concatenate all resources except WikiTitles provided by WMT of the latest available year and filter out duplicated pairs and pairs with the same source and target sentence. For Fr and Cs, we randomly sample 10M sentence pairs from the full corpus. The detailed statistics of bitext data can be found in Table 9.

We randomly sample $1,000$ sentence pairs from each individual validation set and concatenate them to construct a multilingual validation set. We tokenize all data with the SentencePiece model (Kudo and Richardson, 2018), forming a vocabulary shared by all the source and target languages with 32k tokens for bilingual models (16k for Hi and Gu) and 64k tokens for multilingual models.

Code	Language	#Bitext	Validation

Abstract

There exists a token imbalance phenomenon in natural language as different tokens appear with different frequencies, which leads to different learning difficulties for tokens in Neural Machine Translation (NMT). The vanilla NMT model usually adopts trivial equal-weighted objectives for target tokens with different frequencies and tends to generate more high-frequency tokens and less low-frequency tokens compared with the golden token distribution. However, low-frequency tokens may carry critical semantic information that will affect the translation quality once they are neglected. In this paper, we explored target token-level adaptive objectives based on token frequencies to assign appropriate weights for each target token during training. We aimed that those meaningful but relatively low-frequency words could be assigned with larger weights in objectives to encourage the model to pay more attention to these tokens. Our method yields consistent improvements in translation quality on ZH-EN, EN-RO, and EN-DE translation tasks, especially on sentences that contain more low-frequency tokens where we can get 1.68, 1.02, and 0.52 BLEU increases compared with baseline, respectively. Further analyses show that our method can also improve the lexical diversity of translation.

1 Introduction

Neural machine translation (NMT) systems (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017) are data driven models, which highly depend on the training corpus. NMT models have a tendency towards over-fitting to frequent observations (e.g. words, word co-occurrences) while neglecting those low-frequency observations. Unfortunately, there exists a token imbalance phenomenon in natural languages as different tokens appear with different frequencies, which roughly obey the Zipf's Law (Zipf, 1949). Table 1 shows that there is a serious imbalance between high-frequency tokens and low-frequency tokens. NMT models rarely have the opportunity to learn and generate those ground-truth low-frequency tokens in the training process.

Token Order (Descending)	Average Frequency	Reference	Vanilla NMT
$[0, 10\%)$	$10,857$	81.75%	87.26%
$[10\%, 30\%)$	516	11.40%	9.06%
$[30\%, 50\%)$	133	3.43%	2.21%
$[50\%, 70\%)$	60	1.95%	0.99%
$[70\%, 100\%]$	25	1.47%	0.48%

Table 1: The average frequency on the NIST training set and proportion of tokens with different frequencies in reference and the translation of the vanilla NMT model (a Transformer model) on the NIST test sets. All the target tokens (BPE sub-words with 30K merge operations) of the training set are ranked by their frequencies in descending order. The 'Token Order' column represents the frequency interval ($[10\%, 30\%)$ means the frequency of token is between top 10% and 30%). The 'Average Frequency' column represents the average frequencies of the tokens in each interval, which show the token imbalance phenomenon in natural language. The last two columns show the vanilla NMT model tends to generate more high-frequency tokens and less low-frequency tokens than reference.

November 16–20, 2020.

Some work tries to improve the rare word translation by maintaining phrase tables or back-off vocabulary (Luong et al., 2015; Jean et al., 2015; Li et al., 2016; Pham et al., 2018) or adding extra components (Gülçehre et al., 2016; Zhao et al., 2018), which bring in extra training complexity and computing expense. Some NMT techniques which are based on smaller translation granularity can alleviate this issue, such as hybrid word-character-based model (Luong and Manning, 2016), BPE-based model (Sennrich et al., 2016) and word-piece-based model (Wu et al., 2016). These effective work alleviate the token imbalance phenomenon to a certain extent and become the *de-facto* standard in most NMT models. Although sub-word based NMT models have achieved significant improvements, they still face the token-level frequency imbalance phenomenon, as Table 1 shows.

Furthermore, current NMT models generally assign equal training weights to target tokens without considering their frequencies. It is very likely for NMT models to ignore the loss produced by the low-frequency tokens because of their small proportion in the training sets. The parameters related to them can not be adequately trained, which will, in turn, make NMT models tend to prioritize output fluency over translation adequacy, and ignore the generation of low-frequency tokens during decoding, which is illustrated in Table 1. It shows that the vanilla NMT model tends to generate more high-frequency tokens and less low-frequency tokens. However, low-frequency tokens may carry critical semantic information which may affect translation quality once they are neglected.

To address the above issue, we proposed token-level adaptive training objectives based on target token frequencies. We aimed that those meaningful but relatively low-frequency tokens could be assigned with larger loss weights during training so that the model will learn more about them. To explore suitable adaptive objectives for NMT, we first applied existing adaptive objectives from other tasks to NMT and analyzed their performance. We found that though they could bring modest improvement on the translation of low-frequency tokens, they did much damage to the translation of high-frequency tokens, which led to an obvious degradation on the overall performance. This implies that the objective should ensure the training of high-frequency tokens first. Then, based on our observations, we proposed two heuristic criteria for designing the token-level adaptive objectives based on the target token frequencies. Last, we presented two specific forms for different application scenarios according to the criteria. Our method yields consistent improvements in translation quality on ZH-EN, EN-RO, and EN-DE translation tasks, especially on sentences that contain more low-frequency tokens where we can get 1.68, 1.02, and 0.52 BLEU increases compared with baseline, respectively. Further analyses show that our method can also improve the lexical diversity of translation.

Our contributions can be summarized as follows:

- We analyzed the performance of the existing adaptive objectives when they were applied to NMT. Based on our observations, we proposed two heuristic criteria for designing token-level adaptive objectives and present two specific forms to alleviate the problem brought by the token imbalance phenomenon.
- The experimental results validate that our method can improve not only the translation quality, especially on those low-frequency tokens, but also the lexical diversity.

2 Background

In our work, we apply our method in the framework of *Transformer* (Vaswani et al., 2017) which will be briefly introduced here. We denote the input sequence of symbols as $\mathbf{x} = (x_1, \dots, x_J)$, the ground-truth sequence as $\mathbf{y}^* = (y_1^*, \dots, y_K^*)$ and the translation as $\mathbf{y} = (y_1, \dots, y_K)$.

The Encoder & Decoder The encoder is composed of N identical layers. Each layer has two sublayers. The first sublayer is a multi-head attention unit used to compute the self-attention of the input, named *self-attention multi-head sublayer*, and the second one is a fully connected feed-forward network, named *FNN sublayer*. Both of the sublayers are followed by a residual connection operation and a layer normalization operation. The input sequence $\mathbf{x}$ will be first converted to a sequence of vectors $\mathbf{E}_x = [E_x[x_1]; \dots ; E_x[x_J]]$, where $E_x[x_j]$ is the sum of the word embedding and the position embedding of the source word x_j. Then, this input sequence of vectors will be fed into the encoder and the output of the N-th layer will be taken as source hidden states. The decoder is also composed of N identical layers. In addition to the same kind of two sublayers in each encoder layer, the third *cross-attention sublayer* is inserted between them, which

	Valid	High	Low
Baseline	45.46	49.27	41.35
Linear	45.33*(-0.13)*	48.59*(-0.68)*	41.64*(+0.29)*
Focal	44.91*(-0.55)*	48.17*(-1.10)*	41.36*(+0.01)*
Focal + 1	45.71*(+0.25)*	49.36*(+0.09)*	41.93*(+0.58)*

Table 2: BLEU on the validation set of the Chinese-English translation task. 'Low' is the subset of the validation set which contains more low-frequency tokens while 'High' contains more high-frequency tokens.

performs multi-head attention over the output of the encoder. The final output of the N-th layer gives the target hidden states $\mathbf{S} = [\mathbf{s}_1; \ldots; \mathbf{s}_I]$, where $\mathbf{s}_i$ is the hidden states of y_k.

The Objective The model is optimized by minimizing a cross-entropy loss with the ground-truth:

$$\mathcal{L} = -\frac{1}{K}\sum_{k=1}^{K} \log p(y_k^*|\mathbf{y}_{<k}, \mathbf{x}), \qquad (1)$$

where K is the length of the target sentence.

3 Method

Our work aims to explore suitable adaptive objectives that can not only improve the learning of low-frequency tokens but also avoid harming the translation quality of high-frequency tokens. We first investigated two existing adaptive objectives, which were proposed for solving the token imbalance problems in other tasks, and analyzed their performance. Then, based on our observations, we introduced two heuristic criteria for designing the adaptive objective. Based on the proposed criteria, we put forward two simple but effective functional forms from different perspectives, which can be adapted to various application scenarios in NMT.

3.1 Existing Adaptive Objectives Investigation

The form of adaptive objective is as follows:

$$\mathcal{L} = -\frac{1}{I}\sum_{i=1}^{I} w(y_i) \log p(y_i|\mathbf{y}_{<i}, \mathbf{x}), \qquad (2)$$

where $w(y_i)$ is the weight assigned to the target token y_i, which varies as the token frequency changes. Actually, there are some existing adaptive objectives which have been proven effective for other tasks. It can help us understand what is necessary for a suitable adaptive objective for NMT if we apply these methods to it. The first objective we have investigated is the form in Focal loss (Lin et al., 2017), which was proposed for solving the label imbalance problem in the object detection task:

$$w(y_i) = (1 - p(y_i))^\gamma. \qquad (3)$$

Although it doesn't utilize the frequency information directly, it actually reduces the weights of the high-frequency classes more because they are usually easier to classify with higher prediction probabilities. We set γ to 1 as suggested by their experiments. We noticed that this method greatly reduced the weights of high-frequency tokens, and the variance of weights is large. The second is the linear weighting function (Jiang et al., 2019), which was proposed for the dialogue response generation task:

$$w(y_i) = -\frac{\texttt{Count}(y_i)}{\max(\texttt{Count}(y_k))} + 1, y_k \in \mathrm{V}_t, \quad (4)$$

where $\texttt{Count}(y_k)$ is the frequency of token y_k in the training set and V_t denotes the target vocabulary. Then, the normalized weights $w(y_i)$, which have a mean of 1, are assigned to the target tokens. We noticed that the weights of high-frequency tokens are only slightly less than 1, and the variance of weights is small. We tested these two objectives on the Chinese to English translation task and the results on the validation set are given in Table 2[1]. To verify their effects on the high- and low-frequency tokens, we also divided the validation set into two subsets based on the average token frequency of the sentences, the results of which are also given in Table 2. It shows that although these two methods can bring modest improvement in the translation of the low-frequency tokens, it does much harm to high-frequency tokens, which has a negative impact on the overall performance. We noted that both of these two methods reduced the weights of the high-frequency tokens to different degrees, and we argued that when the high-frequency tokens account for a large proportion in NMT corpus, this hinders the normal training of them. To validate our argument, we simply add 1 to the weighting term of focal loss:

$$w(y_i) = (1 - p(y_i))^\gamma + 1. \qquad (5)$$

The results are also given in Table 2 (Row 5), which indicates that this method actually avoids the damage to the high-frequency tokens. The overall results indicate that it is not robust enough to improve

---

[1] The details about the data will be given in the experiment section

the learning of low-frequency tokens by reducing the weight of high-frequency tokens during the training of NMT. Although our goal is to improve the training of low-frequency tokens, we should first ensure the training of high-frequency tokens, and then increase the weights of low-frequency tokens appropriately. Based on the above findings, we proposed the following criteria.

3.2 Heuristic Criteria for Token Weighting

We proposed two heuristic criteria for designing the token-level training weights:

Minimum Weight Ensurence. The training weight of any token in the target vocabulary should be equal to or bigger than 1, which can be described as:

$$\forall y_k \in \mathrm{V}_t, w(y_k) \geq 1 \tag{6}$$

Although we can force the model to pay more attention to low-frequency tokens by shrinking the weights of high-frequency tokens, the previous analyses have proved that the training performance is more sensitive to the change of high-frequency tokens' weights due to their large proportion in the training set. A relatively small decrease in the weights of high-frequency tokens will prevent the generation probabilities of ground-truth tokens from ascending continually, which may result in an obvious degradation of the overall performance. Therefore, we ensure that all the token weights are equal to or bigger than 1 considering the training stability as well as designing convenience.

Weights Expectation Range Control. On the condition that the first criterion is satisfied, those high-frequency tokens could have already been well learned without any extra attention. Now, those low-frequency tokens could be assigned with higher weights. Meanwhile, we also need to ensure that the weights of low-frequency tokens can't be too large, or it will hurt the training of high-frequency tokens certainly. Therefore, the expectation of the training weights on the whole training set should be in $[1, 1+\delta]$:

$$\frac{\sum_{k=1}^{|\mathrm{V}_t|} \mathtt{Count}(y_k) w(y_k)}{\sum_{k=1}^{|\mathrm{V}_t|} \mathtt{Count}(y_k)} = 1+\delta, \delta \geq 0, \tag{7}$$

where $|\mathrm{V}_t|$ denotes the size of the target vocabulary, δ is a relatively small number compared with 1. A larger weight expectation means we allocate larger weights to those low-frequency tokens. In contrast, an appropriate weight expectation as defined in this criterion can help improve the overall performance.

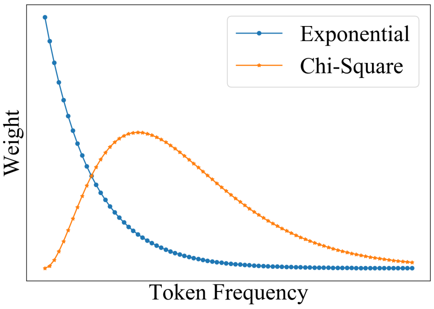

Figure 1: Plots of our two weighting functions. The blue curve is the Exponential form and the orange curve is the Chi-Square form. Both of the hyperparamters are set to 1.

The two criteria proposed here are not the only options for NMT, but the adaptive objective satisfying these two criteria can improve not only the translation performance of low-frequency tokens but also the overall performance based on our experimental observations.

3.3 Two Specific Adaptive Objectives

In this paper, we proposed two simple functional forms for $w(y_k)$ heuristically based on the previous criteria and justified them with some intuitions.

Exponential: Given the target token y_k, we define the exponential weighting function as:

$$w(y_k) = \mathrm{A} \cdot e^{-\mathrm{T} \cdot \mathtt{Count}(y_k)} + 1. \tag{8}$$

There are two hyperparameters in it, i.e., A and T, which control the shape and the value range of the function. They can be set up according to the two criteria above. The plot of this weighting function is presented in Figure 1. In this case, we don't consider the factor of noisy tokens so that the weight increases monotonically as the frequency decreases. Therefore, this weighting function is suitable for cleaner training data where the extremely low-frequency tokens only take up a small proportion.

Chi-Square: The exponential form weighting function is not suitable for the training data which contain many noisy tokens, because they would be assigned with relatively large weights and have bigger impacts when their weights are summed together. To alleviate this problem, we proposed another form of the weighting function:

$$w(y_k) = \mathrm{A} \cdot \mathtt{Count}^2(y_k) e^{-\mathrm{T} \cdot \mathtt{Count}(y_k)} + 1. \tag{9}$$

The form of this function is similar to the form of chi-square distribution, so we named it as chi-square. Plot of this weighting function is presented in Figure 1. We can see from the plot that the weight increases as the frequency decreases at first. Then, after a specific frequency threshold, which is decided by the hyperparameter T, the weight decreases as the frequency decreases. In this case, the most frequent tokens and the extremely rare tokens, which could be noise, all will be assigned with small weights. Meanwhile, those middle-frequency words will have larger weights. Most of them are meaningful and valuable for translation but can't be well learned with an equal-weighted objective function. This form of weighting function is suitable for more noisy training data.

4 Experiments

4.1 Data Preparation

ZH→EN. The training data consists of 1.25M sentence pairs from LDC corpora which has 27.9M Chinese words and 34.5M English words, respectively [2]. The data set MT02 was used as validation and MT03, MT04, MT05, MT06, MT08 were used for the test. We tokenized and lowercased English sentences using the Moses scripts[3], and segmented the Chinese sentences with the Stanford Segmentor[4]. The two sides were further segmented into subword units using Byte-Pair Encoding (BPE) (Sennrich et al., 2016) with 30K merge operations separately.

EN→RO. We used the preprocessed version of the WMT2016 English-Romanian dataset released by Lee et al. (2018) which includes 0.6M sentence pairs. We used news-dev 2016 for validation and news-test 2016 for the test. The two languages shared the same vocabulary generated with 40K merge operations of BPE.

EN→DE. The training data is from WMT2016 which consists of about 4.5M sentences pairs with 118M English words and 111M German words. We chose the news test-2013 for validation and news-test 2014 for the test. 32K merge operations BPE were performed on both sides jointly.

4.2 Systems

We used the open-source toolkit called *Fairseq-py* (Edunov et al., 2017) released by Facebook as our Transformer system.

- **Baseline**. The baseline system was implemented as the base model configuration in Vaswani et al. (2017) strictly. Since our method is further trained based on the pre-trained model at a low learning rate, we also trained another baseline model following the same procedures as our methods have except that all the target tokens share equal weights in the objective, denoted as **Baseline-FT**.
- **Fine Tuning** (Luong and Manning, 2015). This model was first trained with all the training sentence pairs and then further trained with sentences containing more low-frequency tokens. To filter out sentences containing more low-frequency tokens, the method in Platanios et al. (2019) was adopted as our judging metric with a small modification:

$$d_{\text{rarity}}(\mathbf{y}) \triangleq -\frac{1}{I}\sum_{i=1}^{I}\log\frac{\texttt{Count}(y_i)}{\sum_{k=1}^{|\text{V}_t|}\texttt{Count}(y_k)}, \tag{10}$$

where I is the sentence length. We added a factor $\frac{1}{I}$ to eliminate the influence of sentence length. All the target sentences were ranked by this metric in ascending order and the bottom one third of the training sentences were chosen as the in-domain data. This method tries to utilize frequency information at the sentence level, while our work uses it at the token level in contrast.
- **Sampler** (Chu et al., 2017). This method oversampled the sentences containing more low-frequency tokens filtered by Eq. 10 three times and then concatenated them with the rest of the training data. Thus the NMT model will be trained with more low-frequency tokens in every epoch.
- **Entropy Regularization (ER)** (Pereyra et al., 2017). This method was proposed for solving the overconfidence problem, which adds a confidence penalty term to the original objective:

$$\mathcal{L}_{\text{ER}} = L - \alpha\frac{1}{I}\sum_{i=1}^{I}p(y_i|\mathbf{x})\log(p(y_i|\mathbf{x})). \tag{11}$$

It is known that token imbalance is one of the causes of overconfidence problem (Jiang and de Rijke, 2018), so this method may also alleviate the token imbalance problem. We varied α from 0.05 to 0.4 and chose the best one according to the results on the validation sets for different languages. Noting that the label smoothing is applied in the vanilla transformer model which has a similar effect on the output, we removed it from the model when we tested this method.

---

	5.00	-	34.10	25.95

Table 3: Performance of our methods on the validation sets for all the three language pairs with different hyperparameters T. Although the best hyperparameter for different languages may be different, it is easy for our method to get a stable improvement.

- **Linear** (Jiang et al., 2019). This method was proposed for solving the token imbalance problem in the the dialogue response generation task:

$$w(y_i) = -\frac{\texttt{Count}(y_i)}{\max(\texttt{Count}(y_k))} + 1, y_k \in \mathrm{V}_t. \quad (12)$$

Then, the normalized weights, which had a mean of 1, were applied to the training objective.

- **Our_Exp**. This system was first trained with the normal objective (Equation 1), where all the target tokens have the same training weights. Then the model was further trained with the adaptive objective at a low learning rate. The weights were produced by the Exponential form (Equation 8). For computing stability, we used $\frac{\texttt{Count}(y_k)}{\mathrm{C}_{\text{median}}}$ instead of $\texttt{Count}(y_k)$ in the weighting function, where $\mathrm{C}_{\text{median}}$ is the median of the token frequency.
- **Our_K2**. This system was trained following the same procedure as system Our_Exp except that the training weights were produced by the Chi-Square form (Equation 9).

The translation quality was evaluated by 4-gram BLEU (Papineni et al., 2002) with the *multi-bleu.pl* script. Besides, we used beam search with a beam size of 4 and a length penalty of 0.6 during the decoding process.

4.3 Hyperparameters

There are two hyperparameters in our weighting functions, A and T. In our experiments, we fixed A to narrow search space and the overall weight range is $[1, e]$. We tuned another hyperparameter T on the validation data sets under the criteria proposed in section 3.2. The results are shown in Table 3. According to the results, the best hyperparameters differed across different language pairs. It is affected by the proportion of low-frequency words and high-frequency words. Generally speaking, when the proportion of low-frequency words gets smaller, the hyperparameter T should be set smaller too. But it also shows that it is easy for our methods to get a stable improvement over the baseline system following the criteria above. Finally, we used the best hyperparameters as found on the validation data sets for the final evaluation of the test data sets. For example, $\mathrm{T} = 0.35$ in the exponential form for ZH→EN and $\mathrm{T} = 4.00$ in the chi-square form for EN→RO.

4.4 Main Results

The results are shown in Table 4. It shows that the contrast methods can not bring stable improvements over the baseline system. They bring excessive damages to the translation of high-frequency tokens which can be proved by the analyzing experiments in the next section. As a contrast, our methods can bring stable improvements over Baseline-FT almost without any additional computing or storage expense. On the EN→RO and EN→DE translation tasks, Our_Exp is more effective than Our_K2 while on the ZH→EN translation task the result is reversed. The reason is that the NIST training data set contains more noisy tokens, which can be ignored by the Our_K2 method. More analyses based on the token frequency are shown in the next section.

5 Analysis

5.1 Effects on Translation Quality with Considering Token Frequencies

To further illustrate the effects of our method, we evaluated the performance based on the token frequency. For the ZH→EN translation task, we concatenated the MT03-08 test sets together as a big test set. For the EN→RO and EN→DE translation tasks, we just used their test sets. Each sentence was scored according to Eq. 10 and sorted in ascending order. Then the test set was divided into

	ZH→EN							EN→RO		EN→DE	
	MT03	MT04	MT05	MT06	MT08	AVE	Δ	WMT16	Δ	WMT16	Δ
Baseline	44.63	45.79	44.03	43.78	35.63	42.77		32.85		27.15	
Baseline-FT	44.69	46.24	44.01	44.33	35.83	43.02		33.15		27.21

Our_Exp	28.91(*+0.03*)	27.33*(*+0.36*)	26.07**(*+0.52*)
Our_K2	28.90(*+0.02*)	27.28*(*+0.31*)	25.99*(*+0.44*)

Table 6: EN→DE BLEU scores on different test subsets. The conclusion is identical to that in Table 5.

three subsets with equal size, denoted as HIGH, MIDDLE, and LOW, respectively. Sentences in the subset LOW contain more low-frequency tokens while the HIGH is reverse.

The results are given in Table 5 and Table 6. The contrast methods outperform the Baseline-FT on the LOW subset but are worse than it in the HIGH and MIDDLE subsets, which indicates that the gains on the translation of low-frequency tokens come at the expense of the translation of high-frequency tokens. As a contrast, both of our methods can not only bring a significant improvement on the LOW subset but also get a modest improvement on the HIGH and MIDDLE subsets. It can be concluded that our methods can ameliorate the translation of low-frequency tokens without hurting the translation of high-frequency tokens.

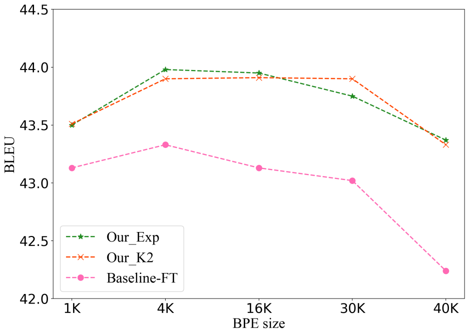

Figure 2: BLEU with different BPE sizes on ZH→EN translation task. It shows that our method can always bring a stable improvement compared with the baseline.

5.2 Effects on Translation Quality with Different BPE Sizes

It is known that the BPE sizes have a large impact on the data distribution. Intuitively, a smaller size of BPE will bring a more balanced data distribu-

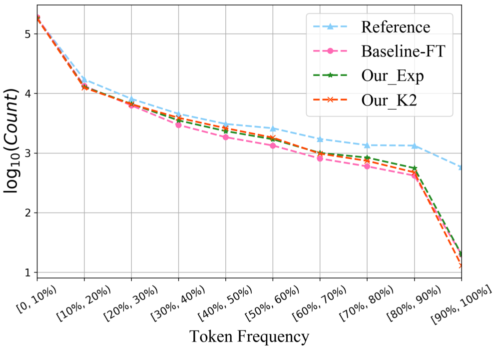

Figure 3: The count of tokens with different frequencies in references, translations of the baseline systems and our methods on the ZH→EN translation task. The tokens are ranked by their frequencies in the training sets. The x-axis represents the frequency interval ([20%, 30%) means the frequency of tokes is between top 20% and 30%), the y-axis is the count of the tokens applied with a common logarithm operation in each interval.

	TTR($\times 10^{-2}$)	HD-D	MTLD
Baseline-FT	5.32	0.829	59.1
Our_Exp	5.87	0.836	62.2
Our_K2	5.95	0.835	61.9
Reference	6.79	0.852	69.2

Table 7: The lexical diversity of translations. A larger value represents higher diversity. The results show that our method can improve the lexical diversity.

tion, but it will also increase the average sentence length and neglect some token co-occurrences. To verify the effectiveness of our method with different BPE sizes, we varied the BPE sizes from 1K to 40K on the ZH→EN translation task. The results are shown in Figure 2. It shows that as the number of BPE size increases, the BLEU of baseline rises first and then declines. Compared with the baseline systems, our method can always bring improvements, and the larger the BPE size, i.e., the more imbalanced the data distribution, the larger the improvement brought by our method. In practice, the BPE size either comes from the experience or is chosen from several trial-and-errors. No matter what the situation is, our method can always bring a stable improvement.

5.3 Effects on Token Distribution and Lexical Diversity

Compared with the reference, the outputs of the vanilla NMT model contain more high-frequency tokens and have lower lexical diversity (Vanmassenhove et al., 2019b). To verify whether our methods can alleviate these problems, we did the following experiments based on the ZH→EN translation task. The tokens in the target vocabulary were first arranged in descending order according to their token frequencies. Then they were divided into ten intervals equally. Finally, we counted the number of tokens in each token frequency interval of the reference and the translation of different systems. The results are shown in Figure 3 and we did a common logarithm for display convenience. It shows that there is an obvious gap between the Baseline-FT and reference, and the curve of Baseline-FT is lower than the curve of reference in every frequency interval except for the top 10%. As a contrast, our methods can reduce this gap, and the tokens distribution is closer to the real distribution. Besides, we also measure the lexical diversity of the translations with several criteria, namely, type-token ratio (TTR) (Templin, 1957), the approximation of hypergeometric distribution (HD-D) and the measure of textual lexical diversity (MTLD) (Mccarthy and Jarvis, 2010). The results are given in Table 7. It shows that our method can also improve the lexical diversity of the translation.

Table 8: Translation examples of the Basline-FT and our methods. The results show that our methods can generate low-frequency but more accurate tokens.

5.4 Case Study

Table 8 shows two translation examples in the ZH→EN translation direction. In the first sentence, the Baseline-FT system failed to generate the low-frequency noun '*coalmine*' (frequency: 43), but generated a relatively high-frequency word '*mine*' (frequency: 1155). We can see that this low-frequency token carries the central information of this sentence, and the mistranslation of it prevents people from understanding this sentence correctly. In the second sentence, our methods generated the low-frequency verb '*assigned*' (frequency: 841) correctly, while the Baseline-FT generated a more frequent token '*match*' (frequency: 1933), which reduced the translation accuracy and fluency. These examples can be part of the evidence to show the effectiveness of our methods.

6 Related Work

Rare Word Translation. Rare word translation is one of the key challenges for NMT. For word-level NMT models, NMT has its limitation in handling a larger vocabulary because of the training complexity and computing expense. Some work tries to solve this problem by maintaining phrase tables or back-off vocabulary (Luong et al., 2015; Jean et al., 2015; Li et al., 2016). The subword-based NMT (Sennrich et al., 2016; Luong and Manning, 2016; Wu et al., 2016) reduces the size of vocabulary greatly and become the mainstream technology gradually. Gowda and May (2020) gave a detailed analysis about the effects of the BPE size on the data distribution and translation quality. Some recent work tried to further improve the translation of the rare words with the help of the memory network or the pointer network (Zhao et al., 2018; Pham et al., 2018). In contrast, our methods can improve the translation performance without extra cost and can be combined with other techniques.

Class Imbalance. Class imbalance means the total number of some classes of data is far less than the total number of other classes. This problem can be observed in various tasks (Wei et al., 2013; Johnson and Khoshgoftaar, 2019). In NMT, the class imbalance problem might be the underlying cause of, among others, the gender-biased output problem (Vanmassenhove et al., 2019a), the inability of MT system to handle morphologically richer language correctly (Passban et al., 2018), or the exposure bias problem (Ranzato et al., 2016; Shao et al., 2018; Zhang et al., 2019). The methods of trying to solve this can be divided into two types. The data-based methods (Baloch and Rafi, 2015; Ofek et al., 2017) make use of over- and under-sampling to reduce the imbalance. The algorithm-based methods (Zhou and Liu, 2005; Lin et al., 2017) give extra reward to different classes. Our method is algorithm-based which brings no extra cost.

Word Frequency-based Methods. Some work also makes use of word frequency information to help learning, such as in the word segmentation (Sun et al., 2014) and term extraction (Frantzi et al., 1998; Vu et al., 2008). In NMT, word frequency information is used for curriculum learning (Kocmi and Bojar, 2017; Zhang et al., 2018; Platanios et al., 2019) and domain adaptation data selection (Wang et al., 2017; Zhang and Xiong, 2018; Gu et al., 2019). Wang et al. (2020) analyzed the miscalibration problem on the low-frequency tokens. Jiang et al. (2019) proposed a linear weighting function to solve the word imbalance problem in the dialogue response generation task. Compared with it, our method is more suitable for NMT.

7 Conclusion

In this work, we focus on the token imbalance problem of NMT. We show that the output of vanilla NMT contains more high-frequency tokens and has lower lexical diversity. To alleviate this problem, we investigated existing adaptive objectives for other tasks and then proposed two heuristic criteria based on the observations. Next, we gave two simple but effective forms based on the criteria, which can assign appropriate training weights to target tokens. The final results show that our methods can achieve significant improvement in performance, especially on sentences that contain more low-frequency tokens. Further analyses show that our method can also improve the lexical diversity.

Abstract

Transformer models (Vaswani et al., 2017) achieve remarkable success in Neural Machine Translation. Many efforts have been devoted to deepening the Transformer by stacking several units (i.e., a combination of Multihead Attentions and FFN) in a cascade, while the investigation over multiple parallel units draws little attention. In this paper, we propose the **M**ulti-**U**nit **T**ransform**E**rs (**MUTE**), which aim to promote the expressiveness of the Transformer by introducing diverse and complementary units. Specifically, we use several parallel units and show that modeling with multiple units improves model performance and introduces diversity. Further, to better leverage the advantage of the multi-unit setting, we design biased module and sequential dependency that guide and encourage complementariness among different units. Experimental results on three machine translation tasks, the NIST Chinese-to-English, WMT'14 English-to-German and WMT'18 Chinese-to-English, show that the MUTE models significantly outperform the Transformer-Base, by up to +1.52, +1.90 and +1.10 BLEU points, with only a mild drop in inference speed (about 3.1%). In addition, our methods also surpass the Transformer-Big model, with only 54% of its parameters. These results demonstrate the effectiveness of the MUTE, as well as its efficiency in both the inference process and parameter usage. [1]

1 Introduction

Transformer based models (Vaswani et al., 2017) have been proven to be very effective in building the state-of-the-art Neural Machine Translation (NMT) systems via neural networks and attention mechanism (Sutskever et al., 2014; Bahdanau et al., 2014). Following the standard *Sequence-to-Sequence* architecture, Transformer models consist of two essential components, namely the encoder and decoder, which rely on stacking several identical layers, i.e., multihead attentions and position-wise feed-forward network.

Multihead attentions and position-wise feed-forward network, together as a basic unit, plays an essential role in the success of Transformer models. Some researchers (Bapna et al., 2018; Wang et al., 2019a) propose to improve the model capacity by stacking this basic unit many times, i.e., deep Transformers, and achieve promising results. Nevertheless, as an orthogonal direction, investigation over multiple parallel units draws little attention.

Compared with single unit models, multiple parallel unit layout is more expressive to capture complex information flow (Tao et al.; Meng et al., 2019; Li et al., 2018, 2019) in two aspects. First, this multiple-unit layout boosts the model by its varied feature space composition and different attentions over inputs. With this diversity, multi-unit models advance in expressiveness. Second, for the multi-unit setting, one unit could mitigate the deficiency of other units and compose a more expressive network, in a complementary way.

In this paper, we propose the **M**ulti-**U**nit **T**ransform**E**rs (**MUTE**), which aim to promote the expressiveness of transformer models by introducing diverse and complementary parallel units. Merely combining multiple identical units in parallel improves model capability and diversity by its varied feature compositions. Furthermore, inspired by the well-studied bagging (Breiman, 1996) and gradient boosting algorithms (Friedman, 2001) in the machine learning field, we design biased units with a sequential dependency to further boost model performance. Specifically, with the help of a module named bias module, we apply different kinds of noises to form biased inputs for corre-

November 16–20, 2020.

sponding units. By doing so, we explicitly establish information gaps among units and guide them to learn from each other. Moreover, to better leverage the power of *complementariness*, we introduce sequential ordering into the multi-unit setting, and force each unit to learn the residual of its preceding accumulation.

We evaluate our methods on three widely used Neural Machine Translation datasets, NIST Chinese-English, WMT'14 English-German and WMT'18 Chinese-English. Experimental results show that our multi-unit model yields an improvement of +1.52, +1.90 and +1.10 BLEU points, over the baseline model (Transformer-Base) for three tasks with different sizes, respectively. Our model even outperforms the Transformer-Big on the WMT'14 English-German by 0.7 BLEU points with only 54% of parameters. Moreover, as an interesting side effect, our model only introduces mild inference speed decrease (about 3.1%) compared with the Transformer-Base model, and is faster than the Transformer-Big model.

The contributions of this paper are threefold:

- We propose the **M**ulti-**U**nit **T**ransform**E**rs (**MUTE**), to promote the expressiveness of Transformer models by introducing diverse and complementary parallel units.
- Aside from learning with identical units, we extend the **MUTE** by introducing bias module and sequential ordering to further model the diversity and complementariness among different units.
- Experimental results show that our models substantially surpass baseline models in three NMT datasets, NIST Chinese-English, WMT'14 English-German and WMT'18 Chinese-English. In addition, our models also show high efficiency in both the inference speed and parameter usage, compared with Transformer baselines.

2 Transformer Architecture

The Transformer Architecture (Vaswani et al., 2017) for Neural Machine Translation (NMT) generally adopts the standard encoder-decoder paradigm. In contrast to RNN architectures, the Transformer stacks several identical self-attention based layers instead of recurrent units for better parallelization. Specifically, given an input sequence $X = \{x_1, x_2, \cdots, x_n\}$ in source language (e.g., English), the model is asked to predict its corresponding translation $Y = \{y_1, y_2, \cdots, y_m\}$ in target language (e.g., German).

Encoder. Digging into the details of the model, a Transformer encoder consists of N_e stacked layers, where each layer consists of two sub-layers, a multihead self-attention sub-layer and a position-wise feed-forward network (FFN) sub-layer.

$$s^k = \text{SelfAttn}(X^k) + X^k, \tag{1}$$

$$F^e(X^k) = s^k + \text{FFN}(s^k), \tag{2}$$

where $X^k \in \mathbb{R}^{n \times d}$ and $F^e(X^k) \in \mathbb{R}^{n \times d}$ denote the inputs and outputs of the k-th encoder layer, respectively, and d is the hidden dimension.

Decoder. The decoder follows a similar architecture, with an additional multihead cross-attention sub-layer for each of N_d decoder layers.

$$s^k = \text{SelfAttn}(Y^k) + Y^k, \tag{3}$$

$$c^k = \text{CrossAttn}(s^k, F^e(X^{N_e})) + s^k, \tag{4}$$

$$F^d(Y^k) = c^k + \text{FFN}(c^k), \tag{5}$$

where $Y^k \in \mathbb{R}^{m \times d}$ and $F^d(Y^k) \in \mathbb{R}^{m \times d}$ represent the inputs and outputs of k-th decoder layer.

Here, we omit layer norms among sub-layers for simplicity. We take the bundle of cascading subcomponents (i.e., attention modules and FFN) as a unit, and refer to the original Transformer and its variants with such cascade units as *Single-Unit Transformer*. For ease of reading, we refer to a single unit of encoder and decoder as F^e and F^d in the following sections.

Then, the probability $P(Y|X)$ is produced with another Softmax layer on top of decoder outputs,

$$P(Y|X) = \text{Softmax}(W_s \cdot F^d(Y^{N_d}) + b), \tag{6}$$

where $W_s \in \mathbb{R}^{d \times |V|}$ and $b \in \mathbb{R}^{|V|}$ are learnable parameters, and $|V|$ denotes the size of target vocabulary. Then, a cross-entropy objective is computed by,

$$\mathcal{L}_{CE} = \sum_{t \in (1,m)} Y_t \log P(Y_t|X), \tag{7}$$

where t represents the t-th step for decoding phase.

3 Model Layout

3.1 MUTE

In this section, we briefly describe the Multi-Unit Transformer (MUTE), shown in Figure 1(a). As mentioned before, we take the bundle of cascading sub-components (i.e., attention modules and FFN) as a single unit. By combining units in parallel, we have a basic Multi-Unit Transformer (MUTE) layer.

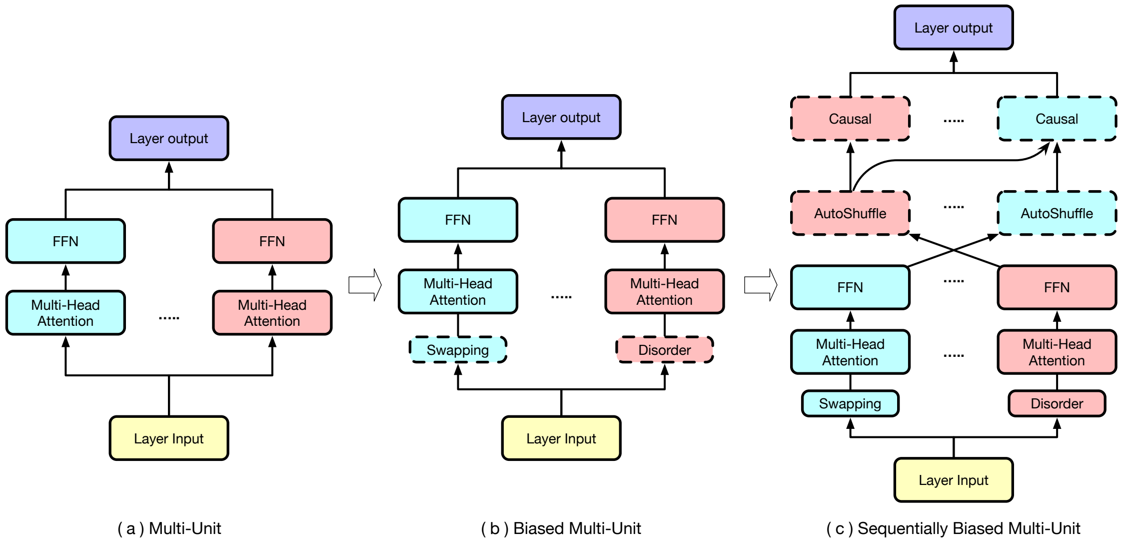

Figure 1: Layer architecture for Multi-Unit Transformer. White arrow indicates model change from Multi-Unit to Biased Multi-Unit, to Sequentially Biased Multi-Unit, with dashed lines representing the newly added modules.

Then, we follow the standard usage by stacking several MUTE layers to constitute our encoder and decoder.

In general, the encoder and decoder of the Transformer network share a similar architecture and can be improved with the same techniques. Without losing generality, we take the encoder as an example to further illustrate the MUTE. Given input X^k of k-th layer, we feed it into I identical units $\{F_1, \cdots, F_i, \cdots, F_I\}$ with different learnable parameters.

$$s_i^k = \mathrm{SelfAttn}_i(X^k) + X^k, \tag{8}$$

$$F_i^e(X^k) = s_i^k + \mathrm{FFN}_i(s_i^k), \tag{9}$$

where i denotes the i-th unit. After collecting outputs for all I units, we combine them by a weighted sum,

$$F^e(X^k) = \sum_{i \in (1,I)} \alpha_i \cdot F_i^e(X^k), \tag{10}$$

where $\alpha_i \in \mathbb{R}^1$ represents the learnable weight for the i-th unit (Section 5.8) and $F^e(X^k) \in \mathbb{R}^{n \times d}$ is the final output for the k-th layer.

3.2 Biased MUTE

The multi-unit setting for Transformer resembles the well-known ensemble techniques in machine learning fields, in that it also combines several different modules into one and aims for better performance. In that perspective, borrowed from the idea of bagging (Breiman, 1996), we propose to use biased units instead of identical units, which results in creating information gaps among units and makes them learn from each other.

More specifically, in training, we introduce a *Bias-Module* to create biased units, as shown in Figure 1(b). For each layer, instead of giving the same inputs $X^k \in \mathbb{R}^{n \times d}$ to all units, we transform each input with corresponding type of noises (e.g., swap, reorder, mask), in order to force the model to focus on different parts of inputs:

$$X_i^k = \mathrm{Bias}_i(X^k), \tag{11}$$

$$F^e(X^k) = \sum_{i \in (1,I)} \alpha_i \cdot F_i^e(X_i^k), \tag{12}$$

where Bias_i denotes the noise function for i-th unit. The noise operations [2] we investigated include,

- **Swapping**, randomly swap two input embeddings up to a certain range (i.e., 3).
- **Disorder**, randomly permutate a subsequence within a certain length (i.e., 3).
- **Masking**, randomly replace one input embedding with a learnable mask embedding.

Note that, the identity mapping (i.e., no noise) can be seen as a special case of bias module and is included in our model design.

Additionally, to get deterministic outputs, we disable the noises in the testing phase, which brings in the inconsistency between training and testing. Hence, we propose a switch mechanism with a sample rate p_β that determines whether to enable the bias module in training. This mechanism forces the model to adapt to golden inputs and mitigate the aforementioned inconsistency.

---

[2] To avoid a distortion of input sequence, each operation is performed only once for corresponding bias module.

3.3 Sequentially Biased MUTE

Although the bias module guides units of learning from each other by formulating such information gaps, it still lacks explicit complementarity modeling, i.e., mitigating these gaps. Here, based on the Biased MUTE, we propose a novel method to explicitly introducing a deep connection among units by utilizing the power of order (Figure 1(c)).

Sequential Dependency. Given the outputs from biased units $F_i^e(X_i^k)$, we permute these outputs by a certain ordering function $p(i)$ (e.g., $i \in \{1, 2, 3, 4\}$ to $p(i) \in \{4, 2, 3, 1\}$),

$$\{G_i^e = F_{p(i)}^e(X_{p(i)}^k) | i \in (1, I)\}, \tag{13}$$

where G_i^e is the i-th permutated output. The implementation of $p(i)$ will be illustrated later.

Then, we explicitly model the complementariness among units by introducing sequential dependency. Specifically, we compute an accumulated sequence $\{\hat{G}_i^e | i \in (1, I)\}$ over the permutated outputs G_i^e,

$$\hat{G}_i^e = \hat{G}_{i-1}^e + G_i^e, \tag{14}$$

where $\hat{G}_i^e \in \mathbb{R}^{n \times d}$ is the i-th *accumulated* output, and $\hat{G}_0^e = 0$. Through this sequential dependency, each permutated output G_i^e learns the residual of previous *accumulated* outputs $\hat{G}_{i-1}^e$ (He et al., 2016) and serves as a complement to previous accumulated outputs.

Finally, we normalize this accumulated sequence to keep the output norm stable and fuse all *accumulated* outputs.

$$F^e(X^k) = \sum_{i \in (1,I)} \alpha_i \cdot \frac{\hat{G}_i^e}{i}. \tag{15}$$

Autoshuffle. Until now, we have modeled the sequential dependency between each of the units. The only problem left is how to gather a proper ordering of units. We propose to use the AutoShuffle Network (Lyu et al., 2019). Mathematically, shuffling with specific order equals to a multiplication by a permutation matrix (i.e., every row and column contains precisely a single 1 with 0s elsewhere). Nevertheless, a permutation matrix only contains discrete values and can not be optimized by gradient descent. Therefore, we use a continuous matrix $M \in \mathbb{R}^{I \times I}$ with non-negative values $M_{i,j} \in (0, 1), i, j \in (1, I)$ to approximate the discrete permutation matrix.

Particularly, M is regarded as a learnable matrix and is used to multiply the outputs of units,

$$[\cdots ; F_{p(i)}^e(X_{p(i)}^k); \cdots] = M^\top \times [\cdots ; F_i^e(X_i^k); \cdots], \tag{16}$$

where $[\cdot;\cdot]$ means the concatenation operation.

To ensure M remains an approximation for the permutation matrix during training, we normalize M after each optimization step.

$$M_{i,j} = \max(M_{i,j}, 0), \tag{17}$$

$$M_{i,j} = \frac{M_{i,j}}{\sum_{\hat{i}} M_{\hat{i},j}}, M_{i,j} = \frac{M_{i,j}}{\sum_{\hat{j}} M_{i,\hat{j}}}. \tag{18}$$

Then, we introduce a Lipschitz continuous nonconvex penalty, as proposed in Lyu et al. (2019) to guarantee M converge to a permutation matrix.

$$\begin{aligned} \mathcal{L}_p = & \sum_{i=1}^{I}[\sum_{j=1}^{I} |M_{i,j}| - (\sum_{j=1}^{I} M_{i,j}^2)^{\frac{1}{2}}] \\ & + \sum_{j=1}^{I}[\sum_{i=1}^{I} |M_{i,j}| - (\sum_{i=1}^{I} M_{i,j}^2)^{\frac{1}{2}}], \end{aligned} \tag{19}$$

Please refer to Appendix D for proof and other details.

Finally, the penalty is added to cross-entropy loss defined in equantion (7) as our final objective,

$$\mathcal{L} = \mathcal{L}_{CE} + \lambda \sum_k \mathcal{L}_p^k, \tag{20}$$

where λ is a hyperparameter to balance two objectives and $\mathcal{L}_p^k$ is the penalty for the k-th layer.

4 Experimental Settings

In this section, we elaborate our experimental setup on three widely-studied Neural Machine Translation tasks, NIST Chinese-English (Zh-En), WMT'14 English-German (En-De) and WMT'18 Chinese-English.

Datasets. For NIST Zh-En task, we use 1.25M sentences extracted from LDC corpora[3]. To validate the performance of our model, we use the NIST 2006 (MT06) test set with 1664 sentences as our validation set. Then, the NIST 2002 (MT02), 2003 (MT03), 2004 (MT04), 2008 (MT08) test sets are used as our test sets, which contain 878, 919, 1788 and 1357 sentences, respectively.

For the WMT'14 En-De task, following the same setting in Vaswani et al. (2017), we use 4.5M preprocessed data, which has been tokenized and split using byte pair encoded (BPE) (Sennrich et al.,

2016) with 32k merge operations and a shared vocabulary for English and German. We use *newstest2013* as our validation set and *newstest2014* as our test set, which contain 3000 and 3003 sentences, respectively.

For the WMT'18 Zh-En task, we use 18.4M preprocessed data, which is also tokenized and split using byte pair encoded (BPE) (Sennrich et al., 2016). We use *newstest2017* as our validation set and *newstest2018* as our test set, which contains 2001 and 3981 sentences, respectively.

Evaluation. For evaluation, we train all the models with maximum 150k/300k/300k steps for NIST Zh-En, WMT En-De and WMT Zh-En, respectively, and we select the model which performs the best on the validation set and report its performance on the test sets. We measure the case-insensitive/case-sensitive BLEU scores using *multi-bleu.perl* [4] with the statistical significance test (Koehn, 2004) [5] for NIST Zh-En and WMT'14 En-De, respectively. For WMT'18 Zh-En, we use case sensitive BLEU scores calculated by Moses *mteval-v13a.pl* script [6] .

Model and Hyper-parameters. For all our experiments, we basically follow two model settings illustrated in (Vaswani et al., 2017), namely *Transformer-Base* and *Transformer-Big*. In *Transformer-Base*, we use 512 as hidden size, 2048 as filter size and 8 heads in multihead attention. In *Transformer-Big*, we use 1024 as hidden size, 4096 as filter size, and 16 heads in multihead attention.

Besides, since noise types like swapping and reordering are of no effect on Transformer models with absolute position information, the MUTE models are implemented using relative position information (Shaw et al., 2018). In addition, we only apply multi-unit methods to encoders, provided that the encoder is more crucial to model performance (Wang et al., 2019a). All experiments on MUTE models are conducted with *Transformer-Base* setting. For the basic MUTE model, we use four identity units. As for the Biased MUTE and Sequentially Biased MUTE, we use four units including one identity unit, one swapping unit, one disorder unit and one masking unit. The sample rate p_β is set to 0.85. For more implementation details and experiments on sample rate, please refer to Appendix A and B.

5 Results

Through experiments, we first evaluate our model performance (Section 5.1 and 5.2). Then, we analyze how each part of our model works (Section 5.4 and 5.6). Finally, we conduct experiments to further understand the behavior of our models (Sec-

tion 5.7 and 5.8).

5.1 Results on NIST Chinses-English

As shown in Table 1, we list the performance of our re-implemented Transformer baselines and our approaches. We also list several existing strong NMT systems reported in previous work to validate the effectiveness of our models. By investigating results in Table 1, we have the following observations.

First, compared with existing NMT systems, our re-implemented Transformers are strong baselines.

Second, all of our approaches substantially outperform our baselines, with improvement ranging from 1.12 to 1.52 BLEU points. Comparing our methods to "Transformer + Relative (Base)", our best approach (i.e., "MUTE + Bias + Seq. (Base, 4 Units)") still achieves a significant improvement of 1.0 BLEU points on multiple test sets.

Third, among our approaches, we find that, even though our basic MUTE model has already surpassed existing strong NMT systems and our baselines, the bias module and sequential dependency can further boost the performance (i.e., from +1.12 to +1.52), which demonstrates that introducing complementariness does help the Multi-Unit Transformers.

Fourth, we find it interesting that compared with the "Transformer + Relative (Big)", the basic "MUTE (Base, 4 Units)" can achieve better BLEU performance with only 54% of parameters, which indicates that our multi-unit approaches can leverage parameters more effectively and efficiently.

5.2 Results on WMT'14 English-German

The results on WMT'14 En-De are shown in Table 2. We list several competitive NMT systems for comparison, which are divided into models based on *Transformer-Base* and models based on *Transformer-Big*.

First of all, our models show significant BLEU improvements over two baselines in the *Transformer-Base* setting, ranging from +1.4 to +1.9 for "Transformer (Base)" and from +0.6 to +1.1 for "Transformer+Relative (Base)". That proves our methods perform consistently across languages and are still useful in large scale datasets.

Next, among our own NMT methods, the sequentially biased model further improves the BLEU performance over our strong Multi-Unit model (from 28.8 to 29.3), which is consistent with our findings in the Zh-En[7] task and further proves the power of complementariness.

Finally, compared with the existing NMT systems, we find that our models achieve comparable / better performance with much fewer parameters. The only exception is (Wang et al., 2019a), which learns a very deep (30 layers) Transformer. We regard these deep Transformer methods as orthogonal methods to ours, and it can be integrated with our MUTE models in future work. Additionally, we list several systems related to our multi-unit setting ("*Existing Multi-Unit Style NMT Systems*"), with diversity modeling or features space composition. As shown, MUTE models also outperform these methods, demonstrating the superiority of our methods in diverse and complementary modeling.

5.3 Results on WMT'18 Chinese-English

In this section, we represent our results on WMT18 Chinese-English. The results are shown in Table

---

[7] We find that improvements on the larger scale WMT'14 En-De dataset is bigger than that on NIST Zh-En. We attribute this phenomenon to the overfitting problem caused by the small Zh-En dataset.

System	#Param.	BLEU	Δ

- identity unit.	47.01 (-0.79)
- swapping unit.	47.13 (-0.67)
- disorder unit.	47.15 (-0.65)
- mask unit.	47.36 (-0.44)
- bias module	47.28 (-0.52)
- sequential dependency	47.45 (-0.35)

Table 4: Ablation study for BLEU scores (%) over the NIST Zh-En validation set.

3. As we can see, our MUTE model still strongly outperforms the baseline "Transformer (Base)" and "Transformer+Relative (Base)" with +1.1 and +0.7 BLEU points. Noting that WMT'18 Zh-En has a much larger dataset (18.4M), and these findings proves that our model perform consistently well with different size of datasets.

5.4 Ablation Study

In this section, we conduct the ablation study to verify each part of our proposed model. The results are shown in Table 4. From our strongest Sequentially Biased model, we remove each of the four different units to validate which unit contributes the most to the performance. Then, we remove the bias module and sequential dependency independently to investigate each module's behavior.

We come to the following conclusions:

(1) All units make substantial contributions to "MUTE + Bias + Seq.", ranging from 0.44 to 0.79, proving the effectiveness of our design.

(2) Among all units, the identity unit contributes most to our performance, which is consistent with our intuition that the identity unit should be responsible most for complementing other biased units.

(3) The bias module and sequential dependency both contribute much to our Multi-Unit Transformers. We find it intriguing that, without the bias module, sequential dependency only provides marginal improvements. We conjecture that the complementary effect becomes minimal with no information gap among units.

Methods	BLEU Score
Transformer + Relative	44.83
+ average last 5 saves	44.97
+ average 5 seeds	*Fails*
MUTE	45.43
MUTE + Bias + Seq.	**45.82**

Table 5: Comparison with averaging checkpoints in terms of BLEU scores (%) over the NIST Zh-En datasets. The reported BLEU scores is the average of all test sets.

5.5 Comparison with Averaging Checkpoints

As we mentioned before, our MUTE models are inspired by ensembling methods. Therefore, it is necessary to compare our model with representative ensemble methods, e.g., averaging model checkpoints. Here, the comparison results of our MUTE model and averaging checkpoints in NIST Zh-En are shown in Table 5. Since averaging checkpoints often leads to better generalization, we report the average BLEU scores over all test sets.

We adopt two settings, namely averaging the last several (i.e., 5) checkpoints and averaging over models initialized with different seeds. The experiment with different initialization seeds fails. We conjecture the reason is that different seeds make models fall in different sub-optimals, and brutally combining them together makes the model perform badly. Then we average checkpoints over the last 5 saves, which gives us 44.97 BLEU points, which only outperforms the best checkpoint marginally (+0.14 in average), and MUTE performs much better (45.43 and 45.82 BLEU points). Specificially, our naive MUTE model suprasses the averaginig checkpoint method, and the sequential ordering and bias module enable a better interaction over different units.

5.6 Quantitative Analysis of Model Diversity

Here, we empirically investigate which granularity should be used for better diversity among units. To verify the impact of multiple units compared with the single unit, we evaluate three different models:

- **4 Self. + 4 FFN**, the model with four different self-attention modules and four different FFNs.
- **4 Self. + 1 FFN**, the model with four self-attention modules and one shared FFN.
- **1 Self. + 4 FFN**, the model with one shared self-attention module and four different FFNs.

Methods	Att Pos.	Att Sub.	FFN Sub.
MUTE + Bias + Seq.	**0.475**	**0.602**	**0.460**
4 Self. + 4 FFN	0.447	0.576	0.449
4 Self. + 1 FFN	0.420	0.520	0.404
1 Self. + 4 FFN	-	-	0.381

Table 6: Quantitative analysis on diversity scores. **Att Pos.**, **Att Sub.** and **FFN Sub.** denote the diversity scores for self-attention weights, self-attention outputs and FFN outputs, respectively. A larger score means better diversity.

To control variables, these models include neither bias module nor sequential dependency.

For each model, we evaluate the diversity among units for three outputs: (1) the outputs of self-attention modules, (2) the attention weights of self-attention modules, (3) the outputs of FFN modules. The diversity scores are computed by the exponential of the negative cosine distance among units, the same as proposed in (Li et al., 2018).

$$\mathrm{DIV} = \exp\left(-\frac{o_i^\top o_j}{|o_i| \cdot |o_j|}\right), \qquad (21)$$

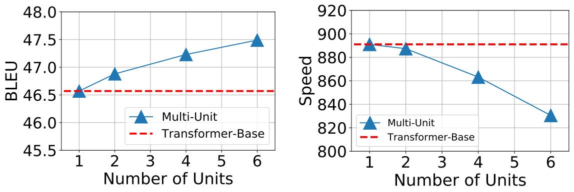
where DIV $\in (0, 1)$ represents the diversity score for module outputs $o_i \in \mathbb{R}^d$ and $o_j \in \mathbb{R}^d$. The results are shown in Table 6.

Above all, we find that multiple FFN layers can introduce diversity. As seen, “1 Self. + 4 FFN” produces a 0.381 diversity score on “FFN Sub.”. Since we use a shared self-attention layer, which brings no diversity in the input-side of FFN layers, the difference is only brought by different FFN modules. We think the reason is that the RELU activation inside the FFN module serves as selective attention to filter out input information.

Next, “4 Self. + 1 FFN” achieves 0.420 and 0.520 diversity scores for self-attention modules, which indicates that multiple self-attention modules focus on different parts of the input sequence and lead to diverse outputs.

Then, “4 Self. + 4 FFN” has higher diversity scores than “4 Self. + 1 FFN” and “1 Self. + 4 FFN”, which verifies our choice of using a combination of self-attention module and FFN as a basic unit.

Finally, concerning the diversity scores among all models, we find that our full model with biased inputs and sequential dependency achieves the best diversity scores for all three outputs, which also achieves the best BLEU scores in previous experiments.



(a) Effects on BLEU (b) Effects on Speed

Figure 2: The effect on the number of units: (a) BLEU scores (%) against number of units used in the MUTE model. (b) Inference speed (tokens per second) on GPU against number of units used in the MUTE model. Experiments are conducted on the valid set of NIST Zh-En with decoding batch size = 30 and beam size = 4.

5.7 Effects on the Number of Units

Another concern is how the MUTE models perform when increasing the number of units. Thus, in this section, we empirically investigate the effects on the number of units, in terms of model performance and inference speed. Here we use the basic Multi-Unit Transformer[8].

As shown in Figure 2(a) and 2(b), increasing the number of units from 1 to 6 yields consistent BLEU improvement (from 46.5 to 47.5) with only mild inference speed decrease (from 890 tokens/sec to 830 tokens/sec). Besides, our model with four unit used in other experiments is faster than Transfomrer-Big (863 tokens/sec vs 838 tokens/sec). These results prove the computational efficiency of our MUTE model. We attribute this mild speed decrease (about 3.1% for four units and 6.7% for six units) for two reasons. First, the multi-unit model is naturally easy for parallelization. Each unit can be computed independently without waiting for other functions to finish. Second, we only widen the encoder, which is only computed once for each sentence translation.

5.8 Visualization

We also present a visualization example of the learnable weights α for units, shown in Figure 3.

As we can see, learnable weights α show similar trends in “MUTE” and “MUTE + Bias”. The weights for each unit within the same layer fall in a similar range (0.2 to 0.35), dispelling the worries that the biased units may be omitted or skipped. As for the “MUTE + Bias + Seq.”, the weight distribution is very different. The weights nearly increase progressively when the unit index increases.

---

[8] The number of combinations of different noise types is exponentially large. Moreover, introducing sequential dependency and bias module hardly affects the inference speed.

Because the model weights are learned with backpropagation, the larger the weight, the more the model favors the corresponding unit. Thus, to some extent, this phenomenon demonstrates that the latter accumulated outputs are more potent than the preceding ones, and therefore, the latter single unit output complements the previous accumulation.

6 Related Work

Recently Transformer-based models (Vaswani et al., 2017; Ott et al., 2018; Wang et al., 2019a) become the de facto methods in Neural Machine Translation, owing to high parallelism and large model capacity.

Some researchers devise new modules to improve the Transformer model, including combining the transformer unit with convolution networks (Wu et al., 2019; Zhao et al., 2019; Lioutas and Guo, 2020), improving the self-attention architecture(Fonollosa et al., 2019; Wang et al., 2019b; Hao et al., 2019), and deepening the Transformer architecture by dense connections(Wang et al., 2019a). Since our multi-unit framework makes no limitation about its unit, these models can be easily integrated into our multi-unit framework.

There are also some works utilizing the power of multiple modules to capture complex feature representations in NMT. Shazeer et al. (2017) use a vast network and a sparse gated function to select from multiple experts (i.e., MLPs). Ahmed et al. (2017) train a weighted Transformer by replacing the multi-head attention by self-attention branches. Nevertheless, these models ignore the modeling of relations among different modules. Then, some multihead attention variants (Li et al., 2018, 2019) introduce modeling of diversity or interaction among heads. However, complementariness is not taken into account in their approaches. Our MUTE models differ from their methods in two aspects. First, we use a powerful unit with a strong performance in diversity (Section 5.6). Second, we explicitly model the complementariness with bias module and sequential dependency.

7 Conclusion

In this paper, we propose Multi-Unit Transformers for NMT to improve the expressiveness by introducing diverse and complementary units. In addition, we propose two novel techniques, namely bias module and sequential dependency to further improve the diversity and complementariness among units. Experimental results show that our methods can significantly outperform the baseline methods and achieve comparable / better performance compared with existing strong NMT systems. In the meantime, our methods use much fewer parameters and only introduce mild inference speed degradation, which proves the efficiency of our models.

A Implementation Details

All models are trained using *Opennmt-py* framework (Klein et al., 2017). The batch size for each GPU is set to 4096 tokens. The beam size is set to 4, and the length penalty is 0.6 among all experiments. For the WMT'14 En-De and WMT'18 Zh-En task, all experiments are conducted using 4 NVIDIA Tesla V100 GPUs, while we use 2 GPUs for the NIST Zh-En task. That gives us about 8k/16k/16k tokens per update for NIST Zh-En/WMT'14 En-De/WMT'18 Zh-En. All models are optimized using Adam (Kingma and Ba, 2014) with $\beta_1 = 0.9$ and $\beta_2 = 0.998$, and learning rate is set to 1.0 for all experiments. Label smoothing is set to 0.1 for all three tasks. We use dropout of 0.4/0.2/0.1 for NIST Zh-en/WMT En-de/WMT Zh-en, respectively. All our Transformer models contain 6 encoder layers and 6 decoder layers, following the standard setting in (Vaswani et al., 2017).

All the hyperparameters are empirically set by our previous experiences or manually tuned. The criterion for selecting hyperparameters is the BLEU score on validation sets for both tasks. The average runtimes are one GPU day for NIST Zh-En and 4 GPU days for WMT'14 En-De and WMT'18 Zh-EN.

B Effect of Sample Rate

As we mentioned above, we use sample rate to mitigate the incosistency between training and testing, and force the model to adapt to golden inputs. Here, we conduct hyper-parameter search for sample rate with 4 empirically set values, 0.5, 0.75, 0.85, 1.0. The results are shown in Figure 4.

As seen, we make the following observations: 1. The trends of BLEU scores for sequentially biased model and biased model are very similar, when we increases the sample rate p_β. The best performance for both models appear when the sample rate is 0.85. Therefore, we set sample rate to 0.85 among all of our experiments. 2. Introducing sample rate is essential for both biased model and sequentially biased model. Compared with alway injecting noises, i.e., the sample rate $p_\beta = 1.0$, consistent improvements is observed for both models. BLEU scores increase from 47.27 to 47.48 (+0.21) for biased model, and from 47.56 to 47.80 (+0.24) for sequentially biased model.

The aforementioned observations prove that introducing sample rate when using bias module is an essential way to mitigate the inconsistency between training and testing.

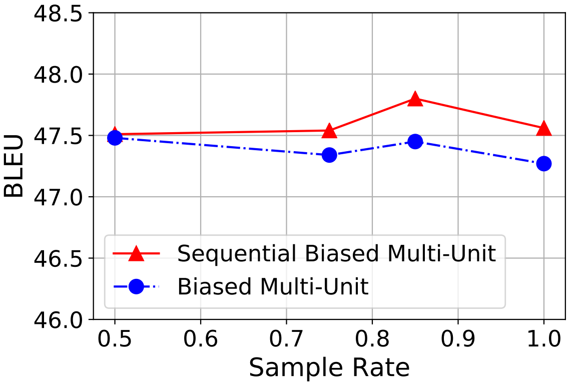

Figure 4: BLEU scores (%) changes on NIST Zh-En valid set when increasing the sample rate p_β. Bigger value means a better chance to inject noises. 1.0 for sample rate means always injecting noises.

C Case Study

We also provide a visualization example to show how our proposed methods improve complementariness among units. As shown in Figure 5, the top one is the attention weights of Basic Multi-Unit model. The attention weights for each of the units mainly focus on same parts of the inputs. In contrast to this phenomenon, the biased model and sequentially biased model attend with more diverse weights. Moreover, we find that the sequentially biased model pays more attention to what the previous unit miss, which proves that our proposed method can actually encourage complementariness.

D Simple Proof for Lipschitz Penalty

Here we give a intuitive proof why the Lipschitz penalty (Lyu et al., 2019) would lead our learnable matrix M towards a permutation matrix, i.e., every row and column contains precisely a single 1 with 0s elsewhere.

Recall the penalty for matrix M,

$$\begin{aligned}\mathcal{L}_p = &\sum_{i=1}^{I}[\sum_{j=1}^{I}|M_{i,j}| - (\sum_{j=1}^{I} M_{i,j}^2)^{\frac{1}{2}}] \\ &+ \sum_{j=1}^{I}[\sum_{i=1}^{I}|M_{i,j}| - (\sum_{i=1}^{I} M_{i,j}^2)^{\frac{1}{2}}].\end{aligned} \tag{22}$$

By the Cauchy-Schwarz inequality, we have

$$(\sum_{j=1}^{I}|M_{i,j}|) - (\sum_{j=1}^{I} M_{i,j}^2)^{\frac{1}{2}} \geq 0, \forall i, \tag{23}$$

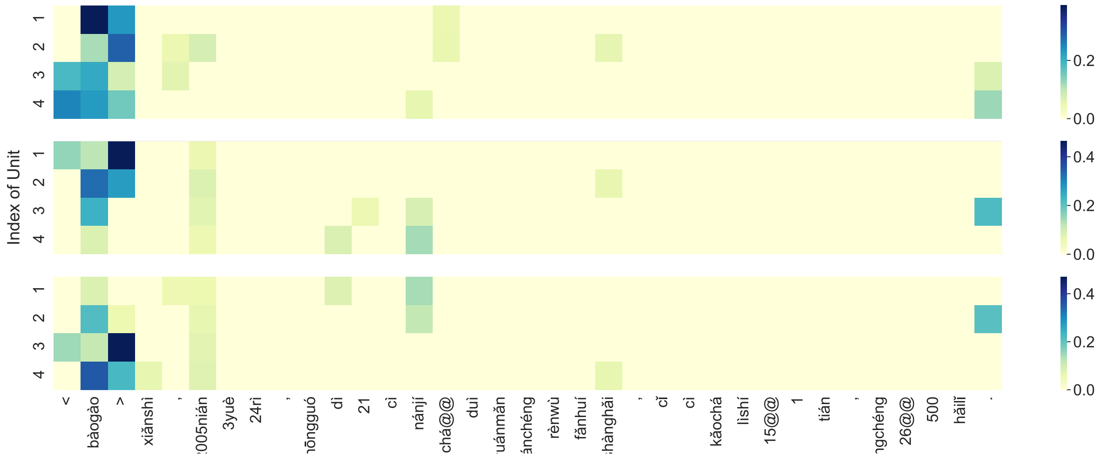

Figure 5: A visualization of example attention weights of the *Multi-Unit*, *Biased Multi-Unit* and *Sequentially Biased Multi-Unit* models, top to bottom. We filter out the weights smaller than 0.05 for ease of understanding.

with the equality holds if and only if there exists maximum one 1 for each row,

$$|\{j : M_{i,j} \neq 0\} <= 1|, \forall i. \tag{24}$$

Then, in conjunction with our normalization that perserves,

$$M_{i,j} \geq 0, \forall i, j; \tag{25}$$

$$\sum_{j=1}^{I} M_{i,j} = 1, \forall i; \sum_{i=1}^{I} M_{i,j} = 1, \forall j, \tag{26}$$

the equality only holds if and only if there exists only one 1 for each row,

$$|\{j : M_{i,j} \neq 0\} = 1|, \forall i. \tag{27}$$

Likewise,

$$(\sum_{i=1}^{I} |M_{i,j}|) - (\sum_{i=1}^{I} M_{i,j}^2)^{\frac{1}{2}} \geq 0, \forall j, \tag{28}$$

with equality if and only if $|\{j : M_{i,j} \neq 0\} = 1|, \forall i$. Therefore, when the penalty (22) becomes 0, M converges to a permutaion matrix. For more detailed mathematical proof about the Lipschitz penalty, we refer readers to Lyu et al. (2019).

Abstract

Modern neural machine translation (NMT) models employ a large number of parameters, which leads to serious over-parameterization and typically causes the underutilization of computational resources. In response to this problem, we empirically investigate whether the redundant parameters can be reused to achieve better performance. Experiments and analyses are systematically conducted on different datasets and NMT architectures. We show that: 1) the pruned parameters can be rejuvenated to improve the baseline model by up to +0.8 BLEU points; 2) the rejuvenated parameters are reallocated to enhance the ability of modeling low-level lexical information.

1 Introduction

Modern neural machine translation (NMT) (Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017) models employ sufficient capacity to fit the massive data well by utilizing a large number of parameters, and suffer from the widely recognized issue, namely, over-parameterization. For example, See et al. (2016) showed that over 40% of the parameters in an RNN-based NMT model can be pruned with negligible performance loss. However, the low utilization efficiency of parameters results in a waste of computational resources (Qiao et al., 2019), as well as renders the model stuck in a local optimum (Han et al., 2017; Yu et al., 2019).

In response to the over-parameterization issue, network pruning has been widely investigated for both computer vision (CV) (Han et al., 2016; Luo et al., 2017) and natural language processing (NLP) tasks (See et al., 2016; Lan et al., 2020). Recent work has proven that such spare parameters can be reused to maximize the utilization of models in CV tasks such as image classification (Han et al., 2017; Qiao et al., 2019). The leverage of parameter rejuvenation in sequence-to-sequence learning, however, has received relatively little attention from the research community. In this paper, we empirically study the efficiency issue for NMT models.

Specifically, we first investigate the effects of weight pruning on advanced Transformer models, showing that 20% parameters can be directly pruned, and by continuously training the sparse networks, we can prune 50% with no performance loss. Starting from this observation, we then exploit whether these redundant parameters are able to be re-utilized for improving the performance of NMT models. Experiments are systematically conducted on different datasets (i.e. Zh⇒En, De⇒En and En⇒Fr) and NMT architectures (i.e. Transformer, RNNSearch and LightConv). Results demonstrate that the rejuvenation approach can significantly and consistently improve the translation quality by up to +0.8 BLEU points. Further analyses reveal that the rejuvenated parameters are reallocated to enhance the ability to model the source-side low-level information, lacking of which leads to a number of problems in NMT models (Tu et al., 2016; Dou et al., 2018; Emelin et al., 2019).

Contributions Our key contributions are:

- We try early attempts to empirically investigate parameter rejuvenation for NMT models across different datasets and architectures.
- We explore to interpret where the gains come from in two perspectives: learning dynamics and linguistic insights.

2 Approach

A standard NMT model directly optimizes the conditional probability of a target sentence $\mathbf{y} = y_1, \ldots, y_J$ given its corresponding source sentence $\mathbf{x} = x_1, \ldots, x_I$, namely $P(\mathbf{y}|\mathbf{x}; \theta) =$

$\prod_{j=1}^{J} P(y_j|\mathbf{y}_{<j}, \mathbf{x}; \theta)$, where θ is a set of model parameters and $\mathbf{y}_{<j}$ denotes the partial translation. The parameters of the NMT model are trained to maximize the likelihood of a set of training examples. Given a well-trained NMT model, we first prune its inactive parameters, and then rejuvenate them. Our implementation details are as follows.

Pruning The redundant parameters in neural networks can be pruned according to a certain criterion while the left ones are significant to preserve the accuracy of the model. Specifically, we mask weight connections with low magnitudes in the forward pass and these weights are not updated during optimization. Given the weight matrix W with N parameters, we rank the parameters according to their absolute values. Supposed that the pruning ratio is γ (i.e. $\gamma\%$ of parameters should be pruned), we keep the top n parameters ($n = N \times (1-\gamma)$), and remove the others with a binary mask matrix, which is the same size of W. We denote the pruned parameters as θ_p, subject to $\theta_p \subset \theta$. There are two pruning strategies (Liu et al., 2019): 1) local pruning, which prunes $\gamma\%$ of parameters in each layer; and 2) global pruning, which compares the importance of parameters across layers. Following See et al. (2016), we retrain the pruned networks after the pruning phase. Specifically, we continue to train the remaining parameters, but maintain the sparse structure, that is we optimize $P(\mathbf{y}|\mathbf{x}; \theta)$ with the constraint: $a = 0, \forall a \in \theta_p$.

Rejuvenation After the pruning and retraining phases, we aim to restore the model capacity by rejuvenating the pruned parameters. This is a common method in optimization to avoid useless computations and further improve performances (Han et al., 2017; Qiao et al., 2019). Thus, we release the sparsity constraint ($a = 0, \forall a \in \theta_p$), which inversely recovers the pruned connections, and re-dense the whole networks. The recovered weight connections are then initialized by some strategy (e.g. zero or external). The entire networks are retrained with one order of magnitude lower learning rate since the sparse network is already at a good local optimum. As seen, the rejuvenation method contains three phases: 1) training a baseline model (BASE); 2) pruning $\gamma\%$ parameters and then retraining remaining ones (PruTrain); 3) restoring pruned parameters and training entire networks (RejTrain).

3 Experiments

3.1 Setup

Data We conduct experiments on English⇒German (En⇒De), Chinese⇒English (Zh⇒En), German⇒English (De⇒En) and English⇒French (En⇒Fr) translation tasks. For En⇒De task, we use WMT14 corpus which contains 4 million sentence pairs. The Zh⇒En task is conducted on WMT17 corpus, consisting of 21 million sentence pairs. We follow Dou et al. (2018) to select the development and test sets. Furthermore, we evaluate low-resourced translation on IWSLT14 De⇒En and IWSLT17 En⇒Fr corpora. We preprocess our data using byte-pair encoding (Sennrich et al., 2016) with 40K merge operations for En⇒De, 32K for Zh⇒En, and 10K for De⇒En and En⇒Fr, and keep all tokens in the vocabulary. We use 4-gram BLEU score (Papineni et al., 2002) as the evaluation metric and sign-test (Koehn, 2004) for statistical significance.

Models We implement our approach on top of three popular architectures, namely Transformer (Vaswani et al., 2017), RNNSearch (Luong et al., 2015) and LightConv (Wu et al., 2019) with

the open-source toolkit – fairseq (Ott et al., 2019). For Transformer, we investigate *big*, *base* and *small* settings. About RNNSearch and LightConv, we employ corresponding configurations in fairseq. The implementation is detailed in Appendix §A.1. All baseline models are trained for 100K updates using Adam optimizer (Kingma and Ba, 2015). Based on the baselines, the proposed pruning and rejuvenation methods are trained with additional 100K updates (i.e. 50K for each one). To rule out the circumstance that more training steps may bring improvements, we also conduct continuous training (ConTrain) as strong baselines and they employ the same training steps as our approach.

3.2 Results of Pruning

To study the effect of sparsity, we investigate the effects of different pruning ratios on Transformer *base* models. Experiments are conducted on WMT14 En⇒De and WMT17 Zh⇒En tasks. As shown in Figure 1, over 20% of parameters can be directly pruned without degrading the translation performance. When adding a simple continuous training phase after pruning, we are able to prune 50% with no performance loss. Compared with findings in See et al. (2016), Transformer is less over-parameterized than RNN-based NMT models (20% vs. 40% and 50% vs. 80%). This provides the evidence that different NMT models are over-parameterized to a different extent. Accordingly, we set the pruning threshold of 50% as a default in the following experiments (i.e. Tables 1−4).

3.3 Results of Rejuvenation

Ablation Study As shown in Table 1, we systematically compare different pruning and rejuvenation strategies on the translation task. As seen, the local pruning strategy performs better than the global one, especially with the rejuvenation counterpart (28.12 vs. 28.08 BLEU). However, See et al. (2016) found that the global pruning outperforms the local one without considering rejuvenation factors. Regarding the rejuvenation strategy, zero and external initialization perform similarly in terms of BLEU score. Therefore, we use local pruning and zero initialization strategies for the rest of the experiments (i.e. Tables 2−4).

Main Results We evaluate the rejuvenation approach on the Transformer using En⇒De dataset. As shown in Table 2 (Rows 1−4), our model (RejTrain) outperforms the baseline model and continuous training method (ConTrain) by +0.58 and +0.38 BLEU points, respectively. In addition, iterative rejuvenation can incrementally improve the baseline model up to 28.33 BLEU points (+0.79 and +0.59 over BASE and ConTrain). The results clearly demonstrate the effectiveness of rejuvenating redundant parameters for NMT models.

To verify the robustness, we evaluate different model sizes. As shown in Table 2 (Rows 5−7), the Transformer BIG model performs better than the *base* with an increase of 196.7M parameters. Surprisingly, the performance can be further improved by +0.57 BLEU points by our method. As seen, the continuous training can only slightly gain +0.2 BLEU over BIG, and RejTrain outperforms the strong baseline. This confirms that the rejuvenation method can consistently improve NMT models by alleviating the over-parameterization issue.

Different Datasets Table 3 shows results on three datasets: Zh⇒En, De⇒En and En⇒Fr, cov-

#	Model	Para.	BLEU	Δ
1	Transformer	108.6M	27.54	–
2	+ ConTrain	108.6M	27.74	+0.20
3	+ RejTrain	108.6M	28.12$^{\Uparrow}$	+0.58
4	RNNSearch	197.0M	22.98	–
5	+ ConTrain	197.0M	22.98	+0.00
6	+ RejTrain	197.0M	23.30	+0.32
7	LightConv	304.2M	28.01	–
8	+ ConTrain	304.2M	28.32	+0.31
9	+ RejTrain	304.2M	28.52$^{\Uparrow}$	+0.51

Table 4: Translation quality of different NMT models on WMT14 En⇒De.

ering large-scale and small-scale training data (i.e. 21M, 0.16M and 0.22M). Trained with large-scale data (Zh⇒En), the continuous training achieves +0.17 BLEU point over the baseline while the rejuvenation approach obtains +0.42 improvement. For low-resource translation (De⇒En and En⇒Fr), ConTrain can not further improve the performance since it is easy to get stuck in a local optimum. However, RejTrain can jump out of local optimum with improved performances (+0.37 and +0.54 over De⇒En and En⇒Fr baselines, respectively). Compared with continuous training, the proposed method significantly and incrementally improves the translation quality in all cases. This again demonstrates the effectiveness of our method across different datasets varied in aspects of language and size.

Different Model Architectures As shown in Table 4, we conduct the experiments on WMT14 En⇒De translation task with RNNSearch, LightConv, Transformer models. Our approach achieves consistent and significant improvements over the baseline and ConTrain models across three architectures. For RNNSearch, continuous training cannot further improve the performance while our model achieves better performance (+0.32 over ConTrain). Furthermore, LightConv works better than the Transformer BASE model since it has 3× more parameters. However, RejTrain still outperforms the ConTrain model and achieves 28.52 BLEU scores. This demonstrates the effectiveness and universality of our approach.

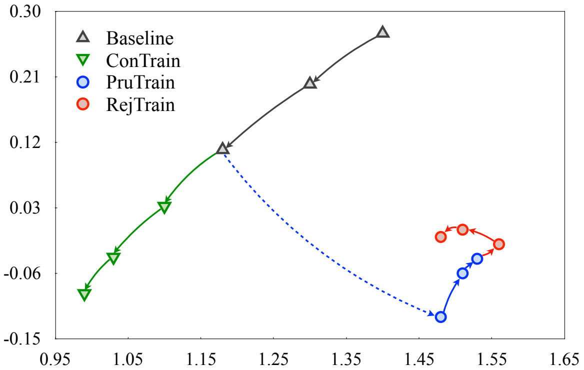

Figure 2: Visualization of encoder representations in different training phases. For each phase, we select sequentially three models. The solid arrow represents the changes in each phase. The dotted arrow represents the changes from the baseline to the pruning phase.

4 Analysis

To better understand the effectiveness of the proposed method, the analyses are carried out in two ways: representation visualization and linguistic probing. Furthermore, we study the translation outputs in terms of adequacy and fluency.

Escaping from Local Optimum To study how our method help models to escape from local optimum, we analyze the change of source representations during different training phases. The analysis is conducted on the Transformer BASE model and En⇒De. Following Zeng et al. (2018), we feed source sentences in the development set into a checkpoint and output an element-wise averaged vector from representations of the last encoder layer. With the dimension-reduction technique of TruncatedSVD (Du et al., 2017), we can plot the dimensionally reduced values in Figure 2. Among the training phases (i.e. Baseline, ConTrain, PruTrain, RejTrain), we select checkpoints at which interval training updates are equal. As seen, within each phase, the representations change smoothly in direction and quantity. The continuous training still transforms the representations in the same direction as the baseline phase (i.e. grey vs. green lines). However, the pruning training dramatically changes the representations (i.e. blue vs. grey lines). Finally, the rejuvenation training jumps to a different place compared with the ConTrain (i.e. red vs. green lines). This demonstrates that our method can efficiently change the direction of optimization, thus providing more chances for the model to escape from the local optimum.

Linguistic Insights We follow Conneau et al. (2018) to conduct the linguistic probing task, which aims to measure the linguistic knowledge embedded in the encoder representations learned by the

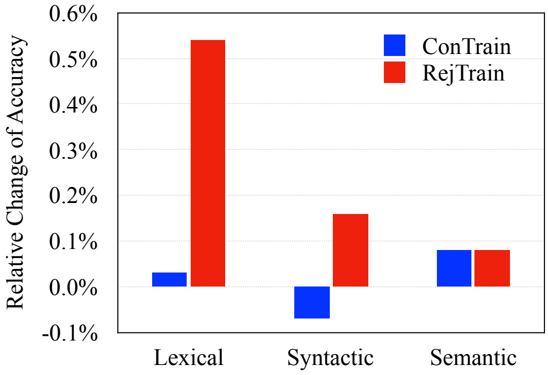

Figure 3: Relative change of performance on linguistic probing tasks compared with the baseline. "Lexical", "Syntactic", "Semantic" denote the averaged accuracy over corresponding tasks in each category.

model. Specifically, it contains 10 classification subtasks with 3 linguistic categories, including lexical, syntactic and semantic ones. We average the predicted accuracies of subtasks in the same category and calculate the relative changes of ConTrain and RejTrain over the baseline model. The analysis is conducted on the Transformer BASE model and En⇒De translation task. As shown in Figure 3, the RejTrain model performs better on the lower level of linguistic subtasks, especially on lexical ones (i.e. 0.6%). The details are listed in Appendix §A.2. The improvements are significant compared with those in Wang et al. (2019a). We hypothesize that better capturing lexical knowledge can improve the adequacy and fluency of translation, which is verified in next part.

Adequacy and Fluency Table 5 shows an example randomly selected from the test set in the Zh⇒En task. As seen, incorporating the rejuvenation approach into NMT can generate more fluent translation with higher adequacy. For instance, the Chinese word "奥运会" is under-translated by the baseline model, while the RejTrain model can correctly translate it into "olympics". Besides, the nominal modifier "21岁的" is mistranslated into a simple number by the baseline while RejTrain can fix the error. This confirms that the rejuvenation improves the adequacy of translation by enhancing the ability to understand the lexical information. To better evaluate the fluency of our models, we calculate the perplexity on the WMT14 En-De test set. As shown in Table 6, the RejTrain model can achieve lower perplexity than baseline and Contrain models (5.08 vs. 5.14/5.15). An interesting finding is that PruTrain increases the perplexity, which may harm the fluency of translation outputs (5.25 vs. 5.14). This demonstrates that our rejuvenation approach improves the fluency of translation.

5 Conclusion

In this paper, we prove that existing NMT systems are over-parameterized and propose to improve the utilization efficiency of parameters in NMT models by introducing a rejuvenation approach. Empirical results on a variety of language pairs and architectures demonstrate the effectiveness and universality of the presented method. We also analyze the gains from perspectives of learning dynamics and linguistic probing, which give insightful research directions for future work.

Future directions include continuing the exploration of this research topic for large sequence-to-sequence pre-training models (Liu et al., 2020) and multi-domain translation models (Wang et al., 2019b). We will employ recent analysis methods to better understand the behaviors of rejuvenated models (He et al., 2019; Yang et al., 2020).

A Supplemental Material

A.1 Experimental Setup

In the model configuration of Transformer, the BASE and BIG models differ in the hidden layer size (512 vs. 1024), filter size (2048 vs. 4096) and the number of attention heads (8 vs. 16). The encoder and decoder are composed of a stack of 6 layers. The best model parameters are determined based on the model performance on the development set. All the models are trained on 8 NVIDIA P40 GPUs where each is allocated with a batch size of 4,096 tokens. For IWSLT14 De⇒En and IWSLT17 En⇒Fr tasks, we use the SMALL model, where the encoder and decoder are composed of a stack of 2 layers respectively and which is trained on 1 GPU with a batch size of 4,096 tokens.

Model		BASE	ConTrain	RejTrain
Lexical	SeLen	91.35%	91.40%	91.54%
	WC	75.96%	75.98%	76.85%
	Avg.	83.66%	83.69%	84.20%
Syntactic	TeDep	44.58%	44.61%	44.67%
	ToCo	76.89%	76.71%	77.25%
	BShif	72.18%	72.11%	72.20%
	Avg.	64.55%	64.48%	64.71%
Semantic	Tense	87.61%	87.77%	88.04%
	SubN	85.25%	85.18%	85.03%
	ObjN	84.79%	84.67%	84.57%
	SoMo	53.60%	53.30%	53.26%
	CoIn	60.85%	61.58%	61.62%
	Avg.	74.42%	74.50%	74.50%

Table 7: Performance on the linguistic probing tasks of evaluating linguistics embedded in the encoder outputs. "BASE", "ConTrain" and "RejTrain" respectively denote the baseline model, continuous training and rejuvenation training. "Avg." denotes the average accuracy of each category.

A.2 Probing Task

In order to gain linguistic insights into the learned representations when carrying out the rejuvenation method, we conducted 10 probing tasks (Conneau et al., 2018) to evaluate linguistics knowledge embedded in the final encoding representation learned by the model, as shown in Table 7. From the table, we can see that RejTrain can capture more lexical (84.20% vs. 83.66%) and syntactic (64.71% vs. 64.55%) information.

Incorporating a Local Translation Mechanism into Non-autoregressive Translation

Xiang Kong[*], **Zhisong Zhang**[*], **Eduard Hovy**
Language Technologies Institute, Carnegie Mellon University
{xiangk,zhisongz,hovy}@cs.cmu.edu

Abstract

In this work, we introduce a novel local autoregressive translation (LAT) mechanism into non-autoregressive translation (NAT) models so as to capture local dependencies among target outputs. Specifically, for each target decoding position, instead of only one token, we predict a short sequence of tokens in an autoregressive way. We further design an efficient merging algorithm to align and merge the output pieces into one final output sequence. We integrate LAT into the conditional masked language model (CMLM; Ghazvininejad et al., 2019) and similarly adopt iterative decoding. Empirical results on five translation tasks show that compared with CMLM, our method achieves comparable or better performance with fewer decoding iterations, bringing a 2.5x speedup. Further analysis indicates that our method reduces repeated translations and performs better at longer sentences. The code for our model is available at `https://github.com/shawnkx/NAT-with-Local-AT`.

1 Introduction

Traditional neural machine translation (NMT) models (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014; Gehring et al., 2017; Vaswani et al., 2017) commonly make predictions in an incremental token-by-token way, which is called autoregressive translation (AT). Although this strategy can capture the full translation history, it has relatively high decoding latency. To make the decoding more efficient, non-autoregressive translation (NAT) (Gu et al., 2018) is introduced to generate multiple tokens at once instead of one-by-one. However, with the conditional independence property (Gu et al., 2018), NAT models do not directly consider the dependencies among output tokens, which may cause errors of repeated translation and incomplete translation (Wang et al., 2019). There have been various methods in previous work (Stern et al., 2019; Gu et al., 2019; Ma et al., 2018; Wei et al., 2019; Ma et al., 2019; Tu et al., 2020) to mitigate this problem, including iterative decoding (Lee et al., 2018; Ghazvininejad et al., 2019).

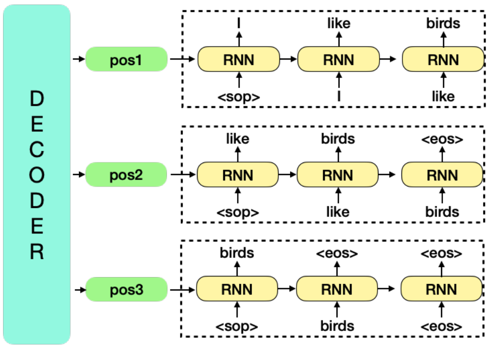

Figure 1: An example of the LAT mechanism. For each decoding position, a short sequence of tokens is generated in an autoregressive way. ⟨sop⟩ is the special start-of-piece symbol. 'pos*' denotes the hidden state from the decoder at that position.

In this work, we introduce a novel mechanism, i.e., local autoregressive translation (LAT), to take local target dependencies into consideration. For a decoding position, instead of generating one token, we predict a short sequence of tokens (which we call a translation piece) for the current and next few positions in an autoregressive way. A simple example is shown in Figure 1.

With this mechanism, there can be overlapping tokens between nearby translation pieces. We take advantage of these redundancies, and apply a simple algorithm to align and merge all these pieces to obtain the full translation output. Specifically, our algorithm builds the output by incrementally aligning and merging adjacent pieces, based on the hypothesis that each local piece is fluent and there are overlapping tokens between adjacent pieces as aligning points. Moreover, the final output se-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1067–1073,
November 16–20, 2020.

quence is dynamically decided through the merging algorithm, which makes the decoding process more flexible.

We integrate our mechanism into the conditional masked language model (CMLM) (Ghazvininejad et al., 2019) and similarly adopt iterative decoding, where tokens with low confidence scores are masked for prediction in more iterations. With evaluations on five translation tasks, i.e., WMT'14 EN↔DE, WMT'16 EN↔RO and IWSLT'14 DE→EN, we show that our method could achieve similar or better performance compared with CMLM and AT models while gaining nearly 2.5 and 7 times speedups, respectively. Furthermore, our method is shown to effectively reduce repeated translations and perform better at longer sentences.

2 CMLM with LAT

2.1 Model

We integrate our LAT mechanism into CMLM, which predicts the full target sequence based on the source and partial target sequence. We adopt a lightweight LSTM-based sequential decoder as the local translator upon the CMLM decoder outputs. For a target position i, the CMLM decoder produces a hidden vector pos_i, based on which the local translator predicts a short sequence of tokens in an autoregressive way, i.e., $t_i^1, t_i^2, ..., t_i^K$. Here K is the number of location translation steps, which is set to 3 in our experiments to avoid affecting the speed much.

2.2 Decoding

During inference, a special token, ⟨sop⟩ (start of piece) is fed into the local translator to generate a short sequence based on the pos_i. After generating the local pieces for all target positions in parallel, we adopt a simple algorithm to merge them into a full output sequence. This merging algorithm is described in detail in Section 3. We also perform iterative decoding following the same Mask-Predict strategy (Ghazvininejad et al., 2019; Devlin et al., 2019). In each iteration, we take the output sequence from the last iteration and mask a subset of tokens with low confidence scores by a special ⟨mask⟩ symbol. Then the masked sequence is fed together with the source sequence to the decoder for the next decoding iteration.

Following Ghazvininejad et al. (2019), a special token LENGTH is added to the encoder, which is utilized to predict the initial target sequence length. Nevertheless, our algorithm can dynamically adjust the final output sequence and we find that our method is not sensitive to the choice of target length as long as it falls in a reasonable range.

2.3 Training

The training procedure is similar to that of Ghazvininejad et al. (2019). Given a pair of source and target sequences S and T, we first sample a masking size from a uniform distribution from [1, N], where N is the target length. Then this size of tokens are randomly picked from the target sequence and replaced with the ⟨mask⟩ symbol. We refer to the set of masked tokens as T_{mask}. Then for each target position, we adopt a teacher-forcing styled training scheme to collect the cross-entropy losses for predicting the corresponding ground-truth local sequences, the size of which is $K = 3$.

Assume that we are at position i, we simply setup the ground-truth local sequence $t_i^1, t_i^2, ..., t_i^K$ as $T_i, T_{i+1}, ..., T_{i+K-1}$, where T_i denotes the i-th token in the full target ground-truth sequence. We include all tokens in our final loss, whether they are in T_{mask} or not, but adopt different weights for the masked tokens that do not appear in the inputs. Therefore, our token prediction loss function is:

$$\mathcal{L} = -\sum_{i=1}^{N}\sum_{j=1}^{K} \mathbb{1}\left\{t_i^j \in T_{mask}\right\} \log(p(t_i^j)) - \sum_{i=1}^{N}\sum_{j=1}^{K} \mathbb{1}\left\{t_i^j \notin T_{mask}\right\} \alpha \log(p(t_i^j))$$

Here, we adopt a weight α for the tokens that are not masked in the target input, which is set as 0.1 so that the model could be trained more on the unseen tokens. Furthermore, we randomly delete certain positions (the number of deletion is randomly sampled from [1, 0.15*N]) from the target inputs to encourage the model to learn insertion-styled operations. The final loss is the addition of the token prediction and the target length prediction loss.

3 Merging Algorithm

In decoding, the model generates local translation pieces for all decoding positions. We adopt a simple algorithm that incrementally builds the output through a piece-by-piece merging process. Our hypothesis is that if the local autoregressive translator is well-trained, then 1) the token sequence inside each piece is fluent and well-translated, 2) there are

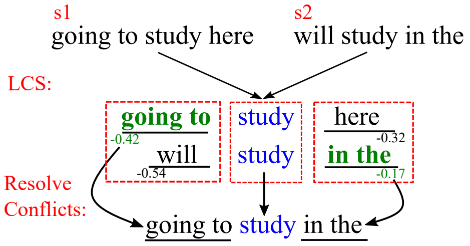

Figure 2: An example of merging two pieces of tokens.

Algorithm 1: Merging two pieces.

```
   Input: Two pieces of tokens: $s1$, $s2$.
   Output: A merged sequence $s'$.
   // Call Longest Common Subsequence
1  MatchedPairs = LCS($s1$, $s2$);
2  if MatchedPairs.size() == 0 then
3      return $s1$+$s2$ ;            // Simple concat
4  else
5      $s'$ = [] ;                   // Initialize
6      $p1$, $p2$ = -1, -1 ;         // Previous idxes
       // Add sentinel indexes.
7      MatchedPairs += [($\infty$, $\infty$)];
8      foreach $i1$, $i2$ in MatchedPairs do
9          $span1$ = $s1$[$p1$+1:$i1$];
10         $span2$ = $s2$[$p2$+1:$i2$];
           // Solve conflicts by scores.
11         if score($span1$) $\geq$ score($span2$) then
12             $s'$ += $span1$;
13         else
14             $s'$ += $span2$;
           // Align the matched ones.
15         if $i1 \neq \infty$ then
16             $s'$ += [align($s1$[$i1$], $s2$[$i2$])];
17         $p1$, $p2$ = $i1$, $i2$;
18     return $s'$;
```

overlaps between nearby pieces, acting as aligning points for merging.

We first illustrate the core operation of merging two consecutive pieces of tokens. Algorithm 1 describes the procedure and Figure 2 provides an example. Given two token pieces $s1$ and $s2$, we first use the Longest Common Subsequence (LCS) algorithm to find matched tokens (Line 1). If there is nothing that can be matched, then we simply do concatenation (Line 3), otherwise we solve the conflicts of the alternative spans by comparing their confidence scores (Line 9-14). Finally we can arrive at the merged output after resolving all conflicted spans.

In the above procedure, we need to specify the score of a span. Through preliminary experiments, we find a simple but effective scheme. From the translation model, each token gets a model score of its log probability. For the score of a span, we average the scores of all the tokens inside. If the span is empty, we utilize a pre-defined value, which is empirically set to $\log 0.25$. For aligned tokens, we choose the highest scores among them for later merging process (Line 16).

With this core merging operation, we apply a left-to-right scan to merge all the pieces in a piece-by-piece fashion. For each merging operation, we only take the last K tokens of $s1$ and the first K tokens of $s2$, while other tokens are directly copied. This ensures that the merging will only be local, to mitigate the risk of wrongly aligned tokens. Here, K is again the local translation step size.

Our merging algorithm can be directly applied at the end of each iteration in the iterative decoding. However, since the output length of the merging algorithm is not always the same as the number of input pieces, we further adopt a length adjustment procedure for intermediate iterations. Briefly speaking, we adjust the output length to the predicted length by adding or deleting certain amounts of special $\langle$mask$\rangle$ symbols. Please refer to the Appendix for more details.

Although our merging algorithm is actually autoregressive, it does not include any neural network computations and thus can run efficiently. In addition to efficiency, our method also makes the decoding more flexible, since the final output is dynamically created through the merging algorithm.

4 Experiments

4.1 Experimental Setup

We evaluate our proposed method on five translation tasks, i.e., WMT'14 EN↔DE, WMT'16 EN↔RO and IWSLT'14 DE→EN. Following previous works (Hinton et al., 2015; Kim and Rush, 2016; Gu et al., 2018; Zhou et al., 2020), we train a vanilla base transformer (Vaswani et al., 2017) on each dataset and use its translations as the training data. The BLEU score (Papineni et al., 2002) is used to evaluate the translation quality. Latency, the average decoding time (ms) per sentence with batch size 1, is employed to measure the inference speed. All models' decoding speed is measured on a single NVIDIA TITAN RTX GPU.

We follow most of the hyperparameters for the CMLM (Ghazvininejad et al., 2019) in the base configuration, i.e., 6 layers for encoder and decoder, 8 attention heads, 512 embedding dimensions and 2048 hidden dimensions. The LAT is an

#	Model	Iterations	WMT'14		WMT'16		IWSLT'14	latency (ms)

LSTM-based neural network of size 512. Finally, we average 5 best checkpoints according to the validation loss as our final model. Please refer to the Appendix for more details of the settings.

4.2 Main results

The main results are shown in Table 1. Compared with CMLM at the same number of decoding iterations (row 2 vs. 3 and row 4 vs. 5), LAT performs much better while keeping similar speed, especially when the iteration number is 1. Note that since our method is not sensitive to predicted length, we only take one length candidate from our length predictor instead of 5 as in CMLM. Furthermore, LAT with 4 iterations could achieve similar or better results than CMLM with 10 iterations (row 5 vs. 6) but have a nearly 2.5x decoding speedup.

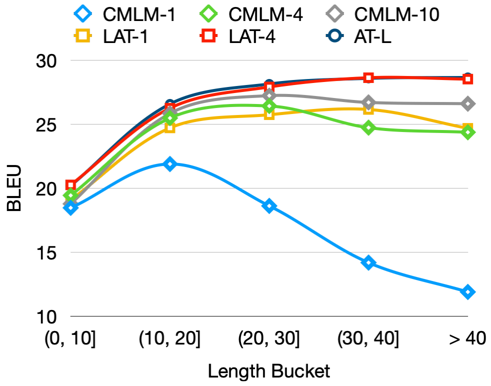

Figure 3: The BLEU scores of various systems with respect to the reference sentence lengths on WMT'14 EN-DE testset.

4.3 Analysis

On local translation step. We also explore the effects of the number of local translation steps (K) on the IWSLT'14 DE-EN dataset. The results are shown in Table 3. Generally, with more local translation steps, there can be certain improvements on BLEU but with an extra cost at inference time.

On repeated translation. We compute the n-gram repeat rate (nrr, what percentage of n-grams are repeated by certain nearby n-grams) of different systems on WMT'14 EN-DE test set and the result is shown in Table 2. The nrr of CMLM with one iteration is much higher than other systems, showing that it suffers from a severe repeated translation problem. On the other hand, LAT can mitigate this problem thanks to the merging algorithm.

On sentence length. We explore how various systems perform on sentences with various lengths. The WMT'14 EN-DE test set is split into 5 length buckets by target length. Figure 3 show that LAT performs better than CMLM on longer sentences, which indicates the effectiveness of our methods at capturing certain target dependencies.

5 Related Work

Gu et al. (2018) begin to explore non-autoregressive translation, the aim of which is to generate sequences in parallel. In order to mitigate multimodality issue, recent work mainly tries to narrow the gap between NAT and AT. Libovickỳ and Helcl (2018) design a NAT model using CTC loss. Lee et al. (2018) uses iteration decoding to refine translation. The conditional masked language model (CMLM) (Ghazvininejad et al., 2019) predicts partial target tokens based on the source text and partially masked target sentence. Ma et al. (2019) employs normalizing flows as the the latent variable to produce sequences. Sun et al. (2019) designs an efficient approximation for CRF for NAT. Besides that, there are some works trying to improving the decoding speed of the autoregressive models. For example, Wang et al. (2018) propose a semi-autoregressive translation model, which adopts locally non-autoregressive, but autoregressive decoding. And works mentioned in Hayashi et al. (2019) use techniques such as knowledge distillation, block-sparse regularization to improve the decoding speed of autoregressive models.

6 Conclusion

In this work, we incorporate a novel local autoregressive translation mechanism (LAT) into non-autoregressive translation, predicting multiple short sequences of tokens in parallel. With a simple and efficient merging algorithm, we integrate LAT into the conditional masked language model (CMLM Ghazvininejad et al., 2019) and similarly adopt iterative decoding. We show that our method could achieve similar results to CMLM with less decoding iterations, which brings a 2.5x speedup. Moreover, analysis shows that LAT can reduce repeated translations and perform better at longer sentences.

Appendices

A Preprocessing

We follow the standard pre-processing procedure in prior works (Vaswani et al., 2017; Lee et al., 2018). All datasets are segmented into subwords through byte pair encoding (BPE) (Sennrich et al., 2016). The BPE code is learnt from the combination of source and target data for WMT datasets. For IWSLT, the bpe code is learned from the source and target data separately. Table 4 lists some details.

Dataset	Vocab. Size	Data size
IWSLT	10k	150k
WMT14 EN↔DE	32k	4.5M
WMT16 EN↔RO	40k	600k

Table 4: Pre-processing details of various translation benchmarks. Vocab. size denotes vocabulary size.

B Optimization

We sample weights from $\mathcal{N}(0, 0.02)$, initialize biases to zero, and set layer normalization parameters to $\beta = 0$, $\gamma = 1$. For regularization, we use 0.3 dropout, 0.01 L2 weight decay, and smoothed cross-entropy loss with $\epsilon = 0.1$. We train batches of 128k tokens using Adam (Kingma and Ba, 2015) with $\beta = (0.9, 0.999)$ and $\epsilon = 10^{-6}$. The learning rate warms up to a peak of 5×10^{-4} within 10,000

Model	Iterations	WMT'14		WMT'16		IWSLT'14
		EN-DE	DE-EN	EN-RO	RO-EN	DE-EN
AT	N	26.13	31.06	34.74	35.76	33.59
CMLM	1	18.47	22.83	26.92	28.77	24.57
LAT		22.14	29.20	32.16	32.07	28.34
CMLM	4	24.73	29.18	33.06	34.31	29.06
LAT		26.03	31.66	33.49	34.77	34.05
CMLM	10	25.25	29.83	33.66	34.65	33.23

Table 5: The comparisons (on BLEU score and decoding latency) of CMLM, LAT and AT models on development sets.

steps, and then decays with the inverse square-root schedule. We train our models for 300k steps with batch size 128k (Ghazvininejad et al., 2019) for WMT datasets. For the IWSLT dataset, we train our models for 50k steps with batch size 32k.

C Model Parameter Size

The averaged size of parameters for all models are shown in Table 6. These three kinds of models have similar number of parameters. LAT models have the most number of parameters due to the LSTM-based local translator.

Model	Parameter size
AT	60M
CMLM	62M
LAT	64M

Table 6: Number of Parameters of different models.

D Validation Performance

The performance of different models on translation tasks' validation sets is reported in the Table 5. We could find the similar trend to the performance on the test set.

E Length Adjustment for Intermediate Iterations

Since our merging algorithm produces the output dynamically, the output length is usually not the same as the number of input pieces. In iterative decoding, we find it helpful to adjust the output sequence's length to the input length in intermediate iterations. This is achieved by adding or deleting the special $\langle mask \rangle$ symbols. Notice that for the final iteration, we do not apply any adjustments and keep the merged output sequence as it is.

For the length adjustment in the intermediate iterations, our goal is to adjust the output length of the merger (L_{out}) to be close to the input target length (L_{in}). If these two lengths are already equal or their relative difference is within a certain range (which is empirically set to 5%), we will do nothing. Otherwise, there can be two cases: 1) when L_{in} is larger than L_{out}, we further insert $L_{in} - L_{out}$ $\langle mask \rangle$ tokens into the sequence; 2) otherwise, we try to delete $L_{out} - L_{in}$ $\langle mask \rangle$ tokens. Notice that the addition or deletion operations happen after the masking procedure for the next iteration.

Here, we describe the addition case in detail. Suppose we need to further insert M masks into the output sequence, we decide the insertion places according to the position gaps. We adopt a simple position scheme for all the tokens. For each original token t_i^j (the j-th token in the i-th piece) in the input translation pieces, we set $i + j$ as its position. For each token in the output sequence after merging, since it can originate from multiple input tokens through aligning, we take the averaged value of all its source input tokens' positions. We calculate the position gap between each pair of nearby unmasked tokens in the output sequence and maintain a priority queue for all these gaps. Then we insert M masks once at a time. For each time, we select the current maximal gap, insert a $\langle mask \rangle$ to that position, and subtract that gap by 1. The case for deletion would be similar but in the opposite direction: select the minimal gap, delete one $\langle mask \rangle$ if there are any, and increase that gap by 1. We will delete nothing if there are no masked tokens in the selected gap.

Self-Paced Learning for Neural Machine Translation

Abstract

Recent studies have proven that the training of neural machine translation (NMT) can be facilitated by mimicking the learning process of humans. Nevertheless, achievements of such kind of curriculum learning rely on the quality of artificial schedule drawn up with the handcrafted features, e.g. sentence length or word rarity. We ameliorate this procedure with a more flexible manner by proposing self-paced learning, where NMT model is allowed to 1) automatically quantify the learning confidence over training examples; and 2) flexibly govern its learning via regulating the loss in each iteration step. Experimental results over multiple translation tasks demonstrate that the proposed model yields better performance than strong baselines and those models trained with human-designed curricula on both translation quality and convergence speed.[1]

1 Introduction

Neural machine translation (NMT) has achieved promising results with the use of various optimization tricks (Hassan et al., 2018; Chen et al., 2018; Xu et al., 2019; Li et al., 2020; Yang et al., 2020). In spite of that, these techniques lead to increased training time and massive hyper-parameters, making the development of a well-performed system expensive (Popel and Bojar, 2018; Ott et al., 2018).

As an alternative mitigation, curriculum learning (CL, Elman, 1993; Bengio et al., 2009) has shown its effectiveness on speeding up the convergence and stabilizing the NMT model training (Zhang et al., 2018; Platanios et al., 2019). CL teaches NMT model from easy examples to complex ones rather than equally considering all samples, where the keys lie in the definition of "difficulty" and the strategy of curricula design (Krueger and Dayan, 2009; Kocmi and Bojar, 2017). Existing studies artificially determine data difficulty according to prior linguistic knowledge such as sentence length (SL) and word rarity (WR) (Platanios et al., 2019; Zhang et al., 2019; Zhou et al., 2020), and manually tune the learning schedule (Liu et al., 2020; Fomicheva et al., 2020). However, neither there exists a clear distinction between easy and hard examples (Kumar et al., 2010), nor these human intuitions exactly conform to effective model training (Zhang et al., 2018).

Instead, we resolve this problem by introducing self-paced learning (Kumar et al., 2010), where the emphasis of learning can be dynamically determined by model itself rather than human intuitions. Specifically, our model measures the level of confidence on each training example (Gal and Ghahramani, 2016; Xiao and Wang, 2019), where an easy sample is actually the one of high confidence by the current trained model. Then, the confidence score is served as a factor to weight the loss of its corresponding example. In this way, the training process can be dynamically guided by model itself, refraining from human predefined patterns.

We evaluate our proposed method on IWSLT15 En⇒Vi, WMT14 En⇒De, as well as WMT17 Zh⇒En translation tasks. Experimental results reveal that our approach consistently yields better translation quality and faster convergence speed than TRANSFORMER (Vaswani et al., 2017) baseline and recent models that exploit CL (Platanios et al., 2019). Quantitative analyses further confirm that the intuitive curriculum schedule for a human does not fully cope with that for model learning.

2 Self-Paced Learning for NMT

As mentioned above, translation difficulty for humans may not match that for neural networks. Even

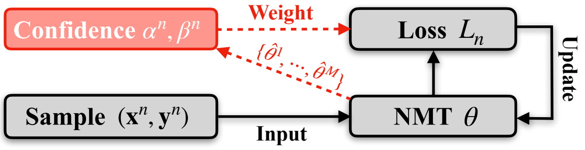

Figure 1: Illustration of the proposed self-paced learning. The black components compose the vanilla NMT training process, while our model (red) assigns confidence scores for each input to weight its loss.

if these artificial supervisions are feasible, the long sequences or rare tokens are not always "difficult" as the model competence increases. From this view, we design a self-paced learning algorithm that offers NMT the abilities to 1) estimate the confidences over samples appropriated for the current training state; and 2) automatically control the focus of learning through regulating the training loss, as illustrated in Fig. 1.

2.1 Confidence Estimation

We propose to determine the learning emphasis according to the model confidence (Ueffing and Ney, 2005; Soricut and Echihabi, 2010), which quantifies whether the current model is confident or hesitant on translating the training samples. The model confidence can be quantified by Bayesian neural networks (Buntine and Weigend, 1991; Neal, 1996), which place distributions over the weights of network. For efficiency, we adopt widely used Monte Carlo dropout sampling (Gal and Ghahramani, 2016) to approximate Bayesian inference.

Given current NMT model parameterized by θ and a mini-batch consisting of N sentence pairs $\{(\mathbf{x}^1, \mathbf{y}^1), \cdots, (\mathbf{x}^N, \mathbf{y}^N)\}$, we first perform M passes through the network, where the m-th pass $\hat{\theta}^m$ randomly deactivates part of neurons. Thus, each example yields M sets of conditional probabilities. The lower variance of translation probabilities reflects higher confidence that the model has with respect to the instance (Dong et al., 2018; Wang et al., 2019). We propose multi-granularity strategies for confidence estimation:

Sentence-Level Confidence (SLC) A natural choice for measuring the confidence of sentence pair $(\mathbf{x}^n, \mathbf{y}^n)$ is to assess the variance of translation probability $\text{Var}\{P(\mathbf{y}^n|\mathbf{x}^n, \hat{\theta}^m)\}_{m=1}^{M}$. Accordingly, confidence score $\hat{\alpha}^n$ can be formally expressed as:

$$\hat{\alpha}^n = (1 - \text{Var}\{P(\mathbf{y}^n|\mathbf{x}^n, \hat{\theta}^m)\}_{m=1}^{M})^k, \quad (1)$$

Here, we assign a hyper-parameter k to scale the gap between scores of confident and unconfident examples. The larger absolute value of k represents higher discriminative manner and vice versa. In some extreme cases, all the confidence scores in a mini-batch may tend to small or big value, e.g. the estimation at the early stage of the training.[2] In order to stabilize the training process and maintain the same loss scale as conventional model, we normalize the confidence scores by $softmax$:

$$\alpha^n = \frac{\exp(\hat{\alpha}^n)}{\sum_{t=1}^{N} \exp(\hat{\alpha}^t)}. \quad (2)$$

Token-Level Confidence (TLC) Intuitively, confidence scores can be evaluated at more fine-grained level. We extend our model into token-level so as to estimate the confidence on translating each element in target sentence $\mathbf{y}^n$. The confidence $\hat{\beta}_j^n$ of the j-th token $\mathbf{y}_j^n$ is:

$$\hat{\beta}_j^n = (1 - \text{Var}\{P(\mathbf{y}_j^n|\mathbf{x}^n, \mathbf{y}_{<j}^n, \hat{\theta}^m)\}_{m=1}^{M})^k, \quad (3)$$

where $\text{Var}\{P(\mathbf{y}_j^n|\mathbf{x}^n, \mathbf{y}_{<j}^n, \hat{\theta}^m)$ denotes the variance of the translation probability with respect to $\mathbf{y}_j^n$. Similar to sentence-level strategy, the confidence scores of tokens are normalized as:

$$\beta_j^n = \frac{\exp(\hat{\beta}_j^n)}{\sum_{t=1}^{J} \exp(\hat{\beta}_t^n)}, \quad (4)$$

where J indicates the length of target sentence $\mathbf{y}^n$.

2.2 Training Strategy

A larger confidence score indicates that the current model is confident on the corresponding example. Therefore, the model should learn more from the predicted loss. In order to govern the learning schedule automatically, we leverage the confidence scores as factors to weight the loss, thus controlling the update at each time step. To this end, the sentence log-likelihood can be defined as:

$$\mathcal{L}_n = \sum_{j=1}^{J} \beta_j^n \log P(\mathbf{y}_j^n|\mathbf{x}^n, \mathbf{y}_{<j}^n, \theta), \quad (5)$$

Finally, the loss of a batch is calculated as:

$$\mathcal{L} = \sum_{n=1}^{N} \alpha^n \mathcal{L}_n. \quad (6)$$

---

[2] When implementing the computation of SLC&TLC scores, we use negative log-likelihood values instead of conventional probabilities. Besides, we use the maximum value to refactorize them within $[0, 1]$ by division.

At the early stage of the study, the model learns more from confident samples, thus accelerating the training. The hesitant samples are not completely ignorant, but relatively few can be learned. As training proceeds, the loss of high-confidence samples gradually reduce, and the model will pay more attention on "complex" samples with low prediction accuracy, thus raising their confidence. In this way, the loss of different samples are dynamically revised, eventually balancing the learning.

Contrast to related studies (Zhang et al., 2018, 2019; Kumar et al., 2019; Platanios et al., 2019) which adopt CL into NMT with predefined patterns, the superiority of our model lies in its flexibility on both learning emphasis and strategy. Several researchers may concern about the processing speed when integrating Monte Carlo Dropout sampling. Contrary to prior studies which estimate confidence during inference (Dong et al., 2018; Wang et al., 2019), we only perform forward propagation $M = 5$ times in training time, which avoids the auto-regressive decoding for efficiency.

3 Experiments

We evaluate our method upon TRANSFORMER-*Base*/*Big* model (Vaswani et al., 2017) and conduct experiments on IWSLT15 English-to-Vietnamese (En⇒Vi), WMT14 English-to-German (En⇒De) and WMT17 Chinese-to-English (Zh⇒En) tasks. For fair comparison, we use the same experimental setting as Platanios et al. (2019) for En⇒Vi and follow the common configuration in Vaswani et al. (2017) for En⇒De and Zh⇒En.

During training, we apply 0.3 dropout ratio and batch size as 4,096 for En⇒Vi task, and experiments are conducted upon one Nvidia GTX1080Ti GPU device. For En⇒De and Zh⇒En task, we use 32,768 as batch size, and use four Nvidia V100 GPU devices for experiments. We use beam size as 4, 5, 10, and decoding alpha as 1.5, 0.6, 1.35 for each task, respectively (Vaswani et al., 2017). We compare our models with two baselines:

- *Base* and *Big* represent the vanilla TRANSFORMER (Vaswani et al., 2017) models.

- +CL is the recent NMT model that exploits CL (Platanios et al., 2019). Difficulty of each training sample is estimated according to its sentence length (SL) or averaged word rarity (WR). The curriculum schedule depends on the number of training step.

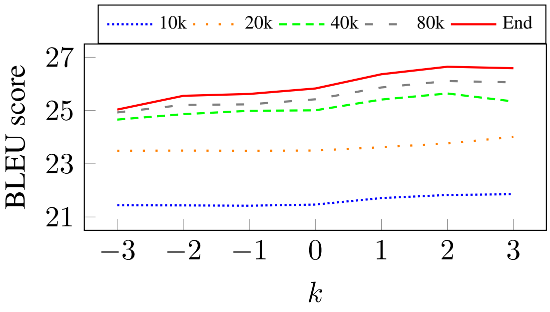

Figure 2: Affects of k on best performance after certain training steps upon En⇒De dev set. At the early stage of the training, a higher k yields better translation quality, denoting a faster convergence speed.

3.1 Confidence/Unconfidence Balancing

As mentioned in Sec. 2.1, we assign k to balance the extent of discrimination between confident and unconfident examples. We first conduct experiments on En⇒De to evaluate the impact of k. Fig. 2 shows that, the larger k, the faster convergence speed. However, the final performance slightly decreases when $k > 2$. We believe that the overlarge k leads to overfit on confident samples and ignore initial hesitated samples. This demonstrates that an appropriate balance on the discriminative manner contributes to both convergence acceleration and final performance.

Besides, when k is negative, models will pay more attention to unconfident examples. This circumstance is identical to reverse-CL (Zhang et al., 2019), where training is advised to offer examples in a hard-to-easy order. Our results confirm that unconfidence-first strategy ($k < 0$) performs worse than baseline, which is similar with previous findings on CL (Zhang et al., 2018). We attribute this to the fact that the heuristic design forces NMT model to unceasingly learn more from unconfident examples, and finally leads to the strait of catastrophic forgetting (Goodfellow et al., 2014). Therefore, we set $k = 2$ for subsequent experiments.

3.2 Main Results

As shown in Tab. 1, our baseline models outperform the reported results (Vaswani et al., 2017; Platanios et al., 2019) on the same data, making the evaluation convincing. The proposed self-paced learning method (SPL) achieves better results than existing CL approaches that artificially determine the difficulty (SL or WR), demonstrating the effectiveness of our method. Specifically, removing either SLC or TLC decreases the translation quality,

Model	IWSLT15 En⇒Vi	WMT14 En⇒De	WMT17 Zh⇒En	Acc.
TRANSFORMER-*Base*	30.05 ± 0.14	27.90 ± 0.24	24.11 ± 0.10	-
+CL-SL	29.91 ± 0.13	27.99 ± 0.22	24.10 ± 0.08	1.02
+CL-WR	30.05 ± 0.17	28.02 ± 0.24	24.25 ± 0.09	1.06
SPL	**31.21 ± 0.15**↑	**28.87 ± 0.19**↑	**24.86 ± 0.12**↑	1.46
w/o TLC	30.91 ± 0.17↑	28.51 ± 0.21↑	24.62 ± 0.12↑	1.17
w/o SLC	31.14 ± 0.14↑	28.73 ± 0.24↑	24.79 ± 0.10↑	1.28

SPL	**31.45 ± 0.15**↑	**29.68 ± 0.25**↑	**25.26 ± 0.15**↑	1.21

Table 1: Overall experimental results of all approaches upon three translation tasks. Each cell contains the mean value and standard variance of BLEU scores derived from 5 independent experimental runs. "SPL": proposed self-paced learning model. "Acc.": Acceleration ratio of training time required to achieve the best performance of baseline. "↑": the improvement is significant by contrast to TRANSFORMER-*Base/Big* baseline model ($p < 0.01$).

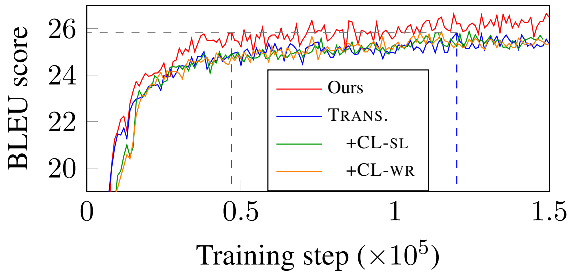

Figure 3: Learning curves of models on validation set. Our model achieves reductions in iterations of 2.43x.

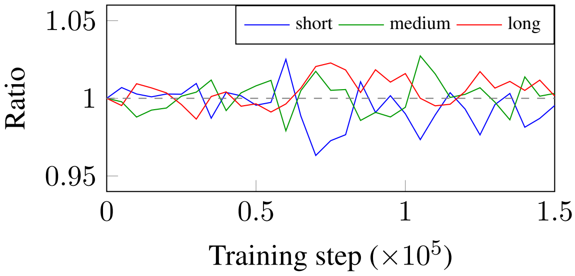

Figure 4: The ratios between averaged SLC scores gained by our model and baseline. Obviously, the model confidence on training samples with different lengths change constantly during model training.

indicating that two confidence estimations are complementary to each other. TLC outperforms its SLC counterpart, which confirms that more fine-grained information benefits to the training. Moreover, our method consistently improves the translation quality with around 1 BLEU score across all involved tasks and multiple model settings. This shows the universality and effectiveness of SPL on different scales of training data and model sizes.

4 Analysis

In this section, we further investigate how the proposed method exactly affects the NMT model training by conducting experimental analyses on 1) convergence speed, 2) self-paced adjustment and 3) sequential bucketing.

4.1 Convergence Speed

As aforementioned, one motivation of exploiting self-paced learning is to accelerate the convergence of model training. We visualize the learning curve of examined models on En⇒De dev set in Fig. 3. As seen, the vanilla NMT model reaches its convergence at step 120k, while the proposed one gets the same performance at step 47k, yielding 2.43 times faster. Although Monte Carlo Dropout sampling requires extra time to forward-pass the neural network at each iteration step, our method can still reach comparable result on dev set with shorter training time, achieving 1.46x faster training speed (column "Acc." in Tab. 1). Besides, we also observe that two methods proposed by Platanios et al. (2019) reveal a comparable tendency with baseline. We explain this with the view that Platanios et al. (2019) examined these approaches with a batch of 5,120 tokens, much smaller than that used in our experiments (32,768). Since larger batch size can considerably facilitate the training (Popel and Bojar, 2018; Ott et al., 2018), the benefits of their models may be marginal with this change.

4.2 Self-Paced Adjustment

It is interesting to investigate how our model adjusts its learning. We randomly extract 300 En⇒De training examples, which then be categorized into 3 subsets according to their sentence lengths. Fig. 4 shows the ratios of averaged SLC scores between our method and vanilla NMT system at different checkpoints. As seen, at the beginning of the training, the ratio of confidence score with respect to short sentences is greater than 1, indicating our model pays more attention to shorter examples than baseline. This is identical with human intuition that the short sentences seem easier and should be learned earlier (Zhang et al., 2019; Zhao et al., 2020). However, as training continues, our model focuses on short and long sentences simultaneously and hesitates on sentences with medium length, which goes against human intuition and indicates that long sentences may easier than its medium counterparts for current model. From then on, the curves fluctuate and interlace continuously, revealing that SPL automatically regulates its learning emphasis. These phenomena show the flexibility of our model, and confirm that predefined data difficulty and learning schedule is insufficient to fully match the model learning.

4.3 Sequential Bucketing

Conventional model training sorts examples with similar lengths into buckets to keep efficiency. This may introduce bias when estimating confidence scores, because longer sequence may gain far less attention due to the productive multiplication of probabilities for SLC estimation. Generally, larger window size for bucketing increases the diversity of length within each batch, but reduce the efficiency of training due to extra padding tokens.

To investigate whether the diversity of sequential lengths within each batch may introduce bias to SLC score computation, we conduct a series of experiments with different settings of sequential bucketing. As shown in Fig.5, we explore the effect of this on En⇒De task, revealing that both baseline and our approach can gain improvement from larger bucket range. Nevertheless, the performance of baseline model decreases along with lower diversity of sequential lengths, whereas that of our model does not diminish. Our model gives better performance with smaller window size compared to baseline. Here we can conclude, that the performance of TRANSFORMER baseline model is bothered by close sequence lengths within each batch, whereas our model shows its flexibility of adjusting its learning to avoid such effect.

For fair comparison as well as keeping the training efficiency, we follow the default setting from Vaswani et al. (2017) by determining 20 as the number of buckets across all experiments.

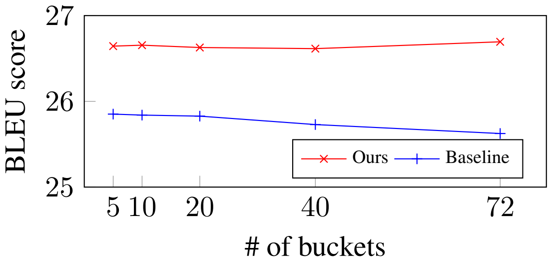

Figure 5: Performance upon WMT14 En⇒De dev set with different bucketing strategy. With window size for sequence bucketing being smaller, the number of buckets accordingly increases, and our model can maintain its performance whereas baseline drops.

5 Conclusion

In this paper, we propose a novel self-paced learning model for NMT in which the learning schedule is determined by model itself rather than being intuitively predefined by humans. Experimental results on three translation tasks verify the universal effectiveness of our approach. Quantitative analyses confirm that exploiting self-paced strategy presents a more flexible way to facilitate the model convergence than its CL counterparts. It is interesting to combine with other techniques (Li et al., 2018; Hao et al., 2019) to further improve NMT. Besides, as this idea is not limited to machine translation, it is also interesting to validate our model in other NLP tasks, such as low-resource NMT model training (Lample et al., 2018; Wan et al., 2020) and neural architecture search (Guo et al., 2020).

Long-Short Term Masking Transformer: A Simple but Effective Baseline for Document-level Neural Machine Translation

Pei Zhang, Boxing Chen, Niyu Ge, Kai Fan[*]
Alibaba Group Inc.
{xiaoyi.zp,boxing.cbx,niyu.ge,k.fan}@alibaba-inc.com

Abstract

Many document-level neural machine translation (NMT) systems have explored the utility of context-aware architecture, usually requiring an increasing number of parameters and computational complexity. However, few attention is paid to the baseline model. In this paper, we research extensively the pros and cons of the standard transformer in document-level translation, and find that the auto-regressive property can simultaneously bring both the advantage of the consistency and the disadvantage of error accumulation. Therefore, we propose a surprisingly simple long-short term masking self-attention on top of the standard transformer to both effectively capture the long-range dependence and reduce the propagation of errors. We examine our approach on the two publicly available document-level datasets. We can achieve a strong result in BLEU and capture discourse phenomena.

1 Introduction

Recent advances in deep learning have led to significant improvement of Neural Machine Translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015; Vaswani et al., 2017). Particularly, the performance on the sentence-level translation of both low- and high- resource language pairs is dramatically improved (Kudugunta et al., 2019; Lample et al., 2018; Lample and Conneau, 2019). However, when translating text with long-range dependencies, such as in conversations or documents, the original mode of translating one sentence at a time ignores the discourse phenomena (Voita et al., 2019a,b), introducing undesirable behaviors such as inconsistent pronouns across different translated sentences.

Document-level NMT, as a more realistic translation task in these scenarios, has been systematically investigated in the machine translation community. Most literatures focused on looking back a fixed number of previous source or target sentences as the document-level context (Tu et al., 2018; Voita et al., 2018; Zhang et al., 2018; Miculicich et al., 2018; Voita et al., 2019a,b). Some latest works innovatively attempted to either get the most out of the entire document context or dynamically select the suitable context (Maruf and Haffari, 2018; Yang et al., 2019a; Maruf et al., 2019; Jiang et al., 2019). Because of the scarcity of document training data, the benefit gained from such an approach, as reflected in BLEU, is usually limited. We therefore elect to pay attention to the context in the previous n sentences only where n is a small number and usually does not cover the entire document.

Almost all of the latest studies chose the standard transformer model as their baseline which translates each sentence in the document with the model trained on the sentence-level data. The cohesion and consistency are in general poor. A more reasonable baseline is to train the transformer with the context prepended, and this modification could be simply implemented via data preprocessing. Bawden et al. (2018) conducted a detailed analysis of RNN-based NMT models on the topic of whether or not to include the extended context. Consistency and precision is often viewed as a trade-off of each other. We conduct a detailed analysis of the effect of document context on consistency in transformer architecture accepting multi-sentence input.

When it comes to leveraging the contextual information, the common approach is to model the interaction between the sentence and its context with specially designed attention modules (Kim et al., 2019). Such works tend to include more than one encoder or decoder, with a substantial number of parameters and additional computations. In our work, we reduce the contextual and regular attention modules into one single encoder and

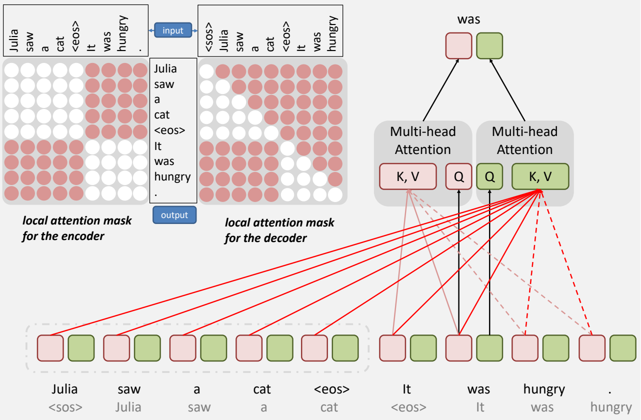

Figure 1: Illustration of the Long-Short Term Masking Self-Attention. Green nodes: global self-attention, which is the same as the standard self-attention. Pink nodes: local self-attention, which does not have access to the information from the document context. The red dash lines is removed in the decoder attention.

decoder. Our idea is motivated by the one transformer decoder with the two-stream self-attention (Yang et al., 2019b). In particular, we maintain two different sets of hidden states and employ two different masking matrices to capture the long and short term dependencies.

The contributions of this paper are threefold: i) we extensively research the performance of the standard transformer in the setting of multi-sentence input and output; ii) we propose a simple but effective modification to adapting the transformer for document NMT with the aim of ameliorating the effect of error accumulation; iii) our experiments demonstrate that even the simple baseline can achieve comparable results.

2 The Proposed Approach

The standard transformer NMT follows the typical encoder-decoder architecture with using stacked self-attention, pointwise fully connected layers, and the encoder-decoder attention layers. The self-attention in the decoder allows only those positions from the left up to the current one to be attended to, preventing information flow to the right beyond the current target and preserving the auto-regressive property. The illegal connections will be masked out by setting as $-\infty$ before the softmax operation. The attention probability can be succinctly written in a unified formulation.

$$A = \textbf{Softmax}\left(\frac{QK^\top}{\sqrt{d/h}} + M\right) \tag{1}$$

where the matrices Q, K represent queries and keys in attention module (Vaswani et al., 2017), and M is the masking matrix. For the encoder self-attention and the encoder-decoder attention, $M = \mathbf{0}$. For the decoder self-attention, M is an upper triangular matrix with zero on the diagonal and non-zero ($-\infty \approx -10^9$) everywhere else.

2.1 Long-Short Term Masking Transformer

The basic setup in this work is multi-sentence input and output, denoted as k-to-k model. In other words, both the encoder and decoder need to consume k sentences during training and inference. Therefore, in our modified transformer, the regular self-attention is substituted by the long-short term masking self-attention (illustrated in Figure 1). While the idea of most context-aware model is to introduce another isolated attention module, we propose to maintain two stream attentions via the local and global representations, but the parameters to calculate queries, keys and values are shared.

The global self-attention, simply following the calculation in Eq (1), serves a similar role to the standard hidden states in transformer. The keys and values can broadly look around from the first token to the last one, and the global hidden state of the next layer will summarize the information of both the context and current sentence. The query vector directly comes from the global hidden states of the previous layer via a fully connect layer.

The local self-attention only accesses the information of the current sentence, where the contextual information from the previous sentence(s) is blocked when computing the keys and values. Similar to the masking strategy of the transformer decoder, the implementation of the local self-attention is to mask out the tokens of the context via $-\infty$ inside the scaled dot-product operation. Figure 1 depicts the masking matrices of the local self-attention for the encoder and decoder respectively. They are both diagonal block matrices, where each block represents the local self-attention of current sentence and the blank and maroon dots denote value 0 and $-\infty$. When calculating attention weights, we only need to replace the M in Eq (1) with the block masking matrices.

For the two sets of hidden representations in the final layer, we can either aggregate them with element-wise operation (such as summation or concatenation) or directly use global states to predict the distribution of target language model. In our work, we adopt the concatenation, and subse-

quently transform them via a fully connected layer to reduce dimensionality.

3 Experiments

Experimental Setup

We carry out experiments with the Chinese-English IWSLT TED talks dataset[1] and English-Russian open-subtitle dataset[2]. The widely used Zh-En IWSLT dataset contains around 200K training sentence pairs divided into 1713 documents. As is the convention, dev2010 and tst2010-2013 are used for validation and testing respectively. The En-Ru subtitle dataset contains around 1.5M conversations, where each conversation includes exactly 4 sentences. Two randomly selected subsets of 10,000 instances from movies not included in the training are used for development and test[3].

The BPE tokenization is separately learnt with 32K operations for each language in the dataset. The resulting source / target vocabulary sizes for En-Zh and En-Ru datasets are 10296 / 16018 and 12273 / 22642, respectively. The token-level batch sizes are 8192 and 16384 for training the Zh-En and En-Ru datasets on two and four P-100 GPUs.

The model hyper-parameters and the optimizer of standard transformer baseline follow the base setting in (Vaswani et al., 2017). We set the layers in encoder and decoder to 6, and the attention heads to 8. The dimensionality of input and output is 512. In addition, we add a feed-forward layer before the decoder output layer, with dimensionality 1024, to combine the local and global stream. We use the Adam optimizer with $\beta 1$ = 0.9, $\beta 2$ = 0.98 and ϵ = 10^{-9}, with 16000 warm-up steps and scale of 4. The batch size for each GPU is 4000.

BLEU score is calculated with the script `mteval-v13a.pl` in Moses[4]. All reported values are evaluated on the test set with the best checkpoint on the development set.

3.1 Evaluation on BLEU

We first conduct a detailed analysis on the k-to-k translation model with respect to the IWSLT Zh-En dataset. In this scenario, the k source and target sentences are concatenated as the input and output to train the transformer. During inference, for every consecutive k source sentences, the model produces k target sentences. To translate a test set in a $k-to-k$ model, we keep a sliding window of size k. Each sentence is translated k times (excpet for the first $k-1$ sentences), each time as a j^{th} ($j \leq k$) sentence. For example, in a 4-to-4 model, sentence 5 is translated 4 times – the 1^{st} time as the last sentence in the chunk s_2, s_3, s_4, s_5, the 2^{nd} time as the 3^{rd} sentence in the chunk s_3, s_4, s_5, s_6, and so on. We thus can assemble different versions of the final translated test set where each sentence is translated as the j^{th} sentence ($j \leq k$) in the translation process. Each of these final documents is evaluated separately. The results are illustrated in Figure 2.

We can make two inferences from the results. First, with the Standard transformer, the 1^{st} sentence BLEU always the highest (Figure 2(a)). This is likely the results of error propagation to subsequent sentences from the auto-regressive property mentioned above. Second, larger k, i.e. more contextual information will not necessarily result in better BLEU score. In this case, $k = 2$ or 3 is better than $k = 4$. We hypothesize that training with longer sentences requiring learning longer range dependencies is fundamentally difficult, especially for such a small dataset.

When we compare the results of our model with the standard transformer, we have two other findings. First, the BLEU scores of our k-to-k model outperform those of the standard transformer, and for the j-th sentence BLEU, the score does not decline as much as in the standard transformer.

Table 2: En-Ru: The comparison on the accuracy of four consistency metrics. **i)** multi-bleu are as reported in the original paper. We opt for mteval-v13a because it does not depend on tokenization. **ii)** Beam size won't affect the values of consistency metrics. **iii)** Concat Baseline means standard transformer with 4-to-4.

We believe that our long-short term masking self-attention can, to some extent, relieve the effect of error accumulation. Second, when document information is used (i.e., $k > 1$), decoding each sentence as the last sentence (ie. using all previous context) achieves higher BLEU scores than decoding each sentence individually in the standard transformer. We pay more attention to the last sentence because presumably it has the richest contextual information; this is also the setting for the results in the next section.

Two qualitative examples are shown in Table 3 (more examples can see in the supplementary materials). In the first case, compared to Sys0 and Sys1, Sys2 is more consistent in the segments "Before I die" and "I want to" of three sentences. In the second case, the translation of "boat" in Sys1 or Sys0 is either omitted or inconsistent in the second sentence, while Sys2 performs better in consistency.

3.2 Evaluation on Consistency

The publicly available open-subtitle En-Ru dataset has a special test data to evaluate consistency of document-level translation systems. The details of the data can be found in Voita et al. (2019b). The context of the training and test data contains exactly 3 sentences, so we mainly adopt a 4-to-4 model in our experiments and each sentence is translated as the last sentence in a chunk of 4 sentences. In this section, we follow previous works to focus on the accuracy of Deixis, Lexical cohesion, Verb phrase ellipsis and Ellipsis (inflection) [5].

In Table 2, we summarize the results of BLEU as well as consistency performance. s-hier-to-2.tied (Bawden et al., 2018) is an RNN-based NMT, so its performance is relatively worse than the other transformer-based models. In contrast, our approach can achieve better performance with respect to both BLEU and consistency, except for lexical cohesion. Especially the accuracy of lexical cohesion of Partial Copy (Jean et al., 2019) exceeds ours by a large margin. Jean et al. (2019) filled the missing context with partial copy strategy, since the repetition can naturally enhance the lexical cohesion. Therefore, when we also apply the partial copy trick to our model, the lexical cohesion can boost by 27% but the BLEU is sacrificed. The Lexical Cohesion of CADec (Voita et al., 2019b)

---

[5] See a short introduction in the supplementary materials.

is a bit higher than our approach without partial copy. Considering that CADec is almost double-sized of our standard transformer and complicated architecture with the backbone of the deliberation networks (Xia et al., 2017), the gain over baseline is much higher cost than ours. In summary, our model can achieve a strong result in both BLEU and consistency with few extra model parameters.

4 Discussions and Conclusions

In this work, we present a simple but effective variation with the long-short term masking strategy, and we performed comparative studies with the k-to-k translation model of the standard transformer. Just as the big, complex neural network architectures with great many parameters has its power, small but efficient modification like ours to the classical transformer has its unique appeals. Other examples of simple but impactful ideas are data augmentation and the round-trip back-translation (Voita et al., 2019a), to name just a few. Big or small, complex or simple, each has its distinct advantages. We're encouraged by our findings that in tandem with the great machinery that could bring powerful results, simplistic approaches could be just as efficacious.

A Appendix

A.1 Evaluation Metrics of Consistency

BLEU is a commonly used metric to evaluate the precision-based quality of the translation in terms of n-gram, but it is not fit to evaluate discourse phenomena, because n-gram precision does not specifically reflect the cohesion and consistency in the long-range dependencies. **Deixis** addresses the error related to personal pronouns, specifically gender marks and informal/formal distinction. **Lexical cohesion** is refers to the consistency of a word or phrase when it occurs multiple times. **Ellipsis** is the omission of words that are understood from the context and it sometimes involves replacement of generic term for a specific term (such as 'did' for 'saw' in English). Since the target language is Russian, we care about both the verb and inflection.

A.2 Code in TensorFlow

We present the code snippet for generating local masking matrix for transformer encoder. The matrix for transformer decoder is simply add the above encoder matrix to the regular decoder self-attention masking matrix.

```
def generate_masking(inputs, sentence_sep_id):
    """Generate Long Short Term Masking
    Args:
        inputs: a dense vector [batch, length] of source or target word ids
        sentence_sep_id: the id of the sentence separation token
    """
    shape = tf.shape(inputs)
    length = shape[1]
    sentence_sep_id_matrix = sentence_sep_id * tf.ones(shape, dtype=inputs.dtype)
    sentence_end = tf.cast(tf.equal(inputs, sentence_sep_id), tf.float32)
    sentence_end_mask = tf.cumsum(sentence_end, axis = -1)
    sentence_end_mask_expand_row = tf.expand_dims(sentence_end_mask, -1)
    sentence_end_mask_expand_row = tf.tile(sentence_end_mask_expand_row, [1, 1, length])
    sentence_end_mask_expand_column = tf.expand_dims(sentence_end_mask, -2)
    sentence_end_mask_expand_column = tf.tile(sentence_end_mask_expand_column, [1, length, 1])
    mask = tf.cast(tf.equal(sentence_end_mask_expand_row, sentence_end_mask_expand_column), tf.float32)
    mask = -1e9 * (1.0 - mask)
    mask = tf.reshape(mask, [-1, 1, length, length])

    return mask
```

A.3 More Examples

We randomly selected three translation examples and illustrated in Table 3. For Example 1, the proposed system learnt "And" at the beginning of the translation, which is a side effect of document-level training. For Example 2, whether using "love" or "love to" is consistency in the proposed system and 1-to-1 baseline transformer. It seems that 1-to-1 baseline can approximately translate "极" to "radical", which does not even appear in the reference. I personally think "extremely" is a better translation. For Example 3, the reference seems not consistency in "how are we" and "how do we", but our proposed system prefers to keep in consistency using "how do we".

Abstract

Despite the improvement of translation quality, neural machine translation (NMT) often suffers from the lack of diversity in its generation. In this paper, we propose to generate diverse translations by deriving a large number of possible models with Bayesian modelling and sampling models from them for inference. The possible models are obtained by applying concrete dropout to the NMT model and each of them has specific confidence for its prediction, which corresponds to a posterior model distribution under specific training data in the principle of Bayesian modeling. With variational inference, the posterior model distribution can be approximated with a variational distribution, from which the final models for inference are sampled. We conducted experiments on Chinese-English and English-German translation tasks and the results shows that our method makes a better trade-off between diversity and accuracy.

1 Introduction

In the past several years, neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Gehring et al., 2017; Vaswani et al., 2017; Zhang et al., 2019) based on the end-to-end model has achieved impressive progress in improving the accuracy of translation. Despite its remarkable success, NMT still faces problems in diversity. In natural language, due to lexical, syntactic and synonymous factors, there are usually multiple proper translations for a sentence. However, existing NMT models mostly implement one-to-one mapping between natural languages, that is, one source language sentence corresponds to one target language sentence. Although beam search, a widely used decoding algorithm, can generate a group of translations, its search space is too narrow to extract diverse translations.

There are some researches working at enhancing translation diversity in recent years. Li et al. (2016) and Vijayakumar et al. (2016) proposed to add regularization terms to the beam search algorithm so that it can possess greater diversity. He et al. (2018) and Shen et al. (2019) introduced latent variables into the NMT model, thus the model can generate diverse outputs using different latent variables. Moreover, Sun et al. (2019) proposed to combine the structural characteristics of Transformer and use the different weights between each head in the multi-head attention mechanism to obtain diverse results. In spite of improvement in balancing accuracy and diversity, these methods do not represent the diversity in the NMT model directly.

In this paper, we take a different approach to generate diverse translation by explicitly maintaining different models based on the principle of Bayesian Neural Networks (BNNs). These models are derived by applying concrete dropout (Gal et al., 2017) to the original NMT model and each of them is given a probability to show its confidence in generation. According to Bayesian theorem, the probabilities over all the possible models under a specific training dataset forms a posterior model distribution which should be involved at inference. To make the posterior model distribution obtainable at inference, we further employ variational inference (Hinton and Van Camp, 1993; Neal, 1995; Graves, 2011; Blundell et al., 2015) to infer a variational distribution to approximate it, then at inference we can sample a specific model based on the variational distribution for generation.

We conducted experiments on the NIST Chinese-English and the WMT'14 English-German translation tasks and compared our method with different strong baseline approaches. The experiment results show that our method can get a good trade-off in translation diversity and accuracy with little train-

ing cost.

Our contributions in this paper are as follows:

- We introduce Bayesian neural networks with variational inference to NMT tasks to explicitly maintain different models for diverse generation.

- We apply concrete dropout to the NMT model to derive the possible models which only demands a small cost in computation.

2 Background

Assume a source sentence with n words $\boldsymbol{x} = x_1, x_2, ..., x_n$, and its corresponding target sentence with m words $\boldsymbol{y} = y_1, y_2, ..., y_m$, NMT models the probability of generating $\boldsymbol{y}$ with $\boldsymbol{x}$ as the input. Based on the encoder-decoder framework, NMT model Θ encodes source sentence into hidden states by its encoder, and uses its decoder to find the probability of t-th word $\boldsymbol{y}_t$, which depends on the hidden states and the first $t-1$ words of target sentence $\boldsymbol{y}$. The translation probability from sentence $\boldsymbol{x}$ and $\boldsymbol{y}$ can be expressed as:

$$P(\boldsymbol{y}|\boldsymbol{x}) = \prod_{t=1}^{m} P(y_t|y_{<t}, \boldsymbol{x}; \Theta) \quad (1)$$

Given a training dataset with source-target sentence pairs $\mathcal{D} = \{(\boldsymbol{x_1}, \boldsymbol{y_1^*}), ..., (\boldsymbol{x_D}, \boldsymbol{y_D^*})\}$, the loss function we want to minimize in the training is the sum of negative log-likelihood of Equation 1:

$$L = -\sum_{(\boldsymbol{x_i}, \boldsymbol{y_i^*}) \in \mathcal{D}} \log P(\boldsymbol{y} = \boldsymbol{y_i^*}|\boldsymbol{x} = \boldsymbol{x_i}; \Theta) \quad (2)$$

In practice, by properly designing neural network structures and training strategies, we can get the specific model parameters that minimize Equation 2 and obtain translation results through the model with beam search.

One of the most popular model in NMT is Transformer, which was proposed by Vaswani et al. (2017). Without recurrent and convolutional networks, Transformer constructs its encoder and decoder by stacking self-attention and fully-connected network layers. Self attention is operated with three inputs: query(Q), key(K) and value(V) as:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}}V) \quad (3)$$

where the dimension of key is d_k.

Note that Transformer implements the multi-head attention mechanism, projecting inputs into h group inputs to generate h different outputs in Equation 3, and these outputs are concatenated and projected into final outputs:

$$head_i = \text{Attention}(QW_i^Q, KW_i^K, VW_i^V) \quad (4)$$
$$\text{Output} = \text{Concat}(head_1, ..., head_h)W^O \quad (5)$$

where W_i^Q, W_i^K, W_i^V and W^O are the projection matrices. The output of Equation 5 is then fed into the fully-connected layer named feed-forward network. The feed-forward network uses two linear networks and a ReLU activation function:

$$\text{FFN}(x) = \text{ReLU}(xW_1 + b_1)W_2 + b_2 \quad (6)$$

We only give a brief description of Transformer above. Please refer to Vaswani et al. (2017) for more details.

3 Uncertainty Modeling

3.1 Bayesian Neural Networks with Variational Inference

For most of machine learning tasks based on neural networks, a model with specific parameters is trained to explain the observed training data. However, there are usually a large number of possible models that can fit the training data well, which leads to model uncertainty. Model uncertainty may result from noisy data, uncertainty in model parameters or structure uncertainty, and it is represented as the confidence which model to choose to predict with. In order to express model uncertainty, we consider all possible models with parameters $\boldsymbol{\omega}$ and define a prior distribution $P(\boldsymbol{\omega})$ over the model (i.e., the space of the parameters) to denote model uncertainty. Then given a training data set $(\boldsymbol{X}, \boldsymbol{Y})$, the predicted distribution for $\boldsymbol{Y}$ can be denoted as $P(\boldsymbol{Y}|\boldsymbol{X}, \boldsymbol{\omega})$.

Following Gal et al. (2017), we employ Bayesian neural networks (BNNs) to represent the $P(\boldsymbol{\omega}|\boldsymbol{X}, \boldsymbol{Y})$, which is the posterior distribution of the models under $(\boldsymbol{X}, \boldsymbol{Y})$. BNNs offer a probabilistic interpretation of deep learning models by inferring distributions over the models' parameters which are trained using Bayesian inference. The posterior distribution can be got by invoking Bayes' theorem as:

$$P(\boldsymbol{\omega}|\boldsymbol{X},\boldsymbol{Y}) = \frac{P(\boldsymbol{Y}|\boldsymbol{X},\boldsymbol{\omega})P(\boldsymbol{\omega})}{P(\boldsymbol{Y}|\boldsymbol{X})} = \frac{P(\boldsymbol{Y}|\boldsymbol{X},\boldsymbol{\omega})P(\boldsymbol{\omega})}{\mathbb{E}_{\boldsymbol{\omega}}[P(\boldsymbol{Y}|\boldsymbol{X},\boldsymbol{\omega})]}. \tag{7}$$

Then according to BNNs, given a new test data $\boldsymbol{x'}$, the predictive distribution of the output $\boldsymbol{y'}$ is:

$$P(\boldsymbol{y'}|\boldsymbol{x'},\boldsymbol{X},\boldsymbol{Y}) = \mathbb{E}_{\boldsymbol{\omega}\sim P(\boldsymbol{\omega}|\boldsymbol{X},\boldsymbol{Y})}[P(\boldsymbol{y'}|\boldsymbol{x'},\boldsymbol{\omega})] \tag{8}$$

The expectations in Equation 7 and 8 are integrated over model distribution $\boldsymbol{\omega}$, and the huge space of $\boldsymbol{\omega}$ makes it intractable to obtain the results. Therefore, inspired by Hinton and Van Camp (1993), Graves (2011) proposes a variational approximation method, using a variational distribution $Q(\boldsymbol{\omega}|\theta)$ with the parameters θ to approximate the posterior distribution $P(\boldsymbol{\omega}|\boldsymbol{X},\boldsymbol{Y})$. To this end, the training objective is to minimize the Kullback-Leibler (KL) divergence between the model distribution and the posterior distribution $\mathrm{KL}(Q(\boldsymbol{\omega}|\theta)||P(\boldsymbol{\omega}|\boldsymbol{X},\boldsymbol{Y}))$. With variational inference, the objective is equivalent to maximizing its evidence lower bound (ELBO), so we get

$$\theta^* = \arg\max_{\theta} \mathbb{E}_{Q(\boldsymbol{\omega}|\theta)} \log P(\boldsymbol{Y}|\boldsymbol{X},\boldsymbol{\omega}) - \mathrm{KL}((Q(\boldsymbol{\omega}|\theta)||P(\boldsymbol{\omega})) \tag{9}$$

As we can see in Equation 9, the first term on the right side is the expectation of the predicted probability over model distribution on the training set, which can be unbiased estimated with the Monte-Carlo method. And the second term is the KL divergence between the approximate model distribution and the prior distribution. From the perspective of Hinton and Van Camp (1993) and Graves (2011), with the above objective, we can express model uncertainty under the training data and meanwhile regularize model parameters and avoid over-fitting. Therefore, at inference, we can use the distribution $Q(\boldsymbol{\omega}|\theta)$ instead of $P(\boldsymbol{\omega}|\boldsymbol{X},\boldsymbol{Y})$ to evaluate model confidence (i.e., model uncertainty).

3.2 Model distribution with Dropout

To derive the BNN, we need to first decide how to explore for the possible models and then decide the prior distribution and the variational distribution for the models. As in Gal et al., 2017, we can define a simple model with parameters $\boldsymbol{\omega}_{\boldsymbol{W}}$ ($\boldsymbol{W} \in \mathbb{R}_{m\times n}$) and then drop out some column of $\boldsymbol{\omega}_{\boldsymbol{W}}$ to get the possible models. We use matrix Gaussian distribution as the prior model distribution and Bernoulli distribution as the posterior model distribution.

Using $\boldsymbol{W}.j$ to denote the j-th column of $\boldsymbol{W}$, we draw a matrix Gaussian distribution as the probability distribution of dropping out the j-th column as

$$P(\boldsymbol{\omega}_{\boldsymbol{W}_{\cdot j}}) \sim \mathcal{MN}(\boldsymbol{\omega}_{\boldsymbol{W}_{\cdot j}}; 0, I/l, I/l) \tag{10}$$

where l is the hyper-parameter.

The above matrix Gaussian distribution is used as the prior distribution of the models got by dropping out the j-th column. Then we introduce $\boldsymbol{p}$ ($\boldsymbol{p} \in \mathbb{R}_{1\times n}$) as the probability vector of dropping out the columns of $\boldsymbol{\omega}_{\boldsymbol{W}}$, which means dropping out the j-th column with the probability of $\boldsymbol{p}_j$, and keeping the j-th column unchanged with the probability of $1-\boldsymbol{p}_j$. Therefore the posterior model distribution of dropping out the j-th column is defined as

$$Q(\boldsymbol{\omega}_{\boldsymbol{W}_{\cdot j}}|\theta) = \begin{cases} 1-\boldsymbol{p}_j & \boldsymbol{\omega}_{\boldsymbol{W}_{\cdot j}} = \boldsymbol{W}_{\cdot j} \\ \boldsymbol{p}_j & \boldsymbol{\omega}_{\boldsymbol{W}_{\cdot j}} = \boldsymbol{0} \end{cases} \tag{11}$$

where $\boldsymbol{W} \in \theta$ and $\boldsymbol{p} \in \theta$ are trainable parameters.

With Equation 10 as prior, the KL divergence for the j-th column of the matrix can be represented as:

$$\begin{aligned} &\mathrm{KL}(Q(\omega_{\boldsymbol{W}_{\cdot j}}|\theta)||P(\omega_{\boldsymbol{W}_{\cdot j}})) \\ =&\mathcal{R}(\boldsymbol{p}_{\boldsymbol{W}_{\cdot j}}, \boldsymbol{W}_{\cdot j}, l) - \mathcal{H}(\boldsymbol{p}_{\boldsymbol{W}_{\cdot j}}) \end{aligned} \tag{12}$$

where

$$\mathcal{R}(\boldsymbol{p}_{\boldsymbol{W}_{\cdot j}}, \boldsymbol{W}_{\cdot j}, l) = \frac{(1-\boldsymbol{p}_j)l^2}{2}\sum_{i=1}^{m} \boldsymbol{W}_{ij}^2 \tag{13}$$

and

$$\mathcal{H}(\boldsymbol{p}_{\boldsymbol{W}_{\cdot j}}) = -[\boldsymbol{p}_j \log(\boldsymbol{p}_j) + (1-\boldsymbol{p}_j)\log(1-\boldsymbol{p}_j)] \tag{14}$$

Since the probability distribution among different neural networks and different columns of neural network are independent. For a complex multi-layer neural network θ, the KL divergence between model distribution $Q(\omega|\theta)$ and prior distribution $P(\omega)$ is

$$\begin{aligned} &\mathrm{KL}(Q(\omega|\theta)||P(\omega)) \\ =&\sum_{\boldsymbol{W}_{m\times n},\boldsymbol{p}\in\theta}\sum_{j=1}^{n} \mathcal{R}(\boldsymbol{p}_{\boldsymbol{W}_{\cdot j}}, \boldsymbol{W}_{\cdot j}, l) - \mathcal{H}(\boldsymbol{p}_{\boldsymbol{W}_{\cdot j}}) \end{aligned} \tag{15}$$

4 Application to Transformer

Previous sections show how to use concrete dropout to realize variational approximation of the posterior model distribution. In this section we will introduce the implementation in representing model distribution for Transformer with aforementioned methods.

4.1 Dropout in Transformer

Stated in detail in Vaswani et al. (2017), in Transformer, dropout is commonly used to the output of modules, including the output of embedding, attention layer and feed-forward layer. Also, from Equation 13, we find it's important to find the network W corresponding to the dropout module. The correspondences in Transformer are as follows:

Embedding module Embedding module works for mapping the words into embedding vectors. The embedding module contains a matrix $W_E \in \mathbb{R}_{l_d \times d}$, where l_d is the length of dictionary and d is the dimension of embedding vector. For the i-th word in the dictionary, its embedding vector is the i-th column of W_E. Since dropout the j-th dimension of word embedding is equivalent to dropping out the j-th row of W_E, we utilize W_E^T and its corresponding dropout in Equation 13.

Attention module For attention modules, as we can see in 5, their outputs are generated by concatenating the output of different heads and projecting by matrix W^O. Since dropout is used in the output of attention module, we take W^O and its corresponding dropout in calculating Equation 13.

Feed-forward module As shown in Equation 6, the output is generated through W_2 with bias b_2. As we can see, for network $y = xW + b$, we can find that

$$y = \mathrm{Concat}(x, 1) \cdot \mathrm{Concat}(W^T, b^T)^T \tag{16}$$

as we can see, dropout to the output of the feed-forward module can be regraded as dropping out W_2 and b_2. So, during training, we use $\mathrm{Concat}(W^T, b^T)^T$ to calculate Equation 13.

4.2 Training and Inference

Although dropout is frequently utilized in Transformer, there are some networks in Transformer like W_i^Q, W_i^K, W_i^V in Equation 4, and their output is not masked by dropout. So, in our implementation, we obtain the model distribution by fine-tuning the pre-trained model, freezing their parameters and only updating dropout probabilities. Moreover, we choose different trained modules to train their output dropout probability, and in calculating Equation 15, we only take those trained dropout probabilities into consideration. By allowing dropout probabilities to change, our method can better represent model distributions under the training dataset than the fixed dropout probabilities. The mini-batch training algorithm is expressed in Equation 1. It is worth to mention that since we train the model distribution with batches of data, we scale the KL divergence with the proposition of the batch in the entire training dataset.

Algorithm 1 Mini-batch Training of Bayesian NN using Variational Inference with Dropout in NMT

```

During updating the dropout probability, due to the discrete characteristics of the Bernoulli distribution, we cannot directly calculate the gradient of the first term in Equation 9 to the dropout probability. So, we adopt concrete dropout, which is used in Gal et al. (2017). As a continuous relaxation of dropout, for its input $\boldsymbol{y}$, the output can be expressed as $\boldsymbol{y}' = \boldsymbol{y} \odot \boldsymbol{z}$, and vector $\boldsymbol{z}$ satisfies:

$$\boldsymbol{z} = \mathrm{sigmoid}(\frac{1}{t}(\log(p) - \log(1-p) + \log(u) - \log(1-u))) \tag{17}$$

where $u \sim \mathcal{U}(0, 1)$, p is dropout probability.

In the inference stage, we just randomly mask model parameters with trained dropout probabilities, with different random seeds, NMT models with different parameters are sampled. Since diverse translations are demanded, we performed several forward passes through different sampled NMT models, and different translations are generated with different model outputs and beam search.

5 Experiment Setup

Dataset In our experiment, we select datasets in the following translation tasks:

- NIST Chinese-to-English (NIST Zh-En). Its dataset is based on LDC news corpus and contains about 1.34 million sentence pairs. It also includes 6 relatively small datasets, MT02, MT03, MT04, MT05, MT06, and MT08. In our experiments, we use MT02 as the development set, and the rest work as the test sets. Without special explanation, we use average result of test sets as final results.
- WMT'14 English-to-German (WMT'14 En-De). Its dataset comes from the WMT'14 news translation task, which contains about 4.5 million sentence pairs. In our experiment, we use newstest2013 as the development set and newstest2014 as the test set.

For above two datasets, We adopt Moses tokenizer (Koehn et al., 2007) in English and German corpus. We also use the byte pair encoding (BPE) algorithm (Sennrich et al., 2015), and limit the size of the vocabulary $K = 32000$. And we train a joint dictionary for WMT'14 En-De. For NIST, we use THULAC toolkit (Sun et al., 2016) to segment Chinese sentence into words. In addition, we remove the examples in datasets from the above two tasks where length of the source language sentence or target language sentence exceed 100 words.

Model Architecture In our experiments, we all adopt the Transformer Base model in Vaswani et al. (2017). Transformer base model has 6 layers in encoder and decoder, and it has hidden units with 512 dimension, except for the feed-forward network, where the inner-layer output dimension is 2048. The number of heads in Transformer base model is 8 and the default dropout probability is 0.1. And our model is implemented in python3 with the Fairseq-py (Ott et al., 2019) toolkit.

Experimental Setting During training, in order to improve the accuracy, we use the label smoothing (Szegedy et al., 2016) with $\epsilon = 0.1$. In terms of optimizer, we adopt the Adam optimizer (Kingma and Ba, 2014), the main parameters of the optimizer is $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 10^{-9}$. As for the learning rate, we adopt the dynamic learning rate method in Vaswani et al. (2017) with $\mathrm{warmup\_steps} = 4000$. Also, we use mini-batch training with $\mathrm{max\_token} = 4096$.

Metrics In terms of evaluation metrics, referring to Shen et al. (2019), we adopt the BLEU and Pairwise-BLEU to evaluate translation quality and diversity. Both two metrics are calculated with case-insensitive BLEU algorithm in Papineni et al. (2002). In our experiments, the BLEU is to measure the average similarity between the output translations and the standard translation. The higher the BLEU value, the better the accuracy of translation. And the Pairwise-BLEU reflects the average similarity between the output translations of different groups. The lower the Pairwise-BLEU value, the lower the similarities, and the more diverse the translations. In our experiment, we use the NLTK toolkit to calculate the two metrics.

6 Experiment Results

6.1 Analysis of Training Modules and Hyper-parameter

In this experiment, we train models with different training modules and hyper-parameter l with NIST dataset to evaluate their effects, and some results are shown in Table 1.

As we can see in Table 1, for those training modules, when l is small, with the same hyper-parameter l, choosing smaller part of training modules will lead to lower BLEU and Pairwise-BLEU, showing that accuracy of the generate translations increases while diversity decreases. We also find that in the same training modules, with the increase of l, the Pairwise-BLEU decreases steadliy, and then increases when the BLEU is close to zero; and the BLEU has similar trends with Pairwise-BLEU, however, when l is relatively low, the BLEU tends to stablize.

For the above-mentioned experimental results, we can interpret as follows: in training modules, since Equation 15 is the sum of the training modules' KL divergence, with the training modules increase, the KL divergence accordingly increases, pushing the dropout probability higher and making translations diverse. In terms of hyper-parameter l, as we can see in Equation 10, when l increases, the prior distribution is squeezed to zero matrix; thus during training, the dropout probabilities will get higher to make the model distribution close to

l^2		10^1	10^2	10^3	10^4	10^5	10^6	10^7	10^8
Decoder's 1-3 Layer	BLEU	42.48	42.47	42.56	41.33	26.83	8.68	5.14	2.90
	Pairwise-BLEU	80.97	79.66	72.12	62.16	43.11	33.24	25.43	35.18
Decoder	BLEU	42.34	42.30	42.25	38.17	7.79	12.22	0.59	0.26
	Pairwise-BLEU	75.89	74.52	67.26	49.67	16.86	20.47	56.99	58.92
Encoder+Decoder	BLEU	42.20	42.12	41.69	32.70	2.43	0.83	0.37	0.68
	Pairwise-BLEU	69.75	68.08	58.99	38.02	9.85	79.80	56.76	58.54

Table 1: Results with 3 different training modules and hyper-parameter l. From the table we can see the BLEU and Pairwise-BLEU change with training modules. Also, the BLEU decreases with the increase of l, and the Pairwise-BLEU decreases steadily and then increases when the BLEU value is close to its minimum.

prior distribution. However, when the l is too high to make most of dropout probabilities close to 1, uncertainty of model parameters decreases, making Pairwise-BLEU increases.

6.2 Results in Diverse Translation

From the previous section, we can see that by selecting different training modules and hyper-parameter, translations with different accuracy and diversity can be obtained. Then we conduct experiments to generate 5 groups of different translations on NIST Zh-En dataset and WMT'14 En-De dataset, and compare the diversity and accuracy of the translations generated by our method and the following baseline approaches:

- Beam Search: we choose the optimal 5 results directly generated by beam search in this paper.
- Diverse Beam Search (DBS) (Vijayakumar et al., 2016): it works by grouping the outputs and adding regularization terms in beam search to encourage diversity. In our experiment, the number of output translations of groups are all 5.
- HardMoE (Shen et al., 2019): it trains model with different hidden states and obtains different translations by controlling hidden state. In our experiment, we set the number of hidden states is 5.
- Head Sampling (Sun et al., 2019): it generate different translations by sampling different encoder-decoder attention heads according to their attention weight, and copying the samples to other heads in some conditions. Here, we set the parameter K = 3.

The results are shown in Figure 1. In Figure 1 we plot the BLEU versus Pairwise-BLEU, the scattered points show the results of baseline approaches, and the points on the curves are results in the same training modules with different hyper-

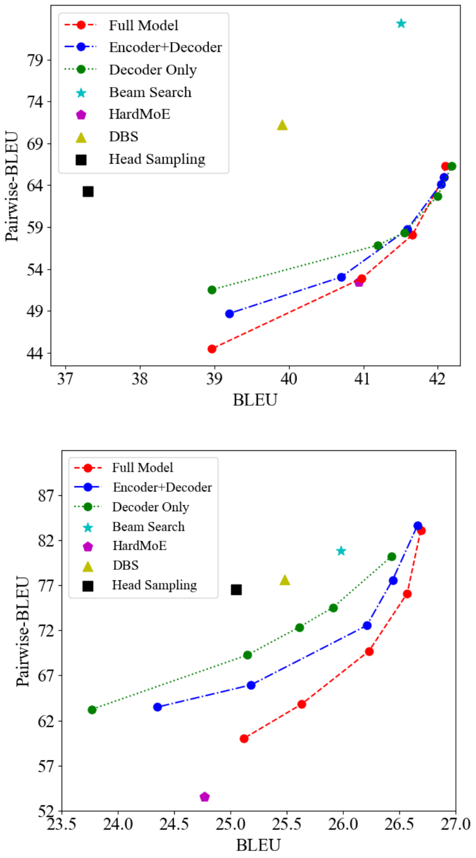

Figure 1: Experiment result in NIST Zh-En (upper one) and WMT'14 En-De (lower one). The X axis and Y axis represents BLEU and Pairwise-BLEU value. The first three groups in legend (connected with curves) are results with our methods under specific training modules with different prior parameters l, and the latter four groups (scattered points) are results from baseline methods.

Table 2: Translation examples in NIST Zh-En Task. Results of our work is generated by training dropout in decoder with $l^2 = 1000$. The result shows that by adjusting model parameters, our method can generate translations with higher diversity while maintaining accuracy.

parameter l. From Figure 1, firstly, we can verity that choosing different training modules can lead to different balance of translation diversity and accuracy, for NIST Zh-En and WMT'14 En-De, training dropout probabilities in the full model can get better translations.

Also, we suggest that in NIST Zh-En task, by adjusting training modules and hyper-parameter l, our results which has higher BLEU and lower Pairwise-BLEU values than baselines without HardMoE, even for HardMoE itself, our method is comparable with proper l while training the whole model. In WMT'14 En-De, we also find that our method exceeds the baseline approach except HardMoE. For the gap in performace with HardMoE, we interpreted that since our models are randomly sampled from the model distribution, it could be hard for our models to represent such distinguishable characteristics like HardMoE, which trains multiple different latent variables.

Also, to intuitively display the improvement of diversity in our translations, we choose a case from NIST Zh-En task, the results are shown in Table 2. The case shows that compared with beam search, which only varies in few words, our method can obtain more diverse translations while ensuring the accuracy of translation, and diversities are not only shown in words, but also reflected in lexical characteristic.

6.3 Analyzing Module Importance with Dropout Probability

Some researches (Voita et al., 2019; Michel et al., 2019; Fan et al., 2019) found that a well-trained Transformer model is over-parameterized. Useful information gathers in some parameters and some modules and layers can be pruned to improve the efficiency during test time. Since dropout can play the role of regularization and there are differences in the trained dropout probabilities of different neuron, we conjecture that the trained dropout probability and the importance of each module are correlated. To investigate this, we choose the model in which dropout probabilities of the full model is trained with $l^2 = 400$ in NIST Zh-En task, and separately calculate the average dropout probability $\bar{p}_{dropout}$ of different attention modules. Also, we manually pruned the corresponding modules of the model, obtained translations and calculated its BLEU. the more the BLEU drops, the more important the module is to translation. To quantify their relevance, we calculate the Pearson correlation coefficient (PCC) ρ in different kinds of training modules, and highlights the highest and lowest results.

Results of our experiment are shown in Table 3. Firstly, we can see that the average dropout probabilities and BLEU are not fully positively correlated, which might be explained by the contingency of sampling from model distribution during training. But from the maximum and minimum of

	Encoder		Decoder			
	Self-attention		Self-attention		E-D Attention	
Layer	$\bar{p}_{dropout}$	BLEU	$\bar{p}_{dropout}$	BLEU	$\bar{p}_{dropout}$	BLEU
1	**0.0400**	**32.65**	0.0484	40.20	**0.0915**	**42.15**
2	0.0858	40.97	**0.0793**	**41.67**	0.0798	41.03
3	**0.0863**	**41.70**	0.0670	40.83	0.0620	35.65
4	0.0763	39.87	**0.0460**	39.56	0.0556	37.29
5	0.0632	40.17	0.0476	**37.93**	0.0394	32.18
6	0.0769	39.15	0.0490	40.88	**0.0335**	**18.48**
ρ	0.919		0.689		0.858	

Table 3: Average dropout probabilities of each module and BLEU of translations generated by model where the module is pruned. From the maximum and minimum of $\bar{p}_{dropout}$ and BLEU, and correlation coefficient ρ in different modules, it is obvious that dropout probabilities of module and its importance is correlated.

$\bar{p}_{dropout}$ and BLEU, we can find that the dropout probabilities $\bar{p}_{dropout}$ and the BLEU of translations show some similar information in module importance. Also, we quantify the correlation between the $\bar{p}_{dropout}$ and BLEU, finding that it is highly correlated in self-attention module in encoder and in E-D attention in decoder, since its correlation coefficient $\rho > 0.8$, and the $\bar{p}_{dropout}$ and BLEU is also correlated in self-attention in decoder.

7 Related Work

Researches in Bayesian Neural Network have a long history, Hinton and Van Camp (1993) firstly proposes a variational inference approximation methods to BNN to minimize the minimum description length (MDL), then Neal (1995) approximate BNN by Hamiltonian Monte Carlo methods. In recent years, Graves (2011) introduces the concept of variational inference, by approximating posterior distribution with model distribution, the model minimizes its MDL and reduces the model weight; and Blundell et al. (2015) proposes an algorithm similar to Graves (2011), however, it uses mixture of Gaussian densities as prior and achieved comparable performance with dropout in regularization.

Introduced by Hinton et al. (2012), dropout, which is easy to implement, works as a stochastic regularization to avoid over-fitting. And there are several theoretical explainations such as getting sufficient model combinations (Hinton et al., 2012; Srivastava et al., 2014) to train and augumenting training data (Bouthillier et al., 2015). Gal and Ghahramani (2016) proposes that dropout can be understood as a bayesian inferences algorithm, and Gal et al. (2017) uses concrete dropout in updating dropout probabilities. Also, the author implements the dropout methods to represent uncertainty in different kinds of deep learning tasks in Gal (2016).

In neural machine translation task, lack of diversity is a widely acknowledged problem, some researches like Ott et al. (2018) investigate the cause of uncertainty in NMT, and some provide metrics to evaluate the translation uncertainty like Galley et al. (2015); Dreyer and Marcu (2012). There are also other researches that put forward methods to obtain diverse translation. Li et al. (2016); Vijayakumar et al. (2016) adjust decoding algorithms, adding different kinds of diversity regularization terms to encourage generating diverse outputs. He et al. (2018); Shen et al. (2019) utilize mixture of experts (MoE) method, using differentiated latent variables to control generation of translation. Sun et al. (2019) generates diverse translation by sampling heads in encoder-decoder attention module in Transformer model, since different heads may present different target-source alignment. Shu et al. (2019) uses sentence codes to condition translation generation and obtain diverse translations. Shao et al. (2018) propose a new probabilistic ngram-based loss to conduct sequence-level training for generating diverse translation.Feng et al. (2020) propose to employ future information to evaluate fluency and faithfulness to encourage diverse translation.

There are also a few papers in interpreting Transformer model, Voita et al. (2019) suggests that some heads play a consistent role in machine translation, and their roles can be interpreted linguistically; also, they implement L_0 penalty to prune heads. Michel et al. (2019) shows that huge amounts of heads in Transformer can be pruned, and the importance of head is cross-domain. Also, Fan et al. (2019) shows that the layers in Transformer are also able to be pruned: similar to our work, during training, they drop the whole layer with dropout and trained their probability; however, variational inference strategy is not used in their paper, and they take different kinds of inference strategies to balance performance and efficiency rather than sampling.

8 Conclusion

In this paper, we propose to utilize variational inference in diverse machine translation tasks. We represent the Transformer model distribution with dropout, and train the model distributions to minimize its distance to the posterior distribution under specific training dataset. Then we generate diverse translations with the models sampled from the trained model distribution. We further analyze the correlations between module importance and trained dropout probabilities. Experiment results in Chinese-English and English-German translation tasks suggest that by properly adjusting trained modules and prior parameters, we can generate translations which balance accuracy and diversity well.

In future work, firstly, since our model is randomly sampled from model distribution to generate diverse translation, it is meaningful to explore better algorithms and training strategies to represent model distribution and search for the most distinguishable results in model distribution. Also, we'll try to extend our methods in a wider range of NLP tasks.

Abstract

This paper presents two strong methods, CTC and Imputer, for non-autoregressive machine translation that model latent alignments with dynamic programming. We revisit CTC for machine translation and demonstrate that a simple CTC model can achieve state-of-the-art for single-step non-autoregressive machine translation, contrary to what prior work indicates. In addition, we adapt the Imputer model for non-autoregressive machine translation and demonstrate that Imputer with just 4 generation steps can match the performance of an autoregressive Transformer baseline. Our latent alignment models are simpler than many existing non-autoregressive translation baselines; for example, we do not require target length prediction or re-scoring with an autoregressive model. On the competitive WMT'14 En→De task, our CTC model achieves 25.7 BLEU with a single generation step, while Imputer achieves 27.5 BLEU with 2 generation steps, and 28.0 BLEU with 4 generation steps. This compares favourably to the autoregressive Transformer baseline at 27.8 BLEU.

1 Introduction

Non-autoregressive neural machine translation (Gu et al., 2018) aims to enable the parallel generation of output tokens without sacrificing translation quality. There has been a surge of recent interest in this family of efficient decoding models, resulting in the development of iterative refinement (Lee et al., 2018), CTC models (Libovicky and Helcl, 2018), insertion-based methods (Stern et al., 2019; Chan et al., 2019b), edit-based methods (Gu et al., 2019; Ruis et al., 2019), masked language models (Ghazvininejad et al., 2019, 2020b), and normalizing flow models (Ma et al., 2019). Some of these methods generate the output tokens in a constant number of steps (Gu et al., 2018; Libovicky and Helcl, 2018; Lee et al., 2018; Ghazvininejad et al., 2019, 2020b), while others require a logarithmic number of generation steps (Stern et al., 2019; Chan et al., 2019b,a; Li and Chan, 2019).

Recent progress has decreased the gap between autoregressive and non-autoregressive models' translation scores. However, non-autoregressive models often suffer from two main limitations:

1. First, most non-autoregressive models assume that the output tokens are conditionally independent given the input. This leads to the weakness of such models in generating multi-modal outputs (Gu et al., 2018), and materializes in the form of *token repetitions* in the decoded outputs. Addressing this limitation generally involves stochastic search algorithms like noisy parallel decoding (Gu et al., 2018), iterative decoding (Ghazvininejad et al., 2019, 2020b), or simple but less effective heuristic methods such as collapsing repetitions (Lee et al., 2018).
2. The second limitation of many prior non-autoregressive models is the requirement of *output length prediction* as a pre-process. Autoregressive models have the ability to dynamically adjust the output sequence length by emitting an `<END>` token at any generation step to stop. Many non-autoregressive models often require a fixed length decoder. Thus they train a separate target length prediction module, and at inference time, first predict and condition on the target length, and then generate the output tokens (Gu et al., 2018). Since the model needs to commit to a fixed predicted length, which cannot be changed dynamically, it is often required to use multiple length candidates and re-score them to produce the final translation (Ghazvininejad et al., 2019, 2020b).

November 16–20, 2020.

This paper addresses the limitations of existing non-autoregressive machine translation models by using *latent alignment models*. Latent alignment models utilize a sequence of discrete latent alignment variables to monotonically align the non-autoregressive predictions of the model and output tokens. Such models use dynamic programming to marginalize out the alignment variables during training. This paper studies two instances of latent alignment models including Connectionist Temporal Classification (CTC) (Graves et al., 2006, 2013; Graves and Jaitly, 2014) and Imputer (Chan et al., 2020). Libovicky and Helcl (2018) have previously applied CTC to non-autoregressive machine translation. However, we report a significant improvement over the work of Libovicky and Helcl (2018) and demonstrate that CTC can achieve the state-of-the-art in single-step non-autoregressive machine translation. We attribute this performance difference primarily to our use of distillation during training, similar to Gu et al. (2018). We adapt latent alignment models to machine translation and demonstrate their effectiveness on non-autoregressive machine translation, advancing state-of-the-art on WMT'14 En↔De and WMT'16 En↔Ro.

The main contributions of this paper include:

1. We adapt latent alignment models to non-autoregressive machine translation.
2. We achieve a new state-of-the-art of 25.8 BLEU on WMT'14 En→De for single step non-autoregressive machine translation.
3. We achieve 27.5 BLEU with 2 step generation, 28.0 BLEU with 4 step generation, and 28.2 BLEU with 8 step generation for WMT'14 En→De, setting a new state-of-the-art for non-autoregressive machine translation with a constant number of generation steps.

2 Latent Alignment Models

We begin by describing the notion of *alignment*, which in the context of this paper is defined as in the CTC literature (Graves et al., 2006, 2013; Graves and Jaitly, 2014) and should not be confused with word alignments in machine translation (Manning et al., 1999; Dyer et al., 2013). Alignment is a mapping between a sequence of predicted tokens and a sequence of target tokens. Alignment can be constructed by inserting special "blank tokens" into the target sequence to match a pre-specified length. Our alignments have the same length as the source sequences, and collapsing the alignment's blank tokens will recover the target sequence.

Let x denote a source sequence and let y denote a target sequence, where $y_i \in \mathcal{V}$ and $\mathcal{V}$ is the target vocabulary. We make two assumptions: 1) there exists a monotonic mapping between the model's predictions and the target sequence, and 2) the source sequence is at least as long as the target sequence, i.e. $|x| \geq |y|$. We define an alignment a between x and y as a discrete sequence in which $a_i \in \mathcal{V} \cup \{\text{“\_”}\}$, $|a| = |x|$, and "_" is a special "blank" token that is removed to convert a to the target sequence y. We define a function $\beta(y)$ that returns all possible alignments for a sequence y of a particular length $|x|$. We also define the collapsing function $\beta^{-1}(a)$ such that $\beta^{-1}(a) = y$ if $a \in \beta(y)$. To avoid token repetitions, it is useful to define the collapsing function $\beta^{-1}(a)$ as first collapsing all consecutive repeated tokens, and then removing all blank tokens. This formulation follows CTC precisely (Graves et al., 2006). For instance, given a source sequence x of length 10, and a target sequence $y = (A, A, B, C, D)$, then a possible alignment a is $(\_, A, A, \_, A, B, B, C, \_, D)$.

The log-likelihood of the target sequence is recovered by marginalizing the latent alignments:

$$\log p_\theta(y|x) = \log \sum_{a \in \beta(y)} p_\theta(a|x) \tag{1}$$

The summation in (1) is typically intractable, since there are a combinatorial number of alignments. In the next two sub-sections, we will briefly describe two variants of latent alignment models that leverage dynamic programming to tractably compute the log-likelihood, Connectionist Temporal Classification (CTC) (Graves et al., 2006) and Imputer (Chan et al., 2020).

2.1 Connectionist Temporal Classification

Connectionist Temporal Classification (CTC) (Graves et al., 2006, 2013; Graves and Jaitly, 2014) models the alignment distribution with a strong conditional independence assumption:

$$p_\theta(a|x) = \prod_i p(a_i|x;\theta) \tag{2}$$

Leveraging this strong conditional independence assumption enables CTC to use an efficient dynamic programming algorithm to exactly marginalize out the latent alignments:

$$\log p_\theta(y|x) = \log \sum_{a \in \beta(y)} \prod_i p(a_i|x;\theta) \tag{3}$$

This allows us to compute the log-likelihood and its gradient tractably. We refer the reader to Graves et al. (2006) for the exact details of the dynamic programming algorithm. During inference, CTC generates the alignment distribution in parallel with a single generation step; the output sequence can then be recovered by greedy decoding or beam search (Graves et al., 2006). We use greedy decoding in all our experiments.

2.2 Imputer

The CTC model makes strong conditional independence assumption between alignment token predictions. This assumption licenses CTC to generate the entire alignment in parallel, with a single generation step independent of the number of source or target tokens. However, the strong conditional independence assumption limits its capacity to model complex multi-modal distributions. On the other hand, autoregressive models are capable of modelling such complex multi-modalities with the chain rule factorization, but requires n decoding steps to generate n tokens during inference. Imputer (Chan et al., 2020) aims to address these limitations.

Imputer is an iterative generative model needing only a constant number of generation steps for inference. It makes conditional independence assumptions within a generation step to achieve parallel generation, and models conditional dependencies across generation steps. This approach has been applied successfully in speech recognition (Chan et al., 2020), matching autoregressive models with only a constant number of generation steps. Imputer models the distribution of alignments $p_\theta(a|x)$ as:

$$p_\theta(a|x) = \sum_{\tilde{a} \in \gamma(a)} p_\theta(a|\tilde{a}, x) p(\tilde{a}|x) \tag{4}$$

where $\tilde{a}$ is a (partially masked out) alignment, and $\gamma(a)$ is the set of all possible masking permutations of a. (4) marginalizes over all possible alignments between the input and output sequences, and all possible generation orders. Imputer models the next alignment a conditioned on the previous alignment $\tilde{a}$:

$$p_\theta(a|\tilde{a}, x) = \prod_i p(a_i|\tilde{a}, x; \theta) \tag{5}$$

The key insight to Imputer is that we can construct a log-likelihood lower-bound:

$$\log p_\theta(y|x) \\ \geq \mathbb{E}_{a \sim \beta(y)} \left[\mathbb{E}_{\tilde{a} \sim \gamma(a)} \left[\log \sum_{a' \in \beta'(\tilde{a}, a)} p_\theta(a'|\tilde{a}, x) \right] \right] \tag{6}$$

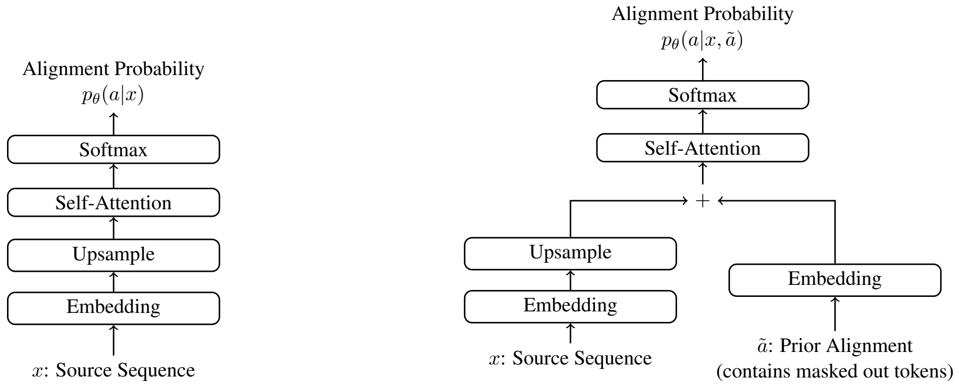
where $a' \sim \beta'(\tilde{a}, a)$ captures all possible alignments a' consistent with $(\tilde{a}, a)$ (Chan et al., 2020). This equation can be solved efficiently via dynamic programming (Chan et al., 2020). This formulation licenses Imputer with an iterative generation process. Tokens are generated independently (and in parallel) within a generation step but are conditioned on the partially predicted alignment $\tilde{a}$ of the last iteration (unlike CTC). In practice, Imputer uses a constant number of decoding iterations independent of the sequence length (Chan et al., 2020).

Both CTC and Imputer have seen much success in tasks like speech recognition (Graves and Jaitly, 2014; Chan et al., 2020). However, to the best of our knowledge, these latent alignment models have not been widely applied to machine translation, with the exception of Libovicky and Helcl (2018). These latent alignment models hold two key advantages over prior non-autoregressive machine translation work (Gu et al., 2018; Ghazvininejad et al., 2019), namely: the *token repetition problem* and the *target length prediction problem*. We will discuss them in detail in Section 3.

3 Latent Alignment Models for Machine Translation

In this section, we will discuss how latent alignment models can be adapted to machine translation, and then describe key advantages offered by these models. Section 2 identified two assumptions made by latent alignment models: 1) there exists a monotonic mapping between the model alignment predictions and the target sequence, and 2) the length of the target sequence is less than or equal to the length of source sequence, i.e. $|y| \leq |x|$. We will now address these issues to adapt our models for machine translation.

Monotonic Assumption. A monotonic structure between model alignment predictions and the target sequence is desired for the dynamic programming algorithm to marginalize out the latent alignments in Equation (1). Unlike tasks such as



(a) CTC (b) Imputer

Figure 1: Visualization of the CTC (a) and Imputer (b) architecture for non-autoregressive machine translation.

speech recognition, a monotonic relationship between the model alignment predictions and the target sequence may not exist in machine translation. For instance, speech-to-text is inherently local, whereas there is typically some global word reordering in machine translation. We hypothesize that if we use a powerful deep neural network like the Transformer (Vaswani et al., 2017), the Transformer will have sufficient computational capacity to learn to reorder the contextual embeddings such that it is approximately monotonic with the target sequence. Libovicky and Helcl (2018) also made a similar assumption.

Length Assumption. By construction, our alignments are the same length as the source sequence, and consequently, we can not generate a target sequence longer than the source sequence. This is not a problem for speech recognition, since the source sequence is generally much longer than the target sequence; however, this is prohibitively restrictive for machine translation. This issue was also discussed in Libovicky and Helcl (2018), and they proposed a simple solution of up-sampling the source sequence to s times the original length. Choosing a sufficient canvas scale of s, we can ensure the alignment is long enough to model the target sequence across our training distribution. We use a very similar up-sampling method applied to the embedding matrix of the source sequence. Given a source sequence embedding $x \in \mathbb{R}^{|x| \times d}$ with d-dimension and length $|x|$, we simply upsample $x' \in \mathbb{R}^{s \cdot |x| \times d}$ via an affine transformation.

3.1 Model Architecture

Our neural architecture is simply a stack of self-attention layers (Vaswani et al., 2017). The source sequence is upsampled (to handle longer target sequences as described above). In the Imputer architecture, the input to our self-attention stack is simply the superpositioning of the upsampled source and the previous alignment. Our work differs from the prior method, 1) our unified architecture does not have separate encoder decoders which require cross-attention mechanisms, 2) our architecture is bidirectional, and does not rely on causality masks. Figure 1 visualizes our architecture.

3.2 Advantages

Latent alignment models mitigate two common issues shared by many non-autoregressive machine translation models – *token repetition* and the requirement for *separate target length prediction*.

3.2.1 Fewer Token Repetitions

Non-autoregressive sequence models make a conditional independence assumption between token predictions. This licenses them to parallel token generation during inference; however, it makes it difficult to model complex multi-modal distributions. This is especially true for single-step generation models which make strong conditional independence assumptions. During inference, this conditional independent generation often results in the *token repetition problem*, where tokens are erroneously repeated in the output sequence.

This issue has been discussed extensively in prior works (Gu et al., 2018; Lee et al., 2018; Ghazvininejad et al., 2019) in the context of machine translation, and has been shown to have a negative impact on performance. To handle these repetitions, Gu et al. (2018) used Noisy Parallel Decoding, wherein they sample a large number of translation hypotheses and use an autoregressive teacher to re-score them to implicitly penalize translations with more erroneous repetitions. Lee et al. (2018) adopted a simple but less effective heuristic of simply removing all consecutive repetitions from the predicted target sequence. Ghazvininejad et al. (2019) hypothesized that iterative decoding can help remove repetitions by allowing the model to condition on parts of the input, thus collapsing the multi-modal distribution into a sharper uni-modal distribution. They empirically show that the first few decoding iterations are crucial for removing repetitions resulting in a sharp increase in performance.

Like other non-autoregressive models, latent alignment models also perform conditionally independent generation, and hence face the issue of token repetitions. Although they differ from the other models in that they do not generate the target sequence directly. Rather, the inference process involves the generation of the target alignment, followed by collapsing the generated alignment into the target sequence using the collapsing function β^{-1}. Recall by construction, β^{-1} collapses repeated tokens (Graves et al., 2006), this inference process enables these models to handle erroneous repetitions implicitly by naturally collapsing them. In particular, for single-step decoding, we show that our CTC based model removes most of the repetitions while collapsing the alignment into target sequence, resulting in a significant improvement in translation quality over prior single step generation models. In addition, we show that Imputer requires just 4 decoding iterations to achieve state-of-the-art translation scores on WMT14 En→De, in contrast to 10 iterations used by Mask-Predict (Ghazvininejad et al., 2019).

3.2.2 No Target Length Prediction Needed

Many prior non-autoregressive models (Gu et al., 2018; Ghazvininejad et al., 2019) first predict the target length, then conditioned on the target length predict the target sequence. This is needed because these architectures utilize an encoder-decoder formulation, and the decoder requires a fixed canvas size to work with. The length is fixed, and it cannot be changed dynamically by the model during decoding. Due to this lack of flexibility, during inference, one typically samples multiple length candidates and performs decoding for each length followed by re-ranking them to get a final translation. This not only requires tuning of a new hyperparameter for determining the number of length candidates to sample during inference but also entails a considerable amount of extra inference computation.

Our latent alignment models do not require target length prediction, but rather implicitly determine the target sequence length through the alignment. This is possible since the alignment is of the same length as the source sequence, thus eliminating the requirement of predicting target length in advance during inference. The caveat is that we can not generate a target sequence longer than the source sequence, which we address in Section 3. Libovicky and Helcl (2018), which also applied CTC to machine translation, made a similar argument, and we further extend this to Imputer. Our approach simplifies the architecture and decoding process, avoiding a need to build a target length prediction model and searching over it during inference.

4 Related Work

There has been significant prior work on non-autoregressive iterative methods for machine translation (Gu et al., 2018), some of which are: iterative refinement (Lee et al., 2018), insertion-based methods (Stern et al., 2019; Chan et al., 2019a; Li and Chan, 2019), and conditional masked language models (Ghazvininejad et al., 2019, 2020b). Like insertion-based models (Stern et al., 2019; Chan et al., 2019c), our work does not commit to a fixed target length; insertion-based models can dynamically grow the canvas size, whereas our work which relies on a latent alignment can only generate a target sequence up to a fixed maximum predetermined length. Compared to conditional masked languages models (Ghazvininejad et al., 2019, 2020b), key differences are: 1) our models do not require target length prediction, and 2) we eschew the encoder-decoder neural architecture formulation, but rather rely on the single simple decoder architecture. KERMIT (Chan et al., 2019b,a) also has a similar neural architecture as us; they also eschew the conventional encoder-decoder architecture and have a unified architecture. Our work relies on the superpositioning of the input and output sequences via the latent alignment, whereas KERMIT relies on concatenation to process the input and output sequences. Their work is also more focused on

Input: Ein weiterer, besonders wichtiger Faktor sei die Vernetzung von Hochschulen und Unternehmen.

Output: Another particularly important factor is the networking of universities and businesses.

Imputer Decoding:

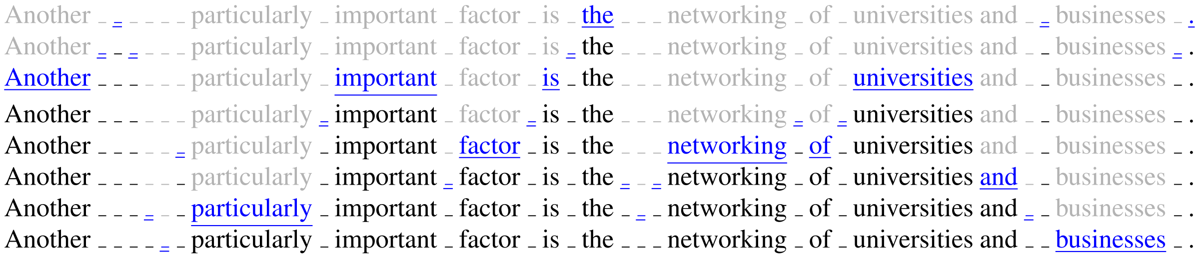


Figure 2: Example of top-*k* decoding using Imputer with 8 decoding steps. For a sentence of length N, the model imputes $\lceil \frac{N}{8} \rceil$ tokens at every decoding step. In each row, blue underlined tokens are the ones being imputed. Tokens that are not generated yet are colored gray.

generative $p(x, y)$ modelling, whereas our work is focused on conditional modelling $p(y|x)$.

Our CTC work is closely related to and inspired heavily by Libovicky and Helcl (2018), which applied CTC single step generation models. The key difference is that our work used data distillation for training, and we find that distillation provides a significant boost in performance for our CTC models.

Finally, our work is closely related to the concurrent work of Ghazvininejad et al. (2020a) on AXE CMLM. Similar to our work, they also assume a latent alignment and use dynamic programming for learning. Their work focused on the single-step generation and demonstrated strong results, while we apply our models to both single step and iterative generation.

5 Experiments

Hyperparameters. We follow the base Transformer (Vaswani et al., 2017) for our experiments. However, since our architecture does not contain an encoder, we double the number of layers in our decoder to maintain the same number of parameters. Our models consist of 12 self-attention layers, with 512 hidden size, 2048 filter size, and 8 attention heads per layer. We use 0.1 dropout for regularization. We batch sequences of approximately same lengths together, with approximately 2048 tokens per batch. We use Adam optimizer (Kingma and Ba, 2015) with $\beta = (0.9, 0.997)$ and $\epsilon = 10^{-9}$. The learning rate warms up to 10^{-3} in the first 10k steps and then decays with the inverse square root schedule following the Tensor2Tensor implementation (Vaswani et al., 2018). We train all our models for 2M steps. We train the Imputer using CTC loss (all masked prior alignment) for 1M steps, followed by Bernoulli masking policy (Chan et al., 2020) for next 1M steps. We average the 5 checkpoints with the best performance on the development set to get the final model. For Imputer, we use top-*k* decoding during inference. We use canvas scale $s = 2$ for all our experiments, meaning we upsample the source sequence by a factor of 2.

Dataset. We perform experiments on WMT'14 En↔De, using newstest2013 as the development set, and report newstest2014 as the test set. We also report our performance on WMT'16 En-Ro. We use SentencePiece (Kudo and Richardson, 2018) to generate a shared subword vocabulary. We evaluate the performance of our models with BLEU (Papineni et al., 2002).

Distillation. We follow prior work (Gu et al., 2018; Lee et al., 2018; Stern et al., 2019; Ghazvininejad et al., 2019) and use data distilled from an autoregressive teacher for training our models. We use autoregressive base Transformers for generating distilled data. For iterative generation, we also report the performance of Imputer model trained on data distilled from autoregressive big Transformers to be comparable with (Ghazvininejad et al., 2019, 2020b) which distilled from a big Transformer. For WMT'16 En-Ro, we use the distilled dataset provided by Ghazvininejad et al. (2019)[1]. We analyze the impact of distillation on the performance of our models in Section 6.3.

5.1 Single Step Decoding

We first report the performance of latent alignment models for single-step decoding. CTC makes full conditional independence assumption allowing the generation of the entire target sequence in a single step. We can also perform non-autoregressive single step generation with Imputer by imputing all of the tokens at once. Table 1 summarizes the performance of our models and other non-autoregressive single step generation models. Our CTC model achieves 25.7 BLEU, and the Imputer model achieves 25.8 BLEU for WMT'14 En→De. We find that our single step generation models outperform the autoregressive GNMT model of Wu et al. (2016) on En→De with 24.6 BLEU. To the best of our knowledge, our CTC and Imputer models outperform all prior work on single-step generation on WMT'14 En↔De and WMT'16 En↔Ro.

5.2 Iterative Decoding

We now analyze the performance of Imputer. Imputer uses a constant number of decoding iterations independent of sequence length. We compare our performance with other sub-linear non-autoregressive models, ranging from models requiring logarithmic to a constant number of decoding iterations. Table 2 summarizes the results of Imputer model.

Our Imputer model using 8 decoding iterations achieves 28.2 BLEU on En→De, slightly outperforming the autoregressive Transformer of 27.8 BLEU. On De→En, we achieve 31.3 BLEU, on par with the autoregressive Transformer model. Similarly, on En↔Ro, Imputer matches the performance of the autoregressive teacher using just 4 decoding iterations. We also observe the robustness of our Imputer model when we reduce the number of decoding iterations from 8 to 2. Using only 2 iterations, we obtain 27.5 BLEU on En→De and 30.2 BLEU on De→En. These results were trained with distillation from a big Transformer model. However, even when we distill from the base Transformer as shown in Table 3, Imputer still performs on par with the autoregressive Transformer achieving 27.9 and 31.1 BLEU on En→De and De→En respectively. Figure 2 shows an example 8-step iterative decoding by Imputer.

6 Analysis

In this section, we present further analysis of our latent alignment models. We analyze the (1) impact on token repetitions in generated translations, (2) impact of the number of decoding iterations on Imputer, (3) impact of distillation on our models, and (4) impact of target length on Imputer.

6.1 Token Repetitions

We compare the repetition rate of our CTC model with single-step Mask-Predict (Ghazvininejad et al., 2019) and the concurrent work AXE CMLM

Table 2: BLEU comparison for various autoregressive and non-autoregressive models. Imputer is able to match the autoregressive Transformer baseline with just 4 generation steps. Numbers reported for Imputer trained with data distilled from big autoregressive transformer for En ↔ De, and base transformer for En ↔ Ro.

8	×3.9

(Ghazvininejad et al., 2020a) in Table 4. We also report the percentage of repetitions in the original test set for reference. We observe a significantly lower rate of token repetitions in our CTC model compared to both the models. This empirical observation supports our hypothesis that β^{-1} helps remove spurious token repetitions.

6.2 Impact of Number of Decoding Iterations

The number of decoding iterations is an important hyperparameter in iterative models, providing a tunable trade-off between quality and inference speed. The ideal parallel decoding model should be robust to the number of decoding iterations, i.e. reducing the number of iterations should have minimal impact on performance. To analyze this capability of our Imputer model, we study the impact of the number of decoding iterations vs BLEU. We use the Imputer trained with data distilled from the autoregressive base Transformer teacher for this analysis. Imputer controls the number of decoding iterations through the top-k hyperparameter, which imputes k tokens per step. On one end, imputing all the tokens ($k = \infty$) in one step results in single-step decoding, while on the other end, imputing 1 token per step ($k = 1$) results in linear autoregressive decoding (but not necessarily left-to-right).

Figure 3 shows the BLEU score vs target length T for WMT'14 En→De test set, where T is the number of decoding iterations. As expected, the performance consistently increases with an increase in T. We find that Imputer is robust to T, sacrificing just 0.6 BLEU points when reducing T

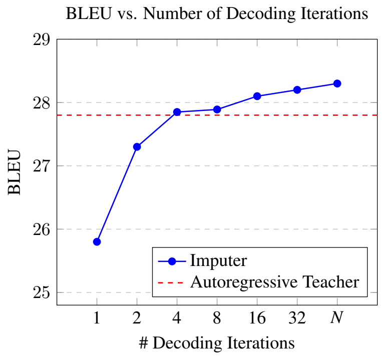

Figure 3: WMT'14 En→De BLEU comparison for different number of decoding iterations for Imputer.

Table 6: WMT'14 En→De BLEU comparison showing the impact of distillation.

Method	**Iterations**	**Original**	**Distillation**
CTC	1	15.6	25.4
Imputer	4	24.7	27.9
	8	25.0	27.9

from 8 to 2. We can match the performance of its autoregressive teacher using just 4 decoding iterations. Interestingly, the performance keeps increasing consistently beyond 8 iterations, and even outperforming the autoregressive teacher slightly. In the extreme case of autoregressive $O(n)$ decoding, we obtain 28.3 BLEU score, exceeding the teacher's performance by 0.5 BLEU points.

6.3 Impact of Distillation

We analyze the impact of distillation on our models by comparing them to original training data versus training data from a base Transformer teacher on the WMT'14 En→De dataset. Table 6 summarizes the results. In all cases, models trained with the distilled data perform significantly better than the model trained with the original data. We observe that the performance gap is largest in the case of the CTC model, and decreases with an increase in the number of decoding iterations. This is consistent with prior work finding distillation to improve model quality (Gu et al., 2018; Zhou et al., 2020).

6.4 Impact of Target Length for Imputer

Figure 4 depicts the impact of number of decoding iterations bucketed by the target sequence length N. We use the `compare-mt` (Neubig et al., 2019) package to bucket test set examples based on target sentence length, and compute BLEU score for each bucket using a different number of decoding iterations. Increase in the number of decoding iterations provides consistent gain across all buckets.

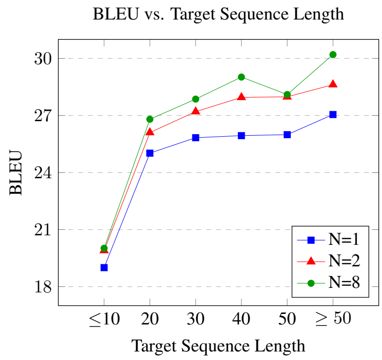

Figure 4: WMT'14 En→De BLEU comparison for sentences binned by target sequence length for Imputer; N is the number of decoding iterations.

7 Conclusion

In this paper, we investigated two latent alignments models, CTC and Imputer, for non-autoregressive machine translation. CTC is a single step generation model, while Imputer is an iterative generative model requiring only a constant number of generation steps. Our models rely on dynamic programming to marginalize out the latent alignments. Unlike many prior works, our models do not need to perform target length prediction, or re-scoring of candidates and our models use a simplified neural architecture without the need of cross-attention mechanism found in many prior encoder-decoder architectures. We demonstrate the ease and effectiveness of the application of these simple latent alignment models primarily used in speech recognition to the task of machine translation. Applying these latent alignment models for parallel translation of long documents can be an interesting research direction.

Abstract

Many extractive question answering models are trained to predict start and end positions of answers. The choice of predicting answers as positions is mainly due to its simplicity and effectiveness. In this study, we hypothesize that when the distribution of the answer positions is highly skewed in the training set (e.g., answers lie only in the k-th sentence of each passage), QA models predicting answers as positions can learn spurious positional cues and fail to give answers in different positions. We first illustrate this *position bias* in popular extractive QA models such as BiDAF and BERT and thoroughly examine how position bias propagates through each layer of BERT. To safely deliver position information without position bias, we train models with various de-biasing methods including entropy regularization and bias ensembling. Among them, we found that using the prior distribution of answer positions as a bias model is very effective at reducing position bias, recovering the performance of BERT from 37.48% to 81.64% when trained on a biased SQuAD dataset.

1 Introduction

Question answering (QA) is a task of answering questions given a passage. Large-scale QA datasets have attracted many researchers to build effective QA models, and with the advent of deep learning, recent QA models are known to outperform humans in some datasets (Rajpurkar et al., 2016; Devlin et al., 2019; Yang et al., 2019). Extractive QA is the task that assumes that answers always lie in the passage. Based on this task assumption, various QA models are trained to predict the start and end positions as the answers. Following the structure of earlier deep learning-based QA models (Wang and Jiang, 2016; Seo et al., 2017; Xiong et al., 2017), recent QA models provide positions of answers without much consideration (Yu et al., 2018; Devlin et al., 2019; Yang et al., 2019).

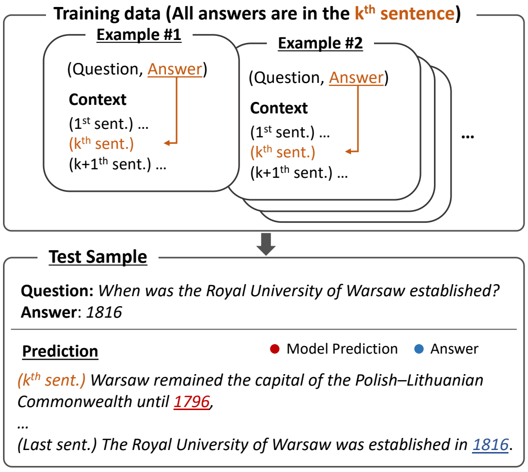

Figure 1: Example of position bias. BERT trained on the dataset with a skewed answer position distribution, provides wrong predictions, biased to the specific sentence position.

The popularity of predicting the answer positions is credited to the fact that it reduces the prediction space to $\mathcal{O}(n)$ where n is the length of an input document. It is more efficient and effective than directly generating answers from a large vocabulary space. Furthermore, it reduces the QA task to a classification task which is convenient to model. Nevertheless, very few studies have discussed the side effects of predicting the answer positions. Could there be any unwanted biases when using answer positions as prediction targets?

In this paper, we demonstrate that the models predicting the position can be severely biased when trained on datasets that have a very skewed answer position distribution. We define this as position bias as shown in Figure 1. Models trained on a biased dataset where answers always lie in the same

Table 1: Performance of QA models trained on the biased SQuAD dataset (SQuAD$^{k=1}_{\text{train}}$), and tested on SQuAD$_{\text{dev}}$. Δ denotes the difference in F1 score with SQuAD$_{\text{train}}$. We use exact match (EM) and F1 score for evaluation.[1]

sentence position mostly give predictions on the corresponding sentence. As a result, BERT (Devlin et al., 2019) trained on a biased training set where every answer appear in the first sentence only achieves 37.48% F1 score in the SQuAD development set whereas the same model trained on the same amount of randomly sampled examples achieves 85.06% F1 score.

To examine the cause of the problem, we thoroughly analyze the learning process of QA models trained on the biased training sets, especially focusing on BERT. Our analysis shows that hidden representations of BERT preserve a different amount of word information according to the word position when trained on the biased training set. The predictions of biased models also become more dependent on the first few words when the training set has answers only in the first sentences.

To tackle the problem, we test various options, ranging from relative position encodings (Yang et al., 2019) to ensemble-based de-biasing methods (Clark et al., 2019; He et al., 2019). While simple baselines motivated by our analysis improve the test performance, our ensemble-based de-biasing method largely improves the performance of most models. Specifically, we use the prior distribution of answer positions as an additional bias model and train models to learn reasoning ability beyond the positional cues.

Contributions of our paper are in threefold; First, we define position bias in extractive question answering and illustrate that common extractive QA models suffer from it. Second, we examine the reason for the failure of the biased models and show that positions can act as spurious biases. Third, we show that the prior distribution of answer positions helps us to build positionally de-biased models, recovering the performance of BERT from 37.48% to 81.64%. We also generalize our findings in many different positions and datasets. [2]

2 Analysis

We first demonstrate the presence of position bias using biased training sets sampled from SQuAD (Rajpurkar et al., 2016) and visualize how position bias propagates in BERT.

2.1 Position Bias on Synthetic Datasets

From the original training set $\mathcal{D}_{\text{train}}$, we subsample a biased training set $\mathcal{D}^{k}_{\text{train}}$ whose answers lie in the k-th sentence.[3] We conduct experiments on SQuAD ($\mathcal{D}$ = SQuAD) as most examples in SQuAD are answerable with a single sentence (Min et al., 2018). Our analysis mainly focuses on SQuAD$^{k=1}_{\text{train}}$ (i.e., all answers are in the first sentence), which has the largest proportion of samples compared to other sentence positions in SQuAD (28,263 out of 87,599). The proportion in the development set (SQuAD$_{\text{dev}}$) is similar, having 3,637 out of 10,570 answers in the first sentence. Note that while our analysis is based on SQuAD$^{k=1}_{\text{train}}$, we also test various sentence positions in our main experiments (Section 4.2). We experiment with three popular QA models that provide positions as answers: BiDAF (Seo et al., 2017), BERT (Devlin et al., 2019), and XLNet (Yang et al., 2019). All three models are trained on SQuAD$^{k=1}_{\text{train}}$ and are evaluated on SQuAD$_{\text{dev}}$. For a fair comparison, we also randomly sample examples from the original training set and make SQuAD$_{\text{train}}$ (Sampled) which has the same number of examples with SQuAD$^{k=1}_{\text{train}}$.

Table 1 shows the performance of the three models trained on SQuAD$^{k=1}_{\text{train}}$. The performances of all models drop significantly compared to the models trained on SQuAD$_{\text{train}}$ or SQuAD$_{\text{train}}$ (Sampled). The relative position encodings in XLNet mitigate position bias to some extent, but its performance

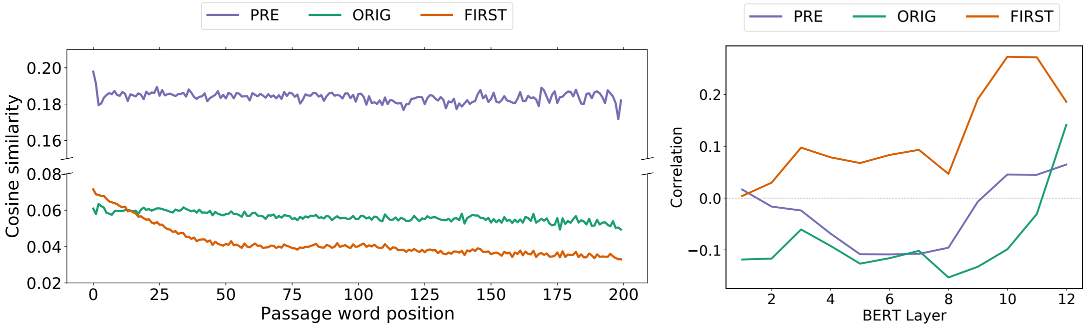
[3] We use Spacy Sentencizer (https://spacy.io/api/sentencizer) for the sentence split.



(a) Average cosine similarity (Layer 12)

(b) Spearman correlation (start)

Figure 2: Visualization of position bias with BERT trained on $\text{SQuAD}_{\text{train}}$ (Orig), $\text{SQuAD}^{k=1}_{\text{train}}$ (First), and BERT without fine-tuning (Pre). See Section See Section 2.2 for more details.

still degrades significantly.

To better understand the cause of position bias, we additionally perform two pre-processing methods on $\text{SQuAD}^{k=1}_{\text{train}}$. First, we truncate each passage up to the first sentence ($\text{SQuAD}^{k=1}_{\text{train}}$ + First Sentence). In this case, most performance is recovered, which indicates that the distributions of answer positions are relatively defined with respect to the maximum sequence length. Shuffling the sentence order of $\text{SQuAD}^{k=1}_{\text{train}}$ ($\text{SQuAD}^{k=1}_{\text{train}}$ + Sentence Shuffle) also recovers most performance, showing that the spreadness of answers matters. However, these pre-processing methods cannot be a solution as more fine-grained biases (e.g., word level positions) could cause the problem again and models cannot learn proper multi-sentence reasoning from a corrupted context.

2.2 Visualization of Position Bias

To visualize how position bias propagates throughout the layers, we compare BERT models, each trained on $\text{SQuAD}^{k=1}_{\text{train}}$ and $\text{SQuAD}_{\text{train}}$ respectively and BERT without any fine-tuning. The uncased version of BERT-base is used for the analysis.

Figure 2 (a) shows the amount of word information preserved in the hidden representations at the last layer of BERT. We define the amount of word information for each word position as the cosine similarity between the word embedding and its hidden representation at each layer. The similarities are averaged over the passage-side hidden representations in $\text{SQuAD}_{\text{dev}}$.

BERT trained on $\text{SQuAD}^{k=1}_{\text{train}}$ (First) has higher similarities at the front of the passages compared with BERT trained on $\text{SQuAD}_{\text{train}}$ (Orig). In the biased model, the similarity becomes smaller after the first few tokens, which shows position bias of BERT.

Figure 2 (b) shows the Spearman's rank correlation coefficient between the final output logits[4] and the amount of word information at each layer defined by the cosine similarity. A higher correlation means that the model is more dependent on the word information kept in that layer. The correlation coefficient is much higher in the biased model (First), especially in the last few layers. Combined with the observation from Figure 2 (a), this indicates that the predictions of the biased model are heavily relying on the information of the first few words.

2.3 Why is Position Bias Bad?

Our analysis shows that it is very easy for neural QA models to exploit positional cues whenever possible. While it is natural for neural models to learn the strong but spurious correlation present in the dataset (McCoy et al., 2019; Niven and Kao, 2019), we argue that reading ability should be cultivated independent of such positional correlation. Our study aims to learn proper reading ability even in extreme cases where all answers are in the k-th sentence. Although exploiting the position distribution within the dataset could help the model improve performance on its corresponding test set, position bias should not be learned since we cannot guarantee realistic test environments to follow similar distribution.

3 Method

To prevent models from learning a direct correlation between word positions and answers, we introduce simple remedies for BERT and a bias

---

[4] We show the results with start position logits and the same pattern is observed with end position logits.

ensemble method with answer prior distributions that can be applied to any QA models.

3.1 Baselines

Randomized Position To avoid learning the direct correlation between word positions and answers, we randomly perturb input positions. We first randomly sample t indices from a range of 1 to maximum sequence length of BERT. We sample $t = 384$ when the maximum sequence length is 512. Then, we sort the indices in an ascending order to preserve the ordering of input words. Perturbed indices then generate position embedding at each token position, which replaces the original position embedding.

Entropy Regularization Inspired by the observation in Section 2.2, we force our model to preserve a constant amount of word information regardless of the word positions. Maximizing the entropy of normalized cosine similarity between the word embeddings and their hidden representations encourages models to maintain a uniform amount of information. As the cosine similarities are not probabilities, we normalize them to be summed to 1. We compute the entropy regularization term from the last layer and add it to the start/end prediction loss with a scaling factor λ.

3.2 Bias Ensemble with Answer Prior

Bias ensemble methods (Clark et al., 2019; He et al., 2019) combine the log probabilities from a pre-defined bias model and a target model to debias. Ensembling makes the target model to learn different probabilities other than the bias probabilities. In our case, we define the prior distribution of the answer positions as our bias model. Specifically, we introduce the sentence-level answer prior and the word-level answer prior.

Bias Ensemble Method Given a passage and question pair, a model has to find the optimal start and end positions of the answer in the passage, denoted as y_s, y_e. Typically, the model outputs two probability distributions p^s and p^e for the start and end positions. As our method is applied in the same manner for both start and end predictions, we drop the superscript from p^s, p^e and subscript from y_s, y_e whenever possible.

For ensembling two different log probabilities from the bias model and the target model, we use a product of experts (Hinton, 2002). Using the product of experts, a probability at the i-th position is calculated as:

$$\hat{p}_i = softmax(\log(p_i) + \log(b_i)) \tag{1}$$

where $\log(p_i)$ is a log probability from the target model and $\log(b_i)$ is a log probability from the bias model. The ensembled probability $\hat{p}$ is used for the training.

To dynamically choose the amount of bias for each sample, Clark et al. (2019) introduce a learned mixing ensemble with a trainable parameter. Probabilities in the training phase are now defined as:

$$\hat{p}_i = softmax(\log(p_i) + g(X)\log(b_i)) \tag{2}$$

We use hidden representations before the softmax layer as X. $g(X)$ then applies affine transformation on the representations to obtain a scalar value. Softplus activation followed by max pooling is used to obtain positive values. As BiDAF has separate hidden representations for the start and end predictions, we separately define $g(X)$ for each start and end representation.

As models often learn to ignore the biases and make $g(X)$ to 0, Clark et al. (2019) suggest adding an entropy penalty term to the loss function. However, the entropy penalty did not make much difference in our case as $g(X)$ was already large enough. Note that we only use $\log(b_i)$ during training, and the predictions are solely based on the predicted log probability $\log(p_i)$ from the model.

We define bias log probability as pre-calculated answer priors. Using prior distributions in machine learning has a long history such as using class frequency in the class imbalance problem (Domingos, 1999; Japkowicz and Stephen, 2002; Zhou and Liu, 2006; Huang et al., 2016). In our case, the class prior corresponds to the prior distribution of answer positions.

Word-level Answer Prior First, we consider the word-level answer prior. Given the training set having N examples having N answers $\{y^{(1)}, y^{(2)}, ..., y^{(N)}\}$, we compute the word-level answer prior at position i over the training set. In this case, our bias log probability at i-th position is:

$$\log(b_i) := \frac{1}{N}\sum_{j=1}^{N}\mathbf{1}[y^{(j)} = i] \tag{3}$$

where we use the indicator function $\mathbf{1}[cond]$. Bias log probabilities for the end position prediction are calculated in a similar manner. Note that the word-level answer prior gives an equal bias distribution for each passage while the distribution is more fine-grained than the sentence-level prior described in the next section.

Sentence-level Answer Prior We also use the sentence-level answer prior which dynamically changes depending on the sentence boundaries of each sample. First, we define a set of sentences $\{S_1^{(j)}, ..., S_L^{(j)}\}$ for the j-th training passage, where L is the maximum number of sentence in whole training passages. Then, the sentence-level answer prior of the i-th word position (for the start prediction) for the j-th sample, is derived from the frequency of answers appearing in the l-th sentence:

$$\log(b_i^{(j)}) := \frac{1}{N}\sum_{k=1}^{N} \mathbf{1}[y^{(k)} \in S_l^{(k)}], \;\; i \in S_l^{(j)} \quad (4)$$

Note that as boundaries of sentences in each sample are different, bias log probabilities should be defined in every sample. Again, bias log probabilities for the end positions are calculated similarly.

It is very convenient to calculate the answer priors for any datasets. For instance, on $\mathcal{D}_{\text{train}}^{k=1}$, we use the first sentence indicator as the sentence-level answer prior as all answers are in the first sentence. More formally, the sentence-level answer prior for $\mathcal{D}_{\text{train}}^{k=1}$ is 1 for $l = 1$, and 0 when $l > 1$:

$$\log(b_i^{(j)}) := \begin{cases} 1 & i \in S_1^{(j)}, \\ 0 & i \notin S_1^{(j)} \end{cases} \quad (5)$$

which is a special case of the sentence-level answer prior. For general datasets where the distributions of answer positions are less skewed, the answer priors are more softly distributed. See Appendix B for a better understanding of the answer priors.

Both word-level and sentence-level answer priors are experimented with two bias ensemble methods: product of experts with bias (**Bias Product**, Equation 1) and learned mixing of two log probabilities (**Learned-Mixin**, Equation 2).

4 Experiments

We first experiment the effects of various de-biasing methods on three different QA models using both biased and full training sets. Our next experiments generalize our findings in different sentence positions and different datasets such as NewsQA (Trischler et al., 2017) and NaturalQuestions (Kwiatkowski et al., 2019).

4.1 Effect of De-biasing Methods

We first train all three models (BiDAF, BERT, and XLNet) on SQuAD$_{\text{train}}^{k=1}$ with our de-biasing methods and evaluate them on SQuAD$_{\text{dev}}$ (original development set), SQuAD$_{\text{dev}}^{k=1}$, and SQuAD$_{\text{dev}}^{k=2,3,...}$. Note that SQuAD$_{\text{dev}}^{k=2,3,...}$ is another subset of SQuAD$_{\text{dev}}$, whose answers do not appear in the first sentence, but in other sentences. We also experiment with BERT trained on the full training set, SQuAD$_{\text{train}}$.

For all models, we use the same hyperparameters and training procedures as suggested in their original papers (Seo et al., 2017; Devlin et al., 2019; Yang et al., 2019), except for batch sizes and training epochs (See Appendix A). λ for the entropy regularization is set to 5. Most of our implementation is based on the PyTorch library.

Results with SQuAD$_{\text{train}}^{k=1}$ The results of applying various de-biasing methods on three models with SQuAD$_{\text{train}}^{k=1}$ are in Table 2. Performance of all models without any de-biasing methods (denoted as 'None') is very low on SQuAD$_{\text{dev}}^{k=2,3,...}$, but fairly high on SQuAD$_{\text{dev}}^{k=1}$. This means that their predictions are highly biased towards the first sentences. In the case of BERT, F1 score on SQuAD$_{\text{dev}}^{k=1}$ is 85.81%, while F1 score on SQuAD$_{\text{dev}}^{k=2,3,...}$ is merely 12.12%. Our simple baseline approaches used in BERT improve the performance up to 34.63% F1 score (Random Position) while the entropy regularization is not significantly effective.

Bias ensemble methods using answer priors consistently improve the performance of all models. The sentence-level answer prior works the best, which obtains a significant gain after applying the Learned-Mixin method. We found that the coefficient $g(X)$ in Equation 2 averages to 7.42. during training for BERT + Learned-Mixin, which demonstrates a need of proper balancing between the probabilities. The word-level answer prior does not seem to provide strong position bias signals as its distribution is much softer than the sentence-level answer prior.

Results with SQuAD$_{\text{train}}$ The results of training BERT with our de-biasing methods on the full training set SQuAD$_{\text{train}}$ are in the bottom of Table 2. Note that the answer prior is more softened than the answer prior used in SQuAD$_{\text{train}}^{k=1}$ as answers are now spread in all sentence positions. While exploiting the positional distribution of the training set

could be more helpful when evaluating on the development set that has a similar positional distribution, our method maintains the original performance. It shows that our method works safely when the positional distribution doesn't change much.

Visualization To investigate the effect of debaising methods, we visualize the word information in each layer as done in Section 2.2. We visualize the BERT trained on SQuAD$_{\text{train}}^{k=1}$ ensembled with sentence-level answer prior in Figure 3. The bias product method (PRODUCT) and the model without any de-biasing methods (NONE) are similar, showing that it still has position bias. The learned-mixin method (MIXIN), on the other hand, safely delivers the word information across different positions.

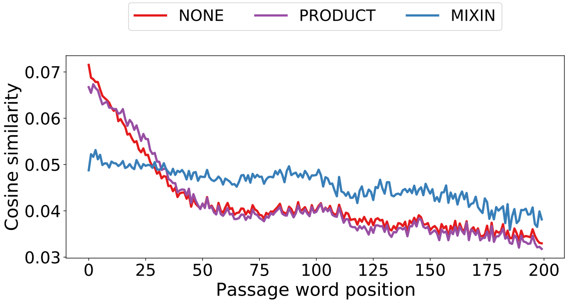

Figure 3: Visualization of BERT models trained on SQuAD$_{\text{train}}^{k=1}$ with and without de-biasing method.

4.2 Generalizing to Different Positions

As the SQuAD training set has many answers in the first sentence, we mainly test our methods on SQuAD$_{\text{train}}^{k=1}$. However, does our method generalize to different sentence positions? To answer this question, we construct four SQuAD$_{\text{train}}^{k}$ datasets based on the sentence positions of answers. Note that unlike SQuAD$_{\text{train}}^{k=1}$, the number of samples becomes smaller and the sentence boundaries are more blurry when $k > 1$, making answer priors much softer. We train three QA models on different biased datasets and evaluate them on SQuAD$_{\text{dev}}$ with and without de-biasing methods.

	$\text{SQuAD}_{\text{dev}}$							
	EM	F1	EM	F1	EM	F1	EM	F1
$\text{SQuAD}^{k}_{\text{train}}$	$k=2$ (20,593 samples)		$k=3$ (15,567 samples)		$k=4$ (10,379 samples)		$k=5,6,\ldots$ (12,610 samples)	
BiDAF	18.43	25.74	12.26	19.04	9.96	16.50	12.34	19.65

+Learned-Mixin	**68.34**	**80.35**	**69.28**	**79.99**	**70.07**	**80.12**	**73.33**	**82.79**

Table 3: Position bias in different positions. Each model is trained on a biased SQuAD dataset ($\text{SQuAD}^{k}_{\text{train}}$) and evaluated on $\text{SQuAD}_{\text{dev}}$.

(a) BERT (b) BERT + Bias Product (c) BERT + Learned-Mixin

Figure 4: Sentence-wise position bias in SQuAD. Models are trained on $\text{SQuAD}^{k}_{\text{train}}$ and evaluated on $\text{SQuAD}^{k}_{\text{dev}}$. (a) Standard BERT suffers from position bias as the off-diagonal performance is significantly lower. (b), (c) Our de-biasing method successfully handles the bias and provides consistently higher performance.

Results As shown in Table 3, all three models suffer from position bias in every sentence position while the learned-mixin method (+Learned-Mixin) successfully resolves the bias. Due to the blurred sentence boundaries, position bias is less problematic when k is large. We observe a similar trend in BERT and XLNet while a huge performance drop is observed in BiDAF even with a large k.

Visualization Figure 4 visualizes the sentence-wise position biases. We train BERT, BERT + Bias Product and BERT + Learned Mixin on different subsets of SQuAD training set ($\text{SQuAD}^{k}_{\text{train}}$) and evaluated on every $\text{SQuAD}^{k}_{\text{dev}}$ whose answers lie only in the k-th sentence. As a result, the low performance in the off-diagonal represent the presence of position bias. The figure shows that the biased model fails to predict the answers in different sentence positions (Figure 4 (a)) while our de-biased model achieves high performance regardless of the sentence position (Figure 4 (c)). Again, as the value of k increases, the boundary of the k-th sentence varies a lot in each sample, which makes the visualization of sentence-wise bias difficult.

4.3 NewsQA and NaturalQuestions

We test the effect of de-basing methods on datasets having different domains and different degrees of position bias. NewsQA (Trischler et al., 2017) is an extractive QA dataset that includes passages from CNN news articles. NaturalQuestions (Kwiatkowski et al., 2019) is a dataset containing queries and passages collected from the Google search engine. We use the pre-processed dataset provided by the MRQA shared task (Fisch et al., 2019).[5]

For each dataset, we construct two sub-training datasets; one contains samples with answers in the first sentence ($k = 1$), and the other contains

---

$\textbf{NewsQA}^{k}_{\text{train}}$	$\textbf{NewsQA}_{\text{dev}}$ $k=$ All	$k = 1$	$k = 2, 3, ...$
BERT	**69.94**	27.99	56.15
+Bias Product	69.46	28.81	56.86
+Learned-Mixin	69.42	**44.50**	**58.22**

Table 4: F1 scores on NewsQA. Models are evaluated on the original development dataset ($\text{NewsQA}_{\text{dev}}$).

$\textbf{NQ}^{k}_{\text{train}}$	$\textbf{NQ}_{\text{dev}}$ $k=$ All	$k = 1$	$k = 2, 3, ...$
BERT	78.79	56.79	49.59
+Bias Product	78.84	56.77	53.34
+Learned-Mixin	**79.04**	**72.83**	**60.63**

Table 5: F1 scores on NaturalQuestions. Models are evaluated on the original development dataset (NQ_{dev}).

the remaining samples ($k = 2, 3, ...$). Models are trained on the original dataset and two sub-training datasets and evaluated on the original development set.

Implementation Details For NewsQA, we truncate each paragraph so that the length of each context is less than 300 words. We eliminate training and development samples that become unanswerable due to the truncation. For NaturalQuestions, we choose firstly occurring answers for training extractive QA models, which is a common approach in weakly supervised setting (Joshi et al., 2017; Talmor and Berant, 2019).

From NewsQA and NaturalQuestions, we construct two sub-training datasets having only the first annotated samples ($\mathcal{D}^{k=1}_{\text{train}}$) and the remaining samples ($\mathcal{D}^{k=2,3,...}_{\text{train}}$). For a fair comparison, we fix the size of two sub-training sets to have 17,000 (NewsQA) and 40,000 samples (NaturalQuestions).

Results In Table 4 and Table 5, we show results of applying our methods. In both datasets, BERT, trained on biased datasets ($k = 1$ and $k = 2, 3, ...$), significantly suffers from position bias. Position bias is generally more problematic in the $k = 1$ datasets while for NaturalQuestions, $k = 2, 3, ...$ is also problematic. Our de-biasing methods prevent performance drops in all cases without sacrificing the performance on the full training set ($k =$ All).

5 Related Work

Various question answering datasets have been introduced with diverse challenges including reasoning over multiple sentences (Joshi et al., 2017), answering multi-hop questions (Yang et al., 2018), and more (Trischler et al., 2017; Welbl et al., 2018; Kwiatkowski et al., 2019; Dua et al., 2019). Introduction of these datasets rapidly progressed the development of effective QA models (Wang and Jiang, 2016; Seo et al., 2017; Xiong et al., 2017; Wang et al., 2017; Yu et al., 2018; Devlin et al., 2019; Yang et al., 2019), but most models predict the answer as positions without much discussion on it.

Our work builds on the analyses of dataset biases in machine learning models and ways to tackle them. For instance, sentence classification models in natural language inference and argument reasoning comprehension suffer from word statistics bias (Poliak et al., 2018; Minervini and Riedel, 2018; Kang et al., 2018; Belinkov et al., 2019; Niven and Kao, 2019). On visual question answering, models often ignore visual information due to the language prior bias (Agrawal et al., 2016; Zhang et al., 2016; Goyal et al., 2017; Johnson et al., 2017; Agrawal et al., 2018). Several studies in QA also found that QA models do not leverages the full information in the given passage (Chen et al., 2016; Min et al., 2018; Chen and Durrett, 2019; Min et al., 2019). Adversarial datasets have been also proposed to deal with this type of problem (Jia and Liang, 2017; Rajpurkar et al., 2018). In this study, we define position bias coming from the prediction structure of QA models and show that positionally biased models can ignore information in different positions.

Our proposed methods are based on the bias ensemble method (Clark et al., 2019; He et al., 2019). Ensembling with the bias model encourages the model to solve tasks without converging to bias shortcuts. Clark et al. (2019) conducted de-biasing experiments on various tasks including two QA tasks while they use tf-idf and the named entities as the bias models.

It is worth noting that several models incorporate the pointer network to predict the answer positions in QA (Vinyals et al., 2015; Wang and Jiang, 2016; Wang et al., 2017). Also, instead of predicting positions, some models predict the n-grams as answers (Lee et al., 2016; Seo et al., 2019), generate answers in a vocabulary space (Raffel et al., 2019), or use a generative model (Lewis and Fan, 2019). We expect that these approaches suffer less from position bias and leave the evaluation of position bias in these models as our future work.

6 Conclusion

Most QA studies frequently utilize start and end positions of answers as training targets without much considerations. Our study shows that most QA models fail to generalize over different positions when trained on datasets having answers in a specific position. Our findings show that position can work as a spurious bias and alert researchers when building QA models and datasets. We introduce several de-biasing methods to make models to ignore the spurious positional cues, and find out that the sentence-level answer prior is very useful. Our findings also generalize to different positions and different datasets. One limitation of our approach is that our method and analysis are based on a single paragraph setting which should be extended to a multiple paragraph setting to be more practically useful.

A Implementation Details

Details of Training For all experiments, we use uncased BERT-base and cased XLNet-base. We modify the open-sourced Pytorch implementation of models.[6] BiDAF is trained with the batch size of 64 for 30 epochs and BERT and XLNet are trained for 2 epochs with batch sizes 12 and 10, respectively. The choice of hyperparameters mainly comes from the limitation of our computational resources and mostly follows the default setting used in their original works. Note that our de-biasing methods do not require additional hyperparameters.

For all three models, the number of parameters remains the same as default settings with bias product and increases by a single linear layer with learned-mixin. We trained models on a single Titan X GPU. The average training time of the bias ensemble method is similar to the original models.

B Examples of Answer Prior

To provide a better understanding of our methods, Figure B.1 shows examples of answer priors, which are used as bias models. See section 3 for detail.

C Visualization of Position Bias

In Figure C.1, we plot the preserved amount of word information in the middle layers of BERT. Figure C.2 shows the effect of applying the debiasing methods in each layer of BERT. See Section 2 and 4.1 for more detail. We plot the results of layers 1, 4, 7, 10, and 11.

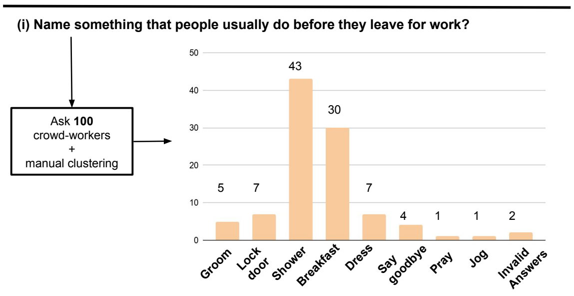
Abstract

Given questions regarding some prototypical situation — such as *Name something that people usually do before they leave the house for work?* — a human can easily answer them via acquired experiences. There can be multiple right answers for such questions, with some more common for a situation than others.

This paper introduces a new question answering dataset for training and evaluating common sense reasoning capabilities of artificial intelligence systems in such prototypical situations. The training set is gathered from an existing set of questions played in a long-running international game show – FAMILY-FEUD. The hidden evaluation set is created by gathering answers for each question from 100 crowd-workers. We also propose a generative evaluation task where a model has to output a ranked list of answers, ideally covering all prototypical answers for a question. After presenting multiple competitive baseline models, we find that human performance still exceeds model scores on all evaluation metrics with a meaningful gap, supporting the challenging nature of the task.

1 Introduction

Humans possess the ability to implicitly reason using a wealth of common background knowledge, much of which is acquired through shared experiences. For example, consider the question in Figure 1 — "*Name something that people usually do before they leave the house for work.*". Humans can agree about the details and characteristics of a prototypical event or situation (Schank and Abelson, 1975, 1977) due to commonalities in their shared lived experiences, cultural norms and expectations. This rough agreement extends beyond an agreement on a single top response, but can be viewed as a ranked list of plausible answers, as demonstrated in Figure 1. Such sets of diverse answers represent the nature of common sense knowledge and may be useful in applications such as dialogue systems, where multiple responses are appropriate for a given context (Zhang et al., 2019b).



(ii) Name a piece of equipment that you are likely to find at your office and not at home?
Categories: *printer/copier (**37**), office furniture (**15**), computer equipment (**17**), stapler (**11**) files (**10**), office appliances (**5**), security systems (**1**)*

(iii) Name something that an athlete would not keep in her refrigerator.
Categories: *unhealthy / fast food (**36**), unhealthy drinks (**24**), clothing/shoes (**24**) accessories (**7**)*

(iv) Name something that you might forget in a hotel room?
Categories: *phone (**24**), toothbrush/towels (**17**), clothing/shoes (**15**) keys (**14**), purse/wallet (**14**), accessories (**8**), charger (**5**)*

Figure 1: We focus on common-sense reasoning over prototypical situations when there could be many different answers but some are more common than others. Our task is in generative style (*not* multiple-choice format). Answers to a question are crowd-sourced from 100 workers and are then manually clustered into categories. To perform well, a model has to output a ranked list of answers covering multiple categories.

We present a new question/answer dataset capturing both the plausibility of the answers and the ranking preference of each answer about such prototypical situations inspired by the long-running American game show FAMILY-FEUD, which also provides the training data for the task.[1] The game show is played by prompting participants with queries such as *Name something that people usually do before they leave the house for work* (as shown in

Figure 1). The answers to such questions are provided by 100 randomly selected individuals and clustered into general categories by a professional polling company. Contestants attempt to provide an answer which matches these categories and get points according to the proportion of surveyed responses within a matched category. For example, when we polled 100 people with the same question (Figure 1), they provided 43 answers involving showering/cleaning, 30 answers mentioning breakfast, and the remainder fell into smaller groups such as locking a door/grabbing keys, saying goodbye, and praying. In a FAMILY-FEUD game, if two participants on a team answered "grab a shower" and "eggs and coffee", they would receive 73 points for providing answers which matched these two large categories. We suggest that this is an appealing paradigm for such question answering tasks where a wide range of acceptable answers exist, as it encourages both highly popular answers as well as wide coverage over the range of good answers.

We frame this task as a generative evaluation task in which a model outputs a ranked list of answers to a given question. Each answer string is then matched to one or more clusters of reference answers for that question. Matching an answer cluster gives the model a score equal to the cluster size. Our evaluation metrics (§ 3) reward models which provide the most common answers, while also measuring the model's ability to provide a diverse set of answers in order to match all the answer clusters. While such an approach can penalize a correct model prediction when it does not match an existing reference answer, we counter this issue by (a) gathering and clustering a large number of reference answers, and (b) utilizing methods of matching non-exact matches, such as WordNet (Miller, 1995) and contextual language models such as RoBERTa (Liu et al., 2019). Generative evaluation approaches are also used in other NLP tasks such as summarization (Radev et al., 2003) and translation (Callison-Burch et al., 2010).

We evaluate on a set of competitive baseline models — from QA models powered by large masked LMs such as BERT, to the direct prediction of answers in a language-modeling paradigm using a large GPT-2 LM (Radford et al., 2018), as well as GPT-2 fine-tuned upon the training data. While most models perform quite poorly at this challenging task, when GPT-2 was fine-tuned using the FAMILY-FEUD training set its performance did improved drastically, although remaining significantly below the score of human-level performance.

The contributions of this paper are as follows.

1. We introduce a large-scale QA dataset of 9.7k questions regarding common sense knowledge of prototypical situations with 7-8 labeled answer categories per question, and a corresponding evaluation set of 15,400 crowdsourced human judgments over 154 unseen questions.

2. We present methods for robust evaluation of this task to encourage models to provide diverse answers covering all plausible answer categories.

3. We evaluate against a range of plausible baselines, showing that while large contextualized language models fine-tuned on this data can perform well at the task, a meaningful gap still exists between model and human performance, suggesting room for improvement.

2 Dataset Creation and Analysis

2.1 Training Corpus Collection

A number of fan websites exist which have transcribed FAMILY-FEUD questions and answer clusters. We use publicly available text from two such websites to provide a training dataset on this task.[2] Well over 10,000 questions (with answer clusters) were collected, and a set of 9,762 questions remained after filtering, quality control, and deduplication.

That filtering included the omission of questions that were taxonomic in character rather than probing common sense knowledge, such as *name a vegetable*, as well as the omission of questions encoding stereotypes. A small set of training instances which ascribe specific stereotypes or expectations to a particular group or gender – such as *"name something little boys love to build models of"* – were separated from the main training data set to avoid encouraging trained models to learn such biases [3]. We note, however, that common sense questions may carry a wide range of more nuanced culturally-specific information and biases. Studying the bias in such datasets, and natural stereotypical biases which pre-trained language models have been shown to have (Sheng et al., 2019), would be a valuable topic of future work.

[2] Scraping details and site names are provided in the datasheet (following Gebru et al. (2018)) provided with the data

[3] Criteria for exclusion are listed in the appendix

2.2 Test Corpus Collection

In order to establish a rich, open-ended answer generation task, we created new questions similar to those seen in the training set, collected 100 answers for each question[4] from the crowd-sourcing platform FigureEight[5] and manually clustered them. Because we gathered large sets of possible answers and clustered them, the evaluation set represents rough distributions over the expected raw string answers for each question, thereby increasing the ability to recognize any way of expressing one of those answers.

We attempted to make sure that this set of new questions maintained the same domain and the same common sense reasoning seen in the training data. In order to maintain similarity to existing questions, these questions were created by removing a set of questions from the scraped data and perturbing important aspects, making sure that the perturbations were sufficient to meaningfully change the answer set (thus being similar to the "counterfactually augmented" permutations of Kaushik et al. (2019)). For example, given an existing question of "*Name something a person might forget to put on if they leave the house in a hurry.*", changes of polarity and events would derive a related question "*Name something that people usually do before they leave the house for work*". Deriving such unseen test questions was especially important to avoid the risk of having a publicly-available question be included in the training data for contextual language models; by making new data, we can be confident that any high-performing model has not yet seen the data. In order to control the quality of perturbed questions, the quality of each each perturbed question was scored by four experts (criteria listed in the appendix), and only the top-scoring questions were used to build the evaluation set.

We then created tasks on FigureEight for each selected question to be answered by 100 workers. To match the training data (which is inherently grounded in US culture), we limited workers to US locations. Low-quality workers were automatically detected through test questions during annotation, and the clustering pass provided a second manual quality control check. This left us with 154 questions which we split into a test set and development set of 102 and 52 respectively.

2.3 Answer Clustering

Each list of 100 raw string answers was manually clustered by two different experts familiar with the task. Clusters were assigned separately and then compared, and a final clustering was agreed on.[6] During this clustering phase answers could be marked as invalid as well — most commonly, either due to low-quality annotations or a clear misunderstanding of a question. In order to keep these clusters roughly similar to the granularity of answers used in the training data and to avoid low-quality evaluation we eliminated questions for which the 8 most popular clusters did not contain at least 85 of the 100 responses.

Since each set of answers was clustered twice and adjudicated, we measure the agreement with a cluster agreement metric BLANC (Recasens and Hovy, 2011; Luo et al., 2014), an extension of the Rand index used to score coreference clustering. Using this, the similarity between the clusters produced by any two annotators averaged out to a BLANC score of 83.17, suggesting a coherent amount of agreement regarding the clustering of answers.

2.4 Analysis of the Dataset

The data presented here involves a range of different types of common sense knowledge. To explore the distribution of different kinds of reasoning, and to test whether that distribution of reasoning varied between the publicly available data and the crowdsourced development and test set, we propose a small inventory of six types of common sense reasoning.

We are not aware of an agreed-upon typology of all commonsense reasoning types. Categorizations of different types of commonsense reasoning exist (LoBue and Yates, 2011; Boratko et al., 2018), but since each provided categorizations needed for specific tasks (RTE and the ARC dataset, respectively), neither fully covered the range of commonsense types seen in the current work. After consulting both those prior works and a separate part of the training data, we characterize the data into the following six types.

These types consist of (1) MENTAL OR SOCIAL REASONING, (2) KNOWLEDGE OF PROTOTYPICAL SITUATIONS which one is familiar with, (3) REASONING ABOUT NOVEL, COMPLEX

---

[4] Each worker, on average, provides 41 judgments, and 5 cents per judgment.

[5] Now `https://appen.com/`.

[6] The four total expert annotators annotated a random set of 10 questions together to calibrate their clustering granularity. Furthermore, two annotator's results are aggregated by a third person to reduce bias.

Question	Example Answers	Types
Name a profession where you might be fired if you lost your voice	radio host , teacher	3, 4, 6
Name something a boy scout might learn.	knot tying, camping	2, 5, 6
Name a bad sport for someone who is afraid of the water.	diving, water polo	1, 3 ,6
Name something a monk probably would not own.	weapons, smartphone	2, 4, 6
Name something parents tell their kids not to do	steal, smoke	1, 2, 4, 6
Name a reason why someone would wear gloves	cold weather, cleaning	2, 3

Table 1: Examples of questions from collected (top 3) and crowd-sourced (bottom 3) development sets, characterized with reasoning types described in § 2.4

EVENTS, (4) NEGATION AND EXCEPTIONS and understanding their consequences, (5) SPECIFIC ENTITY KNOWLEDGE of named people, locations, or organizations, and finally (6) KNOWLEDGE OF HABITUAL ACTIVITIES of specific occupations or types of entities.

Following other characterizations of reasoning type (LoBue and Yates, 2011; Boratko et al., 2018), we annotated a random sample of questions (25 from dev and 25 from train) using six basic common sense reasoning categories in order to provide a simple approximation of the distribution over reasoning types contained in the data. Table 1 illustrates examples of questions with these types, and one can see the frequency of each type used in Table 2. The counts shown for each dataset illustrate that while the creation methodology varied between the two resources, the kind of common sense reasoning tasks evaluated by these models is quite similar between the two corpus types. The greatest difference to note is that the crowd-sourced data makes less use of questions regarding specific entities, which were avoided as they tended to involve fact-based world-knowledge rather than common sense reasoning.

Reasoning type	Scraped Dev	Crowd-sourced
Mental/Social	16%	12%
Prototypical Events	68%	80%
Event Reasoning	28%	40%
Negation	12%	20%
Specific Entities	20%	4%
Habitual Activity	40%	24%

Table 2: Percentage of questions utilizing each reasoning type

3 Evaluation

We present a number of methods for evaluating system-generated answers against these sets of clustered answers. In each, models are evaluated by providing a ranked list of answers in response to a question. These answers are then compared to the set of reference answers for that question and scored based upon how similar they are to the known answers. While one might instead convert question-answer pairs into a multiple-choice paradigm by generating negatives, it is difficult to generate good negative examples, and the quality of a dataset can be compromised if such examples are either too easy or easily identified using biases in the negative example generation process (Mostafazadeh et al., 2016; Zellers et al., 2018; Talmor et al., 2019; Schwartz et al., 2017; Gururangan et al., 2018; Poliak et al., 2018).

We outline here our proposed method for scoring these ranked lists of predicted answers. The dataset ground truth is a ranked list of clusters of answers, including weights(cluster sizes) associated with each cluster. A first component in such an evaluation is to match each answer to an existing cluster of answers, if any cluster is acceptable. We try both simple methods such as exact match as well as more flexible ways of matching to clusters, such as using synonyms from WordNet (Miller, 1995) or a vector-based similarity method using RoBERTa (Liu et al., 2019). The second component in this generative evaluation is to provide an overall score for the entire ranked list of answers by mapping individual answers to answer clusters or marking them wrong. Scoring answers against clusters alone does not take into account the ranking. To that end, we propose two different metrics, one similar to hits@k in traditional information retrieval task and one which limits the number of incorrect answers, which is closer to how humans are typically evaluated on this task.

In each case the score reported is calculated as a percentage of the oracle score. Both proposed methods of scoring reward models which provide a

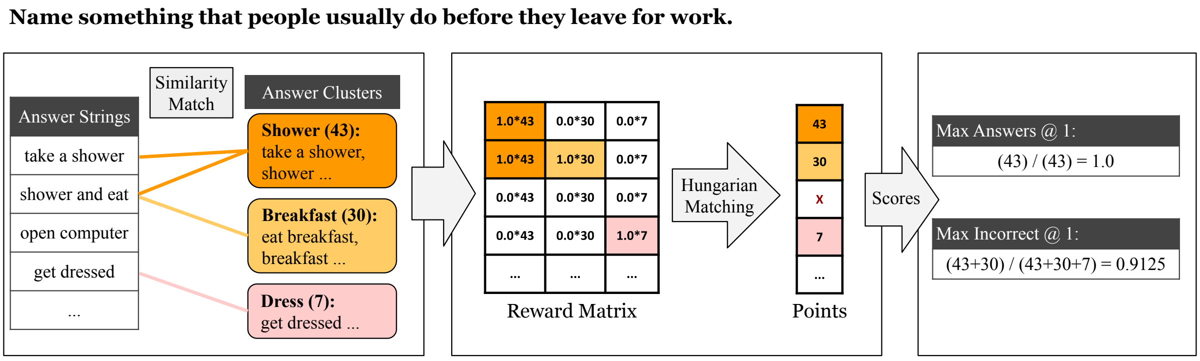

Figure 2: Example steps for evaluating a ranked list of answers

diverse set of guesses to a given query and penalize models which provide many variations of the same answer. (See figure 2 for a general idea of the steps involved.)

3.1 Matching Answers to Clusters

3.1.1 Exact Match

In our simplest way of matching answers to clusters, we compare each answer with the answer strings from crowd-source workers for a given cluster, returning a score of 1 if it matched any string in the cluster and returning 0 if not. By construction, therefore, a given answer string will match at most a single cluster with this method.

3.1.2 WordNet Similarity

Reasonable answer strings may be incorrectly marked as wrong with an exact string match, even when they are clear synonyms of a reference answer. METEOR (Banerjee and Lavie, 2005; Lavie and Denkowski, 2009) addressed similar issues in machine translation via stemming and synonym matching. We take a similar approach, tokenizing a proposed answer string and comparing it to the tokenization of the answers in each answer cluster. Since some words in WordNet are multi-word phrases (eg. “chewing gum”) we furthermore perform this matching on all possible partitions of the tokenization. For each answer in an answer cluster we return the maximum (over all possible partitions) of the average number of matched tokens. The assignment of answers to clusters proceeds as in the exact match case. Further details are included in the appendix.

3.1.3 RoBERTa Similarity

Recent works in MT evaluation (Zhang et al., 2019a; Sellam et al., 2020) used pre-trained language models to compare predictions to reference answers. We implement a simple version of such vector-based comparisons, but this current task differs in that we assign each predicted answer to a particular cluster of correct answers, or decide whether to reject the answer. As clusters vary in size and specificity we cannot determine a universal threshold for how similar a mention must be to a cluster. Instead, we train a small classifier in L2 distance space for each answer cluster in order to decide membership in that answer cluster. We do this by obtaining a vector representation of each answer from RoBERTa (Liu et al., 2019), concatenating each answer with the question, and taking the mean of answer token representations. For each cluster we train a small one-vs-all classifier over the 100 answers to that question, predicting membership in that cluster (using gaussian process regression (Williams and Rasmussen, 1996) with an RBF kernel). At test time, a given answer is assigned to the highest-scoring cluster, as long as its likelihood of membership exceeds a minimum probability threshold, set at 0.1. Such an approach allows us to match answers to clusters while omitting answers which do not match existing clusters.

3.2 Evaluating Diverse Lists of Answers

As mentioned previously, we want to design evaluation metrics that favor models which take into account the ranking while still covering all plausible answer categories. We first compute an alignment score between each answer in the ranked list and each of our answer clusters. After computing the alignment scores between all pairs of answers and clusters we create a reward matrix where, for each answer and cluster, we assign a reward equal to the cluster size if the alignment score was a 1 and 0 otherwise. We employ the Hungarian matching algorithm (Kuhn, 1955; Munkres, 1957) to compute the exact optimal matching of answers to clusters based on this reward matrix, so that an answer is assigned to only one cluster. It is worth noting that a model which produces a ranked list of answers only in one cluster will do worse than a model which maximally covers all plausible clusters. Lastly, to make the comparison between lists of different lengths uniform, we propose the following metrics.

1. MAX ANSWERS@k limits the total number of answers allowed to up to k answers.[7]
2. MAX INCORRECT@k allows unlimited answers, but stops after k unmatched answers are provided.

In both conditions, we report the score as the percentage of the max score one could receive given that number of guesses, and only give credit for a given cluster once.

4 Baselines

We explore three baseline models for this task: a QA-based model which retrieves related posts in a discussion forum for each question, a language-modeling baseline which examines how well modern pre-trained language models do at directly producing the answers, and a fine-tuned version of the language-model baseline.

4.1 Question-Answering Baseline

As this dataset is in the form of questions and answers it may be treated as a QA dataset, although the content is far from the fact-based data usually modeled in QA tasks. As the training set only shows answers out of context, one must use distant supervision in order to train a QA model on the data, a well-explored situation in modern QA work (Joshi et al., 2017). Unlike factoid-based QA, one may expect a limit in the performance of such QA models for common sense reasoning, as common sense data is well-known to have a *reporting bias* (Gordon and Van Durme, 2013) wherein many facts that are part of the common ground of known knowledge are less likely to be stated.

To train a model in this approach, we collected up to 20 documents for each of the 9.7k questions in the FAMILY-FEUD training dataset by using a web search for each question constrained to Reddit. This resulted in a set of 85,781 Reddit posts total. Searches were constrained to Reddit in order to focus upon advice and personal narratives which might discuss common sense questions. For any post matching that query, any strings matching an answer to that question in the training data would be treated as a positive example for the QA model. The QA model used was the "Bert for QA" implementation within the Hugging Face Transformers package (Wolf et al., 2019); training details, and examples of the kind of noisy training data generated through this process, are provided in the appendix.

At test time documents were obtained by searching for the question in a google search restricted to Reddit, and the QA model was run on that set, taking the 20 best answers in context as possible answer strings. Those best answer strings from each passage were combined together, summing scores for identical strings, to provide a ranked list.

4.2 Language Model Baseline

We also report a language model generation baseline, due to the improved representation power of modern language models and recent evidence of their power in modeling common sense reasoning tasks (Weir et al., 2020; Tamborrino et al., 2020). The baseline is performed using the AI2 GPT-2 large model (Radford et al., 2019) (specifically, the Hugging Face PyTorch implementation (Wolf et al., 2019)). We perform both a zero-shot evaluation and an evaluation after fine-tuning with using our training data.

Because the original FAMILY-FEUD prompts are not structured as completion tasks, we transform the original question by hand-designed transformation rules in order for it to be compatible with the GPT-2 training data. E.g "Name something people do when they wake up." → "One thing people do when they wake up is ...". The hand-designed rules are including in the appendix. The transformed questions are used as input to the language model, and GPT-2 finishes the sentence. The reported fine-tuning result is trained on the scraped training corpus and the best model selected based on performance on our annotated development set. Training details and parameter setting for the model is provided in the appendix.

In order to generate diverse answers for a given sentence we use Nucleus Sampling (Holtzman et al., 2019) as our decoding method. We get 300 sampled answers for each question and group them by counts, returning a ranked list of 20 answers from most to least common.

---

[7] Note that since our scores are always calculated as a percentage of the max score one could receive, MAX ANSWERS is slightly different than hits@k in this setting.

Metrics %			QA Model	GPT-2	GPT-2 Fine Tune	Human
Exact Match	Max Answers	1	2.1	5.6	29.4	**78.4**
		3	4.4	15.9	37.6	**74.4**
		5	6.8	18.3	40.1	**72.5**
		10	11.0	23.2	45.9	**73.3**
	Max Incorrect	1	0.8	3.3	18.7	**55.8**
		3	3.6	15.1	35.0	**69.4**
		5	6.4	19.3	41.1	**72.4**
WordNet Similarity	Max Answers	1	3.4	6.2	36.4	**78.4**
		3	6.4	18.5	44.4	**76.8**
		5	9.1	23.0	46.6	**76.0**
		10	15.7	30.5	53.5	**77.0**
	Max Incorrect	1	1.4	4.3	26.1	**59.0**
		3	5.3	17.9	41.7	**74.0**
		5	8.4	24.2	48.2	**77.9**
RoBERTa Similarity	Max Answers	1	49.1	38.7	55.0	**81.2**
		3	53.3	48.8	60.7	**78.9**
		5	57.1	52.0	63.0	**80.1**
		10	65.0	60.5	71.2	**83.5**
	Max Incorrect	1	49.1	38.7	55.0	**81.2**
		3	53.3	48.8	60.7	**78.9**
		5	57.1	52.0	63.0	**80.1**

Table 3: Results on the annotated test set. Scores are normalized by the maximum score obtainable with that number of guesses, and therefore may go down as k increases

4.3 Human Performance

To measure human performance against such models, we collected 30 additional human responses per question with the same setup in collecting test data and aggregated them by counts, just as the sampled answers from GPT-2 models were ranked. The last column in table 3 reports this human performance. We can see that the best-performing automatic system is still meaningfully behind human performance in all metrics.

5 Discussion and Analysis

Table 3 shows the results of the baseline models using different measures of similarity, and different measures for the MAX ANSWERS and MAX INCORRECT metrics. One can see that GPT-2 without fine-tuning outperforms the baseline QA implementation, and fine-tuned GPT-2 outperforms both, but a large gap still remains between human performance and any of the baselines, even on the generous RoBERTa-based similarity metric. The human baseline scores are relatively stable regardless of which similarity metric is used, whereas the model scores change drastically (most significantly for the QA model) as more generous similarity metrics are used. We suggest that WordNet Similarity be used as the primary similarity metric as it strikes a reasonable balance between precision and recall, as discussed in § 5.2.

5.1 Knowledge Base Comparison

To show the dataset indeed containing meaningful commonsense knowledge, we did an additional analysis between our dataset and ConceptNet. ConceptNet (Speer et al., 2017) is a knowledge base containing triples related to common sense which has been shown to be helpful for various downstream tasks (Zhong et al., 2019; Wang et al., 2019) and conversational text generation (Wu et al., 2020; Zhang et al., 2020). We evaluate its potential relevance to this task by evaluating how often a (question, answer cluster) pair has a possible matching triple within ConceptNet. We extract a list of keywords from the question and a ground-truth answer string (by removing stop words) and similarly extract keywords from the head and tail of each ConceptNet relation. We then evaluate whether a given question-answer pair has potential "coverage" in ConceptNet by checking whether a keyword in the question is related to a keyword in the answer. For example, given the question "*Besides music, name something you might hear on a morning radio show*" and the answer "*weather report*", we would find the triples *(listen to radio, Cause, you hear local weather report)* and *(listen to radio, HasSubevent, hear weather report)*. By this measure, we find that 24.3% of the answer clusters in our

	Precision	Recall	F1
Exact Match	**1.0**	0.466	0.636
WordNet Similarity	0.996	0.581	**0.734**
RoBERTa Similarity	0.762	**0.661**	0.708

Table 4: Measurement of different score function against human cluster assignment.

development set have some match within ConceptNet. This suggests that a common sense KB might provide a useful resource for this task, however ConceptNet has a large number of relations with no direct ability to provide a ranking and thus we exclude such a model from our baseline comparisons. A similar analysis shows that the human baseline match 46.5% of the clusters, whereas a list of 20 top answers from the fine-tuned GPT-2 model match 30.3%.

5.2 Score Function Comparison

In order to compare the various similarity functions outlined in § 3, we manually annotated answers – from both the human baseline and fine-tuned GPT-2 outputs – to the correct answer clusters. Four annotators separately mapped each answer string to an existing cluster.

Table 4 measures how well different similarity functions performed in comparison to the manual human cluster assignment. Precision in this context measures how often an answer assigned by the automatic similarity measure is correctly assigned; recall measures how often an answer which a should be assigned to a cluster is correctly assigned. Unsurprisingly, exact match has perfect precision in this context, but has relatively low recall. WordNet similarity increases recall while adding very little false positives. As was hoped, RoBERTa similarity does dramatically increase how often an answer is mapped to the correct cluster, but does so at the expense of a large loss in precision; we therefore suggest that the WordNet similarity is the safest evaluation option.

5.3 Error Analysis

To provide some notion for the tendencies of different models on this task we provide actual model outputs in Table 5. One can see that, before fine-tuning, GPT-2 results are often acceptable and plausible situations (e.g. refrigerators might be replaced), but can fail to answer the specific criteria requested by the prompt. In contrast, the QA-based model is much noisier – occasionally providing very good answers, but often (as in the examples provided) failing to find answers that are even plausible. Fine-tuned GPT-2, in contrast to both, clearly learns to actually focus upon the expected format and details of such prototypical activities, however it fails in situations where a high-scoring answer would be very rarely discussed, such as knowing that light bulbs are commonly changed around the house.

6 Related Work

A wide variety of common sense reasoning datasets address related topics. Many datasets cover physical and spatial reasoning (Bisk et al., 2019), social common sense (Sap et al., 2019b), and common sense understanding of plausible sequences of events (Zellers et al., 2018, 2019; Huang et al., 2019; Bhagavatula et al., 2019; Sap et al., 2019a) or understanding of the entailments of a sentence (Zhang et al., 2017; Bowman et al., 2015; Roemmele et al., 2011; Levesque et al., 2012). There is also a long history of work in modeling scripts and frames (Schank and Abelson, 1977; Chambers and Jurafsky, 2009; Fillmore et al., 1976; Ferraro and Van Durme, 2016; Weber et al., 2020), which is related to the current focus on prototypical situations.

Recent works have also sought to characterize the ability of pre-trained language models to understand common sense reasoning, showing such models perform well at common sense reasoning tasks even without fine-tuning, allowing one to explore the common sense reasoning inherent in those models (Tamborrino et al., 2020; Weir et al., 2020). Of particular relevance to the current work, Weir et al. (2020) explored the ability of pre-trained models to predict *stereotypic tacit assumptions*, generalizing about entire classes of entities with statements such as "everyone knows that a bear has ________".

Interestingly, ProtoQA is not the first time FAMILY-FEUD has been referenced in the commonsense literature. Common Consensus (Lieberman and et al., 2007) was a web-based game created with the intention of being a self-sustaining platform to collect and validate commonsense knowledge based on human goals. Prior work had established the idea of using online games to simultaneously entertain and collect commonsense

Prompt	***Name something around the house that's often replaced.***			
Human	light bulbs	toilet paper	furniture	food
GPT-2	TV	refrigerator	fridge	trash
GPT-2 Fine Tune	dishes	toilet	kitchen	furniture
QA	tune	time	name	song
Prompt	***Name something a monk probably would not own***			
Human	gun	wife	knife	pornography
GPT-2	gun	car	sword	motorcycle
GPT-2 Fine Tune	weapon	sword	car	cell phone
QA	arch	everything	togashi	power
largest cluster	cluster 2	cluster 3	smaller clusters	

Table 5: Top responses from human and model predictions for each prompt, color-coded with the answer cluster they might be aligned to

knowledge (Ahn et al., 2006), however the authors of Common Consensus found that the format of FAMILY-FEUD questions was more amenable to high-quality commonsense knowledge acquisition. Common Consensus serves as an excellent proof of concept for future gamification of the style of data presented in this dataset.

ProtoQA differs from other datasets in three different ways:

1. ProtoQA focuses on proto-typical situations. Humans can agree about the details and characteristics of a prototypical event or situation due to commonalities in their shared lived experiences, cultural norms and expectations. This rough agreement extends beyond an agreement on a single top response and that's why our task and evaluation values diversity of answers.

2. The evaluation ProtoQA is a generative evaluation task where a model has to output a ranked list of answers, ideally covering all prototypical answers for a question.

3. ProtoQA has a large number of annotations for each example which makes the generation evaluation possible.

7 Conclusion

We have presented a new common sense dataset with many novel features. The collection of a large set of raw answer strings and further clustering of these strings facilitates a generative evaluation method, enabling actual use of trained models to answer real common sense questions. The inclusion of counts over clusters of answers provides a very rich dataset for training and evaluation. As shown in table 3, existing fine-tuned state-of-the-art models have a way to go before modeling the distribution of this common sense data.

In addition to the elements of this task which are appealing from a common sense modeling perspective, the inherent appeal of this task to humans opens a number of possibilities for future data collection and evaluation. Millions of people have played phone-based games based upon this same premise[8], and prior works have obtained valuable annotations from trivia game participants (Rodriguez et al., 2019). This dataset lays the foundation for larger-scale data collection which leverages people's natural interest to encourage high-quality answers to more common sense questions.

Acknowledgments

We thank the IESL and NLP lab at UMass Amherst for their efforts in assisting with data collection. This work was supported in part by the Center for Intelligent Information Retrieval and the Center for Data Science, in part by the Chan Zuckerberg Initiative under the project Scientific Knowledge Base Construction, and in part by DARPA. A WordNet Similarity Function

1. Let S be the set of synsets in WordNet, and let $S(x)$ be the set of synsets associated with the string x.

2. Let $\text{SynsetSim}(X,Y) : S \times S \to [0,1]$ be a score for synset similarity, eg.

$$\text{SynsetSim}(X,Y) := \begin{cases} 1 & \text{if } X = Y, \\ 0 & \text{otherwise.} \end{cases}$$

3. A given string may corresponse to multiple synsets. Given two strings x and y we define

$$\text{SynsetsScore}(x,y) = \max\{\text{SynsetSim}(S_x,S_y) : S_x \in S(x), S_y \in S(y)\}.$$

4. Some valid answer strings may not correspond to a synset at all, so we define

$$\text{SubstringScore} = \max(\text{SynsetsScore}(x,y), \text{ExactMatch}(x,y))$$

5. Some answers are several words long, and therefore won't map to a synset even if some substring would. To account for this, we tokenize and strip stopwords from both the predicted and ground-truth answer strings. To compare these sets of tokens A,B we let $M(A,B)$ be the set of all possible (partial) matchings between elements in A and B, and then define

$$\text{TokensScore}(A,B) = \max_{m \in M(A,B)} \frac{\sum_{(a,b)\in m} \text{SubstringScore}(a,b)}{\max(|A|,|B|)}$$

6. We repeat this process for every element in an answer cluster C, which is a set of strings obtained from the survey, and then set the overall score for this answer cluster to be

$$\text{WordNetScore}(x,C) = \max\{\text{TokensScore}(T(x),T(y)) : y \in C\}$$

Remark. *Fully tokenizing the input has the potential to lose information, since some WordNet clusters are labeled with multiple words. Consider comparing "chewing gum" with "gum". The above process would assign this a score of* 0.5*, because tokenizing yields ["chewing", "gum"], however "chewing gum" is, itself, in the same WordNet synset as "gum". The solution to this problem in general is to compare all possible* partitions *of the tokens, and define the overall* PartitionsScore *to be the maximum among all pairs of possible partitions for the predicted answer and the ground-truth string. We replace the* TokensScore *with this* PartitionsScore *to capture such situations.*

With a scoring method as described, it is possible for an answer to receive a positive score for multiple clusters. We take the following approach:

1. Round the scores to $\{0,1\}$ to make a "hard" cluster decision.

2. For a given question, if some predicted answers match with multiple clusters, we choose the maximum matching with respect to the final score.

B GPT-2 Transformation rules

Original Sentence	Transformed Sentence
Name something ...	One thing ... is
Tell me something ...	One thing ... is
Name a/an ...	One ... is
How can you tell ...	One way to tell ... is
Give me a/an ...	One ... is

Table 6: Transformation rules from original question sentence to GPT-2 format sentence

In order to make the question more natural for GPT-2 model to answer, we use rule in Table 6 to re-write the questions.

C Criteria for test question acceptance

When creating new questions using the perturbation method described in § 2.2, we scored each question with the following criteria in mind:

- Most people are expected to be able to answer.
- The answer set category is relatively small; less than eight big categories of different answers.
- The question is hard for systems relying on co-occurrence patterns to answer, e.g., BERT
- The answers to the question are not too culturally dependent (e.g., we want to avoid questions such as *Name a dish made with ground meat*).

- Not accidentally re-creating a well-explored question: We then searched all Family Feud data to ensure that no questions were being re-created, and searched online to make sure no obvious lists of answers can be found via search with Google. E.g., if we create a question and the top search for that question is a list of answers to that question, regardless of origin, we remove the question.

D Criteria for stereotypical bias issues

We define a relatively strict measure for stereotypical bias, primarily to avoid having overly problematic examples; we expect that more nuanced issues of stereotypes are common in the data, but are not as easy to measure with an all-or-nothing measure. We rule out questions if they match any of the following:

1. Attaining the right answer requires stereotypes regarding what activities are affiliated with each gender (e.g., that only girls play with dolls)
2. Questions that measure activities a particular gender would be proud or embarrassed to do.
3. We could not find any questions addressing race, sexual orientation, religion, or national origin, but these were searched for and would have also been removed if found.

Types of potentially biased questions which we could not consistently remove from all the training data, but which we note to be worthy of consideration, are:

1. Questions with heteronormative assumptions (questions about what women like, romantically, in men or vice versa)
2. Questions that can be specific to Western US culture: a vast array of questions would have different distributions over answers if asked to people of specific cultures, where stereotypical foods, greetings, habits, or objects may be different.
3. Questions that reference gender, but which might have similar answer clusters if the gender was removed – e.g., *Name something your parents always want to know about the man you're dating*.

E QA model details

For the baseline results reported, we fine-tune the "Bert for QA" model of the Huggingface transformers package, v2.6.0 (Wolf et al., 2019), using BERT-large-uncased (Devlin et al., 2019).

Table 7 illustrates examples of answer strings for the query "name something you do at a concert", illustrating both that such a method finds passages that are relevant to the questions, but also illustrating the kind of noise being introduced by such a distance learning approach.

Q: Name something you do at a concert:
A: *But you are always expected to* ***clap*** *for the spalla .*
A: *I'll often buy a* ***drink*** *for something to do, or check my email on my phone, or whatever, to kill time . once the band starts i 'm focused on that*

Table 7: Examples of distant-learning positive examples used for training QA baseline

F GPT-2 model details

For the baseline results reported, we fine-tune GPT-2 Large model using the scrapped training data. The parameter for the best performing model is as follows: batch_size:1, training epoch: 1, gradient accumulation step: 8. The other parameters are the default value in the hugging face implementation. In generation phrase, the temperature is 0.69, top_p is 0.9, and other parameter values are using the default values. All parameters are tuned using dev data, and searched via greed search. The code will be publicly available upon publication.

G Alternative Human Performance Answers

The human performance numbers reported in § 4.3 were collected to be maximally similar to the proposed task: like both the training data and the crowdsourced evaluation data, they were generated by asking many humans for a single best answer. We also collected sets of answers from a small set of in-person annotators using a slightly different questioning paradigm, providing a prompt and asking a single annotator to provide eight different answers to that question. In practice, we found that this shift in evaluation this could penalize human performance. One primary issue with this was that the human annotator asked for all answers to

Prompt	*Name something around the house that's often replaced.*			
Single-human ranking	food	toilet paper	paper towels	garbage bags
Prompt	*Name something a monk probably would not own.*			
Single-human ranking	a fancy car	a fancy house	too much food	a bank account
largest cluster	cluster 2	cluster 3	smaller clusters	

Table 8: Top three responses from human ranking evaluation for the same data

Metrics %			**Single-Human Ranking**
Exact Match	**Max Answers**	1	40.5
		3	39.4
		5	41.0
		10	45.6
	Max Incorrect	1	23.9
		3	36.0
		5	40.5
WordNet Similarity	**Max Answers**	1	45.2
		3	47.8
		5	50.7
		10	55.3
	Max Incorrect	1	29.2
		3	44.6
		5	50.6
RoBERTa Similarity	**Max Answers**	1	59.0
		3	64.0
		5	66.2
		10	71.7
	Max Incorrect	1	59.0
		3	64.0
		5	66.2

Table 9: Results for the "single human" ranking scores, replaced by a human evaluation closer to actual task

the same question would generally only provide a single answer string corresponding to the top answer clusters. This means that even if the human matched the correct answer, they would miss that answer cluster entirely if they provided a novel string for that answer cluster. Annotators also found it be to be quite difficult to provide many answers for the same prompt and would go far afield with later answers, making such answers differ from the distribution of answers in the train and evaluation set. To avoid confusion using these noticeably different human performance scores, we shifted reporting to a set of data that is closer to the actual task evaluation but report those ranking scores here for transparency. One can see from Table 8 and 9 that such human answers look good, but that the actual scores are dramatically lower than what is seen when humans are evaluated on the same task as the evaluation set, and only barely outperforms a fine-tuned GPT-2 system.

IIRC: A Dataset of Incomplete Information Reading Comprehension Questions

James Ferguson[◇*] **Matt Gardner**[♣] **Hannaneh Hajishirzi**[◇♣]

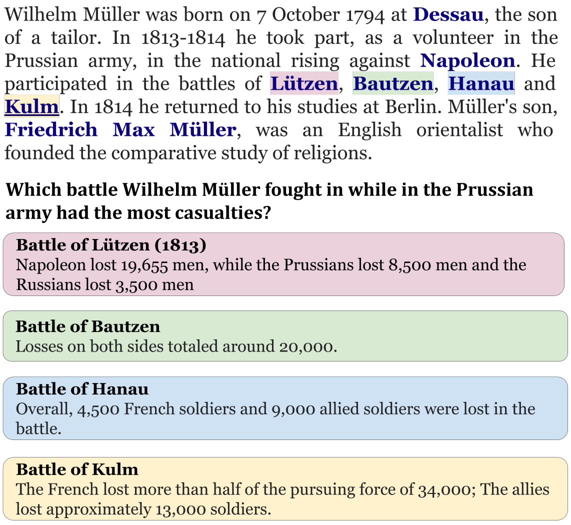
Abstract

Humans often have to read multiple documents to address their information needs. However, most existing reading comprehension (RC) tasks only focus on questions for which the contexts provide all the information required to answer them, thus not evaluating a system's performance at identifying a potential lack of sufficient information and locating sources for that information. To fill this gap, we present a dataset, **IIRC**, with more than 13K questions over paragraphs from English Wikipedia that provide only partial information to answer them, with the missing information occurring in one or more linked documents. The questions were written by crowd workers who did not have access to any of the linked documents, leading to questions that have little lexical overlap with the contexts where the answers appear. This process also gave many questions without answers, and those that require discrete reasoning, increasing the difficulty of the task. We follow recent modeling work on various reading comprehension datasets to construct a baseline model for this dataset, finding that it achieves 31.1% F1 on this task, while estimated human performance is 88.4%. The dataset, code for the baseline system, and a leaderboard can be found at `https://allennlp.org/iirc`.



Wilhelm Müller was born on 7 October 1794 at **Dessau**, the son of a tailor. In 1813-1814 he took part, as a volunteer in the Prussian army, in the national rising against **Napoleon**. He participated in the battles of **Lützen**, **Bautzen**, **Hanau** and **Kulm**. In 1814 he returned to his studies at Berlin. Müller's son, **Friedrich Max Müller**, was an English orientalist who founded the comparative study of religions.

Which battle Wilhelm Müller fought in while in the Prussian army had the most casualties?

Battle of Lützen (1813)
Napoleon lost 19,655 men, while the Prussians lost 8,500 men and the Russians lost 3,500 men

Battle of Bautzen
Losses on both sides totaled around 20,000.

Battle of Hanau
Overall, 4,500 French soldiers and 9,000 allied soldiers were lost in the battle.

Battle of Kulm
The French lost more than half of the pursuing force of 34,000; The allies lost approximately 13,000 soldiers.

Figure 1: An example from **IIRC**. At the top is a context paragraph which provides only partial information required to answer the question. The bold spans in the context indicate links to other Wikipedia pages. The colored boxes below the question show snippets from four of these pages that provide the missing information for answering the question. The answer is the underlined span.

1 Introduction

Humans often read text with the goal of obtaining information. Given that a single document is unlikely to contain all the information a reader might need, the reading process frequently involves identifying the information present in the given document, and what is missing, followed by locating a different source that could potentially contain the missing information. Most recent reading comprehension tasks, such as SQuAD 2.0 (Rajpurkar et al., 2018), DROP (Dua et al., 2019b), or Quoref (Dasigi et al., 2019), evaluate models using a relatively simpler setup where all the information required to answer the questions (including judging them as being unanswerable) is provided in the associated contexts. While this setup has led to significant advances in reading comprehension (Ran et al., 2019; Zhang et al., 2020), the tasks are still limited since they do not evaluate the capability of models at identifying precisely what information, if any, is missing to answer a question, and where that information might be found.

On the other hand, open-domain question answering tasks (Chen et al., 2017; Joshi et al., 2017; Dhingra et al., 2017) present a model with a ques-

---

[*] Work done as an intern at the Allen Institute for AI.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1137–1147,
November 16–20, 2020.

tion by itself, requiring the model to retrieve relevant information from some corpus. However, this approach loses grounding in a particular passage of text, and it has so far been challenging to collect diverse, complex question in this setting.

Alternatively, complex questions grounded in context can be converted to open-domain or incomplete-information QA datasets such as HotpotQA (Yang et al., 2018). However, they do not capture the information-seeking questions that arise from reading a single document with partial information (Min et al., 2019b; Chen and Durrett, 2019).

We present a new dataset of incomplete information reading comprehension questions, **IIRC**, to address both of these limitations. **IIRC** is a crowdsourced dataset of 13441 questions over 5698 paragraphs from English Wikipedia, with most of the questions requiring information from one or more documents hyperlinked to the associated paragraphs, in addition to the original paragraphs themselves. Our crowdsourcing process (Section 2) ensures the questions are naturally information-seeking by decoupling question and answer collection pipelines. Crowd workers are instructed to ask follow-up questions after reading a paragraph, giving links to pages where they would expect to find the answer. This process results in questions like the one shown in Figure 1. As illustrated by the example, this setup results in questions requiring complex reasoning, with an estimated 39% of the questions in **IIRC** requiring discrete reasoning. Moreover, 30% of the questions in **IIRC** require more than one linked document in addition to the original paragraph and 30% of them are unanswerable even given the additional information. When present, the answers are either extracted spans, boolean, or values resulting from numerical operations.

To evaluate the quality of the data, we run experiments with a modified version of NumNet+ (Ran et al., 2019), a state-of-the-art model from DROP (Dua et al., 2019b), chosen because a significant portion of questions in **IIRC** require numerical reasoning similar to that found in DROP. Because DROP uses only a single paragraph of context, we add a two-stage pipeline to retrieve necessary context for the model from the linked articles. The pipeline first identifies which links are pertinent, and then selects the most relevant passage from each of those links, concatenating them to serve as input for the model (Section 3).

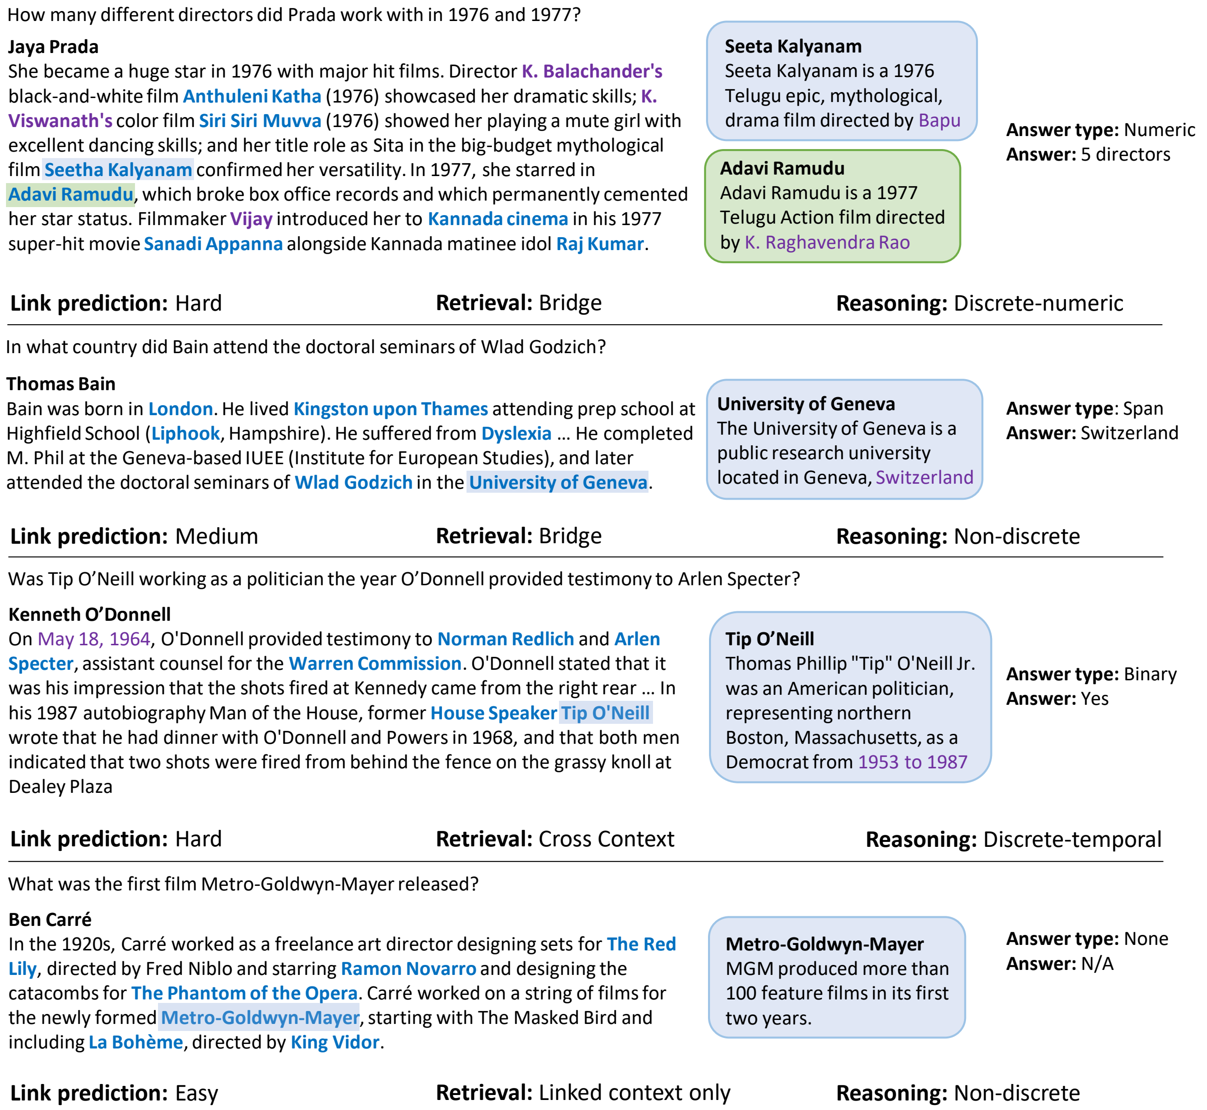
This baseline achieves an F_1 score of 31.1% on **IIRC**, while the estimated human performance is 88.4% F_1. Even giving the model oracle pipeline components results in a performance of only 70.3%. Taken together, these results show that substantial modeling is needed both to identify and retrieve missing information, and to combine the retrieved information to answer the question (Section 4). We additionally perform qualitative analysis of the data, and find that the errors of the baseline model are evenly split between retrieving incorrect information, identifying unanswerable questions, and successfully reasoning over the retrieved information.

By construction, all examples in **IIRC** require identifying missing information. Even though current model performance is quite low, a model trained on this data could theoretically leverage that fact to achieve artificially high performance on test data, because it does not have to first determine *whether* more information is needed. To account for this issue, we additionally sample questions from SQuAD 2.0 (Rajpurkar et al., 2018) and DROP (Dua et al., 2019b), which have similar question language to what is in **IIRC**, putting forward this kind of combined evaluation as a challenging benchmark for the community. Predictably, our baseline model performs substantially worse in this setting, reaching only 28% F_1 on the **IIRC** portion of this combined evaluation (Section 5).

2 Building IIRC

We used Wikipedia to build **IIRC** and relied on the fact that entities in Wikipedia articles are linked to other articles about those entities, providing more information about them. Our goals were to build a dataset with naturally information-seeking questions anchored in paragraphs with incomplete information, such that identifying the location of missing information is non-trivial, and answering the questions would require complex cross-document reasoning.

We ensured that the questions are information-seeking by separating question and answer collection processes, and by not providing the question writers access to the contexts where the answers occur. This process also ensured that we get questions that have minimal lexical overlap with the answer contexts. We used Wikipedia paragraphs with many outgoing links to increase the difficulty of identifying the articles that provide the missing information. To ensure complex cross-document



How many different directors did Prada work with in 1976 and 1977?

Jaya Prada
She became a huge star in 1976 with major hit films. Director **K. Balachander's** black-and-white film **Anthuleni Katha** (1976) showcased her dramatic skills; **K. Viswanath's** color film **Siri Siri Muvva** (1976) showed her playing a mute girl with excellent dancing skills; and her title role as Sita in the big-budget mythological film **Seetha Kalyanam** confirmed her versatility. In 1977, she starred in **Adavi Ramudu**, which broke box office records and which permanently cemented her star status. Filmmaker **Vijay** introduced her to **Kannada cinema** in his 1977 super-hit movie **Sanadi Appanna** alongside Kannada matinee idol **Raj Kumar**.

Seeta Kalyanam
Seeta Kalyanam is a 1976 Telugu epic, mythological, drama film directed by Bapu

Adavi Ramudu
Adavi Ramudu is a 1977 Telugu Action film directed by K. Raghavendra Rao

Answer type: Numeric
Answer: 5 directors

Link prediction: Hard **Retrieval:** Bridge **Reasoning:** Discrete-numeric

In what country did Bain attend the doctoral seminars of Wlad Godzich?

Thomas Bain
Bain was born in **London**. He lived **Kingston upon Thames** attending prep school at Highfield School (**Liphook**, Hampshire). He suffered from **Dyslexia** ... He completed M. Phil at the Geneva-based IUEE (Institute for European Studies), and later attended the doctoral seminars of **Wlad Godzich** in the **University of Geneva**.

University of Geneva
The University of Geneva is a public research university located in Geneva, Switzerland

Answer type: Span
Answer: Switzerland

Link prediction: Medium **Retrieval:** Bridge **Reasoning:** Non-discrete

Was Tip O'Neill working as a politician the year O'Donnell provided testimony to Arlen Specter?

Kenneth O'Donnell
On May 18, 1964, O'Donnell provided testimony to **Norman Redlich** and **Arlen Specter**, assistant counsel for the **Warren Commission**. O'Donnell stated that it was his impression that the shots fired at Kennedy came from the right rear ... In his 1987 autobiography Man of the House, former **House Speaker Tip O'Neill** wrote that he had dinner with O'Donnell and Powers in 1968, and that both men indicated that two shots were fired from behind the fence on the grassy knoll at Dealey Plaza

Tip O'Neill
Thomas Phillip "Tip" O'Neill Jr. was an American politician, representing northern Boston, Massachusetts, as a Democrat from 1953 to 1987

Answer type: Binary
Answer: Yes

Link prediction: Hard **Retrieval:** Cross Context **Reasoning:** Discrete-temporal

What was the first film Metro-Goldwyn-Mayer released?

Ben Carré
In the 1920s, Carré worked as a freelance art director designing sets for **The Red Lily**, directed by Fred Niblo and starring **Ramon Novarro** and designing the catacombs for **The Phantom of the Opera**. Carré worked on a string of films for the newly formed **Metro-Goldwyn-Mayer**, starting with The Masked Bird and including **La Bohème**, directed by **King Vidor**.

Metro-Goldwyn-Mayer
MGM produced more than 100 feature films in its first two years.

Answer type: None
Answer: N/A

Link prediction: Easy **Retrieval:** Linked context only **Reasoning:** Non-discrete

Figure 2: Examples from **IIRC**, labeled with what kinds of processing are required to answer each question. See Table 1 for more details. The passages on the left are the original passage, with bold spans indicating links. The highlighted sections contain the necessary context found in linked articles. Purple highlights indicate either the answer, for the second question, or the information used to compute the answer.

reasoning, we asked the crowd workers to create questions that need information from the seed paragraph as well as one or more linked articles. This constraint resulted in questions that are answerable neither from the original paragraph alone, nor from one of the linked articles alone, often requiring over 3+ passages to answer. The remainder of this section describes our data collection process.

2.1 Seed Paragraphs

We started by collecting paragraphs from Wikipedia articles containing ten or more links to other Wikipedia articles. This resulted in roughly 130K passages. We then created two separate crowdsourcing tasks on Amazon Mechanical Turk[1]; one for collecting questions, and one for collecting answers. Workers for each task were chosen based on a qualification task. Their submissions were manually inspected, and those that produced high quality questions and correct answers, respectively, continued to work on the main annotation tasks.

2.2 Collecting Questions

Given a paragraph with links to other articles highlighted, crowd workers were tasked with writing questions that require information from the paragraph, as well as from one or more of linked articles. Workers could see the links, and the titles of

---

[1] www.mturk.com

	Type	Description	Percentage
Link Prediction	Easy	Link is explicitly mentioned in the question	41%
	Medium	Context is required to determine link target	47%
	Hard	Context is required to determine link targets and number of links	12%
Retrieval	Linked context only	Original passage is not necessary to answer question	14%
	Bridge	Original passage is only necessary to determine links	57%
	Cross context	Original passage is necessary to find relevant information in links	29%
Reasoning	Non-discrete	No discrete reasoning is required	61%
	Discrete-numeric	Discrete reasoning is required	11%
	Discrete-temporal	Discrete reasoning involving time is required	28%
Answer	Span	Answer is one or more spans selected from question or context	45%
	Numeric	Answer is a number (with a unit provided)	17%
	Binary	Answer is either *yes* or *no*	8%
	None	Question cannot be answered given the provided context	30%

Table 1: Frequency of different types of retrieval, reasoning, and answers that appear in **IIRC**.

the articles they pointed to, but not the contents of the linked articles. Since the linked articles were not provided, the workers were asked to frame questions based on the information they think would be contained in the those articles. For each human intelligence task (HIT), workers were presented with a collection of ten paragraphs, and were asked to write a total of ten questions using any of those paragraphs, with two questions requiring following two or more links. For example given a passage about an actor that mentions *Rasulala had roles in Cool Breeze (1972), Blacula (1972), and Willie Dynamite (1973)*, an example of a question requiring multiple links would be *How many different directors did Rasulala work with in 1972?*.

In order to minimize questions with shortcut reasoning, we provided workers extensive instructions along with examples of good and bad questions to ask. Examples of bad questions included questions that did not require any links - *Who did the Arakanese kings compare themselves to?* when the context included *They compared themselves to Sultans*; and questions that did not require information from the original passage - *What was Syed Alaol's most famous work?* when the context included *Syed Alaol was a renowned poet*.

In addition to writing questions, workers also provided the context from the original paragraph that they thought would be necessary to answer the question, as well as the links they expected to contain the remaining necessary information. Workers were paid $4.00 per set of ten questions, and reported taking 25 minutes on average, coming out to $9.60 per hour. 40 workers passed the qualification and worked on the main task.

2.3 Collecting Answers

For the answer task, workers were given a collection of ten questions, their respective original paragraphs, and the context/links selected by the question writer. For each paragraph, workers were able to see the links, and could follow them to view the text, not including tables or images, of the linked document.

They were then asked to select an answer from one of four types: a span of text from either the question or a document, a number and unit, yes/no, or *no answer*. For answerable questions, i.e. any of the first three types, they were additionally asked to provide the minimal context span(s), necessary to answer the question. For unanswerable questions, there is typically no indication that the answer is not given, so no such context can be provided. For example, the following question was written for a passage about a ship called the Italia: *Who was the mayor of New York City when Italia was transferred to Genoa-NYC?* Following the link to New York City mentions the current mayor, but not past mayors, making it unanswerable.

Annotators were also given the option of labeling a question as bad if it didn't make sense, and these bad questions were then filtered out. For example, if an annotator misinterpreted the passage when writing the question as in the case of the following question written about a horse, Crystal Ocean, and St Leger, which the annotator thought was a horse, but is actually a horse race: *Is Crystal Ocean taller than St Leger?*. Additionally, A small percentage of questions that can be answered from the original paragraph alone were also marked as being bad.

For the training set, comprising 80% of the data, each question was answered by a single annotator.

Number of questions	13441
Number of passages	5698
Average number of links per passage	14.5
Average passage length (words)	197.5
Average question length (words)	13.6

Table 2: Statistics of **IIRC**.

For the development and test sets, comprising 10% each, three annotators answered each question, and only questions where at least two annotators agreed on the answer were kept. Workers were paid \$3.00 per set of ten answers, and reported taking 20 minutes on average, coming out to \$9.00 per hour. 33 workers passed the qualification and worked on the main task.

2.4 Dataset Analysis

In Figure 2 we show some examples from **IIRC**, labeled with different kinds of processing required to solve them. The types are described in detail in Table 1. These types and percentages were computed from a manual analysis of 100 examples.

In Table 2 we provide some global statistics of the dataset. In total, there are 13441 questions over 5698 passages. Each passage contains an average of 14.5 outgoing links. Using the context provided by the answer annotators, we are able to compute a distribution of the number of links required to answer questions in the dataset, included in Table 4. While the majority of questions require information from only one linked document in addition to the original paragraph, 30% of questions require two or more, with some requiring reasoning over as many as 12 documents to reach the answer. This variability in the number of context documents adds an extra layer of complexity to the task.

We also analyzed the initial trigrams of questions to quantify the diversity of questions in the dataset. We found that the most common type of questions, those related to time (eg "How old was", "How long did"), make up 15% of questions. There are 3.5k different initial trigrams across the 10.8k questions in the training set.

3 Modeling IIRC

3.1 Task Overview

Formally, a system tackling **IIRC** is provided with the following inputs: a question Q; a passage P ; a set of links contained in the passage, $L = \{l_i\}_{i=1}^{N}$; and the set of articles those links lead to, $\mathbf{A} = \{a^i\}_{i=1}^{N}$. The surface form of each link, l_i is a sequence of tokens in P and is linked to an article a^i. The target output is either a number, a sequence of tokens in one of P, Q, or a^i, `Yes`, `No`, or `NULL` (for unanswerable questions).

3.2 Baseline Model

To evaluate the difficulty of **IIRC**, we construct a baseline model adapted from a state-of-the-art model built for DROP. We choose a DROP model due to the inclusion of numerical reasoning questions in our dataset. Because the model was not originally used for data requiring multiple paragraphs and retrieval, we first predict relevant context to serve as input to the QA model using a pipeline with three stages:

1. Identify relevant links
2. Select passages from linked articles
3. Pass the concatenated passages to a QA model

3.2.1 Identifying Links

To identify the set of relevant links, L′, in a passage, P, for a question, Q, the model first encodes the concatenation of the question and original passage using BERT (Devlin et al., 2019). It then concatenates the encoded representations of the first and last tokens of each link as input to a scoring function, following the span classification procedure used by Joshi et al. (2013), selecting any links that score above a threshold g.

$$\begin{aligned} P' &= \text{BERT}([Q||P]) \\ \text{Score}(\text{l}) &= f([p'_i||p'_j]), \;\; l = (p_i...p_j, a) \\ L' &= \{l : \text{Score}(l) > g\} \end{aligned}$$

where l is a link covering tokens $p_i...p_j$ linking to article a.

3.2.2 Selecting Context

Given the set, L' from the previous step, the model then must select relevant context passages from the documents. For each document, it first splits the document into overlapping windows[2], $w_0, w_1...w_n$. Each window is then concatenated with the question and prepended with a `CLS` token, and encoded with BERT. The encoded `CLS` tokens are then passed through a linear predictor to score each window, and the highest scoring sections from each document are concatenated as context for the final

---

[2] See section 4.2 for more details.

model, C.

$$c_{a_i} = \max_{w_j \in \text{Split}(a_i)} f(\text{BERT}([Q||w_j]))$$
$$C = [c_{a_i} : a_i \in L']$$

3.2.3 QA Model

As mentioned above, the final step in the pipeline is passing the concatenated context, along with the question and a selected window from the original passage, as input to a QA model. For our experiments, we use NumNet+, because it is the best performing model on the DROP leaderboard with publicly available code. At a high level, NumNet+ encodes the input using RoBERTa (Liu et al., 2019), as well as a numerical reasoning component. It then passes these into a classifier to determine the type of answer expected by the question, which we modified by adding binary and unanswerable as additional answer types. This model is trained using the gold context for answerable questions, and predicted context for unanswerable questions. We do this because by definition, unanswerable questions do not have annotated answer context.

4 Experiments

4.1 Evaluation Metrics

We use two evaluation metrics to compare model performance: Exact-Match (EM), and a numeracy-focused (macro-averaged) F1 score, which measures overlap between a bag-of-words representation of the gold and predicted answers. Due to the number of numeric answers in the data, we follow the evaluation methods used by DROP (Dua et al., 2019b).

Specifically, we employ the same implementation of Exact-Match accuracy as used by SQuAD (Rajpurkar et al., 2016), which removes articles and does other simple normalization, and our F1 score is based on that used by SQuAD. We define F1 to be 0 when there is a number mismatch between the gold and predicted answers, regardless of other word overlap. When an answer has multiple spans, we first perform a one-to-one alignment greedily based on bag-of-word overlap on the set of spans and then compute average F1 over each span. For numeric answers, we ignore the units. Binary and unanswerable questions are both treated as span questions. In the unanswerable case, the answer is a special `NONE` token, and in the binary case, the answer is either *yes* or *no*.

4.2 Implementation Details

For the link selection model, we initialized the encoder with pretrained BERT-base, and fine-tuned it during training. For the scoring function, we used a single linear layer with a sigmoid activation function. The model was trained using Adam, and the score threshold to select links was set to 0.5. Additionally, we truncated any passages longer than 512 tokens to 512. This occurred in less than 1% of the data. This model is trained using a cross-entropy objective with the information provided in the gold context by annotators. Any links pointing to articles with an annotated context span are labeled 1, and all other links are labeled 0.

For the passage selection model, we again initialized the encoder with pretrained BERT-base, and fine-tuned it during training. We set the window size such that the concatenation of all selected contexts, along with the question and a selection from the original passage, has max length 512. More specifically, using the number of links, N_l selected in the previous step, for a question with N_Q tokens, we set the window size to be $\frac{512-(N_Q)}{N_l+1}$. We set the stride to be $\frac{1}{4}$ the window size, i.e. if the first window contains tokens $[0, 200]$, the second window would contain $[50, 250]$. We used a single linear layer with a sigmoid activation as the scoring function. We train this model with a cross-entropy objective. We use the gold context provided by annotators, labeling sections that contain the entirety of the annotated context 1, and all other sections 0.

For NumNet+, we followed the hyperparameter and training settings specified in the original paper (Ran et al., 2019). We trained the model on gold context provided by annotators when available, i.e. for answerable questions, and predicted context from the previous steps otherwise.

4.3 Results and Discussion

Full Task Results Table 3 presents the performance of the baseline model. It additionally shows the results of using gold information at each stage of the pipeline, as well as human performance on computed on a subset of 200 examples from the test set. The model achieves 31.1% F_1, which is well below the human performance of 88.4%. Even with the benefit of the gold input, there is still room for improvement on reasoning over multiple contexts, as performance is still 18% absolute below human levels. The model does a good job of predicting the relevant links, as evidenced by the fact that us-

	Dev		Test	
Model	**EM**	**F1**	**EM**	**F1**
Full model	29.6	33.0	27.7	31.1
Oracle L	30.9	34.7	29.0	32.5
Oracle L+C	63.9	69.2	65.6	70.3
Human	-	-	85.7	88.4

Table 3: Baseline and oracle results on **IIRC**. Human evaluation was obtained from a subset of 200 examples from the test set. We evaluate the model when given oracle links (L) and retrieved contexts (C). Retrieving the correct contexts is a significant challenge, but even given oracle contexts there is a substantial gap between model and human performance.

Number of links	**EM**	**F1**
1 (70%)	33.2	36.7
2 (23%)	27.0	30.6
3 (4%)	25.9	31.5
4+ (3%)	40.9	43.4

Table 4: Exact match and F1 of the baseline model on the **IIRC** dev set broken down by number of links necessary to answer the question. The numbers in parentheses are the percentage of questions in the full dataset that require that number of context documents.

ing the gold links only improves performance by 1 point, but still struggles to identify the appropriate context within the linked documents. This is likely due to annotators not being able to see the linked context when the questions are written. This makes this step more difficult by not providing the model with surface-level lexical cues in the question that it could use to easily select the appropriate context.

Analysis of Number of Linked Documents Table 4 shows the results of running the full pipeline broken down according to the number of linked documents required to answer the question. These performance differences are the result of a few factors. The first is the fact that the more links required to answer a question, the more chances there are for failure to retrieve the necessary information. This is exacerbated by the pipeline nature of our baseline model. However, the spike in performance for questions requiring four or more links is caused by the number of unanswerable questions. Nearly half of the questions in that category are unanswerable, and the model largely predicts *No Answer* on those questions. Finally, the distribution of question types is different conditioned on the number of links. Questions that require more links often also require some form of discrete reasoning, which is more difficult for the model to handle.

Answer Type	**EM**	**F1**
Span	24.0	29.1
Number	20.4	-
Binary	56.5	-
No Answer	32.4	-

Table 5: Exact match and F1 of the baseline model on the **IIRC** dev set broken down by answer type. F1 equals EM for non-span types, so is not repeated.

Input	**P**	**R**	**F1**
Constant baseline	26.7	100.0	42.1
Question only	61.8	54.9	58.1
Question + Passage	64.2	54.9	59.2
Question + Pred Context	62.3	70.1	66.0

Table 6: Precision, recall, and F1 of identifying unanswerable questions in the dev set with various baselines that use different combinations of the question, original passage, and predicted context.

Analyzing Different Answer Types Table 5 shows the performance broken down according to the type of answer each question has. The model performs worst on questions with numeric answers. This is due to the fact that these questions often require the model to do arithmetic to solve, which, as discussed above, the model struggles with relative to other types of questions.

Unanswerable Questions Table 6 shows how well a simple model can identify unanswerable questions with varying amounts of information. We set this up as a binary prediction, either answerable or not, and use a linear classifier that takes the BERT `CLS` token as input. We also include the result of always predicting unanswerable as a baseline. When the model can only see the question, it improves over the baseline by around 10 F1, meaning that there is some signal in the question alone, without any context.

Some types of questions are more likely to be unanswerable, such as those asking for information with regards to a specific year, i.e. *What was the population of New York in 1989?*. This is caused by Wikipedia more generally including current statistics, but not including a specific information for all previous years. Additionally adding the original passage does not significantly improve performance. This is not surprising, as the original passage always contains information relevant to the question, and the question annotators could see that text when writing the question.

4.4 Error Analysis

In order to better understand the challenges of the dataset, we manually analyzed 100 erroneous predictions by the model.

Incorrect context (39%) These are the cases where the model identified the correct links but selected the wrong portion of the linked document. It often selects semantically similar context but misses the crucial information, e.g. selecting the duration instead of end date.

Modeling errors (32%) These are the cases in which the context passed to the final QA model contained all of the necessary information, but the model failed to predict the correct answer. This occurred most commonly for questions requiring math, with the model including unnecessary dates in the computation, resulting in predictions that were orders of magnitude off. For example, predicting *-1984* when the question was asking for the age of a person.

Identifying unanswerable questions (24%) In these cases, the QA model was provided with related context that was missing crucial information, similar to the first class of errors. However, in this case, the full articles also did not contain the necessary information. In these cases the model often selected a related entity, ie for a question asking *In which ocean is the island nation located?*, the model predicted the island nation, *Papua New Guinea* as opposed to the ocean, which was not mentioned.

Insufficient Links (5%) These are cases where insufficient links were selected from the original passage, thus not providing enough information to answer the question. While the model can handle over-selection of links, we found that the vast majority of the time, the system correctly identified both the necessary and sufficient links, rarely over-predicting the required links.

5 Combined Evaluation

By construction, all the questions in **IIRC** require more than the original paragraph to answer. This means that a reading comprehension model built for **IIRC** does not actually have to detect *whether* more information is required than what is in the given paragraph, as it can always assume that this is true. In order to combat this bias, we recommend an additional, more stringent evaluation that combines **IIRC** with other reading comprehension datasets that do not require retrieving additional information. This is in line with recently-recommended evaluation methodologies for reading comprehension models (Talmor and Berant, 2019; Dua et al., 2019a).

Training Data	Links P	Links R	Links F1	QA EM	QA F1
IIRC	88	98	93	32.0	35.6
IIRC + S + D	85	79	82	24.6	28.0

Table 7: Results for link identification and QA when training the baseline model on **IIRC** and sampled questions from SQuAD (S) and DROP (D).

In this section, we present the results of one such evaluation. Noting that **IIRC** has similar properties to both SQuAD 2.0 (Rajpurkar et al., 2018) and DROP (Dua et al., 2019b), and even similar question language in places, we sample questions from these datasets to form a combined dataset for training and evaluating our baseline model.

Sampling from SQuAD 2.0 and DROP To construct the data for the combined evaluation, we sample an additional 3360 questions from SQuAD 2.0 and DROP, so that they make up 20% of the questions in the new data. We sample from SQuAD 2.0 and DROP with a ratio of $3 : 1$ in order to match the distribution of numeric questions in **IIRC** and used a Wikifier (Cheng and Roth, 2013) to identify the links to Wikipedia articles in them.

Results We train the full baseline on **IIRC** augmented with sampled DROP and SQuAD data, and evaluate it on the **IIRC** dev set without any additional sampled data. We don't include any sampled data in the evaluation in order to make a direct comparison to **IIRC** to see how adding questions that don't require external context affects the model's ability to identify necessary context. We also include the results of running just the link identification model trained under each setting. We show the results in table 7. Adding the extra dimension of determining whether extra information is necessary causes the model to become less confident, significantly hurting recall on link selection. These missed predictions then propagate down the pipeline, resulting in a loss of almost 8% F_1 when compared to a model trained on just **IIRC**.

We also evaluated the combination model on a dev set with sampled SQuAD and DROP data to see how well the model learned to identify that no external information was necessary. Given that none of the SQuAD or DROP data requires external links, this evaluation could only negatively impact precision. We find that precision dropped by 8 points, compared to a drop of 28 points when the model trained only on **IIRC** was used, indicating that the model is able to learn to identify when no external information is required.

6 Related Work

Questions requiring multiple contexts Prior multi-context reading comprehension datasets were built by starting from discontiguous contexts, and forming compositional questions by stringing multiple facts either by relying on knowledge graphs as in QAngaroo (Welbl et al., 2018), or by having crowdworkers do so, as in HotpotQA (Yang et al., 2018). It has been shown that many of these questions can be answered by focusing on just one of the facts used for building the questions (Min et al., 2019b). In contrast, each question in **IIRC** was written by a crowdworker who had access to just one paragraph, with the goal of obtaining information missing in it, thus minimizing lexical overlap between questions and the answer contexts. Additionally, **IIRC** provides a unique question type: questions requiring aggregating information from many related documents, such as the second question in Figure 2.

Separation of questions from answer contexts Many prior datasets (e.g.: WhoDidWhat (Onishi et al., 2016), NewsQA (Trischler et al., 2016), DuoRC (Saha et al., 2018), Natural Questions (Kwiatkowski et al., 2019), TyDiQA (Clark et al., 2020)) have tried to remove simple lexical heuristics from reading comprehension tasks by separating the contexts that questions are anchored in from those that are used to answer them. **IIRC** also separates the two contexts, but is unique given that the linked documents elaborate on the information present in the original contexts, naturally giving rise to follow-up questions, instead of open-ended ones.

Open-domain question answering In the open-domain QA setting, a system is given a question without any associated context, and must retrieve the necessary context to answer the question (Chen et al., 2017; Joshi et al., 2017; Dhingra et al., 2017; Yang et al., 2018; Seo et al., 2019; Karpukhin et al., 2020; Min et al., 2019a). **IIRC** is similar in that it also requires the retrieval of missing information. However, the questions are grounded in a given paragraph, meaning that a system must examine more than just the question in order to know what to retrieve. Most questions in **IIRC** do not make sense in an open-domain setting, without their associated paragraphs.

Unanswerable questions Unlike SQuAD 2.0 (Rajpurkar et al., 2018) where the unanswerable questions were written to be close to answerable questions, **IIRC** contains naturally unanswerable questions that were not written with the goal of being unanswerable, a property that our dataset shares with NewsQA (Trischler et al., 2016), Natural Questions (Kwiatkowski et al., 2019), and TyDi QA (Clark et al., 2020). Results shown in Section 4.3 indicate that these questions cannot be trivially distinguished from answerable questions.

Incomplete Information QA A few prior datasets have explored question answering given incomplete information, such as science facts (Mihaylov et al., 2018; Khot et al., 2019). However, these datasets contain multiple choice questions, and the answer choices provide hints as to what information may be needed. Yuan et al. (2020) explore this as well using a POMDP in which the context in existing QA datasets is hidden from the model until it explicitly searches for it.

7 Conclusion

We introduced **IIRC**, a new dataset of incomplete-information reading comprehension questions. These questions require identifying what information is missing from a paragraph in order to answer a question, predicting where to find it, then synthesizing the retrieved information in complex ways. Our baseline model, built on top of state-of-the-art models for the most closely related existing datasets, performs quite poorly in this setting, even when given oracle retrieval results, and especially when combined with other reading comprehension datasets. **IIRC** both provides a promising new avenue for studying complex reading and retrieval problems and demonstrates that much more research is needed in this area.

Abstract

BERT-era question answering systems have recently achieved impressive performance on several question-answering (QA) tasks. These systems are based on representations that have been pre-trained on self-supervised tasks such as word masking and sentence entailment, using massive amounts of data. Nevertheless, additional pre-training closer to the end-task, such as training on synthetic QA pairs, has been shown to improve performance. While recent work has considered augmenting labelled data and leveraging large unlabelled datasets to generate synthetic QA data, directly adapting to target data has received little attention. In this paper we investigate the iterative generation of synthetic QA pairs as a way to realize unsupervised self adaptation. Motivated by the success of the roundtrip consistency method for filtering generated QA pairs, we present iterative generalizations of the approach, which maximize an approximation of a lower bound on the probability of the adaptation data. By adapting on synthetic QA pairs generated on the target data, our method is able to improve QA systems significantly, using an order of magnitude less synthetic data and training computation than existing augmentation approaches.

1 Introduction

Supervised self-training methods have transformed applied machine learning recently. Such tasks serve as "pre-training" for related downstream tasks, and have proven to be essential to attaining state-of-the-art performance, particularly in NLP.

BERT-era Transformer-based question answering systems have recently achieved impressive performance on several question-answering (QA) tasks. These systems are based on representations that have been pre-trained on self-supervised tasks such as word masking and sentence entailment, using massive amounts of data (Devlin et al., 2018; Liu et al., 2019; Yang et al., 2019; Dong et al., 2019; Radford et al., 2019). Nevertheless, additional pre-training closer to the end-task, such as training on synthetic QA pairs, has been shown to improve performance (Alberti et al., 2019; Dong et al., 2019). While recent work has considered augmenting labelled data and leveraging large unlabelled datasets to generate synthetic QA data, directly adapting to target data has, to our knowledge, not been investigated in the context of BERT-era modeling and performance levels.

Recently, roundtrip consistency (RTC) was introduced as a criteria for filtering synthetic question-answer pairs on unlabelled data, and has demonstrated solid gains when applied to large unlabelled datasets to generate millions of RTC-validated pairs as *task-specific* pre-training data (Alberti et al., 2019). Such *unsupervised* self-training can be an effective way to de-emphasize low confidence predictions, adapt to the target input distribution, distill decoding procedures, and instill input response invariances.

In this paper we present new theoretical justification for RTC, and explore novel *iterative* generalizations of RTC for adapting in a *task-specific*, *target data specific* manner. We show that most of these approaches optimize an approximation of a lower bound of the probability of the data, and thereby can, beyond self-training, potentially also adapt to explain the target data more effectively. Under the formulation, the question-answering system is used as a surrogate likelihood function for the question and answer generators. In this manner, the difficult task of modeling the generation of entire contexts is avoided: instead abstractive parts of the context (the answers), whose locations are latent and estimated, are utilized, similar to an autoencoder, but with questions as the latent code,

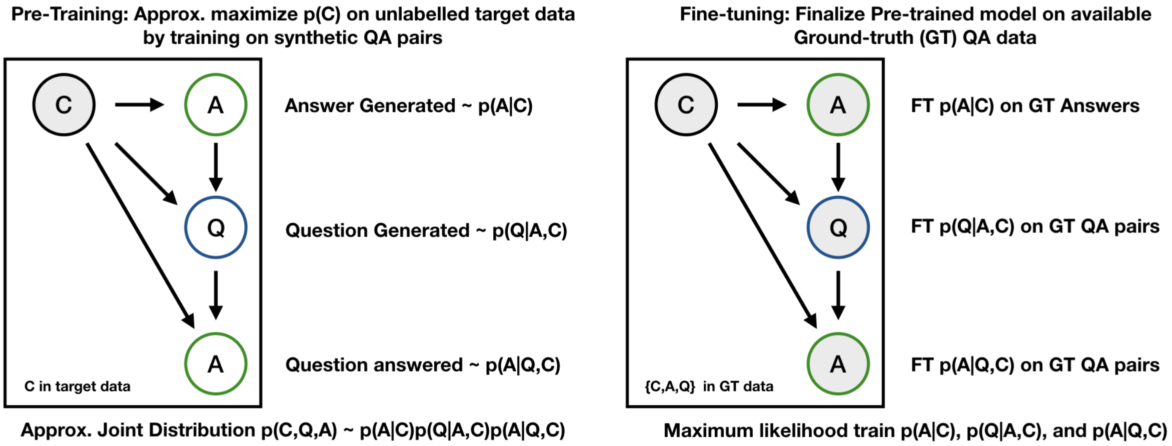

Figure 1: Overview of Approach: We adapt to unlabelled target data by iterating between generating synthetic question answer (QA) pairs and approximately maximizing the probability of the observed contexts C, and fine-tuning on all available ground truth (GT) QA data. Please refer to (6-9) for further details.

and latent answer inputs. By adapting on synthetic QA pairs generated on the target data, our method is able to improve QA systems significantly, using an order of magnitude less synthetic data and training computation than existing augmentation approaches.

The main contributions of this paper are as follows:

- We consider the problem of adapting QA systems to target data using synthetically generated QA pairs, and show that this improves QA systems significantly, while using an order of magnitude less data and computation relative to existing methods that augment using large unlabelled data sets.

- We present a solid theoretical foundation for understanding existing and developing new synthetic data filtering algorithms, including the effective but elusive Roundtrip Consistency (RTC) algorithm.

- We compare several related methods for utilizing synthetic data to adapt to target data, by iteratively pre-training and fine-tuning the QA system and QA generators, and show that some variations optimize an approximation of a lower bound on the probability of the adaptation data, despite being composed on only inference networks.

2 Supervised Training of QA systems

Typically question-answering (QA) systems are trained to produce an abstractive answer A, given a question Q, and the relevant local context C.

The QA model is generally trained to maximize the probability of QA pairs in context:

$$l_{a|g} = \sum_t \log p(A_t^* | Q_t^*, C_t^*) \tag{1}$$

Where $\{Q_t, A_t, C_t\}$ denotes a set of human-annotated question-answer-context triples (Rajpurkar et al., 2016). Supervised training of Question-Answering systems is effective, but ground-truth (GT) QA pairs are cumbersome and expensive to annotate. Bootstrapping from pre-trained representations such as BERT significantly reduces the number of GT QA pairs that are required to train a high quality QA system, but current systems still currently require hundreds of thousands of GT QA pairs on data matching the style and content of the target data to perform at state-of-the-art levels.

3 Generating Synthetic QA Data

To augment an existing QA training set, several authors have used the supervised data to train question generators (Sachan and Xing, 2018; Duan et al., 2017; Alberti et al., 2019; Dong et al., 2019). As with the QA counterparts, these models are typically trained in a supervised manner:

$$l_{q|a} = \sum_t \log p(Q_t^* | A_t^*, C_t^*) \tag{2}$$

and then employed to augment the training set with additional, synthetic questions, for each ground-truth answer.

Most techniques that operate fully unsupervised also train an answer prior in the same manner, which generates answers for a given context, which the question generator then conditions on to generate questions (Alberti et al., 2019):

$$l_a = \sum_t \log p(A_t^* | C_t^*) \tag{3}$$

4 Iterative Pre-train then Fine-tune Based Adaptation

Most existing methods for synthetic data augmentation utilize QA generators trained only on supervised data. This synthetic data is used either as pre-training data for the QA system, which is then fine-tuned on ground-truth data (Alberti et al., 2019), or just simply as additional GT data for training.

In this paper we investigate iteratively pre-training both the QA system and the QA generators on the synthetic data generated by the most recent fine-tuned QA generators. The iterative procedure is as follows:

1. Generate QA pairs using the current fine-tuned QA generators.
2. Pre-train the QA generators and QA system on the (filtered) generated data from scratch.
3. Fine-tune the QA generators and QA system on ground truth data.
4. Repeat until converged or for a maximum number of iterations.

5 Fundamentals of Unsupervised Self-Training

Training a model on it's own predictions, or *pseudo-truth*, has a long history in machine learning and speech and language applications (Scudder, 1965; Novotney and Callison-Burch, 2010). It generally leads to performance improvements, but why? The expected gradient of the log probability of a model $p(y|x)$ trained on its own predictions is zero: $E_{y \sim p_{\hat{\theta}}(y|x)}[\nabla_\theta \log p_\theta(y|x)] = 0$! There are few ways that self-training can improve performance:

- By re-prioritizing the model's capacity based on a target input distribution x that is generated for, i.e., by compensating for *covariate shift* (Sugiyama and Kawanabe, 2012).
- By sharpening the model to eliminate prediction noise, via the distillation of any decoding processes (e.g. beam search) (Grandvalet and Bengio, 2005).
- By introducing perturbations that the model's predictions are trained to be invariant to.

Recently in (He et al., 2019), it was shown that for machine translation, significant gains could be realized via self-training, and that most of this gain could be attributed to the last effect: in particular, invariance to input and dropout noise. In summary, predictive models can benefit substantially from self-training: one does not need to improve a generative model of the data to improve prediction performance on that data. Nevertheless, we will next relate the predictive models used in QA generators and QA systems to underlying implicit generative models, to derive insight and justify existing QA filtering methods, and derive new ones. It turns out that several self-training algorithms for QA optimization actually optimize an approximate lower bound on the probability of the data, and so have the potential to evolve their representations to maximize the probability of the target data.

6 A Generative Framework for Adapting QA Systems

In this section we consider a simple generative framework for understanding predictive QA systems. In unsupervised data settings, only the context C is observed, and the questions $\{Q\}$ and answers $\{A\}$ are latent, and must be inferred.

Here we consider the following generative model for each context:

$$\log p(C) = \log \sum_{Q,A} p(C|Q,A)p(Q|A)p(A) \tag{4}$$

Where the index of the context in the adaptation data has been omitted to avoid notational clutter. Typically the factors of a generative models are explicit, and each factor is endowed with parameters, to maximize the probability of the data. In this paper, these factors, as we shall see, are only implicit, and we explore the possibility of maximizing the probability of the data, using *only* inference networks, which condition on the context: namely the answer generator, $p(A|C)$, the question generator, $p(Q|A,C)$, and the QA system, $p(A|Q,C)$. Our interest in doing so is 3 fold: 1) To avoid having to specify and train a generative model of contexts, which may be difficult to learn. 2) To better understand the theoretical underpinnings of existing augmentation algorithms such as the roundtrip consistency algorithm (RTC) (Alberti et al., 2019), and 3) Foremost, to achieve the end-goal of deriving insight that leads to more effective iterative algorithms for adapting QA systems.

We begin our quest by low-bounding the probability of the data, with a posterior distribution $q(A,Q)$ over the latent questions and answers for the context, as is done for VAES (Kingma and Welling, 2013).

$$\log p(C) \geq \sum_{Q,A} q(Q,A|C) \log \frac{p(C|Q,A)p(Q,A)}{q(Q,A|C)} \tag{5}$$

Expanding the prior term $p(Q,A)$ in terms of question and answer generators, $p(Q|A,C)$ and $p(A|C)$, we have:

$$\begin{aligned}\log p(Q,A) &= \log \sum_{C'} p(Q|A,C')p(A|C')\hat{p}(C') \\ &\geq \log p(Q|A,C)p(A|C)\hat{p}(C) \end{aligned} \tag{6}$$

Where $\hat{p}(C')$ is the current estimate of probability of context C'. In general we expect this lower bound to be quite strong, as $p(Q|A,C')$ and $p(A|C')$ are identically or close to zero for most $C' \neq C$. The resulting lower bound is on $p(C)$ is:

$$\begin{aligned}&\log p(C) \geq \mathcal{L} = \log \hat{p}(C) + \\ &\sum_{Q,A} q(Q,A|C) \log \frac{p(C|Q,A)p(Q|A,C)p(A|C)}{q(Q,A|C)}\end{aligned} \tag{7}$$

Which can be maximized to improve $p(C)$. The resulting bound looks much like a typical variational bound (e.g. 5), the principle difference being that the distributions being optimized are themselves inference networks, and condition on C. The effective joint distribution corresponding to this bound is:

$$p(C,Q,A) \approx p(C|Q,A)p(Q|A,C)p(A|C) \tag{8}$$

7 Defining the inference distribution q

In contrast with how VAEs are typically optimized, here we utilize multiple samples to form a posterior over QA pairs (Burda et al., 2015; Rainforth et al., 2018), and employ a form of prioritized truncated variational inference (TVI) to combat mode-dropping, which was recently shown to be a proper variational bound that can be iterated (Lücke, 2016). TVI in short, utilizes a subset Φ of joint states to define the posterior, i.e. $q(Q,A) \propto p(Q,A,C), \{Q,A\} \in \Phi$, $0\, o.w$, but any subset of states, and any convex set of weights, can be used to form a lower bound.

$$\begin{aligned}\log p(C) &= \log \sum_{Q,A} p(C,Q,A) \\ &\geq \log \sum_{Q,A \in \Phi} p(C,Q,A) \\ &\geq \sum_{Q,A\in\Phi} q(Q,A|C) \log \frac{p(C,Q,A)}{q(Q,A|C)} = \mathcal{L}_\Phi(C)\end{aligned} \tag{9}$$

When $q(Q,A|C) \propto p(Q,A,C)$, $\{Q,A\} \in \Phi$, $0\, o.w$, the second bound is tight. In general $q(Q,A|C)$ takes the form:

$$q(Q,A|C) = \frac{q(Q,A,C)}{q(C)} \tag{10}$$

where:

$$q(C) = \sum_{Q,A\in\Phi} q(Q,A,C) \tag{11}$$

The consequence of this is that all the bounds derived above hold, even if the sums over all QA pairs are taken over a prioritized set. The process of defining q thus can be decomposed into two steps:

1. define the subset of QA pairs to include in the set Φ
2. define the convex weights on the identified set, $q(Q,A|C)$.

8 Training Objectives

Typically when the end goal is data modeling, the probability of each data example is maximized indiscriminately. The maximum likelihood objective over the adaptation dataset $\{C_t\}$ in this case is:

$$O_{ML} = \sum_t \mathcal{L}_\Phi(C_t) \tag{12}$$

However, when training inference networks to make predictions for a given set of contexts in an unsupervised manner, it is natural to put more emphasis on confident predictions. A natural self-training objective in this context is to weigh each context according to it's current estimated probability, so as to avoid re-enforcing poor predictions:

$$O_{ST(\alpha)} = \sum_t q(C_t)^\alpha \mathcal{L}_\Phi(C_t) \tag{13}$$

With $\alpha \geq 0$. When $\alpha = 0$, The standard ML objective is recovered. When $\alpha = 1$, the normalization and the overall objective reduces to self-training on the current estimate of the joint distribution over $\{Q, A, C\}$ triples:

$$O_{ST(1)} = \sum_t \sum_{\{Q,A\} \in \Phi_t} q(Q, A, C_t) \log p(Q, A, C_t) \tag{14}$$

We found that $O_{ST(1)}$ consistently, leads to slightly better QA performance than pre-training with O_{ML}, and so we optimize $O_{ST(1)}$ during the pre-training step for all results in this paper, except where otherwise noted.

9 The question answer posterior (QAP) based likelihood approximation

As discussed above, summing over all QA pairs is intractable, and so we select the set Φ by prioritizing wrt $p(Q|A, C)p(A|C)$ via beam search. Given the set, we need to approximate $p(Q, A, C)$. Here we approximate the likelihood function $p(C|Q, A)$ by the QA posterior $p(A|Q, C)$, which will attribute low scores to poor QA pairs. Since the answers A are abstractive, this is a good approximation. With $p(C|Q, A) \approx p(A|Q, C)$, and Φ prioritizing wrt $p(Q|A, C)p(A|C)$ via beam search, we utilize the tightest possible TVI bound on (7):

$$q(Q, A, C) \propto p(A|Q, C)p(Q|A, C)p(A|C) \tag{15}$$

Treating these prioritized samples as independent samples from $p(Q|A, C)p(A|C)$ [1], the final weight on each sample after importance sampling is proportional to $p(A|Q, C)$. The resulting per example adaptation objective for our generators and QA system are given by:

$$O = \sum_{Q,A \in \Phi} \tilde{p}(A|Q, C)[\log p_{\theta_{a|q}}(A|Q, C) + \log p_{\theta_{q|a}}(Q|A, C) + \log p_{\theta_a}(A|C)] \tag{16}$$

Where $\tilde{p}(A|Q, C) = \frac{p(A|Q,C)}{(\sum_{Q,A\in\Phi} p(A|Q,C))^\alpha}$ when the objective $O_{ST(\alpha)}$ is used ($p(A|Q, C)$ when $\alpha = 1$).

In essence, the generators are trained on the reward signal $\tilde{p}(A|Q, C)$. Note that the expected gradient of the QA term is not zero, because the set set has been prioritized. In addition, dropout is used during training, to encourage invariance to dropout noise on *generated* inputs. Adding noise to the input would similarly improve performance, but we leave this to future work. Effectively this approach further prioritizes the set of questions produced by beam search based on the posterior distribution of the answer that the question was generated for, and encourages prediction consistency over noisy representations.

10 Interpreting existing approaches

Current techniques can be understood in the context of the above bounds, which provides new theoretical justification for these methods, and furthermore justifies the iterative extensions of these methods presented herein.

10.1 Beam Search and Augment (BSA)

The most straightforward approach to incorporating synthetic data is to generate QA pairs using beam search using the generators, $p(A|C), p(Q|A, C)$, and then treating the generated data as ground-truth data with weight 1. Selecting a subset Φ_{QA} of QA pairs here corresponds to an instance of truncated variational inference to define the support of $q(Q, A)$, and using weights of one corresponds to a uniform distribution over the selected set, for lack of any way to approximate the likelihood function, and use of $O_{ST(\alpha)}$ with $\alpha = 1$.

10.2 Roundtrip Consistency

Roundtrip consistency, introduced in (Alberti et al., 2019), generates a set of candidate QA pairs using beam search, and accepts the QA pair only if $\arg\max_A p(A|Q_i, C) = A_i$. The authors sketch two potential avenues for the formal justification of RTC in the appendix, but state that "a key question for future work is to develop a more formal understanding of why the roundtrip method improves accuracy".

Under the presented framework, RTC can be easily interpreted. The RTC procedure for validating QA pairs is an instance of the Iterated Conditional Modes (ICM) algorithm (Besag, 1986) for identifying local modes of a posterior distribution. The

---

[1] In practice prioritized samples often lead to better performance when treated as independent samples (Alberti et al., 2019), we also found that this was the case.

ICM algorithm consists of iteratively maximizing the conditional posterior of one variable (set), given all the others, until convergence. The resulting set of variables is a "conditional mode": the posterior mode of each variable (set), conditioned on all other variables are consistent. RTC performs only one iteration, and discards the example if consistency is not satisfied. In this manner RTC goes further than beam search, and accepts only prioritized generations that are conditional modes of the underlying posterior as members of the set Φ_{QA}. Like BSA, accepted QA pairs are given weight 1, and so like BSA, corresponds to utilizing a uniform distribution over the (smaller) set Φ that satisfies cycle consistency, and the self-training objective $O_{ST(\alpha)}$ (14) with $\alpha = 1$.

The QAP approach to approximating the likelihood represents a soft generalization of RTC, where QA pairs are re-weighted based on the *probabilistic* cycle consistency criterion $q(Q, A) \propto p(A|C)p(Q|A, C)p(A)$, which, as we have shown, produces the tightest bounds on $\log p(C)$ under the model for *any* prioritized set Φ. To retain the speed and performance advantages of selecting only modes, but still assign soft scores, we set a threshold of 0.5 on the QAP filter, so that only modes will be selected, but they will have soft scores associated with them.

11 Related Work

Several authors have recently investigated the use of synthetic data to improve question answering systems, with most of the work we are aware of either augmenting the training set, or generating synthetic QA pairs on auxiliary data (Sachan and Xing, 2018; Du et al., 2017; Duan et al., 2017; Song et al., 2017; Alberti et al., 2019; Dong et al., 2019; Zhang and Bansal, 2019). In most existing work, the generators are trained only on ground-truth data. One exception is (Sachan and Xing, 2018), which jointly self-trains question given answer (RNN) and answer given question (Attentive Reader) models. Another is (Wang et al., 2019), which introduces a domain classifier to adapt to target domain data. However, in contrast with our work, they train their QA system component only on ground-truth source data, because they found that synthetic data degrades QA system performance, whereas our PT QA systems trained *only* on synthetic data often outperform the baseline.

In this work, we focus on using synthetic data to adapt to target data, and iteratively improve both the generators and the QA system during the adaptation process using pre-trained Transformers, by alternating between self-supervised pre-training and ground-truth fine-tuning phases. The closest existing work to ours that we are aware of is the Roundtrip Consistency paper itself (Alberti et al., 2019), whose "fine-tuning only" experiments parallel ours, in that they fine-tune pre-trained BERT models to define the answer and question generators, and the QA system (SQUAD2 gain 0.9 F1 with 3M QA pairs). Note that, in contrast with our work, their generators were trained only on ground-truth data, and the augmentation process was not iterated.

An important element of this work is to show that iterative Roundtrip Consistency filtering and the Answer Posterior filtering method proposed here approximately optimize a lower bound on the probability of the target domain data. In (Lewis and Fan, 2018), the authors propose a generative model for question answering, which purposefully avoids the use of a QA decoder, $p(A|Q, C)$, instead inverting the generative model $p(A|C), p(Q|A, C)$ explicitly over a prioritized set of answers using beam search, so that an answer must be able to generate the question to be an answer. Additional discriminative training is required to make the approach work well, but nevertheless, this desiderata is captured by both Roundtrip Consistency filtering and Answer Posterior filtering: yes, generated questions are verified by virtue of matching generated and predicted answers, but also answers are validated by the generators' ability to communicate it when the answer→ question → answer loop is enforced. Yet another manifestation of this idea is regularizing the question generator $p(Q|A, C)$ and question answering system $p(A|Q, C)$ to encourage them to be consistent during (supervised) training (Tang et al., 2017; Duan et al., 2017).

In (Dong et al., 2019) the authors investigate the use of UniLM on SQUAD and fine-tune UniLM as a question generator to augment the training set with new questions for ground truth answers. Our preliminary experiments indicate that this is a straightforward way to significantly boost baseline QA and Q generator performance before adapting to target data, given that the ground truth answers are available, using the methods described herein.

Method	QAP selection	QAP weight
BSA	$TOPK[p(A \mid C)p(Q \mid A, C)]$	1
RTC	$TOPK[p(A \mid C)p(Q \mid A, C)]$ & $\arg\max_A p(A \mid Q_i, C) = A_i$	1
QAP	$TOPK[p(A \mid C)p(Q \mid A, C)]$ & $p(A_i \mid Q_i, C) > 0.5$	$p(A_i \mid Q_i, C)$

Table 1: Summary of iterative adaptation techniques investigated in this paper: Beam Search Adaptation (BSA), Roundtrip Consistency (RTC), and Question Answer Posterior (QAP). Composition of the approximate QAC likelihood, which defines the weight of each generated example during pre-training, consists of 1) Selecting a set Φ of QA pairs for the context C, and 2) setting a weight for each selected pair.

12 Experiments

12.1 Test Scenarios

To evaluate the efficacy of unsupervised self-training for QA system adaptation, we consider the following scenarios:

- Well Matched Target Conditions, Limited Training Data (WM-LT)
- Well Matched Target Conditions, Plentiful Training Data (WM-PT)
- Mismatched Target Conditions, Plentiful Training Data (MM-PT)

In this paper well matched conditions (WM-LT, WM-PT) are assessed by adapting SQUAD-trained models on SQUAD development data (Rajpurkar et al., 2016), and mismatched conditions by adapting SQUAD-trained models on the portion of the Natural-Questions (NQ) development data (Kwiatkowski et al., 2019) that contains abstractive short answers.

12.2 Models

In this paper all QA generation and answering models are trained by fine-tuning BERT (base, uncased, unless noted otherwise). The question generator is trained as a left-to-right sequence-to-sequence model, which conditions on the observed context. Ground-truth or generated answers are marked in the context by introducing additional segment ids to mark the answer. All models are iteratively pre-trained on synthetic generated data and fine-tuned on SQUAD using essentially the standard BERT fine-tuning recipe for SQUAD (ADAM optimizer, std. parameters; lr=3e-5; 2 epochs, "warmup linear" schedule for both PT and FT). All experiments were conducted on 4 or 8 node V-100 machines, and all models were adapted for two iterations.

Model	EM	F1
Baseline-FT	–/69.6	–/79.7
BAS-PT	56.7/58.1	69.0/71.3
BAS-FT	71.1/71.1	81.2/81.2
RTC-PT	65.6/67.4	75.4/77.5
RTC-FT	71.6/71.6	81.2/81.5
QAP-PT	64.7/66.1	75.2/77.2
QAP-FT	71.5/71.7	81.4/81.8

Table 2: Limited training data scenario: Squad 1.1 QA adaptation EM/F1 results on dev (GT data is 9K of Squad1.1 train, bsize 24, pt bsize 80, 4/8 q/a per c,first/best iter. results shown). See section 12.3 for details, and table 1 for a description of each technique.

12.3 Results: Well Matched, Limited Training Data

Table 2 depicts SQUAD 1.1 QA adaptation results on dev (GT data is 9K of SQUAD 1.1 training set, ft batch size 24, pre-training batch size 80). For this test the answer nbest and question nbest were set to 8 and 4 respectively, yielding 32 QA pairs per paragraph (2554 dev paragraphs) before filtering. The performance of the first and best iteration are depicted for each metric, for all models. Looking at the results, we can see that RTC-FT and QAP-FT, which do additional filtering/re-weighting based on QA feedback, respectively, slightly outperform using the prioritized beam search results as gt adaptation data (BSA-FT). Note however, that both RTC and QAP are generally significantly more efficient to train than BSA, as a significant percentage of the prioritized synthetic data is discarded (the amount discarded depends on both the strength of the generator and how mismatched the target conditions are, see table 5 for further analysis). The performance gap between pre-trained models (PT), which are trained only on generated data, in contrast, is more marked. Filtering improves PT model performance substantially.

Model	EM	F1
Baseline	–/46.8	–/62.6
BSA-PT	34.4/24.4	51.2/51.2
BSA-FT	47.0/47.0	62.8/62.8
RTC-PT	42.9/43.8	58.0/58.7
RTC-FT	47.4/47.8	63.1/63.3
QAP-PT	43.3/44.4	57.8/58.3
QAP-FT	48.1/48.1	63.7/63.7
Baseline (LMPT)	–/47.6	–/63.4
QAP-PT (LMPT)	42.9/44.7	57.2/59.1
QAP-FT (LMPT)	48.2/48.5	63.9/64.1

Table 3: Mismatched Target Data Scenario: NQ results on dev (GT data is all of the Squad1.1 training set, bsize 24, pt bsize 96, 4/16 q/a per c, first/best iter. results shown). See section 12.4 and table 1 for details.

12.4 Results: Mismatched Target Conditions, Plentiful Training Data

Table 3 depicts SQUAD 1.1 QA adaptation results on dev (GT data is all, $\sim$ 90K, of the Squad1.1 training set, ft batch size 24, pre-training batch size 96). For this test the answer nbest and question nbest were set to 16 and 4 respectively, yielding 64 QA pairs per paragraph (3703 dev paragraphs) before filtering. Here we also compare QAP-based adaptation to and in combination with BERT-based bidirectional LM-pretraining (LMPT), and find that 1) QAP outperforms LMPT, and 2) LMPT and then QAP adaptation applied in succession leads to the best results. Iterative QAP significantly outperforms the baseline, and slightly outperforms both iterative RTC and BSA, but all results are significantly lower that on the SQUAD dev set. An important difference between SQUAD and NQ is that NQ answers are often significantly longer, which is a prominent bias in the definition of what an answer is, which may be difficult to overcome with just unsupervised adaptation. Nevertheless, all 3 methods are able to improve the baseline system somewhat, and outperform and improve upon LMPT.

12.5 Results: Well Matched Target Conditions, Plentiful Training Data

Table 4 depicts SQUAD 1.1 QA adaptation results on dev (GT data is 9K of Squad1.1 training set, ft batch size 24, pre-training batch size 80 unless otherwise noted). For this test the answer nbest and question nbest were set to 8 and 4 respectively, yielding 32 QA pairs per paragraph (2554 dev paragraphs) before filtering. Here all filtering/reweighting schemes perform similarly and lead to gains, despite the well matched adaptation data scenario. Increasing the number of answers and questions/answer to 8 and 32 results in additional gain, improving baseline F1 performance from 88.4 → 89.5 with QAP. We also found that not adapting the answer prior $p(A|C)$ and mean-normalizing the data weights further improved performance, particularly for QAP (c.f. Table 5, starred results).

12.6 Performance vs. # Synthesized QA Pairs

Synthetic generation and pre-training time scale linearly with the number of generated QA pairs (the latter dominating, due to backpropagation), but nevertheless, our per-paragraph adaptation levels can be significantly increased to yield significant performance gains. Table 5 compares the performance of RTC and QAP in limited training data conditions. The performance gain moving from 4/8 Q/A to 8/32 Q/A per context paragraph is substantial, and remarkably, the PT models, trained only on generated data, outperform the baseline, thanks largely in part to invariances learned with dropout on during self-training. Figure 2 depicts performance of QAP as a function of iteration and synthesis level in the well-matched, limited training data (WM-LT) condition.

12.7 Speed

Both RTC and QAP generally are significantly faster than basic BSA while performing on-par or better than basic beam search augmentation (7, 6 hrs vs 26 hrs during the first iteration using 8 V-100s, for 32 a., 8 q/a per c, see Table 5). Qualitatively we found that BSA generally doesn't benefit from additional iterations, while the performance of RTC and QAP generally saturates after 2-3 iterations, and delivers consistently better performance with lower total training time.

13 Discussion and Future Work

In this paper we have related self-training of question answering systems to the generative modeling of their associated context, and showed the former can be specified to optimize an approximate lower bound on the probability of the data. We then investigated iterative "pre-train then fine-tune" approaches to target domain adaptation, proposed question answer posterior (QAP) as an alternative form of consistency filtering, and provided theoreti-

Model	EM	F1	A, Q/A
Baseline	–/80.9	–/88.4	4, 8
BSA-PT	66.1/66.1	77.9/77.9	4, 8
BSA-FT	81.6/81.6	89.1/89.1	4, 8
QAP-PT	70.1/70.7	80.5/81.2	4, 8
QAP-FT	81.4/81.4	89.0/89.0	4, 8
QAP-PT*	77.7/78.3	85.5/86.1	8, 32
QAP-FT*	82.1/82.3	89.3/89.5	8, 32

Table 4: Well Matched Target Data Scenario: Squad 1.1 results on dev (GT data is all of the Squad1.1 training set, bsize 24, pt bsize 32, 4/8 q/a per c, first/best iter. results shown). See section 12.5 and table 1 for details. *pt bsize 96; $p(A|C)$ not adapted; 8,32 a,q/a; 3 iterations.

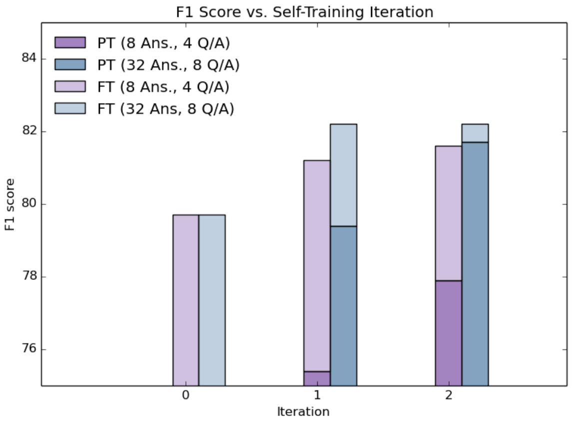

Figure 2: QAP performance as a function of iteration and # QA pairs (WM-LT condition). PT models are trained only on generated data.

Model	EM	F1	A, Q/A	Synth. Data	Relative Speed
Baseline-FT	– / 69.6	– / 79.7	–	–	–
18K Model (2X GTD)	– / 72.3	– / 81.7	–	–	–
BSA-PT/FT	58.8 / 71.9	73.6 / 82.1	32, 8	+1.1M, +1.1M	1X, 1X
RTC-PT/FT	71.6 / 72.6	81.1 / 82.4	32, 8	+220K, +360K	5X, 3X
QAP-PT/FT	72.5 / 72.7	81.7 / 82.2	32, 8	+180K, +320K	6X, 3X
RTC-PT/FT*	71.7 / 72.5	81.4/ 82.3	32, 8	+(220, 350, 422)K	(5,3,4)X
QAP-PT/FT*	72.9 / 73.4	82.2 / 83.0	32, 8	+(180,310,385)K	(6,3,3)X
BSA-PT/FT	58.1 / 71.1	71.3 / 81.2	8, 4	+130K, +130K	1X, 1X
RTC-PT/FT	67.4 / 71.6	77.5 / 81.5	8, 4	+60K, +90K	2X, 1.5X
QAP-PT/FT	68.3 / 71.8	78.0 / 81.6	8, 4	+50K, +80K	2.5X, 1.5X

Table 5: Final PT/FT performance as a function of number of prioritized questions and answers per target data context paragraph. Limited training data scenario: Squad 1.1 QA adaptation EM/F1 results on dev (GT data is 9K of Squad1.1 train). See table 1 for a description of each technique. Remarkably, the PT models, which are trained *only* on generated data, are able to outperform the baseline system, provided a sufficient number of synthetic example per target context paragraph are generated. Each PT iteration with BSA 8,32 takes 13 hrs with an 8 V100s: RTC 8,32 is 5X, and 3X faster during iteration 1&2, respectively, due to data pruning, and QAP 8, 32 is faster than RTC. All 8,32 adapted models outperform an 18K GT only model, trained on 2X the data. When we mean normalize the average training weight, do not adapt the answer prior $p(A|C)$, and adapt for 3 iterations, RTC does not improve, but QAP is significantly more effective (*).

cal justification for Roundtrip Consistency filtering. In general, the techniques work quite well, particularly in better-matched conditions. While effective, iteratively re-training the QA generators and QA system is inefficient, even with strong data filters. How to most efficiently and effectively adapt Transformer-based QA systems remains an important topic for future research.

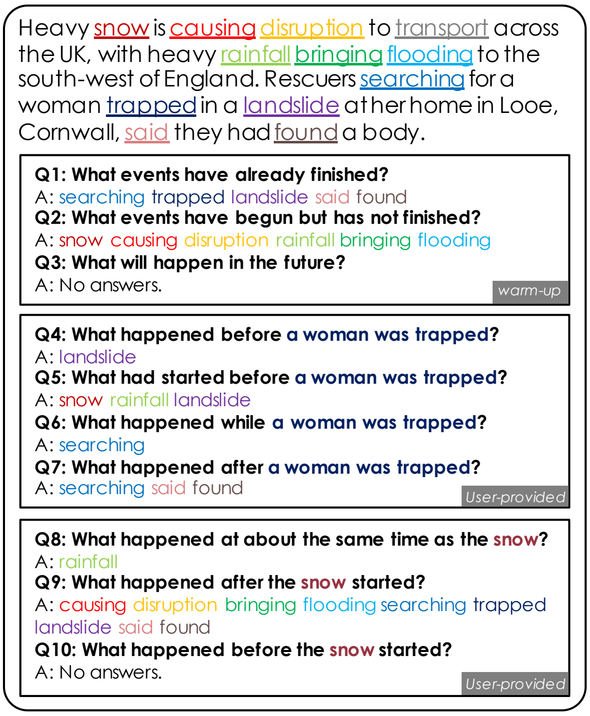
Abstract

A critical part of reading is being able to understand the temporal relationships between events described in a passage of text, even when those relationships are not explicitly stated. However, current machine reading comprehension benchmarks have practically no questions that test temporal phenomena, so systems trained on these benchmarks have no capacity to answer questions such as "what happened *before/after* [some event]?" We introduce TORQUE, a new English reading comprehension benchmark built on 3.2k news snippets with 21k human-generated questions querying temporal relationships. Results show that RoBERTa-large achieves an exact-match score of 51% on the test set of TORQUE, about 30% behind human performance.[1]

1 Introduction

Time is important for understanding events and stories described in natural language text such as news articles, social media, financial reports, and electronic health records (Verhagen et al., 2007, 2010; UzZaman et al., 2013; Minard et al., 2015; Bethard et al., 2016, 2017; Laparra et al., 2018). For instance, *"he won the championship yesterday"* is different from *"he will win the championship tomorrow"*: he may be celebrating if he has already won it, while if he has not, he is probably still preparing for the game tomorrow.

The exact time of an event is often implicit in text. For instance, if we read that a woman is *"expecting the birth of her first child"*, we know that the birth is in the future, while if she is *"mourning the death of her mother"*, the death is in the past. These relationships between an event and a time point (e.g., *"won the championship yesterday"*) or between two events (e.g., "expecting" is *before* "birth" and "mourning" is *after* "death") are called *temporal relations* (Pustejovsky et al., 2003).



Heavy snow is causing disruption to transport across the UK, with heavy rainfall bringing flooding to the south-west of England. Rescuers searching for a woman trapped in a landslide at her home in Looe, Cornwall, said they had found a body.

Q1: What events have already finished?
A: searching trapped landslide said found
Q2: What events have begun but has not finished?
A: snow causing disruption rainfall bringing flooding
Q3: What will happen in the future?
A: No answers.

Q4: What happened before a woman was trapped?
A: landslide
Q5: What had started before a woman was trapped?
A: snow rainfall landslide
Q6: What happened while a woman was trapped?
A: searching
Q7: What happened after a woman was trapped?
A: searching said found

Q8: What happened at about the same time as the snow?
A: rainfall
Q9: What happened after the snow started?
A: causing disruption bringing flooding searching trapped landslide said found
Q10: What happened before the snow started?
A: No answers.

Figure 1: Example annotation of TORQUE. Events are highlighted in color and contrast questions are grouped.

This work studies reading comprehension for temporal relations, i.e., given a piece of text, a computer needs to answer temporal relation questions (Fig. 1). Reading comprehension is a natural format for studying temporal phenomena, as the flexibility of natural language annotations allows for capturing relationships that were not possible in previous formalism-based works. However, temporal phenomena are studied very little in reading comprehension (Rajpurkar et al., 2016, 2018; Dua et al., 2019; Dasigi et al., 2019; Lin et al., 2019), and existing systems are hence brittle when handling questions in TORQUE (Table 1).

Reading comprehension for temporal relationships has the following challenges. First, reading

Table 1: Example system outputs. The correct answers can be seen from the timeline depicted in Fig. 2.

comprehension works rarely require *event* understanding. For the example in Fig. 1, SQuAD (Rajpurkar et al., 2016) and most datasets largely only require an understanding of predicates and arguments, and would ask questions like *"what was a woman trapped in?"* But a temporal relation question would be *"what started before a woman was trapped?"* To answer it, the system needs to identify events (e.g., LANDSLIDE is an event and "body" is not), the time of these events (e.g., LANDSLIDE is a correct answer, while SAID is not because of the time when the two events happen), and look at the entire passage rather than the local predicate-argument structures within a sentence (e.g., SNOW and RAINFALL are correct answers to the question above).

Second, there are many events in a typical passage of text, so temporal relation questions typically query more than one relationship at the same time. This means that a question can have multiple answers (e.g., *"what happened after the landslide?"*), or no answers, because the question may be beyond the time scope (e.g., *"what happened before the snow started?"*).

Third, temporal relations queried by natural language questions are often sensitive to a few key words such as *before*, *after*, and *start*. Those questions can easily be changed to make contrasting questions with dramatically different answers. Models that are not sensitive to these small changes in question words will perform poorly on this task, as shown in Table 1.

In this paper, we present TORQUE, the first reading comprehension benchmark that targets these challenges. We trained crowd workers to label events in text, and to write and answer questions that query temporal relationships between these events. We also had workers write questions with contrasting changes to the temporal keywords, to give a comprehensive test of a machine's temporal reasoning ability and minimize the effect of any data collection artifacts (Gardner et al., 2020). We annotated 3.2k text snippets randomly selected from the TempEval3 dataset (UzZaman et al., 2013). In total, TORQUE has 25k events and 21k user-generated and fully answered temporal relation questions. 20% of TORQUE was further validated by additional crowd workers to be used as test data. Results show that RoBERTa-large (Liu et al., 2019) achieves 51% in exact-match on TORQUE after fine-tuning, about 30% behind human performance, indicating that more investigation is needed to better solve this problem.

2 Definitions

2.1 Events

As temporal relations are relationships between events, we first define *events*. Generally speak-

Events in different modes

The lion had a large meal and slept for 24 hours.

[Negated] The lion didn't sleep after having a large meal.

[Uncertain] The lion may have had a large meal before sleeping.

[Hypothetical] If the lion has a large meal, it will sleep for 24 hours.

[Repetitive] The lion used to sleep for 24 hours after having large meals.

[Generic] After having a large meal, lions may sleep longer.

Figure 3: Various modes of events that prior work needed to categorize. Section 3 shows that they can be handled naturally without explicit categorization.

ing, an event involves a predicate and its arguments (ACE, 2005; Mitamura et al., 2015). When studying *time*, events were defined as actions/states triggered by verbs, adjectives, and nominals (Pustejovsky et al., 2003). Later works on event and time have largely followed this definition, e.g., TempEval (Verhagen et al., 2007), TimeBank-Dense (Chambers et al., 2014), RED (O'Gorman et al., 2016), and MATRES (Ning et al., 2018b).

This work follows this line of event definition and uses *event* and *event trigger* interchangeably. We define an event to be either a verb or a noun (e.g., TRAPPED and LANDSLIDE in Fig. 1). Specifically, in copular constructions, we choose to label the verb as the event, instead of an adjective or preposition. This allows us to give a consistent treatment of *"she was on the east coast yesterday"* and *"she was happy"*, which we can easily teach to crowd workers. Note that from the perspective of data collection, labeling the copula does not lose information as one can always do post-processing using dependency parsing or semantic role labeling to recover the connection between "was" and "happy."

Note that events expressed in text are not always factual. They can be negated, uncertain, hypothetical, or have other associated modalities (see Fig. 3). Prior work dealing with events often tried to categorize and label these various aspects because they were crucial for determining temporal relations. Sometimes certain categories were even dropped due to annotation difficulties (Pustejovsky et al., 2003; O'Gorman et al., 2016; Ning et al., 2018b). In this work, we simply have people label all events, irrespective of their modality, and use natural language to describe relations between them, as discussed in Sec. 3.

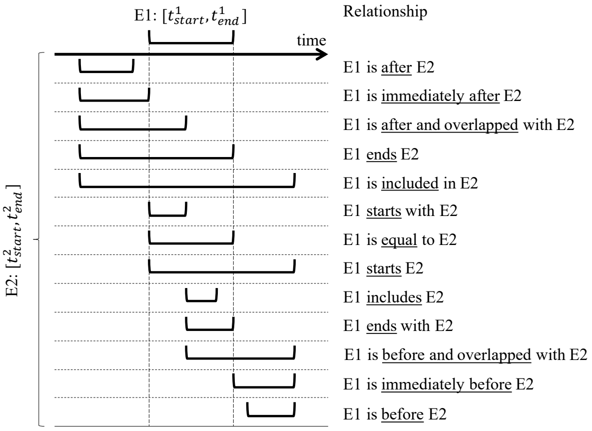

Figure 4: Thirteen relations between two time intervals $[t^1_{start}, t^1_{end}]$ and $[t^2_{start}, t^2_{end}]$.

2.2 Temporal Relations

Temporal relations describe the relationship between two events with respect to time, or between one event and a fixed time point (e.g., *yesterday*).[2] We can use a triplet, (A, r, B), to represent this relationship, where A and B are events or time points, and r is a temporal relation. For example, the first sentence in Fig. 3 expresses a temporal relation (HAD, *happened before*, SLEPT).

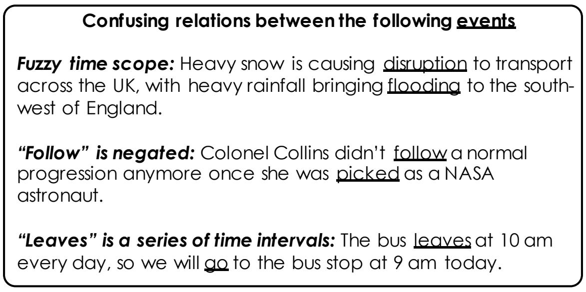
In previous works, every event is assumed to be associated with a time interval $[t_{start}, t_{end}]$. When comparing two events, there are 13 possible relation labels (see Fig. 4) (Allen, 1984). However, there are still many relations that cannot be expressed because the assumption that every event has a time interval is inaccurate: The time scope of an event may be fuzzy, an event can have a non-factual modality, or events can be repetitive and invoke multiple intervals (see Fig. 5). To better handle these phenomena, we move away from the fixed set of relations used in prior work and instead use natural language to annotate the relationships between events, as described in the next section.

3 Natural Language Annotation of Temporal Relations

Motivated by recent works (He et al., 2015; Michael et al., 2017; Levy et al., 2017; Gardner et al., 2019b), we propose using natural language question answering as an annotation for-

---

[2] We could also include relationships between two fixed time points (e.g., compare 2011-03-24 with 2011-04-05), but these are mostly trivial, so we do not discuss them further.



Confusing relations between the following events

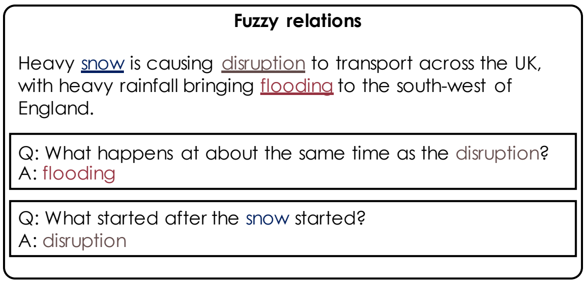
Fuzzy time scope: Heavy snow is causing disruption to transport across the UK, with heavy rainfall bringing flooding to the south-west of England.

"Follow" is negated: Colonel Collins didn't follow a normal progression anymore once she was picked as a NASA astronaut.

"Leaves" is a series of time intervals: The bus leaves at 10 am every day, so we will go to the bus stop at 9 am today.

Figure 5: It is confusing to label these relations using a fixed set of relations: they are not simply *before* or *after*, but they can be fuzzy, can have modalities as events, and/or need multiple time intervals to represent.

mat for temporal relations. Recalling that we denote a temporal relation between two events as (A, r, B), we use $(?, r, B)$ to denote a temporal relation question. We instantiate these temporal relation questions using natural language. For instance, (?, *happened before*, SLEPT) means *"what happened before a lion slept?"* We then expect as an answer the set of all events A in the passage such that (A, r, B) holds, assuming for any deictic expression A or B the time point when the passage was written, and assuming that the passage is true.



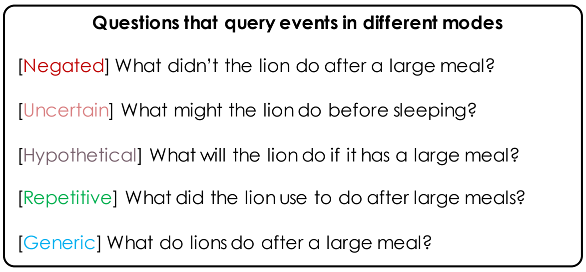
Fuzzy relations

Heavy snow is causing disruption to transport across the UK, with heavy rainfall bringing flooding to the south-west of England.

Q: What happens at about the same time as the disruption?
A: flooding

Q: What started after the snow started?
A: disruption

Figure 6: Fuzzy relations that used to be difficult to represent using a predefined label set can be captured naturally in a reading comprehension task.



Questions that query events in different modes

[Negated] What didn't the lion do after a large meal?

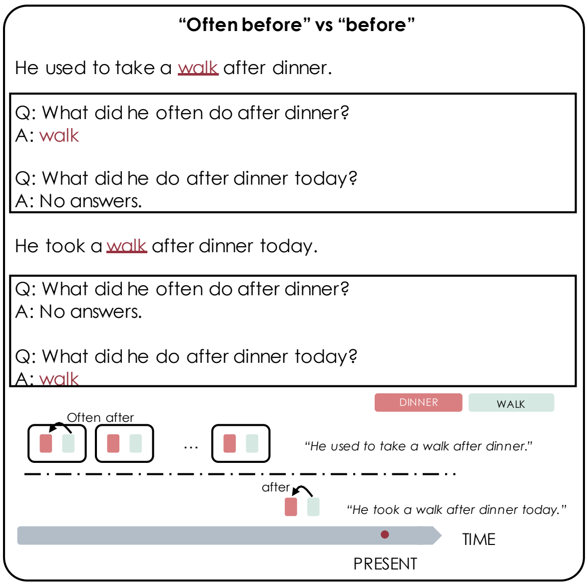
[Uncertain] What might the lion do before sleeping?

[Hypothetical] What will the lion do if it has a large meal?

[Repetitive] What did the lion use to do after large meals?

[Generic] What do lions do after a large meal?

Figure 7: Events in different modes can be distinguished using natural language questions.



"Often before" vs "before"

He used to take a walk after dinner.

Q: What did he often do after dinner?
A: walk

Q: What did he do after dinner today?
A: No answers.

He took a walk after dinner today.

Q: What did he often do after dinner?
A: No answers.

Q: What did he do after dinner today?
A: walk

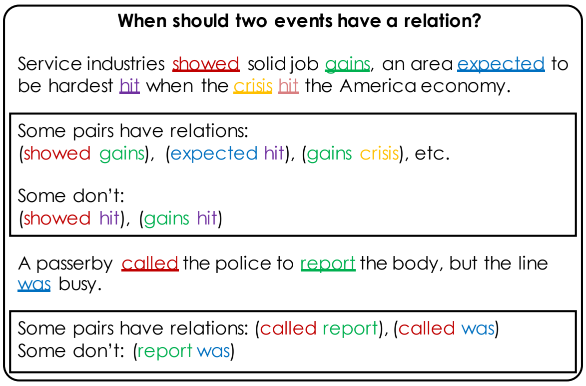
Figure 8: A repetitive event needs multiple time intervals and conveys very different semantics.

3.1 Advantages

Studying temporal relations as a reading comprehension task gives us the flexibility to handle many of the aforementioned difficulties. First, fuzzy relations can be described by natural language questions (after all, the relations are expressed in natural language in the first place). In Fig. 6, DISRUPTION and FLOODING happened at about the same time, but we do not know for sure which one is earlier, so we have to choose *vague*. Similarly for SNOW and DISRUPTION, we do not know which one ends earlier and have to choose *vague* again. In contrast, the question-answer (QA) pairs in Fig. 6 can naturally capture these fuzzy relations.

Second, natural language questions can conveniently incorporate different modes of events. Figure 7 shows how to accurately query the relation between *"having a meal"* and *"sleeping"* in different modes (original sentences can be found in Fig. 3). In contrast, if we could only choose one label, we must choose *before* for all these relations, although these relations are actually different. For instance, a repetitive event may be a series of intervals rather than a single one, and *often before* is very different from *before* (Fig. 8).

Third, a major issue that prior works wanted to address was deciding when two events should have a relation (Cassidy et al., 2014; Mostafazadeh et al., 2016; O'Gorman et al., 2016; Ning et al., 2018b). To avoid asking for relations that do not exist, prior works needed to explicitly annotate certain properties of events as a preprocessing step, but it still remains difficult to have a the-



When should two events have a relation?

Service industries showed solid job gains, an area expected to be hardest hit when the crisis hit the America economy.

Some pairs have relations:
(showed gains), (expected hit), (gains crisis), etc.

Some don't:
(showed hit), (gains hit)

A passerby called the police to report the body, but the line was busy.

Some pairs have relations: (called report), (called was)
Some don't: (report was)

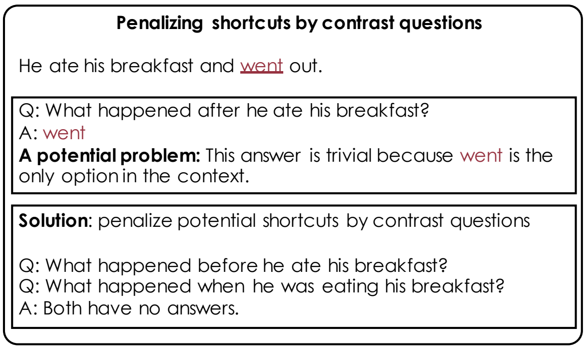
Figure 9: It remains unclear how to determine if two events should have a temporal relation.

ory explaining, for instance, why hit can compare to expected and crisis, but not to gains. Interestingly, when we annotate temporal relations in natural language, the annotator naturally avoids event pairs that do not have relations. For instance, for the sentences in Fig. 9, one will not ask questions like *"what happened after the service industries are hardest hit?"* or *"what happened after a passerby reported the body?"* Instead, natural questions will be *"what was expected to happen when the crisis hit America?"* and *"what was supposed to happen after a passerby called the police?"* The format of natural language questions bypasses the need for explicit annotation of properties of events or other theories.

While using QA as the format gives us many benefits in describing fuzzy relations and incorporating various temporal phenomena, we want to note that it may also lead to potential difficulties in transferring the knowledge to downstream tasks that are not in a QA format, and some special treatment in modeling may be needed (e.g., He et al. (2020)). This paper focuses on constructing this QA dataset covering new phenomena, and the problem of successful transfer learning is beyond our scope here.

3.2 Penalize Shortcuts by Contrast Sets

An important problem in building datasets is to avoid trivial solutions (Gardner et al., 2019a). As Fig. 10 shows, there are two events ATE and WENT in the text. Since ATE is already mentioned in the question, the answer of WENT seems a trivial option without the need to understand the underlying relationship. To address this issue, we create *contrast questions* which slightly modify the original questions, but dramatically change the answers, so that shortcuts are penalized. Specifically, for an existing question $(?, r, B)$ (e.g., *"what happened after he ate his breakfast?"*), one should keep using B and change r (e.g., *"what happened* ***before/shortly after/...*** *he ate his breakfast?"*), or modify it to ask about the start/end time (e.g., *"what happened after he* ***started*** *eating his breakfast?"* or *"what would* ***finish*** *after he ate his breakfast?"*). We also instructed workers to make sure that the answers to the new question are different from the original one to avoid trivial modifications (e.g., changing *"what happened"* to *"what occurred"*).



Penalizing shortcuts by contrast questions

He ate his breakfast and went out.

Q: What happened after he ate his breakfast?
A: went
A potential problem: This answer is trivial because went is the only option in the context.

Solution: penalize potential shortcuts by contrast questions

Q: What happened before he ate his breakfast?
Q: What happened when he was eating his breakfast?
A: Both have no answers.

Figure 10: Penalize potential shortcuts by providing contrast questions.

4 Data Collection

We used Amazon Mechanical Turk to build TORQUE. Following prior work, we focus on passages that consist of two contiguous sentences, as this is sufficient to capture the vast majority of non-trivial temporal relations (Ning et al., 2017). We took all the articles used in the TempEval3 (TE3) workshop (2.8k articles) (UzZaman et al., 2013) and created a pool of 26k two-sentence passages. Given a random passage from this pool, the annotation process for crowd workers was:

1. Label all the events
2. Repeatedly do the following[3]
   (a) Ask a temporal relation question and point out all the answers from the list of events
   (b) Modify the temporal relation to create one or more new questions and answer them

The annotation guidelines[4] and interface[5] are public. In the following sections, we further discuss issues of quality control and crowdsourcing cost.

---

[3] The stopping criterion is discussed in Sec. 4.2.

[4] `https://qatmr-qualification.github.io/`

[5] `https://qatmr.github.io/`

4.1 Quality Control

We used three quality control strategies: qualification, pilot, and validation.

Qualification We designed a separate qualification task where crowd workers were trained and tested on 3 capabilities: labeling events, asking temporal relation questions, and question-answering. They were tested on problems randomly selected from a pool we designed. Crowd workers were considered level-1 qualified if they could pass the test within 3 attempts. In practice, about 1 out of 3 workers passed our qualification.

Pilot We then asked level-1 crowd workers to do a small amount of the real task. We manually checked the annotations and gave feedback to them. Those who passed this inspection were called level-2 workers, and only they could work on the large-scale real task. Roughly 1 out of 3 pilot submissions received a level-2 qualification. In the end, there were 63 level-2 annotators, and 60 of them actually worked on our large-scale task.

Validation We randomly selected 20% of the articles from TORQUE for further validation. We first validated the events by 4 different level-2 annotators (with the original annotator, there were in total 5 different humans). We also intentionally added noise to the original event list so that the validators must carefully identify wrong events. The final event list was determined by aggregating all 5 humans using majority vote. Second, we validated the answers in the same portion of the data. Two level-2 workers were asked to verify the initial annotator's answers; we again added noise to the answer list as a quality control for the validators. Instead of using majority vote as we did for events, the final answers from all workers are considered correct. We did not do additional validation for the questions themselves, as a manual inspection found the quality to be very high already, with no bad questions in a random sample of 100.

4.2 Cost

In each job of the main task, we presented 3 passages. The crowd worker could decide to use some or all of them. For each passage a worker decided to use, they needed to label the events, answer 3 hard-coded warm-up questions, and then ask and answer at least 12 questions (including contrast questions). The final reward is a base pay of \$6 plus \$0.5 for each extra question. Crowd workers thus had the incentive to (1) use fewer passages so that they can do event labeling and warm-up questions fewer times, (2) modify questions instead of asking from scratch, and (3) ask extra questions in each job. All these incentives were for more coverage of the temporal phenomena in each passage. In practice, crowd workers on average used 2 passages in each job. Validating the events in each passage and the answers to a specific question both cost \$0.1. In total, TORQUE cost \$15k for an average of \$0.70/question.

5 TORQUE Statistics

TORQUE has 3.2k passage annotations (∼50 tokens/passage),[6] 24.9k events (7.9 events/passage), and 21.2k user-provided questions (half of them were labeled by crowd workers as modifications of existing ones). Every passage comes with 3 hard-coded warm-up questions asking which events in the passage had already happened, were ongoing, or were still in the future. Table 3 shows some basic statistics of TORQUE. Note the 3 warm-up questions form a contrast set, and we treat the first as "original" and the others "modified."

In a random sample of 200 questions in the test set of TORQUE, we found 94 questions querying about relations that cannot be directly represented by the previous single-interval-based labels. Table 2 gives example questions capturing these phenomena. More analysis of the event, answer, and workload distributions are in Appendix A-D.

5.1 Quality

To validate the event annotations, we took the events provided by the initial annotator, added noise, and asked different workers to validate. We also trained an auxiliary event detection model using RoBERTa-large and added its predictions as event candidates. This tells us about the quality of events in TORQUE in two ways. First, the Worker Agreement with Aggregate (WAWA) F_1 here is 94.2%; that is, compare the majority-vote with all annotators, and perform micro-average on all instances. Second, if an event candidate is labeled by both the initial annotator and the model, then almost all of them (99.4%) are kept by the validators; if neither the initial annotator nor the model labeled a candidate, the candidate is almost surely removed (0.8%). As validators did not know which ones were noise or not before-

---

[6] Since the passages were selected randomly with replacement, there are 2.9k unique passages in total.

Type	Subtype	Example	%
Standard		*"What happened before Bush gave four key speeches?"*	53%
Fuzzy	begin only	*"What started before Mr. Fournier was prohibited from organizing his own defense?"*	15%
	overlap only	*"What events were occurring during the competition?"*	10%
	end only	*"What will end after he is elected?"*	1%
Modality	uncertain	*"What might happen after the FTSE 100 index was quoted 9.6 points lower?"*	10%
	negation	*"What has not taken place before the official figures show something?"*	5%
	hypothetical	*"What event will happen if the scheme is broadened?"*	2%
	repetitive	*"What usually happens after common shares are acquired?"*	1%
Misc.	participant	*"What did Hass do before he went to work as a spy?"*	4%
	opinion	*"What should happen in the future according to Obama's opinion?"*	3%
	intention	*"What did Morales want to happen after Washington had a program to eradicate coca?"*	1%

Table 2: Temporal phenomena in TORQUE. "Standard" are those that can be directly captured by the previous single-interval-based label set, while other types cannot. Percentages are based on manual inspection of a random sample of 200 questions from TORQUE; some questions can have multiple types.

	Q	Q/P	A	A/Q
Overall	30.7k	9.7	65.0k	2.1
Warm-up	9.5k	3	21.6k	2.3
* *Original*	3.2k	1	12.8k	4.0
* *Modified*	6.3k	2	8.8k	1.4
User-provided	21.2k	6.7	43.4k	2.1
* *Original*	10.6k	3.4	25.1k	2.4
* *Modified*	10.6k	3.3	18.3k	1.7

Table 3: Columns from left to right: questions, questions per passage, answers, and answers per question. *Modified* is a subset of questions that is created by slightly modifying an *original* question.

hand, this indicates that the validators could identify noise terms reliably.

Similarly, the WAWA F_1 of the answer annotations is 84.7%, slightly lower than that for events, which is expected because temporal relation QA is intuitively harder. Results show that 12.3% of the randomly added answer candidates were labeled as correct answers by the validators. We manually inspected 100 questions and found 11.6% of the added noise terms were correct answers (very close to 12.3%), indicating that the validators were actually doing a good job in answer validation. More details of the metrics and the quality of annotations can be found in Appendix E.

6 Experiment

We split TORQUE into train (80% of all the questions), dev (5%), and test (15%) and these three parts do not have the same articles. To solve TORQUE in an end-to-end fashion, the model here takes as input a passage and a question, then looks at every token in the passage and makes a binary classification of whether this token is an answer to the question or not. Specifically, the model has a one-layered perceptron on top of BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2019), and the input to the perceptron layer is the transformers' output corresponding to the token we're looking at. We fine-tuned BERT/RoBERTa (both "base" and "large") on the training set of TORQUE. We fixed batch size = 6 (each instance is a tuple of one passage, one question, and all its answers) with gradient accumulation step = 2 in all experiments. We selected the learning rate (from $(1e^{-5}, 2e^{-5})$), the training epoch (within 10), and the random seed (from 3 arbitrary ones) based on performance on the dev set of TORQUE.[7] To compute an estimate of human performance, one author answered 100 questions from the test set and compared with crowd workers' annotations.

Both the human performance and system performances are shown in Table 4. We report the standard macro F_1 and exact-match (EM) metrics in question answering, and also EM consistency, the percentage of contrast question sets for which a model's predictions match exactly to all questions in a group (Gardner et al., 2020). We see warm-up questions are easier than user-provided ones because warm-up questions focus on easier phenomena of past/ongoing/future events. In addition, RoBERTa-large is expectedly the best system, but still far behind human performance, trailing by about 30% in EM.

We further downsampled the training data to test the performance of RoBERTa. We find that with 10% of the original training data, RoBERTa fails to learn anything meaningful and simply pre-

---

	Dev			Test								
				Overall			Warm-up questions			User-provided		
	F_1	EM	C	F_1	EM	C	F_1	EM	C	F_1	EM	C
Human	-	-	-	*95.3*	*84.5*	*82.5*	*95.7*	*89.7*	*90.9*	*95.1*	*82.4*	*79.3*
BERT-base	67.6	39.6	24.3	67.2	39.8	23.6	72.9	46.2	28.8	64.8	37.1	21.3
BERT-large	72.8	46.0	30.7	71.9	45.9	29.1	75.0	50.1	30.3	70.6	44.1	28.5
RoBERTa-base	72.2	44.5	28.7	72.6	45.7	29.9	75.4	48.8	32.3	71.4	44.4	28.8
RoBERTa-large	**75.7**	**50.4**	**36.0**	**75.2**	**51.1**	**34.5**	**77.3**	**54.3**	**36.1**	**74.3**	**49.8**	**33.8**

Table 4: Human/system performance on the test set of TORQUE. System performance is averaged from 3 runs; all std. dev. were $\leq 4\%$ and those in [1%, 4%] are underlined. C (consistency) is the percentage of contrast groups for which a model's predictions have $F_1 \geq 80\%$ for all questions in a group (Gardner et al., 2020).

dicts "not an answer" for all tokens. With 50% of the training data, RoBERTa is slightly lower than but already comparable to that of using the entire training set. This means that the learning curve on TORQUE is already flat and the current size of TORQUE may not be the bottleneck for its low performance. Our data and code are public to facilitate more investigations into TORQUE.[8]

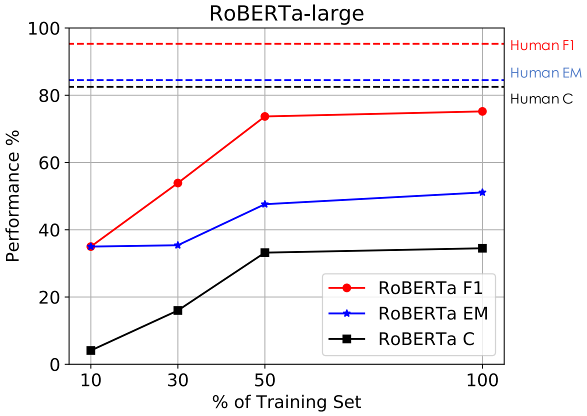

Figure 11: RoBERTa-large with different percentage of training data. Human performance in dashed lines.

7 Related Work

The study of *time* is to understand *when, how long, and how often* things happen. While *how long* and *how often* usually require temporal common sense knowledge (Vempala et al., 2018; Zhou et al., 2019, 2020), the problem of *when* often boils down to extracting temporal relations.

Modeling. Research on temporal relations often focuses on algorithmic improvement, such as structured inference (Do et al., 2012; Chambers et al., 2014; Ning et al., 2018a), structured learning (Leeuwenberg and Moens, 2017; Ning et al., 2017), and neural networks (Dligach et al., 2017; Lin et al., 2017; Tourille et al., 2017; Cheng and Miyao, 2017; Meng and Rumshisky, 2018; Leeuwenberg and Moens, 2018; Ning et al., 2019).

Formalisms. The approach that prior works took to handle the aforementioned temporal phenemona was to define formalisms such as the different modes of events (Fig. 3), a predefined label set (Fig. 4), different time axes for events (Ning et al., 2018b), and specific rules to follow when there is confusion. For example, Bethard et al. (2007); Ning et al. (2018b) focused on a limited set of temporal phenomena and achieved high inter-annotator agreements (IAA), while Cassidy et al. (2014); Styler IV et al. (2014); O'Gorman et al. (2016) aimed at covering more phenomena but suffered from low IAAs even between NLP researchers.

QA as annotation. A natural choice is then to cast temporal relation understanding as a machine reading comprehension (MRC) problem. TORQUE is motivated by the philosophy in QA-SRL (He et al., 2015) and QAMR (Michael et al., 2017), where QA pairs were used as representations for predicate-argument structures. In zero-shot relation extraction (RE), they reduced relation slot filling to an MRC problem so as to build very large distant training data and improve zero-shot learning performance (Levy et al., 2017). However, our work differs from zero-shot RE since it centers around entities, while TORQUE is about events; the way to ask and answer questions, and the way to design a corresponding crowdsourcing pipeline, are thus significantly different between us.

The QA-TempEval workshop (Llorens et al., 2015), desipte its name, is actually not studying temporal relations in an RC setting. The differences between TORQUE and QA-TempEval

---

[8] `https://allennlp.org/torque.html`

are as follows. First, QA TempEval is an evaluation approach for systems that generate TimeML annotations and actually is not a QA task. For instance, QA TempEval is to evaluate whether a system can answer questions like "IS <ENTITY_1> <RELATION> <ENTITY_2>?", where one clearly knows which event that <ENTITY> is referring to and where RELATION is selected from a predefined label set. Second, QA-TempEval's annotation relies on the existence of a TimeML corpus. From the perspective of data collection for studying a particular phenomenon, TORQUE has done more on defining the task and developing a scalable crowdsourcing pipeline. As a result, TORQUE is also much larger than QA-TempEval and the annotation pipeline of TORQUE can be easily adopted to collect even more data.

8 Conclusion

Understanding temporal ordering of events is critical in reading comprehension, but existing works have studied very little about it. This paper presents TORQUE, a new English machine reading comprehension (MRC) dataset of temporal ordering questions. TORQUE has 3.2k news snippets, 9.5k hard-coded questions asking which events had happened, were ongoing, or were still in the future, and 21.2k human-generated questions querying more complex phenomena. We argue that an MRC setting allows for more convenient representation of these temporal phenomena than conventional formalisms. Results show that even a state-of-the-art language model, RoBERTa-large, falls behind human performance by a large margin, necessitating more investigation on improving MRC on temporal relationships in the future.

Appendix

A Event Distribution

As we mentioned in Sec. 5, TORQUE has 24.9k events over 3.2k passages. Figure 12 shows the histogram of the number of events in all these passages. We can see it roughly follows a Gaussian distribution with the mean at around 7-8 events per passage.

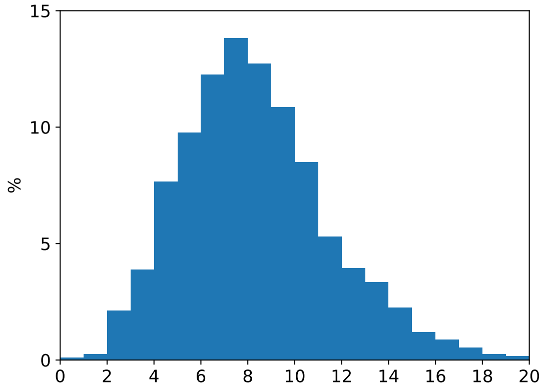

Figure 12: Histogram of the number of events in all passages in TORQUE.

Figure 13 further shows the 50 most common events in TORQUE. Unsurprisingly, the most common events are reporting verbs (e.g., "say", "tell", "report", and "announce") and copular verbs. Other common events such as "meeting", "killed", "visit", and "war" are also expected given that the passages of TORQUE were taken from news articles.

B Question Prefix Distribution

Figure 14 shows a sunburst visualization of the questions provided by crowd workers in TORQUE, including both their original questions and their modifications. Specifically, Fig. 14a shows that almost all of the questions start with "what." The small portion of questions that do not start with "what" are cases where crowd workers switch the order of how they ask. One example of these was *"Before making his statement to the Sunday Mirror, what did the author do?"* Figure 14a also shows the most common following words of "what."

Figures 14b-c further show the distribution of questions starting with "what happened" and "what will." We can see that when asking things in the past, people ask more about "what happened before/after" than "what happened while/during," while when asking things in the future, people ask much more about "what will happen after" than "what will happen before."

C Answer Distribution

The distribution of the number of answers to each question is shown in Fig. 15, where we divide the questions into 4 categories: the original warm-up questions, the modified warm-up questions, the original user questions, and the modified user questions. Note for each passage, there are 3 warm-up questions and they were all hard-coded when crowd workers worked on them. We are treating the first one (i.e., *"What events have already finished?"*) as the original and the other two as modified (i.e., *"What events have begun but have not finished?"* and *"What will happen in the future?"*).

We can see that in both the warm-up and the user questions, "modified" has a larger portion of questions with no answers at all as compared to the "original." This effect is very significant for warm-up questions because in news articles, most of the events were in the past. As for the user-provided questions, the percentage of no-answer questions is higher in "modified," but it is not as drastic as for the warm-up question. This because we only required that the modified question should have different answers from the original one; many of those questions sill have answers after modification.

D Workload Distribution Among Workers

As each annotator may be biased to only ask questions in a certain way, it is important to make sure that the entire dataset is not labeled by only a few annotators Geva et al. (2019). Figure 16a shows the contribution of each crowd worker to TORQUE and we can see even the rightmost worker only provided 5%. Figure 16b further adopts the notion of *Gini Index* to show the dispersion.[9] The Gini index of TORQUE is 0.42.

---

[9] A high Gini Index here means the data were provided by a small group of workers. The Gini Index of family incomes in the United States was 0.49 in 2018 (Semega et al., 2019).

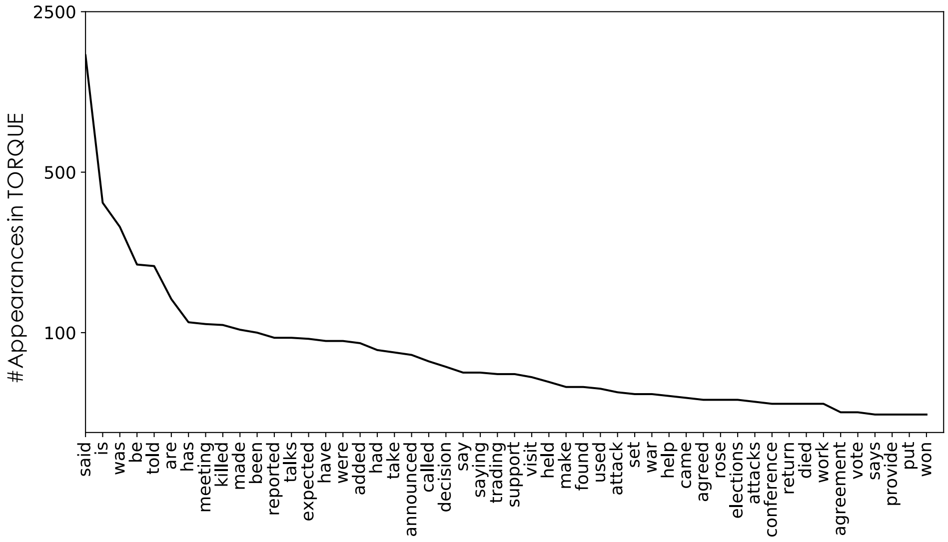

Figure 13: Fifty most common event triggers in TORQUE. Note the y-axis is in log scale.

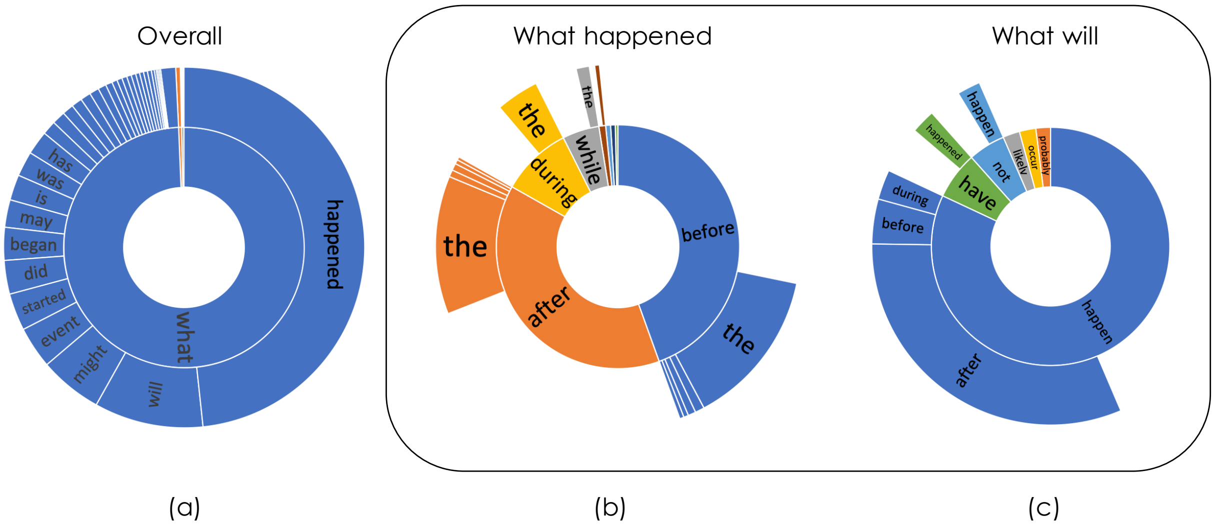

Figure 14: Prefix distribution of user-provided questions.

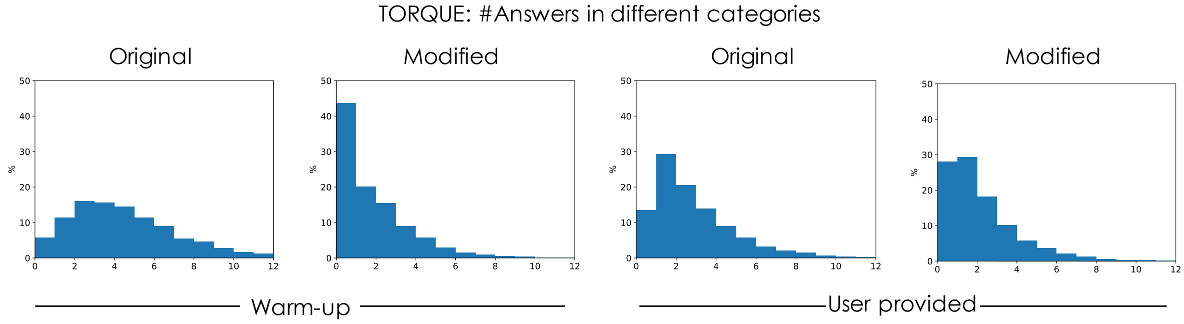

Figure 15: Distribution of the number of answers to each question.

E Worker Agreement With Aggregate

In Sec. 5 we described the worker agreement with aggregate (WAWA) metric for measuring the inter-annotator agreement (IAA) between crowd workers of TORQUE. This WAWA metric is explained in the figure below. It is to first get an aggregated

(a) (b)

Figure 16: If every annotator provided the same number of passages (i.e., perfect equality), the curve would be the straight dashed line and the Gini Index would be 0. If one person provided all the annotations, the Gini Index is 1.

answer set from multiple workers (we used majority vote as the aggregate function), then compare each worker with the aggregated answer set, and finally compute the micro-average across multiple workers and multiple questions.

Tables 5 and 6 show the quality of event annotations and question-answering annotations, respectively. In both of them, the IAA are using the WAWA metric explained above; the "Init Annotator" rows are a slight modification of WAWA, which means that all workers are used when aggregating those answers, but only the first annotator is compared against the aggregated answer set. Table 5 further shows the agreement between the init annotator and an event detection model, which we have described in Sec. 5.

	P	R	F
IAA (WAWA)	94.3%	94.1%	94.2%
Init Annotator	94.9%	89.8%	92.3%
		Init Annotator	
		Yes	No
Model	Yes	99.4%	82.0%
	No	64.1%	0.8%

Table 5: Inter-annotator agreement (IAA) of the event annotations in TORQUE. Above: compare the aggregated event list with either all the annotators or the initial annotator. Below: how many candidates in each category were successfully added into the aggregated event list.

	P	R	F
IAA (WAWA)	82.3%	87.3%	84.7%
Init Annotator	91.3%	82.2%	86.5%

Table 6: IAA of the answer annotations in TORQUE.

F Reproducibility

- We ran our experiments on PyTorch 1.3.1. Pre-trained language models are implemented in the Huggingface transformers library.

- A single GeForce RTX 2080 GPU was used to finetune a model. CUDA Version 10.2. The average time to run an epoch was 38 minutes for the full training section of TORQUE using RoBERTa-large.

- The best performing model consist of RoBERTa-large + final MLP layer, and the number of parameters is 355M + 1024 * 64 + 64 * 2.

Abstract

We present ToTTo, an open-domain English table-to-text dataset with over 120,000 training examples that proposes a controlled generation task: given a Wikipedia table and a set of highlighted table cells, produce a one-sentence description. To obtain generated targets that are natural but also faithful to the source table, we introduce a dataset construction process where annotators directly revise existing candidate sentences from Wikipedia. We present systematic analyses of our dataset and annotation process as well as results achieved by several state-of-the-art baselines. While usually fluent, existing methods often hallucinate phrases that are not supported by the table, suggesting that this dataset can serve as a useful research benchmark for high-precision conditional text generation.[1]

1 Introduction

Data-to-text generation (Kukich, 1983; McKeown, 1992) is the task of generating a target textual description $\boldsymbol{y}$ conditioned on source content $\boldsymbol{x}$ in the form of structured data such as a table. Examples include generating sentences given biographical data (Lebret et al., 2016), textual descriptions of restaurants given meaning representations (Novikova et al., 2017), basketball game summaries given boxscore statistics (Wiseman et al., 2017), and generating fun facts from superlative tables in Wikipedia (Korn et al., 2019).

Existing data-to-text tasks have provided an important test-bed for neural generation models (Sutskever et al., 2014; Bahdanau et al., 2014). Neural models are known to be prone to *hallucination*, i.e., generating text that is fluent but not faithful to the source (Vinyals and Le, 2015; Koehn and Knowles, 2017; Lee et al., 2018; Tian et al., 2019) and it is often easier to assess faithfulness of the generated text when the source content is structured (Wiseman et al., 2017; Dhingra et al., 2019). Moreover, structured data can also test a model's ability for reasoning and numerical inference (Wiseman et al., 2017) and for building representations of structured objects (Liu et al., 2018), providing an interesting complement to tasks that test these aspects in the NLU setting (Pasupat and Liang, 2015; Chen et al., 2019; Dua et al., 2019).

However, constructing a data-to-text dataset can be challenging on two axes: task design and annotation process. First, tasks with open-ended output like summarization (Mani, 1999; Lebret et al., 2016; Wiseman et al., 2017) lack explicit signals for models on what to generate, which can lead to subjective content and evaluation challenges (Kryściński et al., 2019). On the other hand, data-to-text tasks that are limited to verbalizing a fully specified meaning representation (Gardent et al., 2017b) do not test a model's ability to perform inference and thus remove a considerable amount of challenge from the task.

Secondly, designing an annotation process to obtain natural but also clean targets is a significant challenge. One strategy employed by many datasets is to have annotators write targets from scratch (Banik et al., 2013; Wen et al., 2015; Gardent et al., 2017a) which can often lack variety in terms of structure and style (Gururangan et al., 2018; Poliak et al., 2018). An alternative is to pair naturally occurring text with tables (Lebret et al., 2016; Wiseman et al., 2017). While more diverse, naturally occurring targets are often noisy and contain information that cannot be inferred from the source. This can make it problematic to disentangle modeling weaknesses from data noise.

In this work, we propose ToTTo, an *open-domain* table-to-text generation dataset that intro-

Table Title: Gabriele Becker
Section Title: International Competitions
Table Description: None

Year	Competition	Venue	Position	Event	Notes
Representing Germany					
1992	World Junior Championships	Seoul, South Korea	10th (semis)	100 m	11.83
1993	European Junior Championships	San Sebastián, Spain	7th	100 m	11.74
			3rd	4x100 m relay	44.60
1994	World Junior Championships	Lisbon, Portugal	12th (semis)	100 m	11.66 (wind: +1.3 m/s)
			2nd	4x100 m relay	44.78
1995	World Championships	Gothenburg, Sweden	7th (q-finals)	100 m	11.54
			3rd	4x100 m relay	43.01

Original Text: After winning the German under-23 100 m title, she was selected to run at the 1995 World Championships in Athletics both individually and in the relay.
Text after Deletion: she at the 1995 World Championships in both individually and in the relay.
Text After Decontextualization: Gabriele Becker competed at the 1995 World Championships in both individually and in the relay.
Final Text: Gabriele Becker competed at the 1995 World Championships both individually and in the relay.

Table 1: Example in the ToTTo dataset. The goal of the task is given the table, table metadata (such as the title), and set of highlighted cells, to produce the final text. Our data annotation process revolves around annotators iteratively revising the original text to produce the final text.

duces a novel task design and annotation process to address the above challenges. First, ToTTo proposes a *controlled* generation task: given a Wikipedia table and a set of highlighted cells as the source $\boldsymbol{x}$, the goal is to produce a single sentence description $\boldsymbol{y}$. The highlighted cells identify portions of potentially large tables that the target sentence should describe, without specifying an explicit meaning representation to verbalize.

For dataset construction, to ensure that targets are natural but also faithful to the source table, we request annotators to *revise* existing Wikipedia candidate sentences into target sentences, instead of asking them to write new target sentences (Wen et al., 2015; Gardent et al., 2017a). Table 1 presents a simple example from ToTTo to illustrate our annotation process. The table and *Original Text* were obtained from Wikipedia using heuristics that collect pairs of tables $\boldsymbol{x}$ and sentences $\boldsymbol{y}$ that likely have significant semantic overlap. This method ensures that the target sentences are *natural*, although they may only be partially related to the table. Next, we create a clean and controlled generation task by requesting annotators to highlight a subset of the table that supports the original sentence and revise the latter iteratively to produce a final sentence (see §5). For instance, in Table 1, the annotator has chosen to highlight a set of table cells (in yellow) that support the original text. They then deleted phrases from the original text that are not supported by the table, e.g., *After winning the German under-23 100 m title*, and replaced the pronoun *she* with an entity *Gabriele Becker*. The resulting final sentence (*Final Text*) serves as a more suitable generation target than the original sentence. This annotation process makes our dataset well suited for *high-precision* conditional text generation.

Due to the varied nature of Wikipedia tables, ToTTo covers a significant variety of domains while containing targets that are completely faithful to the source (see Table 4 and the Appendix for more complex examples). Our experiments demonstrate that state-of-the-art neural models struggle to generate faithful results, despite the high quality of the training data. These results suggest that our dataset could serve as a useful benchmark for controllable data-to-text generation.

2 Related Work

ToTTo differs from existing datasets in both task design and annotation process as we describe below. A summary is given in Table 2.

Task Design Most existing table-to-text datasets are restricted in topic and schema such as WeatherGov (Liang et al., 2009), RoboCup (Chen and Mooney, 2008), Rotowire (Wiseman et al., 2017, basketball), E2E (Novikova et al., 2016, 2017, restaurants), KBGen (Banik et al., 2013, biology), and Wikibio (Lebret et al., 2016, biographies). In contrast, ToTTo contains tables with various schema spanning various topical categories all over Wikipedia. Moreover, ToTTo takes a different view of content selection compared to

Dataset	Train Size	Domain	Target Quality	Target Source	Content Selection
Wikibio (Lebret et al., 2016)	583K	Biographies	Noisy	Wikipedia	Not specified
Rotowire (Wiseman et al., 2017)	4.9K	Basketball	Noisy	Rotowire	Not specified
WebNLG (Gardent et al., 2017b)	25.3K	15 DBPedia categories	Clean	Annotator Generated	Fully specified
E2E (Novikova et al., 2017)	50.6K	Restaurants	Clean	Annotator Generated	Partially specified
LogicNLG (Chen et al., 2020)	28.5K	Wikipedia (open-domain)	Clean	Annotator Generated	Columns via entity linking
ToTTo	**120K**	**Wikipedia (open-domain)**	**Clean**	**Wikipedia (Annotator Revised)**	**Annotator highlighted**

Table 2: Comparison of popular data-to-text datasets. ToTTo combines the advantages of annotator-generated and fully natural text through a revision process.

existing datasets. Prior to the advent of neural approaches, generation systems typically separated content selection (*what to say*) from surface realization (*how to say it*) (Reiter and Dale, 1997). Thus many generation datasets only focused on the latter stage (Wen et al., 2015; Gardent et al., 2017b). However, this decreases the task complexity, since neural systems have already been quite powerful at producing fluent text. Some recent datasets (Wiseman et al., 2017; Lebret et al., 2016) have proposed incorporating content selection into the task by framing it as a summarization problem. However, summarization is much more subjective, which can make the task underconstrained and difficult to evaluate (Kryściński et al., 2019). We place ToTTo as a middle-ground where the highlighted cells provide some guidance on the topic of the target but still leave a considerable amount of content planning to be done by the model.

Annotation Process There are various existing strategies to create the reference target $\boldsymbol{y}$. One strategy employed by many datasets is to have annotators write targets from scratch given a representation of the source (Banik et al., 2013; Wen et al., 2015; Gardent et al., 2017a). While this will result in a target that is faithful to the source data, it often lacks variety in terms of structure and style (Gururangan et al., 2018; Poliak et al., 2018). Domain-specific strategies such as presenting an annotator an image instead of the raw data (Novikova et al., 2016) are not practical for some of the complex tables that we consider. Other datasets have taken the opposite approach: finding real sentences on the web that are heuristically selected in a way that they discuss the source content (Lebret et al., 2016; Wiseman et al., 2017). This strategy typically leads to targets that are natural and diverse, but they may be noisy and contain information that cannot be inferred from the source (Dhingra et al., 2019).To construct ToTTo, we ask annotators to revise existing candidate sentences from Wikipedia so that they only contain information that is supported by the table. This enables ToTTo to maintain the varied language and structure found in natural sentences while producing cleaner targets. The technique of editing exemplar sentences has been used in semiparametric generation models (Guu et al., 2018; Pandey et al., 2018; Peng et al., 2019) and crowd-sourcing small, iterative changes to text has been shown to lead to higher-quality data and a more robust annotation process (Little et al., 2010). Perez-Beltrachini and Lapata (2018) also employed a revision strategy to construct a cleaner evaluation set for Wikibio (Lebret et al., 2016).

Concurrent to this work, Chen et al. (2020) proposed LogicNLG which also uses Wikipedia tables, although omitting some of the more complex structured ones included in our dataset. Their target sentences are annotator-generated and their task is significantly more uncontrolled due to the lack of annotator highlighted cells.

3 Preliminaries

Our tables come from English Wikipedia articles and thus may not be regular grids.[2] For simplicity, we define a table $\boldsymbol{t}$ as a set of cells $\boldsymbol{t} = \{\boldsymbol{c}_j\}_{j=1}^{\tau}$ where τ is the number of cells in the table. Each cell contains: **(1)** a string value, **(2)** whether or not it is a row or column header, **(3)** the row and column position of this cell in the table, **(4)** The number of rows and columns this cell spans.

Let $\boldsymbol{m} = (m_{\text{page-title}}, m_{\text{section-title}}, m_{\text{section-text}})$ indicate table metadata, i.e, the page title, section title, and up to the first 2 sentences of the section text (if present) respectively. These fields can help provide context to the table's contents. Let $\boldsymbol{s} = (s_1, ..., s_\eta)$ be a sentence of length η. We define an annotation example[3] $\boldsymbol{d} = (\boldsymbol{t}, \boldsymbol{m}, \boldsymbol{s})$ a tuple of table, table metadata, and sentence. Here, $\boldsymbol{D} = \{\boldsymbol{d}_n\}_{n=1}^{N}$ refers to a dataset of annotation

---

[2] In Wikipedia, some cells may span multiple rows and columns. See Table 1 for an example.

[3] An annotation example is different than a task example since the annotator could perform a different task than the model.

examples of size N.

4 Dataset Collection

We first describe how to obtain annotation examples $\boldsymbol{d}$ for subsequent annotation. To prevent any overlap with the Wikibio dataset (Lebret et al., 2016), we do not use infobox tables. We employed three heuristics to collect tables and sentences:

Number matching We search for tables and sentences on the same Wikipedia page that overlap with a non-date number of at least 3 non-zero digits. This approach captures most of the table-sentence pairs that describe statistics (e.g., sports, election, census, science, weather).

Cell matching We extract a sentence if it has tokens matching at least 3 distinct cell contents from the **same row** in the table. The intuition is that most tables are structured, and a row is usually used to describe a complete event.

Hyperlinks The above heuristics only consider sentences and tables on the same page. We also find examples where a sentence $\boldsymbol{s}$ contains a hyperlink to a page with a title that starts with *List* (these pages typically only consist of a large table). If the table $\boldsymbol{t}$ on that page also has a hyperlink to the page containing $\boldsymbol{s}$, then we consider this to be an annotation example. Such examples typically result in more diverse examples than the other two heuristics, but also add more noise, since the sentence may only be distantly related to the table.

Using the above heuristics we obtain a set of examples $\boldsymbol{D}$. We then sample a random subset of tables for annotation, excluding tables with formatting issues: 191,693 examples for training, 11,406 examples for development, and 11,406 examples for test. Among these examples, 35.8% were derived from number matching, 29.4% from cell matching, and 34.7% from hyperlinks.

5 Data Annotation Process

The collected annotation examples are noisy since a sentence $\boldsymbol{s}$ may only be partially supported by the table $\boldsymbol{t}$. We thus define an annotation process that guides annotators through incremental changes to the original sentence. This allows us to measure annotator agreement at every step of the process, which is atypical in existing generation datasets.

The primary annotation task consists of the following steps: **(1)** Table Readability, **(2)** Cell highlighting, **(3)** Phrase Deletion, **(4)** Decontextualization. After these steps we employ a final secondary annotation task for grammar correction. Each of these are described below and more examples are provided in the Table 3.

Table Readability If a table is not readable, then the following steps will not need to be completed. This step is only intended to remove fringe cases where the table is poorly formatted or otherwise not understandable (e.g., in a different language). 99.5% of tables are determined to be readable.

Cell Highlighting An annotator is instructed to highlight cells that support the sentence. A phrase is supported by the table if it is either directly stated in the cell contents or meta-data, or can be logically inferred by them. Row and column headers do not need to be highlighted. If the table does not support any part of the sentence, then no cell is marked and no other step needs to be completed. 69.7% of examples are supported by the table. For instance, in Table 1, the annotator highlighted cells that support the phrases *1995*, *World Championships*, *individually*, and *relay*. The set of highlighted cells are denoted as a subset of the table: $\boldsymbol{t}_{\text{highlight}} \in \boldsymbol{t}$.

Phrase Deletion This step removes phrases in the sentence unsupported by the selected table cells. Annotators are restricted such that they are only able to delete phrases, transforming the original sentence: $\boldsymbol{s} \rightarrow \boldsymbol{s}_{\text{deletion}}$. In Table 1, the annotator transforms $\boldsymbol{s}$ by removing several phrases such as *After winning the German under-23 100 m title*.

On average, $\boldsymbol{s}_{\text{deletion}}$ is different from $\boldsymbol{s}$ for 85.3% of examples and while $\boldsymbol{s}$ has an average length of 26.6 tokens, this is reduced to 15.9 for $\boldsymbol{s}_{\text{deletion}}$. We found that the phrases annotators often disagreed on corresponded to verbs purportedly supported by the table.

Decontextualization A given sentence $\boldsymbol{s}$ may contain pronominal references or other phrases that depend on context. We thus instruct annotators to identify the main topic of the sentence; if it is a pronoun or other ambiguous phrase, we ask them to replace it with a named entity from the table or metadata. To discourage excessive modification, they are instructed to make at most one replacement.[4] This transforms the sentence yet again:

---

[4] Based on manual examination of a subset of 100 examples, all of them could be decontextualized with only one replacement. Allowing annotators to make multiple replacements led to excessive clarification.

Table 3: Examples of annotation process. Deletions are indicated in red strikeouts, while added named entities are indicated in underlined blue. Significant grammar fixes are denoted in orange.

$s_{\text{deletion}} \rightarrow s_{\text{decontext}}$. In Table 1, the annotator replaced *she* with *Gabriele Becker*.

Since the previous steps can lead to ungrammatical sentences, annotators are also instructed to fix the grammar to improve the fluency of the sentence. We find that $s_{\text{decontext}}$ is different than s_{deletion} 68.3% of the time, and the average sentence length increases to 17.2 tokens for $s_{\text{decontext}}$ compared to 15.9 for s_{deletion}.

Secondary Annotation Task Due to the complexity of the task, $s_{\text{decontext}}$ may still have grammatical errors, even if annotators were instructed to fix grammar. Thus, a second set of annotators were asked to further correct the sentence and were shown the table with highlighted cells as additional context. This results in the final sentence s_{final}. On average, annotators edited the sentence 27.0% of the time, and the sentence length slightly increased to 17.4 tokens from 17.2.

6 Dataset Analysis

Basic statistics of ToTTo are described in Table 5. The number of unique tables and vocabulary size attests to the open domain nature of our dataset. Furthermore, while the median table is actually quite large (87 cells), the median number of highlighted cells is significantly smaller (3). This indicates the importance of the cell highlighting feature of our dataset toward a well-defined text generation task.

6.1 Annotator Agreement

Table 6 shows annotator agreement over the development set for each step of the annotation process. We compute annotator agreement and Fleiss' kappa (Fleiss, 1971) for table readability and highlighted cells, and BLEU-4 score between annotated sentences in different stages.

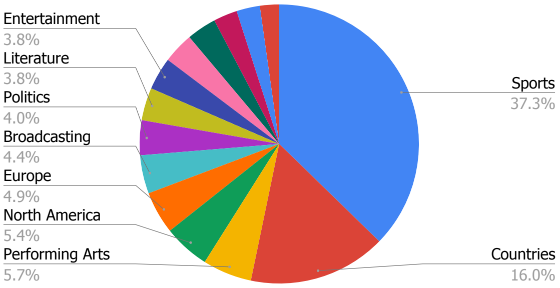

Figure 1: Topic distribution of our dataset.

As one can see, the table readability task has an agreement of 99.38%. The cell highlighting task is more challenging. 73.74% of the time all three annotators completely agree on the set of cells which means that they chose the exact same set of cells. The Fleiss' kappa is 0.856, which is regarded as "almost perfect agreement" (0.81 - 1.00) according to (Landis and Koch, 1977).

With respect to the sentence revision tasks, we see that the agreement slightly degrades as more steps are performed. We compute single reference BLEU among all pairs of annotators for examples in our development set (which only contains examples where both annotators chose $t_{\text{highlight}} \neq \emptyset$). As the sequence of revisions are performed, the annotator agreement gradually decreases in terms of BLEU-4: 82.19 → 72.56 → 68.98. This is considerably higher than the BLEU-4 between the original sentence s and s_{final} (43.17).

6.2 Topics and Linguistic Phenomena

We use the Wikimedia Foundation's topic categorization model (Asthana and Halfaker, 2018) to sort the categories of Wikipedia articles where the

Target Text: Craig finished his eleven NFL seasons with 8,189 rushing yards and 566 receptions for 4,911 receiving yards.

Table 4: An example in the ToTTo dataset that involves numerical reasoning over the table structure.

Property	**Value**
Training set size	120,761
Number of target tokens	1,268,268
Avg Target Length (tokens)	17.4
Target vocabulary size	136,777
Unique Tables	83,141
Rows per table (Median/Avg)	16 / 32.7
Cells per table (Median/Avg)	87 / 206.6
No. of Highlighted Cell (Median/Avg)	3 / 3.55
Development set size	7,700
Test set size	7,700

Table 5: ToTTo dataset statistics.

Annotation Stage	**Measure**	**Result**
Table Readability	Agreement / κ	99.38 / 0.646
Cell Highlighting	Agreement / κ	73.74 / 0.856
After Deletion	BLEU-4	82.19
After Decontextualization	BLEU-4	72.56
Final	BLEU-4	68.98

Table 6: Annotator agreement over the development set. If possible, we measure the total agreement (in %) and the Fleiss' Kappa (κ). Otherwise, we report the BLEU-4 between annotators.

tables come from into a 44-category ontology.[5] Figure 1 presents an aggregated topic analysis of our dataset. We found that the *Sports* and *Countries* topics together comprise 53.4% of our dataset, but the other 46.6% is composed of broader topics such as *Performing Arts*, *Politics*, and *North America*. Our dataset is limited to topics that are present in Wikipedia.

Table 7 summarizes the fraction of examples that require reference to the metadata, as well as some of the challenging linguistic phenomena in the dataset that potentially pose new challenges to current systems. Table 4 gives one example that requires reasoning (refer to the Appendix for more examples).

Types	**Percentage**
Require reference to page title	82%
Require reference to section title	19%
Require reference to table description	3%
Reasoning (logical, numerical, temporal etc.)	21%
Comparison across rows / columns / cells	13%
Require background information	12%

Table 7: Distribution of different linguistic phenomena among 100 randomly chosen sentences.

6.3 Training, Development, and Test Splits

After the annotation process, we only consider examples where the sentence is related to the table, i.e., $t_{\text{highlight}} \neq \emptyset$. This initially results in a training set $\boldsymbol{D}_{\text{orig-train}}$ of size 131,849 that we further filter as described below. Each example in the development and test sets was annotated by three annotators. Since the machine learning task uses $t_{\text{highlight}}$ as an input, it is challenging to use three different sets of highlighted cells in evaluation. Thus, we only use a single randomly chosen $t_{\text{highlight}}$ while using the three s_{final} as references for evaluation. We only use examples where at least 2 of the 3 annotators chose $t_{\text{highlight}} \neq \emptyset$, resulting in development and test sets of size 7,700 each.

Overlap and Non-Overlap Sets Without any modification $\boldsymbol{D}_{\text{orig-train}}$, $\boldsymbol{D}_{\text{dev}}$, and $\boldsymbol{D}_{\text{test}}$ may contain many similar tables. Thus, to increase the generalization challenge, we filter $\boldsymbol{D}_{\text{orig-train}}$ to remove some examples based on overlap with $\boldsymbol{D}_{\text{dev}}$, $\boldsymbol{D}_{\text{test}}$.

For a given example $\boldsymbol{d}$, let $\boldsymbol{h}(\boldsymbol{d})$ denote its set of header values and similarly let $\boldsymbol{h}(\boldsymbol{D})$ be the set of

---

[5] `https://en.wikipedia.org/wiki/Wikipedia:WikiProject_Council/Directory`

header values for a given dataset $\boldsymbol{D}$. We remove examples $\boldsymbol{d}$ from the training set where $\boldsymbol{h}(\boldsymbol{d})$ is both rare in the data as well as occurs in either the development or test sets. Specifically, $\boldsymbol{D}_{\text{train}}$ is defined as:

$$\boldsymbol{D}_{\text{train}} := \{\boldsymbol{d} : \boldsymbol{h}(\boldsymbol{d}) \notin (\boldsymbol{h}(\boldsymbol{D}_{\text{dev}}) \cup \boldsymbol{h}(\boldsymbol{D}_{\text{test}})) \text{ or } \\ \text{count}\big(\boldsymbol{h}(\boldsymbol{d}), \boldsymbol{D}_{\text{orig-train}}\big) > \alpha\}.$$

The $\text{count}(\boldsymbol{h}(\boldsymbol{d}), \boldsymbol{D}_{\text{orig-train}})$ function returns the number of examples in $\boldsymbol{D}_{\text{orig-train}}$ with header $\boldsymbol{h}(\boldsymbol{d})$. To choose the hyperparameter α we first split the test set as follows:

$$\boldsymbol{D}_{\text{test-overlap}} := \{\boldsymbol{d} : \boldsymbol{h}(\boldsymbol{d}) \in \boldsymbol{h}(\boldsymbol{D}_{\text{train}})\}$$
$$\boldsymbol{D}_{\text{test-nonoverlap}} := \{\boldsymbol{d} : \boldsymbol{h}(\boldsymbol{d}) \notin \boldsymbol{h}(\boldsymbol{D}_{\text{train}})\}$$

The development set is analogously divided into $\boldsymbol{D}_{\text{dev-overlap}}$ and $\boldsymbol{D}_{\text{dev-nonoverlap}}$. We then choose $\alpha = 5$ so that $\boldsymbol{D}_{\text{test-overlap}}$ and $\boldsymbol{D}_{\text{test-nonoverlap}}$ have similar size. After filtering, the size of $\boldsymbol{D}_{\text{train}}$ is 120,761, and $\boldsymbol{D}_{\text{dev-overlap}}$, $\boldsymbol{D}_{\text{dev-nonoverlap}}$, $\boldsymbol{D}_{\text{test-overlap}}$, and $\boldsymbol{D}_{\text{test-nonoverlap}}$ have sizes 3784, 3916, 3853, and 3847 respectively.

7 Machine Learning Task Construction

In this work, we focus on the following task: Given a table $\boldsymbol{t}$, related metadata $\boldsymbol{m}$ (page title, section title, table section text) and a set of highlighted cells $\boldsymbol{t}_{\text{highlight}}$, produce the final sentence $\boldsymbol{s}_{\text{final}}$. Mathematically this can be described as learning a function $\boldsymbol{f} : \boldsymbol{x} \to \boldsymbol{y}$ where $\boldsymbol{x} = (\boldsymbol{t}, \boldsymbol{m}, \boldsymbol{t}_{\text{highlight}})$ and $\boldsymbol{y} = \boldsymbol{s}_{\text{final}}$. This task is different from what the annotators perform, since they are provided a starting sentence requiring revision. Therefore, the task is more challenging, as the model must generate a new sentence instead of revising an existing one.

8 Experiments

We present baseline results on ToTTo by examining three existing state-of-the-art approaches (Note that since our tables do not have a fixed schema it is difficult to design a template baseline).

- BERT-to-BERT (Rothe et al., 2020): A Transformer encoder-decoder model (Vaswani et al., 2017) where the encoder and decoder are both initialized with BERT (Devlin et al., 2018). The original BERT model is pre-trained with both Wikipedia and the Books corpus (Zhu et al., 2015), the former of which contains our (unrevised) test targets. Thus, we also pre-train a version of BERT on the Books corpus only, which we consider a more correct baseline. However, empirically we find that both models perform similarly in practice (Table 8).
- Pointer-Generator (See et al., 2017): A Seq2Seq model with attention and copy mechanism. While originally designed for summarization it is commonly used in data-to-text as well (Gehrmann et al., 2018).
- Puduppully et al. (2019): A Seq2Seq model with an explicit content selection and planning mechanism designed for data-to-text.

Details about hyperparameter settings are provided in the Appendix. Moreover, we explore different strategies of representing the source content that resemble standard linearization approaches in the literature (Lebret et al., 2016; Wiseman et al., 2017)

- **Full Table** The simplest approach is simply to use the entire table as the source, adding special tokens to mark which cells have been highlighted. However, many tables can be very large and this strategy performs poorly.
- **Subtable** Another option is to only use the highlighted cells $\boldsymbol{t}_{highlight} \in \boldsymbol{t}$ with the heuristically extracted row and column header for each highlighted cell. This makes it easier for the model to only focus on relevant content but limits the ability to perform reasoning in the context of the table structure (see Table 11). Overall though, we find this representation leads to higher performance.

In all cases, the cells are linearized with row and column separator tokens. We also experiment with prepending the table metadata to the source table.[6]

Evaluation metrics The model output is evaluated using two automatic metrics: BLEU (Papineni et al., 2002) and PARENT (Dhingra et al., 2019). PARENT is a metric recently proposed specifically for data-to-text evaluation that takes the table into account. We modify it to make it suitable for our dataset, described in the Appendix. Human evaluation is described in § 8.2.

8.1 Results

Table 8 shows our results against multiple references with the subtable input format. Both the

---

[6] The table section text is ignored, since it is usually missing or irrelevant.

Model	Overall		Overlap Subset		Nonoverlap Subset

Pointer-Generator	41.6	51.6	50.6	58.0	32.2	45.2
Puduppully et al. (2019)	19.2	29.2	24.5	32.5	13.9	25.8

Table 8: Performance compared to multiple references on the test set for the subtable input format with metadata.

	Model	Fluency (%)	Faithfulness (%)	Covered Cells (%)	Less/Neutral/More Coverage w.r.t. Ref
Overall	*Oracle*	*99.3*	*93.6*	*94.8*	*18.3 / 61.7 / 20.0*
	BERT-to-BERT (Books)	88.1	76.2	89.0	49.2 / 36.2 / 14.5
	BERT-to-BERT (Books+Wiki)	87.3	73.6	87.3	53.9 / 32.9 / 13.2
Overlap	*Oracle*	*99.6*	*96.5*	*95.5*	*19.8 / 62.8 / 17.4*
	BERT-to-BERT (Books)	89.6	78.7	92.1	42.0 / 43.7 / 14.3
	BERT-to-BERT (Books+Wiki)	89.8	81.1	91.0	47.8 / 39.2 / 13.1
Non-overlap	*Oracle*	*99.1*	*91.4*	*94.3*	*17.0 / 60.9 / 22.1*
	BERT-to-BERT (Books)	86.9	74.2	86.4	55.5 / 29.8 / 14.7
	BERT-to-BERT (Books+Wiki)	84.8	66.6	83.8	60.1 / 26.6 / 13.3

Table 9: Human evaluation over references (to compute *Oracle*) and model outputs. For Fluency, we report the percentage of outputs that were completely fluent. In the last column $X/Y/Z$ means X% and Z% of the candidates were deemed to be less and more informative than the reference respectively and Y% were neutral.

Data Format	BLEU	PARENT
subtable w/ metadata	43.9	52.6
subtable w/o metadata	36.9	42.6
full table w/ metadata	26.8	30.7
full table w/o metadata	20.9	22.2

Table 10: Multi-reference performance of different input representations for BERT-to-BERT Books model.

BERT-to-BERT models perform the best, followed by the pointer generator model.[7] We see that for all models the performance on the non-overlap set is significantly lower than that of the overlap set, indicating that slice of our data poses significant challenges for machine learning models. We also observe that the baseline that separates content selection and planning performs quite poorly. We attest this to the fact that it is engineered to the Rotowire data format and schema.

Table 10 explores the effects of the various input representations (subtable vs. full table) on the BERT-to-BERT model. We see that the full table format performs poorly even if it is the most knowledge-preserving representation.

8.2 Human evaluation

For each of the 2 top performing models in Table 8, we take 500 random outputs and perform human evaluation using the following axes:

- **Fluency** - A candidate sentence is fluent if it is grammatical and natural. The three choices are *Fluent*, *Mostly Fluent*, *Not Fluent*.
- **Faithfulness** (Precision) - A candidate sentence is considered faithful if all pieces of information are supported by either the table or one of the references. Any piece of unsupported information makes the candidate unfaithful.
- **Covered Cells** (Recall) - Percentage of highlighted cells the candidate sentence covers.
- **Coverage with Respect to Reference** (Recall) - We ask whether the candidate is strictly more or less informative than each reference (or neither, which is referred to as neutral).

We further compute an oracle upper-bound by treating one of the references as a candidate and evaluating it compared to the table and other references. The results, shown in Table 9, attest to the high quality of our human annotations since the oracle consistently achieves high performance. All the axes demonstrate that there is a considerable gap between the model and oracle performance.

This difference is most easily revealed in the last column when annotators are asked to directly compare the candidate and reference. As expected, the oracle has similar coverage to the reference (61.7% neutral) but both baselines demonstrate considerably less coverage. According to an independent-sample t-test, this difference is significant at a $p < 0.001$ level for both baselines. Furthermore, the baselines are considerably less faithful than the reference. The faithfulness of both models is significantly lower than the reference (χ^2 test with $p < 0.001$). The models do not differ significantly from each other, except for faithfulness

---

[7] Note the BLEU scores are relatively high due to the fact that our task is more controlled than other text generation tasks and that we have multiple references.

ID	Reference	Decoder output (w/ metadata)		w/o metadata
		Full table	Subtable	Subtable

Table 11: Decoder output examples from BERT-to-BERT Books models on the development set. The "subtable with metadata" model achieves the highest BLEU. Red indicates model errors and blue denotes interesting reference language not in the model output.

in the non-overlap case, where we see a moderate effect favoring the book model.

9 Model Errors and Challenges

Table 11 shows predictions from the BERT-to-BERT Books model to illustrate challenges existing models face.

Hallucination The model sometimes outputs phrases such as *first*, *winning* that seem reasonable but are not faithful to the table. This hallucination phenomenon has been widely observed in other existing data-to-text datasets (Lebret et al., 2016; Wiseman et al., 2017). However, the noisy references in these datasets make it difficult to disentangle model incapability from data noise. Our dataset serves as strong evidence that even when the reference targets are faithful to the source, neural models still struggle with faithfulness.

Rare topics Another challenge revealed by the open domain nature of our task is rare or complex topics at the tail of the topic distribution (Figure 1). For instance, example 2 of Table 11 concerns microdrive capacities which is challenging.

Diverse table structure and numerical reasoning In example 3, inferring *six* and *five* correctly requires counting table rows and columns. Similarly, in example 4, the phrases *last* and *career highs* can be deduced from the table structure and with comparisons over the columns. However, the model is unable to make these inferences from the simplistic source representation that we used.

Evaluation metrics Many of the above issues are difficult to capture with metrics like BLEU since the reference and prediction may only differ by a word but largely differ in terms of semantic meaning. This urges for better metrics possibly built on learned models (Wiseman et al., 2017; Ma et al., 2019; Sellam et al., 2020). Thus, while we have a task leaderboard, it should not be interpreted as the definitive measure of model performance.

10 Conclusion

We presented ToTTo, a table-to-text dataset that presents a controlled generation task and a data annotation process based on iterative sentence revision. We also provided several state-of-the-art baselines, and demonstrated ToTTo could serve as a useful research benchmark for model and metric development. ToTTo is available at `https://github.com/google-research-datasets/totto`.

A Appendix

The Appendix contains the following contents:

- Information about the variant of the PARENT metric (Dhingra et al., 2019) used for evaluation.
- More details about the baselines.
- Examples of more complex tables in our dataset (Figure 2-Figure 5).

A.1 PARENT metric

PARENT (Dhingra et al., 2019) is a metric recently proposed specifically for data-to-text evaluation that takes the table into account. We modify it to make it suitable for our dataset. Let $(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n)$ denote one example that consists of a (source, target, prediction) tuple. PARENT is defined at an instance level as:

$$PARENT(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n) = \frac{2 \times E_p(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n) \times E_r(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n)}{E_p(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n) + E_r(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n)}$$

$E_p(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n)$ is the PARENT precision computed using the prediction, reference, and table (the last of which is not used in BLEU). $E_r(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n)$ is the PARENT recall and is computed as:

$$E_r(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n) = R(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n)^{(1-\lambda)} R(\boldsymbol{x}_n, \hat{\boldsymbol{y}}_n)^{\lambda}$$

where $R(\boldsymbol{x}_n, \boldsymbol{y}_n, \hat{\boldsymbol{y}}_n)$ is a recall term that compares the prediction with both the reference and table.

$R(\boldsymbol{x}_n, \hat{\boldsymbol{y}}_n)$ is an extra recall term that gives an additional reward if the prediction $\hat{\boldsymbol{y}}_n$ contains phrases in the table $\boldsymbol{x}_n$ that are not necessarily in the reference (λ is a hyperparameter).

In the original PARENT work, the same table $\boldsymbol{t}$ is used for computing the precision and both recall terms. While this makes sense for most existing datasets, it does not take into account the highlighted cells $\boldsymbol{t}_{highlight}$ in our task. To incorporate $\boldsymbol{t}_{highlight}$, we modify the PARENT metric so that the additional recall term $R(\boldsymbol{x}_n, \hat{\boldsymbol{y}}_n)$ uses $\boldsymbol{t}_{highlight}$ instead of $\boldsymbol{t}$ to only give an additional reward for relevant table information. The other recall and the precision term still use $\boldsymbol{t}$.

A.2 Baseline details

- BERT-to-BERT (Rothe et al., 2020) - Uncased model coupling both encoder and decoder as in original paper, with Adam optimizer (Kingma and Ba, 2015). learning rate = 0.05, hidden size = 1024, dropout = 0.1, beam size = 4.

- Pointer Generator (See et al., 2017) - LSTM with hidden size 300, beam size=8, learning rate = 0.0003, dropout = 0.2, length penalty = 0.0, Adam optimizer (Kingma and Ba, 2015).

- Content planner (Puduppully et al., 2019) - All of the original hyperparameters: content planner: LSTM with hidden size 1x600, realizer LSTM with 2x600, embedding size 600 for both, dropout=0.3, Adagrad optimizer (Duchi et al., 2011), beam size=5.

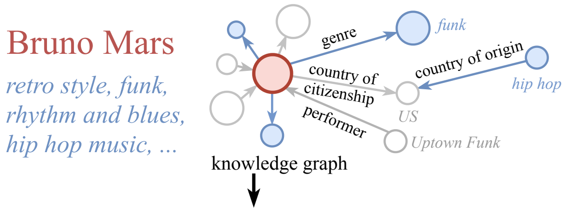
Abstract

Previous works on knowledge-to-text generation take as input a few RDF triples or key-value pairs conveying the knowledge of some entities to generate a natural language description. Existing datasets, such as WIKIBIO, WebNLG, and E2E, basically have a good alignment between an input triple/pair set and its output text. However, in practice, the input knowledge could be more than enough, since the output description may only cover the most significant knowledge. In this paper, we introduce a large-scale and challenging dataset to facilitate the study of such a practical scenario in KG-to-text. Our dataset involves retrieving abundant knowledge of various types of main entities from a large knowledge graph (KG), which makes the current graph-to-sequence models severely suffer from the problems of information loss and parameter explosion while generating the descriptions. We address these challenges by proposing a multi-graph structure that is able to represent the original graph information more comprehensively. Furthermore, we also incorporate aggregation methods that learn to extract the rich graph information. Extensive experiments demonstrate the effectiveness of our model architecture. [1]

1 Introduction

KG-to-text generation, automatically converting knowledge into comprehensive natural language, is an important task in natural language processing (NLP) and user interaction studies (Damljanovic et al., 2010). Specifically, the task takes as input some structured knowledge, such as resource description framework (RDF) triples of WebNLG (Gardent et al., 2017), key-value pairs of WIKIBIO (Lebret et al., 2016) and E2E (Novikova et al., 2017), to generate natural text describing the input knowledge. In essence, the task can be formulated as follows: given a main entity, its one-hop attributes/relations (e.g., WIKIBIO and E2E), and/or multi-hop relations (e.g., WebNLG), the goal is to generate a text description of the main entity describing its attributes and relations. Note that these existing datasets basically have a good alignment between an input knowledge set and its output text. Obtaining such data with good alignment could be a laborious and expensive annotation process. More importantly, in practice, the knowledge regarding the main entity could be more than enough, and the description may only cover the most significant knowledge. Thereby, the generation model should have such differentiation capability.



Peter Gene Hernandez (born October 8, 1985), known professionally as Bruno Mars, is an American singer, songwriter, multi-instrumentalist, record producer, and dancer. He is known for his stage performances, *retro* showmanship and for performing in a wide range of musical styles, including *R&B*, *funk*, *pop*, *soul*, *reggae*, *hip hop*, and *rock*.

Figure 1: An example showing our proposed task.

In this paper, we tackle an entity description generation task by exploring KG in order to work towards more practical problems. Specifically, the aim is to generate a description with one or more sentences for a main entity and a few topic-related entities, which is empowered by the knowledge from a KG for a more natural description. In order to facilitate the study, we introduce a new dataset, namely *entity-to-description* (ENT-DESC)

extracted from Wikipedia and Wikidata, which contains over 110k instances. Each sample is a triplet, containing a set of entities, the explored knowledge from a KG, and the description. Figure 1 shows an example to generate the description of the main entity, i.e., *Bruno Mars*, given some relevant keywords, i.e., *retro style, funk,* etc., which are called topic-related entities of *Bruno Mars*. We intend to generate the short paragraph below to describe the main entity in compliance with the topic revealed by topic-related entities. For generating accurate descriptions, one challenge is to extract the underlying relations between the main entity and keywords, as well as the peripheral information of the main entity. In our dataset, we use such knowledge revealed in a KG, i.e., the upper right in Figure 1 with partially labeled triples. Therefore, to some extent, our dataset is a generalization of existing KG-to-text datasets. The knowledge, in the form of triples, regarding the main entity and topic entities is automatically extracted from a KG, and such knowledge could be more than enough and not necessarily useful for generating the output.

Our dataset is not only more practical but also more challenging due to lack of explicit alignment between the input and the output. Therefore, some knowledge is useful for generation, while others might be noise. In such a case that many different relations from the KG are involved, standard graph-to-sequence models suffer from the problem of low training speed and parameter explosion, as edges are encoded in the form of parameters. Previous work deals with this problem by transforming the original graphs into Levi graphs (Beck et al., 2018). However, Levi graph transformation only explicitly represents the relations between an original node and its neighbor edges, while the relations between two original nodes are learned implicitly through graph convolutional networks (GCN). Therefore, more GCN layers are required to capture such information (Marcheggiani and Perez-Beltrachini, 2018). As more GCN layers are being stacked, it suffers from information loss from KG (Abu-El-Haija et al., 2018). In order to address these limitations, we present a multi-graph convolutional networks (MGCN) architecture by introducing multi-graph transformation incorporated with an aggregation layer. Multi-graph transformation is able to represent the original graph information more accurately, while the aggregation layer learns to extract useful information from the KG. Extensive experiments are conducted on both our dataset and benchmark dataset (i.e., WebNLG). MGCN outperforms several strong baselines, which demonstrates the effectiveness of our techniques, especially when using fewer GCN layers.

Our main contributions include:

- We construct a large-scale dataset ENT-DESC for a more practical task of entity description generation by exploring KG. To the best of our knowledge, ENT-DESC is the largest dataset of KG-to-text generation.
- We propose a multi-graph structure transformation approach that explicitly expresses a more comprehensive and more accurate graph information, in order to overcome limitations associated with Levi graphs.
- Experiments and analysis on our new dataset show that our proposed MGCN model incorporated with aggregation methods outperforms strong baselines by effectively capturing and aggregating multi-graph information.

2 Related Work

Dataset and Task. There is an increasing number of new datasets and tasks being proposed in recent years as more attention has been paid to data-to-text generation. Gardent et al. (2017) introduced the WebNLG challenge, which aimed to generate text from a small set of RDF knowledge triples (no more than 7) that are well-aligned with the text. To avoid the high cost of preparing such well-aligned data, researchers also studied how to leverage automatically obtained partially-aligned data in which some portion of the output text cannot be generated from the input triples (Fu et al., 2020b). Koncel-Kedziorski et al. (2019) introduced AGENDA dataset, which aimed to generate paper abstract from a title and a small KG built by information extraction system on the abstracts and has at most 7 relations. In our work, we directly create a knowledge graph for the main entities and topic-related entities from Wikidata without looking at the relations in our output. Scale-wise, our dataset consists of 110k instances while AGENDA is 40k. Lebret et al. (2016) introduced WikiBio dataset that generates the first sentence of biographical articles from the key-value pairs extracted from the article's infobox. Novikova et al. (2017) introduced E2E dataset in the restaurant domain, which aimed to generate restaurant recommendations given 3 to 8 slot-value pairs. These two datasets were only for a single domain, while ours focuses on multiple domains of over 100 categories, including people, event, location, organization, etc. Another difference is that we intend to generate the first paragraph of each Wikipedia article from a more complicated KG, but not key-value pairs. Another popular task is AMR-to-text generation (Konstas et al., 2017). The structure of AMR graphs is rooted and denser, which is quite different from the KG-to-text task. Researchers also studied how to generate texts from a few given entities or prompts (Li et al., 2019; Fu et al., 2020a). However, they did not explore the knowledge from a KG.

Graph-to-sequence Modeling. In recent years, graph convolutional networks (GCN) have been applied to several tasks (e.g., semi-supervised node classification (Kipf and Welling, 2017), semantic role labeling (Marcheggiani and Titov, 2017) and neural machine translation (Bastings et al., 2017)) and also achieved state-of-the-art performance on graph-to-sequence modeling. In order to capture more graphical information, Velickovic et al. (2017) introduced graph attention networks (GATs) through stacking a graph attentional layer, but only allowed to learn information from adjacent nodes implicitly without considering a more global contextualization. Marcheggiani and Titov (2017) then used GCN as the encoder in order to capture more distant information in graphs. Since there are usually a large amount of labels for edges in KG, such graph-to-sequence models without graph transformation will incur information loss and parameter explosion. Beck et al. (2018) proposed to transform the graph into Levi graph in order to work towards the aforementioned deficiencies, together with gated graph neural network (GGNN) to build graph representation for AMR-to-text problem. However, they face some new limitations brought in by Levi graph transformation: the entity-to-entity information is being ignored in Levi transformation, as also mentioned in their paper. Afterwards, deeper GCNs were stacked (Guo et al., 2019) to capture such ignored information implicitly. In contrast, we intend to use fewer GCN layers to capture more global contextualization by explicitly stating all types of graph information with different transformations.

3 Task Description

In this paper, we tackle a practical problem of entity description generation by exploring KG. In practice, it is difficult to describe an entity in only a few sentences as there are too many aspects for an entity. Now, if we are given a few topic-related entities as topic restrictions to the main entity, the text to be generated could be more concrete, particularly when we are allowed to explore the connections among these entities in KG. As seen in Figure 1, when we are asked to use one or two sentences to introduce "*Bruno Mars*"[2], his popular singles will first come into some people's minds, while his music genres might be in other people's first thought. With the introduction of topic-related entities, the description will have some focus. In this case, when topic-related entities, i.e., *R&B*, *hip hop*, *rock*, etc., are provided, we are aware of describing *Bruno Mars* in the direction of music styles on top of their basic information.

	WebNLG	**AGENDA**	**E2E**	**ENT-DESC**

Table 1: Dataset statistics of WebNLG, AGENDA and our prepared ENT-DESC.

Formally, given a set of entities $\mathbf{e} = \{\mathrm{E}_1, ..., \mathrm{E}_n\}$ and a KG $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where E_1 is main entity, $\mathrm{E}_2, ..., \mathrm{E}_n$ are topic-related entities, $\mathcal{V}$ is the set of entity nodes and $\mathcal{E}$ is the set of directed relation edges. We intend to generate a natural language text $\mathbf{y} = \{y_1, y_2, \cdots, y_T\}$. Meanwhile, we explore $\mathcal{G}$ for useful information to allow a more natural description. Here, the KG $\mathcal{G}$ can also be written as a set of RDF triples: $\mathcal{G} = \{\langle \mathrm{V}_{\mathrm{S}_1}, \mathrm{P}_1, \mathrm{V}_{\mathrm{O}_1} \rangle, ..., \langle \mathrm{V}_{\mathrm{S}_\mathrm{M}}, \mathrm{P}_\mathrm{M}, \mathrm{V}_{\mathrm{O}_\mathrm{M}} \rangle\}$, where M is the total number of triples, $\mathrm{V}_{\mathrm{S}_i}, \mathrm{V}_{\mathrm{O}_i} \in \mathcal{V}$ are the subject and object entities respectively, P_i is the predicate stating the relation between $\mathrm{V}_{\mathrm{S}_i}$ and $\mathrm{V}_{\mathrm{O}_i}$.

4 ENT-DESC Dataset

To prepare our dataset, we first use Nayuki's implementation[3] to calculate the PageRank score for more than 9.9 million Wikipedia pages. We then extract the categories from Wikidata for the top 100k highest scored pages and manually select 90 categories out of the top 200 most frequent ones as

---

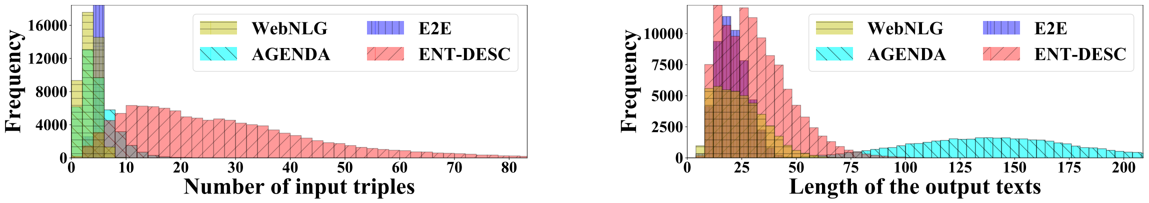
[3] `https://www.nayuki.io/page/computing-wikipedias-internal-pageranks`



(a) Number of the input triples in each dataset.

(b) Length of the output texts in each dataset.

Figure 2: Dataset comparison among WebNLG, AGENDA, E2E and our ENT-DESC.

the seed categories. The domains of the categories mainly include humans, events, locations and organizations. The entities from these categories are collected as our candidate set of main entities. We further process their associated Wikipedia pages for collecting the first paragraphs and entities with hyperlink as topic-related entities. We then search Wikidata to gather neighbors of the main entities and 1-hop/2-hop paths between main entities and their associated topic-related entities, which finally results in a dataset consisting of more than 110k entity-text pairs with 3 million triples in the KG. Although more-hop paths might be helpful, we limit to 1-hop/2-hop paths for the first study. The comparison of our dataset with WebNLG, AGENDA and E2E is shown in Table 1 and Figure 2.

In the comparison of these four datasets, there are some obvious differences. First, our dataset is significantly larger than WebNLG, AGENDA and E2E (i.e., more than twice of their instances). Meanwhile, our vocabulary size and numbers of distinct entities/relations are all much larger. Second, the average number of input triples per instance is much larger than those of the other two. More importantly, our dataset provides a new genre of data for the task. Specifically, WebNLG has a strict alignment between input triples and output text, and accordingly, each input triple roughly corresponds to 8 words. AGENDA is different from WebNLG for generating much longer output, namely paper abstracts, with the paper title also given as input. Moreover, as observed, quite a portion of text information cannot be directly covered by the input triples. E2E focuses on the restaurant domain with relatively simple inputs, including 77 entities and 8 relations in total. Considering the construction details of these 3 datasets, all their input triples provide useful information (i.e., should be used) for generating the output. In contrast, our dataset has a much larger number of input triples, particularly considering the length difference of output texts. Lastly, another unique characteristic of our dataset is that not every input triple is useful for generation, which brings in the challenge that a model should be able to distill the helpful part for generating a better output sequence.

5 Our MGCN Model

Given the explored knowledge, our task can be cast as a problem of generating text from KG. We propose an encoder-decoder architecture with a multi-graph transformation, shown in Figure 3.

5.1 Multi-Graph Encoder

We first briefly introduce the general flow of multi-graph encoder which consists of n MGCN layers. Before the first layer, graph embedding $\mathbf{h}^{(0)}$ representing a collection of node embeddings is initialized from input KG after multi-graph transformation. By stacking n MGCN layers accordingly with multi-graph transformation and aggregation, we obtain the final graph representation by aggregating the outputs of n MGCN layers for decoding. We explain the details of an MGCN layer as follows.

Graph Encoder. Before introducing our multi-graph transformation, we first look at our basic graph encoder in each MGCN layer (i.e., Graph Encoder 1 to 6 in Figure 3 left). In this paper, we adopt graph convolutional networks (GCNs) (Duvenaud et al., 2015; Kearnes et al., 2016; Kipf and Welling, 2017; Marcheggiani and Titov, 2017) as the basic encoder to consider the graph structure and to capture graph information for each node. More formally, given a directed graph $\mathcal{G}^* = (\mathcal{V}^*, \mathcal{E}^*)$, we define a feature vector $\mathbf{x}_\mathrm{V} \in \mathbb{R}^d$ for each node $\mathrm{V} \in \mathcal{V}^*$. In order to capture the information of neighbors $\mathcal{N}(\cdot)$, the node representation $\mathbf{h}_{\mathrm{V}_j}$ for each $\mathrm{V}_j \in \mathcal{V}^*$ is calculated as:

$$\mathbf{h}_{\mathrm{V}_j} = ReLU\Big(\sum_{\mathrm{V}_i \in \mathcal{N}(\mathrm{V}_j)} W_{\mathrm{P}(i,j)} \mathbf{x}_{\mathrm{V}_i} + \mathbf{b}_{\mathrm{P}(i,j)}\Big),$$

where $\mathrm{P}(i,j)$ denotes the edge between node V_i and V_j including three possible directions: (1) V_i to V_j, (2) V_j to V_i, (3) V_i to itself when i equals to

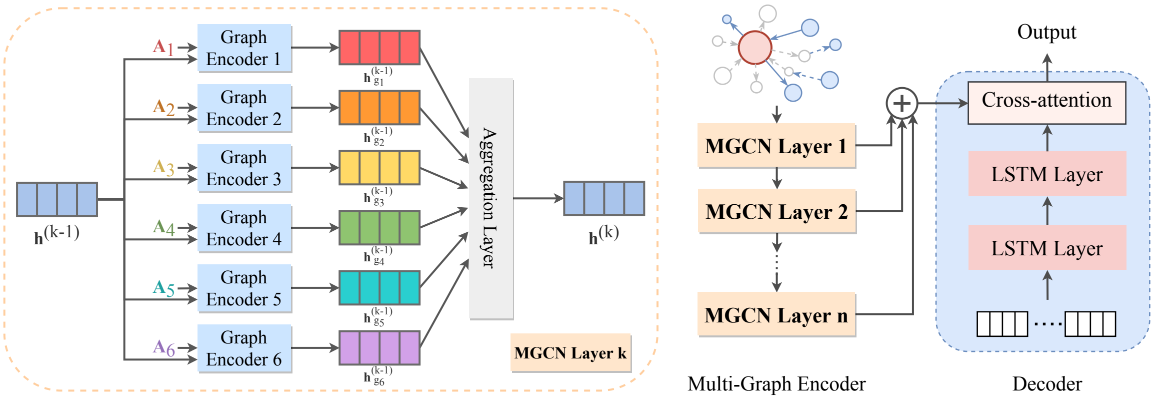


Figure 3: Overview of our model architecture. There are n MGCN layers in the multi-graph encoder, and 2 LSTM layers in the decoder. $\mathbf{h}^{(k-1)}$ is the input graph representation at Layer k, and its 6 copies together with the corresponding adjacent matrices $\mathbf{A}_i$'s of transformed graphs in the multi graph (refer to Figure 4) are fed into individual basic encoders. Finally, we obtain the graph representation $\mathbf{h}^{(k)}$ for the next layer by aggregating the representations from these encoders.

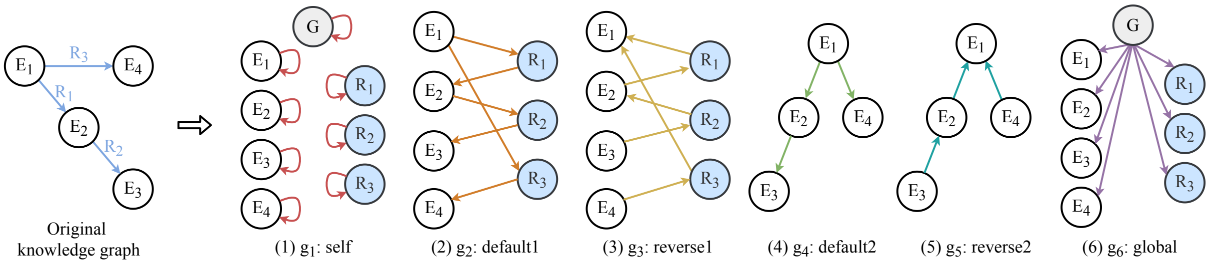
j. Weight matrix $W \in \mathbb{R}^{d\times d}$ and bias $\mathbf{b} \in \mathbb{R}^d$ are model parameters. $ReLU$ is the rectifier linear unit function. Only immediate neighbors of each node are involved in the equation above as it represents a single-layer GCN.

Multi-Graph Transformation. The basic graph encoder with GCN architecture as described above struggles with the problem of parameter explosion and information loss, as the edges are encoded in the form of parameters. Previous works (Beck et al., 2018; Guo et al., 2019; Koncel-Kedziorski et al., 2019) deal with this deficiency by transforming the graph into a Levi graph. However, Levi graph transformation also has its limitations, where entity-to-entity information is learned implicitly. In order to overcome all the difficulties, we introduce a multi-graph structure transformation. A simple example is shown in Figure 4. Given such a directed graph, where $\mathrm{E}_1, \mathrm{E}_2, \mathrm{E}_3, \mathrm{E}_4$ represent entities and $\mathrm{R}_1, \mathrm{R}_2, \mathrm{R}_3$ represent relations in the KG, we intend to transform it into multiple graphs which capture different types of information. Similar to Levi graph transformation, all the entities and relations are represented as nodes in our multi-graph structure. By doing such transformation, we are able to represent relations in the same format as entities using embeddings directly, which avoids the risk of parameter explosion. This multi-graph transformation can be generalised for any graph regardless of the complexity and characteristic of the KG, and the transformed graph can be applied to any model architecture.

In this work, we employ a six-graph structure for our multi-graph transformation as shown in Figure 4. Firstly, in self graph (1), each node is assigned a self-loop edge namely *self* label. Secondly, graphs (2) and (3) are formed by connecting the nodes representing the entities and their adjacent relations. In addition to connecting them in their original direction using *default1* label, we also add a *reverse1* label for the inverse direction of their original relations. Thirdly, we create graphs (4) and (5) by connecting the nodes representing adjacent entities in the input graph, labeled by *default2* and *reverse2*, respectively. These two graphs overcome the deficiency of Levi graph transformation by explicitly representing the entity-to-entity information from the input graph. It also allows us to differentiate entities and relations by adding edges between entities. Finally, in order to consider more global contextualization, we add a global node on top of the graph structure to form graph (6). Each node is assigned with a *global* edge directed from global node. In the end, the set of transformed graphs can be represented by their edge labels $\mathcal{T} = \{self, default, reverse, default2, reverse2, global\}$.

Given the six transformed graphs mentioned above, we construct six corresponding adjacency matrices: $\{\mathbf{A}_1, \mathbf{A}_2, \cdots, \mathbf{A}_6\}$. As shown in Figure 3 (left), these adjacency matrices are used by six basic graph encoders to obtain the corresponding transformed graph representations (i.e., $\mathbf{h}_g$).

Aggregation Layer. After learning 6 embeddings of multi graphs from the basic encoders at the current MGCN layer $k-1$, the model goes through an aggregation layer to obtain the graph



(1) g_1: self (2) g_2: default1 (3) g_3: reverse1 (4) g_4: default2 (5) g_5: reverse2 (6) g_6: global

Figure 4: An example of multi-graph transformation.

embedding for the next MGCN layer k. We can get it by simply concatenating all 6 transformed graph embeddings with different types of edges. However, such simple concatenation of the transformed graphs involves too many features and parameters. In order to address the challenge mentioned above, we propose three aggregation methods for the multi-graph structure: sum-based, average-based and CNN-based aggregation.

Firstly, in sum-based aggregation layer, we compute the representation $\mathbf{h}^{(k)}$ at k-th layer as:

$$\mathbf{h}^{(k)} = \textstyle\sum_{g_i \in \mathcal{T}} \mathbf{h}_{g_i}^{(k-1)},$$

where $\mathbf{h}_{g_i}^{(k-1)}$ represents the i-th graph representation, and $\mathcal{T}$ is the set of all transformed graphs. Sum-based aggregation allows a linear approximation of spectral graph convolutions and helps to reduce data sparsity and over-fitting problems.

Similarly, we apply an average-based aggregation method by normalizing each graph through a mean operation:

$$\mathbf{h}^{(k)} = \tfrac{1}{m} \textstyle\sum_{g_i \in \mathcal{T}} \mathbf{h}_{g_i}^{(k-1)},$$

where m is the number of graphs in $\mathcal{T}$.

We also try to employ a more complex CNN-based aggregation method. Formally, the representation $\mathbf{h}^{(k)}$ at k-th layer is defined as:

$$\mathbf{h}^{(k)} = W_{conv} \mathbf{h}_{mg}^{(k-1)} + \mathbf{b}_{mg}^{(k)} \quad .$$

Here, we use convolutional neural networks (CNN) to convolute the multi-graph representation, where $\mathbf{h}_{mg} = [\mathbf{h}_{g_1}, ..., \mathbf{h}_{g_6}]$ is the representation of multi-graph and $\mathbf{b}_{mg}^{(k)}$ is the bias term.

By applying these aggregation methods, we obtain the graph representation for the next layer $\mathbf{h}^{(k)}$, which is able to capture different aspects of graph information more effectively by learning different types of edges in each transformed graph.

Stacking MGCN Layers. With the introduction of MGCN layer as described above, we can capture the information of higher-degree neighbors by stacking multiple MGCN layers. Inspired by Xu et al. (2018), we employ a concatenation operation over $\mathbf{h}^{(1)}, \cdots, \mathbf{h}^{(n)}$ to aggregate the graph representations from all MGCN layers (Figure 3 right) to form the final layer $\mathbf{h}^{(final)}$, which can be written as follows:

$$\mathbf{h}^{(final)} = \left[\mathbf{h}^{(1)}, \cdots \mathbf{h}^{(n)}\right].$$

Such a mechanism allows weight sharing across graph nodes, which helps to reduce overfitting problems. To further reduce the number of parameters and overfitting problems, we apply the softmax weight tying technique (Press and Wolf, 2017) by tying source embeddings and target embeddings with a target softmax weight matrix.

5.2 Attention-based LSTM Decoder

We adopt the commonly-used standard attention-based LSTM as our decoder, where each next word y_t is generated by conditioning on the final graph representation $\mathbf{h}^{(final)}$ and all words that have been predicted $y_1, ..., y_{t-1}$. The training objective is to minimize the negative conditional log-likelihood. Thus, the objective function can be written as:

$$\mathcal{L} = -\sum_{t=1}^{T} \log p_{\boldsymbol{\theta}}(y_t | y_1, ..., y_{t-1}, \mathbf{h}^{(final)}),$$

where T represents the length of the output sequence, and p is the probability of decoding each word y_t parameterized by $\boldsymbol{\theta}$. As shown in the decoder from Figure 3, we stack 2 LSTM layers and apply a cross-attention mechanism in our decoder.

6 Experiments

6.1 Experimental Settings

We implement our MGCN architecture based on MXNET (Chen et al., 2015) and Sockeye toolkit. Hidden units and embedding dimensions for both encoder and decoder are fixed at 360. We use Adam (Kingma and Ba, 2014) with an initial learning rate of 0.0003 and update parameters with a batch size of 16. The training phase is stopped when detecting the convergence of perplexity on the validation set.

Table 2: Main results of models on ENT-DESC dataset. ↓ indicates lower is better.

During decoding, we use beam search with a beam size of 10. All models are run with V100 GPU.

We evaluate our models by applying both automatic and human evaluations. For automatic evaluation, we use several common evaluation metrics: BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011), TER (Snover et al., 2006), ROUGE$_1$, ROUGE$_2$, ROUGE$_L$ (Lin, 2004), PARENT (Dhingra et al., 2019). We adapt MultEval (Clark et al., 2011) and Py-rouge for resampling and significance test.

6.2 Main Experimental Results

We present our main experiments on ENT-DESC dataset and compare our proposed MGCN models with various aggregation methods against several strong GNN baselines (Bahdanau et al., 2014), GraphTransformer (Koncel-Kedziorski et al., 2019), GRN (Beck et al., 2018), GCN (Marcheggiani and Perez-Beltrachini, 2018) and DeepGCN (Guo et al., 2019), as well as a sequence-to-sequence (S2S) baseline. We re-implement GRN, GCN and DeepGCN using MXNET. We rearrange the order of input triples following the occurrence of entities in output for S2S model to ease its limitation of not able to capture the graph structure. We also apply sequence-to-sequence models on generating outputs directly from entities without exploring KG by (1) randomly shuffling the order of all input entities (E2S) and (2) randomly shuffling the order of all topic-related entities while keeping the **M**ain **E**ntity at **F**ront (E2S-MEF). Furthermore, we apply a delexicalization technique on our dataset. We delexicalize the main entity and topic-related entities by replacing these entities with tokens indicating the entity types and indices.

Main results on our ENT-DESC dataset are shown in Table 2. Here, the numbers of layers in all baseline models and our MGCN models are set to be 6 for fair comparisons. Our models consistently outperform the baseline models on all evaluation metrics. S2S model has poor performance, mainly because the structure of our input triples is complicated as explained earlier. Compared to GRN and GCN models, the BLEU score of MGCN model increases by 1.3 and 0.9, respectively. This result suggests the effectiveness of multi-graph transformation, which is able to capture more comprehensive information compared to the Levi graph transformation used by GCN and GRN (especially entity-to-entity information in the original graph). We then apply multiple methods of aggregation on top of the multi-graph structure. MGCN+CNN and MGCN+SUM report the highest BLEU score of 26.4, followed by MGCN+AVG. By applying our delexicalization technique, the results are further boosted by 3.2 to 3.6 BLEU scores for both baseline and our proposed models. Moreover, our MGCN models and most baseline models outperform E2S and E2S-MEF, suggesting the importance of exploring KG when generating entity descriptions. Compared to E2S and E2S-MEF, there is no further improvement after applying delexicalization (i.e., E2S+delex and E2S-MEF+delex). We speculate it is because the copy mechanism is incorporated in the sequence-to-sequence model. Some useful information in original entities may be lost when further applying the delexicalization.

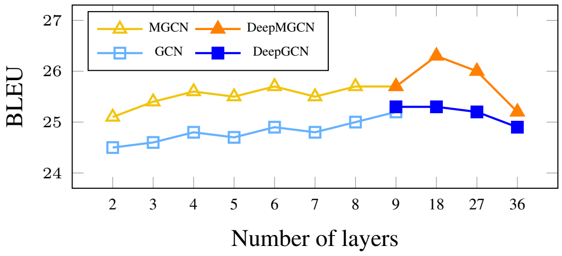

Figure 5: Effect of different numbers of layers.

# Input triples	# Instances	GCN	MGCN+SUM	Δ (BLEU)
1 to 10	1,790	19.4	21.3	+1.9

21 to 30	2,249	23.2	25.0	+1.8
31 to 50	2,830	31.6	32.8	+1.2
51 to 100	1,213	23.9	24.7	+0.8

Table 3: Effect of different numbers of input triples.

6.3 Analysis and Discussion

Effect of different numbers of MGCN layers. In order to examine the robustness of our MGCN models, we conduct further experiments by using different numbers of MGCN layers. The results are shown in Figure 5. We use MGCN to compare with the strongest baseline models using GCN according to the results in Table 2. More specifically, we compare to GCN on 2 to 9 layers and DeepGCN on 9, 18, 27 and 36 layers. As shown in Figure 5, both models perform better initially as more GCN/MGCN layers are being stacked and start to drop afterward. In general, MGCN/DeepMGCN achieves decent performance improvements of 0.3 to 1.0 from 2 to 36 layers, as shown in the line chart. DeepMGCN achieves 26.3 BLEU score at 18 MGCN layers, which is 1.0 higher than deepGCN. It shows that, compared with learning the information implicitly by Levi graph, our multi-graph transformation brings in robust improvements by explicitly representing all types of information in the graph. Another observation is that the BLEU score of MGCN with 3 layers (25.4) is already higher than the best performance of GCN/deepGCN.

Effect of various numbers of input triples. In order to have a deeper understanding of how multi-graph transformation helps the generation, we further explore the model performance under different numbers of triples on the test set. Table 3 shows the BLEU comparison between MGCN+SUM and GCN when using 6 layers. Both models perform the best when the number of triples is between 31 and 50. They both have a poorer performance when the number of triples is too small or too large, which should be due to the fact that the models have insufficient or very noisy input information for generation. Another observation is that the improvement of BLEU (Δ) by our model is greater with a smaller number of input triples. It is plausibly because when the graph is larger, although our transformation techniques still bring in overall BLEU improvements, the increased graph complexity due to the transformation also hinders the generation.

Model	BLEU	Δ (BLEU)
MGCN + SUM	26.4	-
– g_6: *global*	26.0	-0.4
– g_5: *reverse2*	25.8	-0.6
– g_4: *default2*	26.1	-0.3
– g_3: *reverse1*	25.7	-0.7
– g_2: *default1*	26.1	-0.3
MGCN	25.7	-0.7
GCN	24.8	-1.4

Table 4: Results of the ablation study.

Ablation Study. To examine the impact of each graph in our multi-graph structure, we show the ablation study in Table 4. Each transformed graph is removed respectively from MGCN+SUM with 6 layers, except for the g_1 (*self*), which is always enforced in the graph (Kipf and Welling, 2017). We notice that the result drops after removing any transformed graph from the multi-graph. Particularly, we observe the importance of $\{\textit{default2}, \textit{reverse2}\}$ and $\{\textit{default1}, \textit{reverse1}\}$ are equivalent, as the BLEU scores after removing them individually are almost the same. This explains how multi-graph structure addresses the deficiency of Levi graph, i.e., entity-to-entity information is not represented explicitly in Levi graph. Additionally from the results, it is beneficial to represent the edges in the reverse direction for more effective information extraction in directed graphs as there are relatively larger gaps in BLEU drop after removing g_3 (*reverse1*) or g_5 (*reverse2*).

Case Study. Table 5 shows example outputs generated by GCN and MGCN+SUM, as compared to the gold reference. The main entity is highlighted in red, while topic-related entities are highlighted in blue. Given the KG containing all these entities, we intend to generate the description about "*New Jersey Symphony Orchestra*". Firstly, MGCN+SUM is able to cover the main entity and most topic-related entities correctly, while GCN fails to identify the

Gold	The New Jersey Symphony Orchestra is an American symphony orchestra based in the state of New Jersey. The NJSO is the state orchestra of New Jersey, performing concert series in six venues across the state, and is the resident orchestra of the New Jersey Performing Arts Center in Newark, New Jersey.
GCN	The Newark Philharmonic Orchestra is an American orchestra based in Newark, New Jersey, United States.
MGCN +SUM	The New Jersey Symphony Orchestra is an American chamber orchestra based in Newark, New Jersey. The orchestra performs at the Newark Symphony Center at the Newark Symphony Center in Newark, New Jersey.

MGCN + SUM	45.23

Table 6: Results on WebNLG dataset.

main entity. This suggests that without multi-graph transformation or effective aggregation methods, it is hard for GCN to extract useful information given a large number of triples in the KG. Length-wise, the output generated by MGCN+SUM is relatively longer than the one generated by GCN, and thus covers more information. We attribute the reason to GCN's deficiency of information loss, as mentioned earlier.

Human Evaluation In order to further assess the quality of the generated sentences, we conduct human evaluation by randomly selecting 100 sentences from outputs generated by GCN+delex and MGCN+SUM+delex. We hire 6 annotators to evaluate the quality based on three evaluation metrics: fluency, grammar and authenticity. In terms of authenticity, annotators rate this metric based on the KG (i.e., Wikidata). More specifically, we give our annotators all main entities' neighbors, 1-hop and 2-hop connections between main entities and topic-related entities as references. A full score will be given if the statements in the generated sentences are consistent with the facts shown in the KG. All three metrics take values from 1 to 5, where 5 states the highest score. The results are shown in Figure 6. Recall that BLEU scores of GCN+delex and MGCN+SUM+delex are 28.4 and 30.0 respectively, we can see from Figure 6 that MGCN+SUM+delex only performs slightly better than GCN+delex on the two language quality metrics, namely, fluency and grammar. For authenticity, the improvement is more significant. Plausibly it is because the 1.6 BLEU improvement results in more impact on the factual correctness.

6.4 Additional Experiments

To examine our model's efficacy on a dataset of different characteristics, we conduct an auxiliary experiment on WebNLG (Gardent et al., 2017), which shares the most similarity with ENT-DESC dataset among those benchmark datasets (e.g., E2E, AGENDA, WIKIBIO, etc.). The experiments on WebNLG dataset are under the same settings as the main experiments on our ENT-DESC dataset.

As shown in Table 6, we observe that our proposed models outperform the state-of-the-art model MELBOURNE. However, the performance improvement is less obvious on this dataset, largely due to different characteristics between WebNLG and ENT-DESC. As mentioned in the dataset comparison, the input graphs in WebNLG dataset are much simpler and smaller, where all the information is useful for generation. Our MGCN model would show stronger advantages when applied to a larger and more complicated dataset (e.g. ENT-DESC dataset), where extracting more useful entities and relations from the input graphs and effectively aggregating them together is more essential.

7 Conclusions and Future Work

We present a practical task of generating sentences from relevant entities empowered by KG, and construct a large-scale and challenging dataset ENT-DESC to facilitate the study of this task. Extensive experiments and analysis show the effectiveness of our proposed MGCN model architecture with multiple aggregation methods. In the future, we will explore more informative generation and consider applying MGCN to other NLP tasks for better information extraction and aggregation.

Small but Mighty: New Benchmarks for Split and Rephrase

Abstract

Split and Rephrase is a text simplification task of rewriting a complex sentence into simpler ones. As a relatively new task, it is paramount to ensure the soundness of its evaluation benchmark and metric. We find that the widely used benchmark dataset universally contains easily exploitable syntactic cues caused by its automatic generation process. Taking advantage of such cues, we show that even a simple rule-based model can perform on par with the state-of-the-art model. To remedy such limitations, we collect and release two crowdsourced benchmark datasets. We not only make sure that they contain significantly more diverse syntax, but also carefully control for their quality according to a well-defined set of criteria. While no satisfactory automatic metric exists, we apply fine-grained manual evaluation based on these criteria using crowdsourcing, showing that our datasets better represent the task and are significantly more challenging for the models.[1]

1 Introduction

Split and Rephrase is the task of rewriting a presumably long and complex sentence into shorter and simpler sentences, while maintaining the same meaning. For example, one possible way to split the sentence "Voiced by Aoi Koga, Kaguya is the series' titular character, popular among a wide audience." would result in "Kaguya is voiced by Aoi Koga. Kaguya is the series' titular character. Kaguya is popular among a wide audience." While the split sentences have to be coherent, paraphrasing is not enforced. For example, the word "titular" does not have to be replaced. This type of text simplification is challenging as its natural language generation process potentially involves multiple sub-processes such as co-reference resolution, named-entity recognition, semantic role labelling, etc. Split and Rephrase has two main real-world uses: first, to benefit systems whose performance improves with decreasing length of sentences e.g. entity extraction (Zhang et al., 2017) and machine translation (Koehn and Knowles, 2017) by acting as a pre-processing step; second, to benefit human readers, especially those less proficient with the language when reading complex documents such as terms and agreements, in understanding the meaning more easily and accurately (Inui et al., 2003; Siddharthan, 2002).

Datasets of the Split and Rephrase task contain pairs of a *complex sentence* and a presumably meaning-preserving *simplified rewrite* containing multiple simpler sentences. The task was introduced by Narayan et al. (2017), with the release of the WebSplit corpus. Afterwards, Aharoni and Goldberg (2018) proposed the state-of-the-art model to date, a sequence-to-sequence model (Bahdanau et al., 2015) with a copy mechanism (Gu et al., 2016; See et al., 2017) with the observation that most texts are unchanged during a Split and Rephrase operation. Later, Botha et al. (2018) introduced the WikiSplit corpus to be used as large but noisy training data, which the authors reported to be unsuitable as the evaluation data. Also, Sulem et al. (2018) studied the problems of using BLEU as the evaluation metric for this task, while proposing a manually constructed test set called HSplit.

We argue that the widely used benchmark dataset of Split and Rephrase, the WebSplit test set (known as simply WebSplit below), is not suitable for evaluation. Apart from its series of limitations already reported, such as a small vocabulary, unnatural expressions, etc. (Botha et al., 2018), we further show that its complex sentences systematically fol-

low only 3 syntactical patterns marked by lexical cues (Section 2). To demonstrate the implication of such limitations of WebSplit, we show that a simple, unsupervised rule-based model with only 3 corresponding operations can perform even slightly better than the state-of-the-art neural model (Section 3).

To remedy the limitations of WebSplit, we crowdsource two new benchmarks with significantly more diverse syntax in the Wikipedia and legal contract domain with hundreds of human-written complex-simple sentence pairs (Section 4). We carefully control for their quality based on 6 well-defined criteria of what constitutes a good Split and Rephrase rewrite. While most related work reports model performance using the widely criticized BLEU score and manual evaluation with no clear rubric, we perform fine-grained model evaluation using these 6 criteria, rated by crowd workers, showing that our benchmarks present models with greater challenges (Section 5).

2 Issues with WebSplit

WebSplit and Wiki-Split are two widely used datasets for the Split and Rephrase task. Because WikiSplit is derived from the edit history of Wikipedia, versions of passages are not necessarily written by Split and Rephrases operations, as the meaning may not be preserved during edits. Hence, WikiSplit is reported by its authors to be noisy and ill-suited for evaluation for this task (Botha et al., 2018).

WebSplit is used in multiple previous works as the evaluation benchmark. It was created by automatically matching sentences in the WebNLG corpus (Gardent et al., 2017) according to partitions of their meaning representations. The dataset has been shown to have various limitations, such as unnatural expressions, repetition of phrases (Botha et al., 2018), etc.

Furthermore, our preliminary study shows that WebSplit contains several recurring syntactic patterns marked with lexical cues. To demonstrate this, we randomly sample 100 complex sentence from the test set, and are able to categorize them with only 3 syntactical patterns marked by lexical cues (underlined), at which some almost trivial Split and Rephrase operations can take place:

relative clause (rc) (48 out of 100): Scott Adsit voiced Baymax which was created by Duncan Rouleau.

conjunction (conj) (46 out of 100): Above the Veil is from Australia and was preceded by Aenir and Castle.

participle (part) (13 out of 100): Serving the city of Alderney, the 1st runway is made from Poaceae.

It can be further noticed that most complex sentences in WebSplit are short and require only one Split and Rephrase operation. We next show that a rule-based model which only exploits these patterns can perform on par with the state-of-the-art neural model on WebSplit.

3 Rule-Based Model

We design a simple rule-based model to exploit the syntactic cues widely present in WebSplit.

3.1 Algorithm

The rule-based model requires no training data and only uses semantic role labeling (He et al., 2017) and dependency parsing (Dozat and Manning, 2016), running on AllenNLP (Gardent et al., 2017). Given a complex sentence, the model makes 3 splits when applicable. First, using semantic role labeling, the model identifies a Relational Argument and makes a split with the Relational Argument replaced by the Subject Argument. Second, The model looks for the word "and", making a split accordingly. Third, using dependency parsing, the model looks for a node which is joined by the clause, which is extracted, prepended with the subject, and split as a new simple sentence, while the rest of the original complex sentence is split as another new simple sentence.[2]

3.2 Performance

The rule-based model and the state-of-the-art seq2seq model trained on WikiSplit (Aharoni and Goldberg, 2018; Botha et al., 2018) are evaluated using BLEU (Papineni et al., 2002) on WebSplit. The rule-based model achieves a BLEU of 61.3, outperforming the neural model which achieves a BLEU of 56.0. The two models are also evaluated manually on 100 randomly sampled examples, with an identical accuracy of 64% (the criteria of correctness is described in Section 4.2.2). While the rule-based model is imperfect and can likely improve with more and better defined rules, it serves as a strong baseline that exploits the syntactical cues in WebSplit and potentially other benchmarks generated in a similar fashion. The strong performance of such a simplistic model highlights the need of more difficult and diverse benchmark data

---

[2] The detailed algorithm is shown in the Appendix A.

to better capture the complexity of the Split and Rephrase task.

4 New Benchmark Datasets

Considering the limitations of WebSplit, an ideal benchmark must not only be challenging with diverse patterns, but also ensure that the rewrites are strictly meaning-preserving Split and Rephrase. With these two goals, we collect two benchmark datasets, Wiki Benchmark (Wiki-BM) from Wikipedia and Contract Benchmark (Cont-BM) from the legal documents. These two datasets are to be used as gold standard for the evaluation of Split and Rephrase. To systematically control for the quality, we define 6 criteria of what constitutes a good Split and Rephrase, and validate the collected rewrites based on these criteria.

4.1 Collecting Complex Sentences

First, we gather complex sentences as the input for the Split and Rephrase operation.

4.1.1 Wiki Benchmark (Wiki-BM)

While the simplified rewrites in the WikiSplit dataset are not guaranteed to be meaning preserving and cannot be used in a benchmark, the original complex sentences are semantically and syntactically diverse, with adequate complexity. From the 5000 complex sentences from the WikiSplit test set, we randomly select 500 for budget reasons with only alphanumerical characters, whitesspaces, commas and periods, and manually inspect them to ensure that they are well-formed.

4.1.2 Contract Benchmark (Cont-BM)

We collect sentences from publicly available legal procurement contracts online, and contract templates within IBM with no confidential information. We randomly sample and inspect 500 sentences in the same manners as above.

4.1.3 Syntactical Diversity

To demonstrate that our complex sentences are syntactically diverse and are not plagued by patterns analyzed before, we randomly sample 100 complex sentences from each benchmark to annotate them by syntactical patterns. In addition to the 3 patterns outlined before, we define the following new patterns (the examples are truncated to save space):

prepositional phrase (prep): The mausoleum was built in 1894 along the lines specified by Frazer.

Patterns	WebSplit	Wiki-BM	Cont-BM
rc	48	34	29
conj	46	71	66
part	13	34	28
prep	5	12	66
adv	0	19	38
appos	2	10	0
inf	0	5	10
patterns/sent	1.22	1.78	2.37

Table 1: Counts of syntactic patterns for splitting in 100 random examples from each of WebSplit, Wiki Benchmark, and Contract Benchmark. Note that each complex sentence may have more than one pattern.

Entry	WebSplit	Wiki-BM	Cont-BM
Rewritten by human	No	Yes	Yes
# complex	930	403	406
# simple	43958	720	659
# toks/complex	20.6	29.6	41.5
# sents/simple	3.7	3.0	3.0

Table 2: Comparison of statistics among WebSplit, Wiki Benchmark, and Contract Benchmark.

adverbial phrase (adv): Except as may be otherwise specified, Supplier shall invoice Buyer.

apposition clause (appos): Leila married the movie director Ruy Guerra, father of her only daughter.

infinitive clause (inf): Nimfa was forced to take part of a devilish plan to fool the Saavedra family.

The counts from the manual annotation are shown in Table 1. Wiki-BM has more diverse patterns and number of patterns per complex sentence than WebSplit, while Cont-BM has the most. The difference of complexity in the 3 benchmarks would be beneficial for evaluation.

4.2 Collecting Simplified Rewrites

We ask a set of crowd workers to Split and Rephrase the gathered complex sentences on Amazon Mechanical Turk, and another set to ensure their quality[3]. We divide the crowdsourcing workflow into two phases.

4.2.1 Phase 1: Rewrite

For each complex sentence, we ask 3 crowd workers to rewrite it by splitting and rephrasing, with the option to flag the complex sentence as too simple or too problematic to split, which we later discard. We require Master Qualification, and pay \$0.2 per HIT for the complex sentences from Wiki-BM and \$0.4 per HIT for the more challenging Cont-BM. This Phase costs \$1,125 in total.

---

[3] Detailed guidelines are shown in the Appendix B.

WebSplit	sensical	grammatical	no miss fact	no new fact	correct split	enough split	*correct*	BLEU
seq2seq	71.6%/4.55	64.0%/4.40	94.30%	94.30%	87.30%	79.00%	50.1%	62.6%
rule	72.2%/4.35	58.2%/4.01	92.70%	95.70%	83.30%	82.90%	51.7%	65.9%
Wiki-BM	sensical	grammatical	no miss fact	no new fact	correct split	enough split	*correct*	BLEU
seq2seq	55.4%/4.22	47.8%/3.93	98.30%	99.70%	80.30%	76.30%	37.3%	87.0%
rule	59.8%/4.06	54.2%/3.85	94.30%	94.30%	78.70%	47.70%	28.5%	77.2%
human	84.9%/4.76	76.8%/4.61	95.00%	93.70%	88.30%	88.00%	68.4%	77.8%
Cont-BM	sensical	grammatical	no miss fact	no new fact	correct split	enough split	*correct*	BLEU
seq2seq	29.4%/3.45	25.0%/3.04	92.70%	99.00%	52.30%	63.00%	16.7%	78.6
rule	57.9%/3.97	54.8%/3.89	97.70%	96.70%	83.30%	44.70%	25.0%	79.2
human	78.2%/4.53	72.6%/4.43	95.30%	96.30%	93.70%	85.00%	63.3%	73.0%

Table 3: Average crowd ratings by criteria, model and benchmark. For the first two criteria which are on the scope of *0–5*, we report the percentage of *5* and the average. For the rest which are *yes–no* questions, we report the percentage of *yes*.

4.2.2 Phase 2: Rate

For each crowdsourced rewrite submitted in Phase 1, we ask 2 different crowd workers to evaluate its quality, based on the following fine-grained criteria:

1. Is it sensical (scale of 0-5)?
2. Is it grammatical (scale of 0-5)?
3. Does it miss any existing facts (yes/no)?
4. Does it introduce new facts (yes/no)?
5. Does it have splits at the wrong place (yes/no)?
6. Should some of its sentences be further split (yes/no)?

We require Master Qualification, and pay $0.07 per HIT[4]. This Phase costs $508.

In each benchmark, we now have 500 complex sentences, each with 3 rewrites, each with 2 ratings. For each rating, if the worker answers 5 for the first two criteria, and chooses “no” for last four criteria, we denote this rating as *correct*. For each rewrite, if both of its ratings are *correct*, we denote this rewrite as *perfect*. To ensure high quality of the gold standard, we only keep the rewrites that are *perfect* as gold standard corresponding to their complex sentences in our benchmarks.

4.3 Descriptive Statistics

Some descriptive statistics and the comparison with WebSplit are shown in Table 2. While our new benchmarks are smaller than WebSplit, we argue that a small number of human-written, high quality ground-truth simple rewrites are better suited for evaluation than a larger number of automatically generated, noisy ones.

While similar to HSplit (Sulem et al., 2018), our benchmarks include several additional features, such has much more complex sentences from the legal domain, a clear set of rubrics for evaluation, and crowdsourced human judgements to scale.

5 Model Performance

Previous work reports the model performance on this task using two metrics: BLEU on the entire benchmark and manual ratings on a small subset. However, BLEU has long been shown to have little correlation with human judgements in text simplification[5] (Sulem et al., 2018). While other alternatives exist, the focus of our work is not the metrics, but rather the quality and difficulty of benchmarks, which can be illustrated no better than by human evaluation. Previously, manual evaluation has been done without a well-established rubric on what makes a Split and Rephrase rewrite correct. To address these problems, we use crowdsourcing following the process of Phase 2, by asking 3 crowd workers to rate model outputs based on the 6 fine-grained criteria described above.

Table 3 shows the average crowd ratings and BLEU score for each combination of a model and a benchmark. We consider the state-of-the-art seq2seq model trained on WikiSplit (Botha et al., 2018) and our rule-based model. We use all rewrites from Phase 1 including those not included in our benchmarks to measure human performance.

Both the rule-based and seq2seq model have large rooms for improvement, as they significantly

---

[4] The pay exceeds the prorated US minimum wage.

[5] We reinforce this claim in Appendix C.

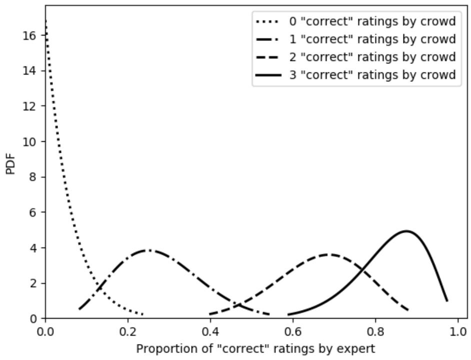

Figure 1: Beta distributions with Laplace smoothing of the proportion of *correct* ratings by expert.

underperform crowd workers in almost all criteria, with significantly lower performance in our proposed benchmarks than in WebSplit. Even for crowd workers, the percentage of overall *correct* is less than 70% in our new benchmarks, whose complex sentences are much more challenging to Split and Rephrase.

6 Reliability of the Crowd

Can we use crowdsourcing to evaluate models no less reliably as experts or authors, as done in previous work? As experts of this task, we manually rate a subset of model-output rewrites as the ground truth for rating, and compare it against the crowd's rating. Since there are 3 benchmarks and 3 models (including human, whose outputs are crowd rewrites we have collected in Wiki-BM and Cont-BM, **but not** WebSplit), there are 8 combinations in total. From the crowd ratings of these combinations, we assign each complex–output pair into one of 4 buckets, determined by the number of *correct* ratings out of 3 crowd ratings. For each bucket, we sample 2 complex–output pairs. In total, $8 \times 4 \times 2 = 64$ complex–output pairs are sampled. The expert rates them independently following the same 6 criteria as the crowd workers. This gives the proportion of expert's *correct* ratings among each bucket.

These statistics allow us to fit a beta distribution for expert rating conditional on each crowd rating bucket, using Laplace prior smoothing. The results are shown in Figure 1. Each distribution corresponds to a bucket with 0, 1, 2, or 3 out of 3 *correct* crowd ratings. For example, the right-most curve represents the probability density function where both the expert and the 3 crowd raters agree on a *correct* rating. According to the figure with a 90% one-sided confidence, when all 3 crowd raters rate a rewrite as *correct*, the expert also rates *correct* in more than around 80% of the samples; when none of the 3 crowd raters rate a rewrite as *correct*, the expert rates *correct* for less than around 10% of the samples.

This shows that crowdsourcing can be a reliable way to evaluate models for this task, with variable reliability depending on the number of raters per sample and their agreement.

7 Conclusion and Future Work

After showing the flaws of the current benchmarks in Split and Rephrase, we release two crowd-sourced benchmarks, Wiki Benchmark and Contract Benchmark, created from Wikipedia articles and legal documents respectively. Our benchmarks contain significantly more diverse syntax and provide additional challenges to models. Using fine-grained crowdsourcing evaluation on 6 well-defined criteria, we show that they provide a greater challenge to models.

We hope our benchmark datasets and human judgements facilitate model development and metric design, respectively. Moreover, future work should inspect the effect of Split and Rephrase on downstream tasks such as machine translation or information retrieval, and examine if models' performance on these tasks correlate with that on our benchmarks.

A Algorithm of the Rule-Based Model

Given a complex sentence, the model runs the following processes once each.

Wh Handling Using semantic role labeling, the model looks for a Relational Argument (R-ARG), and the Subject Argument (asserted to be the ARG preceding the R-ARG). Then, a split is made with the Relational Argument replaced by the Subject Argument.

Conjunction Handling The model looks for the word "and". Using semantic role labeling, if the word following "and" is an argument (ARG), assert that "and" is followed by a sentence, and a split is made. Or, if the word following "and" is a verb (V), the model asserts the Subject Argument to be the ARG preceding the V; a split is made with "and" replaced by the Subject Argument.

Insertion Handling Using dependency parsing, the model looks for a node with type *participle modifier, relative clause modifier, prepositional modifier, adjective modifier,* or *appositional modifier*. The clause with the node as the root is extracted, prepended with the subject, and split as a new simple sentence. The rest of the original complex sentence is split as another new simple sentence.

B Crowdsourcing Guidelines

B.1 Guidelines of Phase 1: Rewrite

Instructions: A long, complex sentence is hard to understand for many people. Please try to rewrite such a sentence by splitting and rephrasing it as several shorter and simpler sentences. A good example:

Benchmarks+Models	sensical	grammatical	no miss fact	no new fact	correct split	enough split	*correct*
WebSplit+s2s	.367	.273	-.037†	-.001†	.184	.046†	.303
WebSplit+rule	.491	.456	.118†	.048†	.425	.276	.480
Wiki-BM+s2s	.231	.319	.190	-.005†	.167†	.256	.412
Wiki-BM+rule	.438	.561	.083†	.075†	.512	-.035†	.232
Cont-BM+s2s	.345	.329	.402	-.062†	.191	.215	.255
Cont-BM+rule	.277	.190	-.007†	.064†	.148†	.115†	.098†
WebSplit+all models	.433	.348	.029†	.023†	.289	.161	.326
Wiki-BM+all models	.340	.425	.179	.122†	.328	.243	.217
Cont-BM+all models	.313	.271	.228	.01†	.199	.142	.165
all benchmarks+s2s	.237	.233	.208	.064†	.167	.146	.141
all benchmarks+rule	.388	.400	.081†	.063†	.347	.089†	.230
all benchmarks+all models	.362	.393	.172	.068†	.315	.168	.251

Table 4: Spearman's correlation between sentence-level BLEU and human judgement on 6 criteria by combinations of benchmarks and models. †: the correlation coefficient is not statistically significant with $\alpha = .05$.

- **Original**: Jonathan Thirkield, currently living in New York City, is an American poet who is known to be prolific.
- **Rewritten** (good): Jonathan Thirkield is an American poet. Jonathan Thirkield is known to be prolific. Jonathan Thirkield is currently living in New York City.
- **Rewritten** (good): Jonathan Thirkield is an American poet. He is currently living in New York City. He is known to be prolific.

Your rewrite must satisfy the following requirements:

1. Grammatical
   Rewritten (bad: ungrammatical): Jonathan Thirkield currently living in New York City. Jonathan Thirkield is an American poet. He is known to be prolific.
2. Sensical and understandable
   Rewritten (bad: non-sensical): Jonathan Thirkield lives in prolific New York City. He is an American poet.
3. Has the same meaning as the original complex sentence, with no new facts and no missing facts (show/hide examples)
   Rewritten (bad: new facts): Jonathan Thirkield is a best- selling American poet. He is currently living in New York City. He is known to be prolific.
   Rewritten (bad: missing fact): Jonathan Thirkield is an American poet. He is currently living in New York City. (does not mention prolific)
4. Split into appropriate number of short sentences (at least two), not too few or too many. If the sentence is too simple to be split, write SIMPLE as your response.
   Rewritten (bad: too few splits): Jonathan Thirkield, currently living in New York City, is an American poet. He is known to be prolific.
   Rewritten (bad: too many splits): Jonathan Thirkield is a poet. He is American. He is currently living somewhere. That somewhere is New York City. He is prolific. Such is known. (too many unnecessary splits)
5. Do NOT use pronouns (it, she, he, they, this, that) if they are ambiguous
   Rewritten (bad: ambiguous pronoun): Walt Whitman is an American poet. Jonathan Thirkield is also an American poet. He is living in New York City.

Your rewrite will be validated by others. You might not receive payment if your rewrite does not satisfy the requirements. You may skip this HIT if you find splitting the given sentence too hard. However, if you manage to appropriately split a sentence which many other workers have skipped, you will receive a bonus.

B.2 Guidelines of Phase 2: Rate

Instructions: Read the two pieces of text below. The second text is an attempt to rewrite the first text, by splitting and rephrasing it into several shorter sentences to be understood more easily. Your job is to judge if this rewrite is good.

1. The Rewritten text **makes sense**
2. The Rewritten text **is grammatical**
3. Does the Rewritten text miss some facts that are present in the Original text?
4. Does the Rewritten text have new facts that are not present in the Original text?
5. Does the Rewritten text split the Original text

at the wrong place or unnecessarily?

6. Does the Rewritten text have one or more sentences that should be further split?

Each question is accompanied by a positive and negative example, the same as in the previous section. The crowd workers answer the first two questions by dragging a draw bar between "Strongly Disagree" and "Strongly Agree", and the last four questions by choosing "yes/no" radio boxes.

C Correlation Between BLEU and Crowd Workers

Does BLEU correlate with human judgement on a large scale? To answer this, we collect crowd-sourced ratings of model outputs. With 3 benchmark datasets (WebSplit, Wiki-BM and Cont-BM) and two models (seq2seq and rule-based), we sample 100 complex sentence and output rewrite pairs from each combination, resulting in 600 in total.[6] Then, we run the same crowdsourcing project as Phase 2 (Sec. 5.2.2) with these 600 pairs, for each of which we collect ratings from 3 crowd raters. The crowd raters are asked to rate based on the same 6 criteria as before (Sec. 3.1). As defined before, if a rating includes 5 for the first two criteria and "no" for the other four, it is considered *correct*.

The Spearman's correlation coefficients between sentence-level BLEU and crowd ratings in each 6 criteria are shown in Table 4. While BLEU has higher correlation with crowd raters on whether the rewrite is sensical or grammatical, most correlation coefficients are less than .5, and many do not imply a positive correlation at all.

This reinforces the claim that BLEU is not a suitable evaluation metric for the Split and Rephrase task, because it has little correlation with human (crowd) judgement.

---

[6] Additionally, we sample 100 pairs each directly from Wiki-BM and Cont-BM with 3 crowd rewrites. These 600 pairs are used to measure human performance, but are not used in this section because they themselves are ground truth.

Online Back-Parsing for AMR-to-Text Generation

Abstract

AMR-to-text generation aims to recover a text containing the same meaning as an input AMR graph. Current research develops increasingly powerful graph encoders to better represent AMR graphs, with decoders based on standard language modeling being used to generate outputs. We propose a decoder that back predicts projected AMR graphs on the target sentence during text generation. As the result, our outputs can better preserve the input meaning than standard decoders. Experiments on two AMR benchmarks show the superiority of our model over the previous state-of-the-art system based on graph Transformer.

1 Introduction

Abstract meaning representation (AMR) (Banarescu et al., 2013) is a semantic graph representation that abstracts meaning away from a sentence. Figure 1 shows an AMR graph, where the nodes, such as "*possible-01*" and "*police*", represent concepts, and the edges, such as "*ARG0*" and "*ARG1*", indicate relations between the concepts they connect. The task of AMR-to-text generation (Konstas et al., 2017) aims to produce fluent sentences that convey consistent meaning with input AMR graphs. For example, taking the AMR in Figure 1 as input, a model can produce the sentence "*The police could help the victim*". AMR-to-text generation has been shown useful for many applications such as machine translation (Song et al., 2019) and summarization (Liu et al., 2015; Yasunaga et al., 2017; Liao et al., 2018; Hardy and Vlachos, 2018). In addition, AMR-to-text generation can be a good test bed for general graph-to-sequence problems (Belz et al., 2011; Gardent et al., 2017).

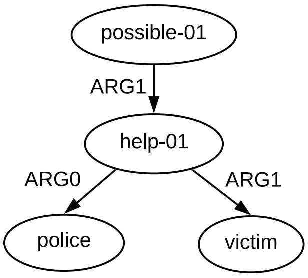

Figure 1: An example AMR graph meaning "*The police could help the victim.*"

AMR-to-text generation has attracted increasing research attention recently. Previous work has focused on developing effective encoders for representing graphs. In particular, graph neural networks (Beck et al., 2018; Song et al., 2018; Guo et al., 2019) and richer graph representations (Damonte and Cohen, 2019; Hajdik et al., 2019; Ribeiro et al., 2019) have been shown to give better performances than RNN-based models (Konstas et al., 2017) on linearized graphs. Subsequent work exploited graph Transformer (Zhu et al., 2019; Cai and Lam, 2020; Wang et al., 2020), achieving better performances by directly modeling the intercorrelations between distant node pairs with relation-aware global communication. Despite the progress on the *encoder* side, the current state-of-the-art models use a rather standard *decoder*: it functions as a language model, where each word is generated given only the previous words. As a result, one limitation of such decoders is that they tend to produce fluent sentences that may not retain the meaning of input AMRs.

We investigate enhancing AMR-to-text decoding by integrating online back-parsing, simultaneously predicting a *projected* AMR graph on the target sentence while it is being constructed. This is largely inspired by work on back-translation (Sennrich et al., 2016; Tu et al., 2017), which shows that back predicting the source sentence given a target translation output can be useful for strengthening neural machine translation. We

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1206–1219,
November 16–20, 2020.

perform *online* back parsing, where the AMR graph structure is constructed through the autoregressive sentence construction process, thereby saving the need for training a separate AMR parser. By adding online back parsing to the decoder, structural information of the source graph can intuitively be better preserved in the decoder network.

Figure 2 visualizes our structure-integrated decoding model when taking the AMR in Figure 1 as input. In particular, at each decoding step, the model predicts the current word together with its corresponding AMR node and outgoing edges to the previously generated words. The predicted word, AMR node and edges are then integrated as the input for the next decoding step. In this way, the decoder can benefit from both more informative loss via multi-task training and richer features taken as decoding inputs.

Experiments on two AMR benchmark datasets (LDC2015E86 and LDC2017T10[1]) show that our model significantly outperforms a state-of-the-art graph Transformer baseline by 1.8 and 2.5 BLEU points, respectively, demonstrating the advantage of structure-integrated decoding for AMR-to-text generation. Deep analysis and human evaluation also confirms the superiority of our model. Our code is available at `https://github.com/muyeby/AMR-Backparsing`.

2 Baseline: Graph Transformer

Formally, the AMR-to-text generation task takes an AMR graph as input, which can be denoted as a directed acyclic graph $G = (V, E)$, where V denotes the set of nodes and E refers to the set of labeled edges. An edge can further be represented by a triple $\langle v_i, r_k, v_j \rangle$, showing that node v_i and v_j are connected by relation type r_k. Here $k \in [1, ..., R]$, and R is the total number of relation types. The goal of AMR-to-text generation is to generate a word sequence $\mathbf{y} = [y_1, y_2, \dots, y_M]$, which conveys the same meaning as G.

We take a graph Transformer model (Koncel-Kedziorski et al., 2019; Zhu et al., 2019; Cai and Lam, 2020; Wang et al., 2020) as our baseline. Previous work has proposed several variations of graph-Transformer. We take the model of Zhu et al. (2019), which gives the state-of-the-art performance. This approach exploits a graph Transformer encoder for AMR encoding and a standard Transformer decoder for text generation.

2.1 Graph Transformer Encoder

The Graph Transformer Encoder is an extension of the standard Transformer encoder (Vaswani et al., 2017), which stacks L encoder layers, each having two sublayers: a self-attention layer and a position-wise feed forward layer. Given a set of AMR nodes $[v_1, v_2, \dots, v_N]$, the l-th encoder layer takes the node features $[h_1^{l-1}, h_2^{l-1}, \dots, h_N^{l-1}]$ from its preceding layer as input and produces a new set of features $[h_1^l, h_2^l, \dots, h_N^l]$ as its output. Here $h_i^{l-1}, h_i^l \in \mathcal{R}^d$, d is the feature dimension, $l \in [1, \dots, L]$, and h_i^0 represents the embedding of AMR node v_i, which is randomly initialized.

The graph Transformer encoder extends the vanilla self-attention (SAN) mechanism by explicitly encoding the relation r_k[2] between each AMR node pair (v_i, v_j) in the graph. In particular, the relation-aware self-attention weights are obtained by:

$$\begin{aligned} \alpha_{ij} &= \frac{\exp(e_{ij})}{\sum_{n\in[1,\dots,N]} \exp(e_{in})}, \\ e_{ij} &= \frac{(W^Q h_i^{l-1})^T (W^K h_j^{l-1} + W^R \gamma_k)}{\sqrt{d}}, \end{aligned} \tag{1}$$

where W^Q, W^K, W^R are model parameters, and $\gamma_k \in \mathcal{R}^{d_r}$ is the embedding of relation r_k, which is randomly initialized and optimized during training, d_r is the dimension of relation embeddings.

With α_{ij}, the output features are:

$$h_i^l = \sum\nolimits_{j\in[1,\dots,N]} \alpha_{ij} (W^V h_j^{l-1} + W^R \gamma_k), \tag{2}$$

where W^V is a parameter matrix.

Similar to the vanilla Transformer, a graph Transformer also uses multi-head self-attention, residual connection and layer normalization.

2.2 Standard Transformer Decoder

The graph Transformer decoder is identical to the vanilla Transformer (Vaswani et al., 2017). It consists of an embedding layer, multiple Transformer decoder layers and a generator layer (parameterized with a linear layer followed by softmax activation). Supposing that the number of decoder layers is the same as the encoder layers, denoted as L. The decoder consumes the hidden states of the top-layer encoder $H^L =$

---

[1] http://amr.isi.edu/

[2] Since the adjacency matrix is sparse, the graph Transformer encoder uses the shortest label path between two nodes to represent the relation (e.g. path (victim, police) = "↑ARG1 ↓ARG0", path (police, victim) = "↑ARG0 ↓ARG1").

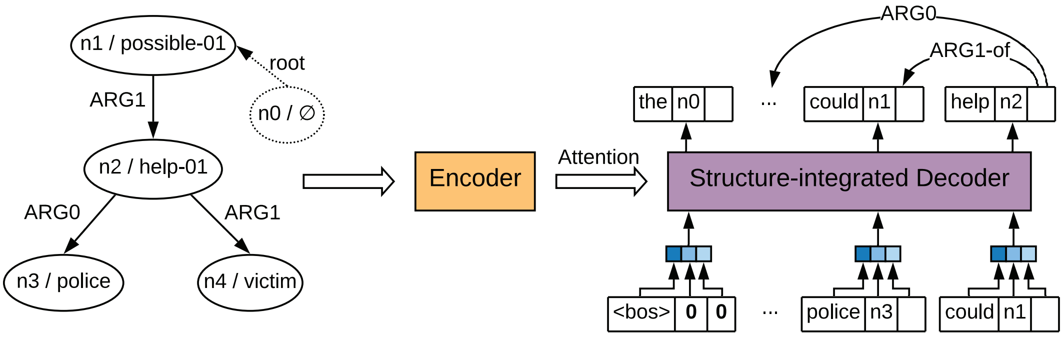

Figure 2: Overview of the proposed model.

$[h^L_1, h^L_2, \ldots, h^L_N]$ as input and generates a sentence $\mathbf{y} = [y_1, y_2, \ldots, y_M]$ word-by-word, according to the hidden states of the topmost decoder layer $S^L = [s^L_1, s^L_2, \ldots, s^L_M]$.

Formally, at time t, the l-th decoder layer ($l \in [1, \ldots, L]$) updates the hidden state as:

$$\begin{aligned} \hat{s}^l_t &= \mathrm{SAN}(s^{l-1}_1, s^{l-1}_2, \ldots, s^{l-1}_t), \\ c^l_t &= \mathrm{AN}(\hat{s}^l_t, H^L), \\ s^l_t &= \mathrm{FF}(c_t, \hat{s}^l_t), \end{aligned} \tag{3}$$

where FF denotes a position-wise feed-forward layer, $[s^{l-1}_1, s^{l-1}_2, \ldots, s^{l-1}_t]$ represent the hidden states of the $l-1$th decoder layer, $[s^0_1, s^0_2, \ldots, s^0_t]$ are embeddings of $[y_s, y_1, \ldots, y_{t-2}, y_{t-1}]$, and y_s denotes the start symbol of a sentence.

In Eq 3, AN is a standard attention layer, which computes a set of attention scores $\beta_{ti} (i \in [1, \ldots, N])$ and a context vector c_t:

$$\begin{aligned} \beta_{ti} &= \frac{\exp(f(\hat{s}^l_t, h^L_i))}{\sum_{j \in [1, \ldots, N]} \exp\left(f(\hat{s}^l_t, h^L_j)\right)}, \\ c^l_t &= \sum\nolimits_{i \in [1, \ldots, N]} \beta_{ti} h^L_i, \end{aligned} \tag{4}$$

where f is a scaled dot-product attention function.

Denoting the output hidden state of the L-th decoder layer at time t as s^L_t, the generator layer predicted the probability of a target word y_t as:

$$p(y_t | \mathbf{y}_{<t}, G) = \mathrm{softmax}(W_g s^L_t), \tag{5}$$

where $\mathbf{y}_{<t} = [y_1, y_2, \ldots, y_{t-1}]$, and W_g is a model parameter.

2.3 Training Objective

The training objective of the baseline model is to minimize the negative log-likelihood of conditional word probabilities:

$$\begin{aligned} \ell_{std} &= -\sum\nolimits_{t \in [1, \ldots, M]} log\ p(y_t | \mathbf{y}_{<t}, G) \\ &= -\sum\nolimits_{t \in [1, \ldots, M]} log\ p(y_t | s^L_t; \Theta), \end{aligned} \tag{6}$$

where Θ denotes the full set of parameters.

3 Model with Back-Parsing

Figure 2 illustrates the proposed model. We adopt the baseline graph encoder described in Section 2.1 for AMR encoding, while enhancing the baseline decoder (Section 2.2) with AMR graph prediction for better structure preservation. In particular, we train the decoder to reconstruct the AMR graph (so called "back-parsing") by jointly predicting the corresponding AMR nodes and *projected* relations when generating a new word. In this way, we expect that the model can better memorize the AMR graph and generate more faithful outputs. In addition, our decoder is trained in an *online* manner, which uses the last node and edge predictions to better inform the generation of the next word.

Specifically, the encoder hidden states are first calculated given an AMR graph. At each decoding time step, the proposed decoder takes the encoder states as inputs and generates a new word (as in Section 2.2), together with its corresponding AMR node (Section 3.1) and its outgoing edges (Section 3.2), These predictions are then used inputs to calculate the next state (Section 3.3).

3.1 Node Prediction

We first equip a standard decoder with the ability to make word-to-node alignments while generating target words. Making alignments can be formalized as a matching problem, which aims to find the most relevant AMR graph node for each target word. Inspired by previous work (Liu et al., 2016; Mi et al., 2016), we solve the matching problem by supervising the word-to-node attention scores given by the Transformer decoder. In order to deal with words without alignments, we introduce a *NULL* node $v_\emptyset$ into the input AMR graph (as shown in

Figure 2) and align such words to it.[3]

More specifically, at each decoding step t, our Transformer decoder first calculates the top decoder layer word-to-node attention distribution $\beta'_t = [\beta'_{t0}, \beta'_{t1}, ..., \beta'_{tN}]$ (Eq 3 and Eq 4) after taking the encoder states $H^L = [h_0^L, h_1^L, h_2^L, \dots, h_N^L]$ together with the previously generated sequence $\mathbf{y}_{<t} = [y_1, y_2, \dots, y_{t-1}]$ (β'_{t0} and h_0^L are the probability and encoder state for the *NULL* node $v_\emptyset$). Then the probability of aligning the current decoder state to node v_i is defined as:

$$p(\texttt{ALI}(s_t) = v_i | H^L, \mathbf{y}_{<t}) = \beta'_{ti}, \tag{7}$$

where ALI is the sub-network for finding the best aligned AMR node for a given decoder state.

Training. Supposing that the gold alignment (refer to Section 4.1) at time t is $\hat{\beta}_t$, the training objective for node prediction is to minimize the loss defined as the distance between β'_t and $\hat{\beta}_t$:

$$\ell_{node} = \sum\nolimits_{t \in [1,\dots,M]} \Delta(\beta'_t, \hat{\beta}_t), \tag{8}$$

where Δ denotes a discrepancy criterion that can quantify the distance between β'_t and $\hat{\beta}_t$. We take two common alternatives: (1) Mean Squared Error (MSE), and (2) Cross Entropy Loss (CE).

3.2 Edge Prediction

The edge prediction sub-task aims to preserve the node-to-node relations in an AMR graph during text generation. To this end, we project the edges of each input AMR graph onto the corresponding sentence according to their node-to-word alignments, before training the decoder to generate the *projected* edges along with target words. For words without outgoing edges, we add a "self-loop" edge for consistency.

Formally, at decoding step t, each relevant directed edge (or *arc*) with relation label r_k starting from y_t can be represented as $\langle y_j, r_k, y_t \rangle$, where $j \leq t$, y_j, y_t and r_k are called "*arc_to*", "*arc_from*", and "*label*" respectively. We modify the deep biaffine attention classifier (Dozat and Manning, 2016) to model these edges. In particular, we factorize the probability for each labeled edge into the "*arc*" and "*label*" parts, computing both based on the current decoder hidden state and the states of all previous words. The "*arc*" score $\psi_{tj}^{\text{arc}} \in \mathcal{R}^1$, which measures whether or not a directed edge from y_t to y_j exists, is calculated as:

$$\begin{aligned} &b_j^{\text{arc\_to}}, b_t^{\text{arc\_from}} = \text{FF}^{\text{arc\_to}}(s_j^L), \text{FF}^{\text{arc\_from}}(s_t^L), \\ &\hat{\psi}_{tj}^{\text{arc}} = \text{Biaff}^{\text{arc}}(b_j^{\text{arc\_to}}, b_t^{\text{arc\_from}}), \\ &\psi_{t1}^{\text{arc}}, \psi_{t2}^{\text{arc}}, \dots, \psi_{tj}^{\text{arc}}, \dots, \psi_{tt}^{\text{arc}} \\ &\quad = \text{softmax}(\hat{\psi}_{t1}^{\text{arc}}, \hat{\psi}_{t2}^{\text{arc}}, \dots, \hat{\psi}_{tj}^{\text{arc}}, \dots, \hat{\psi}_{tt}^{\text{arc}}). \end{aligned} \tag{9}$$

Similarly, the "*label*" score $\psi_{tj}^{\text{label}} \in \mathcal{R}^R$, which is used to predict a label for potential word pair (y_j, y_t), is given by:

$$\begin{aligned} &b_j^{\text{label\_to}}, b_t^{\text{label\_from}} = \text{FF}^{\text{label\_to}}(s_j^L), \text{FF}^{\text{label\_from}}(s_t^L), \\ &\psi_{tj}^{\text{label}} = \text{softmax}\big(\text{Biaff}^{\text{label}}(b_j^{\text{label\_to}}, b_t^{\text{label\_from}})\big). \end{aligned} \tag{10}$$

In Eq 9 and Eq 10, $\text{FF}^{\text{arc\_to}}$, $\text{FF}^{\text{arc\_from}}$, $\text{FF}^{\text{label\_to}}$ and $\text{FF}^{\text{label\_from}}$ are linear transformations. $\text{Biaff}^{\text{arc}}$ and $\text{Biaff}^{\text{label}}$ are biaffine transformations:

$$\text{Biaff}(x_1, x_2) = x_1^T U x_2 + W(x_1 \oplus x_2) + b, \tag{11}$$

where $\oplus$ denotes vector concatenation, U, W and b are model parameters. U is a $(d \times 1 \times d)$ tensor for unlabeled classification (Eq 9) and a $(d \times R \times d)$ tensor for labeled classification (Eq 10), where d is the hidden size.

Defining $p(y_j|y_t)$ as ψ_{tj}^{arc} and $p(r_k|y_j, y_t)$ as $\psi_{tj}^{\text{label}}[k]$, the probability of a labeled edge $\langle y_j, r_k, y_t \rangle$ is calculated by the chain rule:

$$\begin{aligned} p(r_k, y_j | y_t) &= p(r_k | y_j, y_t) p(y_j | y_t) \\ &= \psi_{tj}^{\text{label}}[k] \cdot \psi_{tj}^{\text{arc}}. \end{aligned} \tag{12}$$

Training. The training objective for the edge prediction task is the negative log-likelihood over all *projected* edges E':

$$\ell_{label} = -\sum\nolimits_{\langle y_j, r_k, y_i \rangle \in E'} log\ p(r_k, y_j | y_i) \tag{13}$$

3.3 Next State Calculation

In addition to simple "one-way" AMR back-parsing (as shown in Section 3.1 and 3.2), we also study integrating the previously predicted AMR nodes and outgoing edges as additional decoder inputs to help generate the next word. In particular, for calculating the decoder hidden states $[s_{t+1}^1, s_{t+1}^2, ..., s_{t+1}^L]$ at step $t+1$, the input feature to our decoder is a triple $\langle \vec{y}_t, \vec{v}_t, \vec{e}_t \rangle$ instead of a

---

[3] This node is set as the parent of the original graph root (e.g. *possible-01* in Figure 2) with relation "*root*".

single value $\vec{y}_t$, which the baseline has. Here $\vec{y}_t$, $\vec{v}_t$ and $\vec{e}_t$ are vector representations of the predicted word, AMR node and edges at step t, respectively. More specifically, $\vec{v}_t$ is a weighted sum of the top-layer encoder hidden states $[h_0^L, h_1^L, ..., h_N^L]$, and coefficients are from the distribution of β'_t in Eq 7:

$$\vec{v}_t = \sum\nolimits_{i\in[0,...,N]} \beta'_{ti} \odot h_i^L, \tag{14}$$

where $\odot$ is the operation for scalar-tensor product.

Similarly, $\vec{e}_t$ is calculated as:

$$\begin{aligned}
\vec{e}_t &= \vec{r}_t \oplus \vec{s}_t, \\
\vec{r}_t &= \sum\nolimits_{k=1}^{|R|} \sum\nolimits_{j=1}^{t} p(r_k, y_j | y_t) \gamma_k, \\
\vec{s}_t &= \sum\nolimits_{j=1}^{t} p(y_j | y_t) s_j^L,
\end{aligned} \tag{15}$$

where $\oplus$ concatenates two tensors, $p(r_k, y_j|y_t)$ and $p(y_j|y_t)$ are probabilities given in Eq 12, γ_k is a relation embedding, and s_j^L is the decoder hidden state at step j. $\vec{e}_{t-1}$ is a vector concatenation of $\vec{r}_t$ and $\vec{s}_t$, which are weighted sum of relation embeddings and weighted sum of previous decoder hidden states, respectively.

In contrast to the baseline in Eq 3, at time ***t+1***, the hidden state of the **first** decoder layer is calculated as:

$$\begin{aligned}
\hat{s}_{t+1}^1 &= \text{SAN}(s_1^0, ..., s_t^0, \vec{y}_t, \vec{v}_t, \vec{e}_t), \\
c_{t+1}^1 &= \text{AN}(\hat{s}_{t+1}^1, H^L), \\
s_{t+1}^1 &= \text{FF}(c_{t+1}^1, \hat{s}_{t+1}^1),
\end{aligned} \tag{16}$$

where the definition of H^L, SAN, AN, FF and $[s_1^0, \dots, s_t^0]$ are the same as Eq 3. $\vec{v}_0$ and $\vec{e}_0$ (as shown in Figure 2) are defined as zero vectors. The hidden states of upper decoder layers $([s_{t+1}^2, ..., s_{t+1}^L])$ are updated in the same way as Eq 3.

Following previous work on syntactic text generation (Wu et al., 2017; Wang et al., 2018), we use gold AMR nodes and outgoing edges as inputs for training, while we take automatic predictions for decoding.

3.4 Training Objective

The overall training objective is:

$$\ell_{total} = \ell_{std} + \lambda_1 \ell_{node} + \lambda_2 \ell_{label}, \tag{17}$$

where λ_1 and λ_2 are weighting hyper-parameters for ℓ_{node} and ℓ_{label}, respectively.

Edge Prediction independent	31.13	35.69

Table 1: BLEU and Meteor scores on the LDC2015E86 devset under different model settings.

4 Experiments

We conduct experiments on two benchmark AMR-to-text generation datasets, including LDC2015E86 and LDC2017T10. These two datasets contain 16,833 and 36,521 training examples, respectively, and share a common set of 1,368 development and 1,371 test instances.

4.1 Experimental Settings

Data preprocessing. Following previous work (Song et al., 2018; Zhu et al., 2019), we take a standard simplifier (Konstas et al., 2017) to preprocess AMR graphs, adopting the Stanford tokenizer[4] and Subword Tool[5] to segment text into subword units. The node-to-word alignments are generated by ISI aligner (Pourdamghani et al., 2014). We then project the source AMR graph onto the target sentence according to such alignments.

For node prediction, the attention distributions are normalized, but the alignment scores generated by the ISI aligner are unnormalized hard $0/1$ values. To enable cross entropy loss, we follow previous work (Mi et al., 2016) to normalize the gold-standard alignment scores.

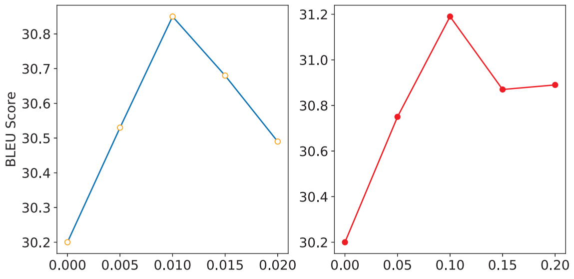
Hyperparameters. We choose the feature-based model[6] of Zhu et al. (2019) as our baseline (G-Trans-F-Ours). Also following their settings, both the encoder and decoder have 6 layers, with each layer having 8 attention heads. The sizes of hidden layers and word embeddings are 512, and the size of relation embedding is 64. The hidden size of the biaffine attention module is 512. We use Adam (Kingma and Ba, 2015) with a learning rate of 0.5 for optimization. Our models are trained for 500K steps on a single 2080Ti GPU. We tune these hyperparameters on the LDC2015E86 development

---

[4] https://nlp.stanford.edu/software/tokenizer.shtml

[5] https://github.com/rsennrich/subword-nmt

[6] We do not choose their best model (G-Trans-SA) due to its large GPU memory consumption, and its performance is actually comparable with G-Trans-F in our experiments.



(a) λ_1 for Node prediction

(b) λ_2 for Edge prediction

Figure 3: BLEU scores on the LDC2015E86 devset against different hyperparameter values.

set and use the selected values for testing[7].

Model Evaluation. We set the decoding beam size as 5 and take BLEU (Papineni et al., 2002) and Meteor (Banerjee and Lavie, 2005; Denkowski and Lavie, 2014) as automatic evaluation metrics. We also employ human evaluation to assess the semantic faithfulness and generation fluency of compared methods by randomly selecting 50 AMR graphs for comparison. Three people familiar with AMR are asked to score the generation quality with regard to three aspects — concept preservation rate, relation preservation rate and fluency (on a scale of [0, 5]). Details about the criteria are:

- Concept preservation rate assesses to what extent the concepts in input AMR graphs are involved in generated sentences.
- Relation preservation rate measures to what extent the relations in input AMR graphs exist in produced utterances.
- Fluency evaluates whether the generated sentence is fluent and grammatically correct.

Recently, significant progress (Ribeiro et al., 2019; Zhang et al., 2020; Çelikyilmaz et al., 2020) in developing new metrics for NLG evaluation has made. We leave evaluation on these metrics for future work.

4.2 Development Experiments

Table 1 shows the performances on the devset of LDC2015E86 under different model settings. For the node prediction task, it can be observed that both cross entropy loss (CE) and mean squared error loss (MSE) give significantly better results than the baseline, with 0.46 and 0.65 improvement in terms of BLEU, respectively. In addition, CE gives a better result than MSE.

Regarding edge prediction, we investigate two settings, with relation embeddings being shared by the encoder and decoder, or being separately constructed, respectively. Both settings give large improvements over the baseline. Compared with the model using independent relation embeddings, the model with shared relation embeddings gives slightly better results with less parameters, indicating that the relations in an AMR graph and the relations between words are consistent. We therefore adopt the CE loss and shared relation embeddings for the remaining experiments.

Model	LDC15	LDC17
LSTM (Konstas et al., 2017)	22.00	–
GGNN (Beck et al., 2018)	–	23.30

G-Trans-W (2M) (Wang et al., 2020)	36.4	-

Table 2: Test-set BLEU scores on LDC2015E86 (LDC15) and LDC2017T10 (LDC17).

Figure 3 presents the BLEU scores of integrating standard AMR-to-text generation with node prediction or edge prediction under different λ_1 and λ_2 values, respectively. There are improvements when increasing the coefficient from 0, demonstrating that both node prediction and edge prediction have positive influence on AMR-to-text generation. The BLEU of the two models reach peaks at $\lambda_1 = 0.01$ and $\lambda_2 = 0.1$, respectively. When further increasing the coefficients, the BLEU scores start to decrease. We thus set $\lambda_1 = 0.01, \lambda_2 = 0.1$ for the rest of our experiments.

4.3 Main Results

4.3.1 Automatic Evaluation

Table 2 shows the automatic evaluation results, where "*G-Trans-F-Ours*" and "*Ours Back-Parsing*" represent the baseline and our full model, respectively. The top group of the table shows the previous state-of-the-art results on the LDC2015E86 and LDC2017T10 testsets. Our systems give significantly better results than the previous systems using different encoders, including LSTM (Konstas et al., 2017), graph gated neural network (GGNN; Beck et al., 2018),

---

[7] Table 8 in Appendix shows the full set of parameters.

Setting	**CPR(%)**	**RPR(%)**	**Fluency**
LDC2015E86			
Baseline	92.19	88.79	4.08
Ours	**95.80**	**91.33**	**4.34**

Baseline	93.36	90.05	4.15
Ours	**96.63**	**92.21**	**4.42**

Table 3: Human evaluation of the sentences generated by different systems on concept presevation rate (CPR), relation preservation rate (RPR) and fluency.

Model	Cause	Contrast	Condition	Coord.
Baseline	0.84	0.92	0.91	**0.98**
Ours	**0.96**	**0.98**	**0.95**	**0.98**

Table 4: Human study for discourse preservation accuracy on LDC2015E86.

graph recurrent network (GRN; Song et al., 2018), densely connected graph convolutional network (DCGCN; Guo et al., 2019) and various graph transformers (G-Trans-F, G-Trans-SA, G-Trans-C, G-Trans-W). Our baseline also achieves better BLEU scores than the corresponding models of Zhu et al. (2019). The main reason is that we train with more steps (500K vs 300K) and we do not prune low-frequency vocabulary items after applying BPE. Note that we do not compare our model with methods by using external data.

Compared with our baseline (G-Trans-F-Ours), the proposed approach achieves significant ($p < 0.01$) improvements, giving BLEU scores of 31.48 and 34.19 on LDC2015E86 and LDC2017T10, respectively, which are to our knowledge the best reported results in the literature. In addition, the outputs of our model have 0.8 more words than the baseline on average. Since the BLEU metric tend to prefer shorter results, this confirm that our model indeed recovers more information.

4.3.2 Human Evaluation

As shown in Table 3, our model gives higher scores of concept preservation rate than the baseline on both datasets, with improvements of 3.6 and 3.3, respectively. In addition, the relation preservation rate of our model is also better than the baseline. This indicating that our model can preserve more concepts and relations than the baseline method, thanks to the back-parsing mechanism. With regard to the generation fluency, our model also gives better results than baseline. The main reason is that the relations between concepts such as *subject-predicate relation* and *modified relation* are helpful for generating fluency sentences.

Model	BLEU	Meteor
Baseline	30.15	35.36
+ Node Prediction	30.49	35.66
+ Node Prediction (Int.)	30.72	35.94
+ Edge Prediction	30.80	35.71
+ Edge Prediction (Int.)	31.07	35.87
+ Both Prediction	30.96	35.92
+ Both Prediction (Int.)	**31.48**	**36.15**

Table 5: Ablation study on LDC2015E86 test set.

Apart from that, we study discourse (Prasad et al., 2008) relations, which are essential for generating a good sentence with correct meaning. Specifically, we consider 4 common discourse relations ("Cause", "Contrast", "Condition", "Coordinating"). For each type of discourse, we randomly select 50 examples from the test set and ask 3 linguistic experts to calculate the discourse preservation accuracy by checking if the generated sentence preserves such information.

Table 4 gives discourse preservation accuracy results of the baseline and our model, respectively. The baseline already performs well, which is likely because discourse information can somehow be captured through co-occurrence in each (AMR, sentence) pair. Nevertheless, our approach achieves better results, showing that our back-parsing mechanism is helpful for preserving discourse relations.

4.4 Analysis

Ablation We conduct ablation tests to study the contribution of each component to the proposed model. In particular, we evaluate models with only the node prediction loss (Node Prediction, Section 3.1) and the edge prediction loss (Edge Prediction, Section 3.2), respectively, and further investigate the effect of integrating node and edge information into the next state computation (Section 3.3) by comparing models without and with (Int.) such integration.

Table 5 shows the BLEU and Meteor scores on the LDC2015E86 testset. Compared with the baseline, we observe a performance improvement of 0.34 BLEU by adding the node prediction loss only. When using the predicted AMR graph nodes as additional input for next state computation (i.e., Node Prediction (Int.)), the BLEU score increases from 30.49 to 30.72, and the Meteor score reaches 35.94, showing that the previously predicted nodes

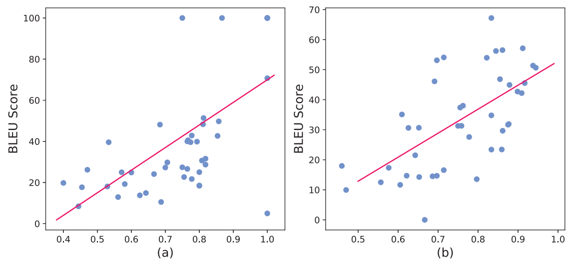

Figure 4: Performance (in BLEU) on the test set with respect to the node (a) and edge (b) prediction accuracy.

Setting	LDC2015E86	LDC2017T10
Node Prediction Acc.	0.65	0.71
Edge Prediction Acc.	0.56	0.59
Both Prediction Acc.	**0.69**	**0.73**

Table 6: The pearson correlation coefficient ρ between the prediction accuracy and BLEU.

are beneficial for text generation. Such results are consistent with our expectation that predicting the corresponding AMR node can help the generation of correct content words (a.k.a. concepts).

Similarly, edge prediction also leads to performance boosts. In particular, integrating the predicted relations for next state computation (Edge Prediction (Int.)) gives an improvement of 0.92 BLEU over the baseline. Edge prediction results in larger improvements than node prediction, indicating that relation knowledge is more informative than word-to-node alignment.

In addition, combining the node prediction and edge prediction losses (Both Prediction) leads to better model performance, which indicates that node prediction and edge prediction have mutual benefit. Integrating both node and edge predictions (Both Prediction (Int.)) further improves the system to 31.48 BLEU and 36.15 Meteor, respectively.

Correlation between Prediction Accuracy and Model Performance We further investigate the influence of AMR-structure preservation on the performance of the main text generation task. Specifically, we first force our model to generate a gold sentence in order to calculate the accuracies for node prediction and edge prediction. We then calculate the corresponding BLEU score for the sentence generated by our model on the same input AMR graph without forced decoding, before drawing correlation between the accuracies and the BLEU score. As shown in Figure 4(a) and 4(b)[8], both node accuracy and edge accuracy have

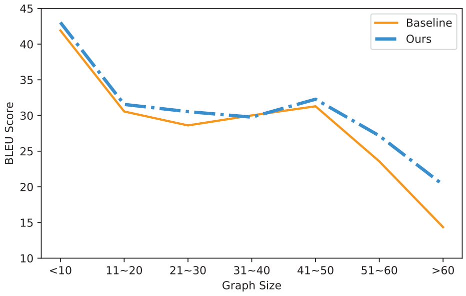

Figure 5: Performances (in BLEU) on the test set with respect to the size of the input AMR graphs.

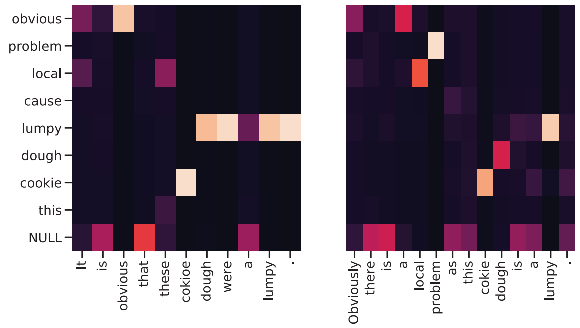

Figure 6: Visualization of word-to-node attention obtained from the baseline graph Transformer (left) and our model with node prediction loss (right).

a strong positive correlation with the BLEU score, indicating that the more structural information is retained, the better the generated text is.

We also evaluate the pearson (ρ) correlation coefficients between BLEU scores and node (edge) prediction accuracies. Results are given in Table 6. Both types of prediction accuracies have strong positive correlations with the final BLEU scores, and their combination yields further boost on the correlation coefficient, indicating the necessity of jointly predicting the nodes and edges.

Performances VS AMR Graphs Sizes Figure 5 compares the BLEU scores of the baseline and our model on different AMR sizes. Our model is consistently better than the baseline for most length brackets, and the advantage is more obvious for large AMRs (size 51+).

4.5 Case Study

We provide two examples in Table 7 to help better understand the proposed model. Each example consists of an AMR graph, a reference sentence (**REF**), the output of baseline model (**Baseline**) and the sentence generated by our method (**Ours**).

As shown in the first example, although the baseline model maintains the main idea of the

---

[8] For clear visualization, we only select the first one out of every 30 sentences from the LDC2015E86 testset.

(1)
```
(o / obvious-01
    :ARG1 (p / problem
        :ARG1-of (l / local-02))
    :ARG1-of (c / cause-01
        :ARG0 (l2 / lumpy
            :domain (d / dough
                :mod (c2 / cookie)
                :mod (t / this)))))
```
REF: Obviously there are local problems because this cookie dough is lumpy .

Baseline: It is obvious that these cookie dough were a lumpy .

Ours: Obviously there is a local problem as this cookie dough is a lumpy .

(2)

        :ARG1 (c2 / case
            :ARG1-of (b / bad-05
                :degree (m / more
                    :quant (m2 / much)))))
    :ARG1 (w / worry :polarity - :mode imperative
        :ARG0 (y / you)
        :ARG1 (t / that)))
```
REF: Doctors have seen much worse cases so don't worry about that !

Baseline: Don't worry about that see much worse cases by doctors .

Ours: Don't worry that , as a doctor saw much worse cases .

Table 7: Examples for case study.

original text, it fails to recognize the AMR graph nodes *"local"* and *"problem"*. In contrast, our model successfully recovers these two nodes and generates a sentence which is more faithful to the reference. We attribute this improvement to node prediction. To verify this, we visualize the word-to-node attention scores of both approaches in Figure 6. As shown in the figure, the baseline model gives little attention to the AMR node *"local"* and *"problem"* during text generation. In contrast, our system gives a more accurate alignment to the relevant AMR nodes in decoding.

In the second example, the baseline model incorrectly positions the terms *"doctor"*, *"see"* and *"worse cases"* while our approach generates a more natural sentence. This can be attributed to the edge prediction task, which can inform the decoder to preserve the relation that *"doctor"* is the subject of *"see"* and *"worse cases"* is the object.

5 Related Work

Early studies on AMR-to-text generation rely on statistical methods. Flanigan et al. (2016) convert input AMR graphs to trees by splitting re-entrances, before translating these trees into target sentences with a tree-to-string transducer; Pourdamghani et al. (2016) apply a phrase-based MT system on linearized AMRs; Song et al. (2017) design a synchronous node replacement grammar to parse input AMRs while generating target sentences. These approaches show comparable or better results than early neural models (Konstas et al., 2017). However, recent neural approaches (Song et al., 2018; Zhu et al., 2019; Cai and Lam, 2020; Wang et al., 2020; Mager et al., 2020) have demonstrated the state-of-the-art performances thanks to the use of contextualized embeddings.

Related work on NMT studies back-translation loss (Sennrich et al., 2016; Tu et al., 2017) by translating the target reference back into the source text (reconstruction), which can help retain more comprehensive input information. This is similar to our goal. Wiseman et al. (2017) extended the reconstruction loss of Tu et al. (2017) for table-to-text generation. We study a more challenging topic on how to retain the meaning of a complex graph structure rather than a sentence or a table. In addition, rather than reconstructing the input *after* the output is produced, we predict the input *while* the output is constructed, thereby allowing stronger information sharing.

Our work is also remotely related to previous work on string-to-tree neural machine translation (NMT) (Aharoni and Goldberg, 2017; Wu et al., 2017; Wang et al., 2018), which aims at generating target sentences together with their syntactic trees. One major difference is that their goal is producing grammatical outputs, while ours is preserving input structural information.

6 Conclusion

We investigated back-parsing for AMR-to-text generation by integrating the prediction of projected AMRs into sentence decoding. The resulting model benefits from both richer loss and more structual features during decoding. Experiments on two benchmarks show advantage of our model over a state-of-the-art baseline.

A Appendices

A.1 Full Experimental Settings

Table 8 lists all model hyperparameters used for experiments. Specifically, we share the vocabulary of AMR node BPEs and target word BPEs. Our implementation is based on the model of Zhu et al. (2019), which is available at `https://github.com/Amazing-J/structural-transformer`. Our re-implementation and the proposed model are released at `https://github.com/muyeby/AMR-Backparsing`.

A.2 More Results

We compare our model with more baselines and use more evaluation metrics (BLEU (Papineni et al., 2002), Meteor (Banerjee and Lavie, 2005; Denkowski and Lavie, 2014) and CHRF++ (Popović, 2017)). The results are shown in Table 9. It can be observed that our approach achieves the best performance on both datasets regardless of the evaluation metrics. This observation is consistent with Table 2.

Reading Between the Lines: Exploring Infilling in Visual Narratives

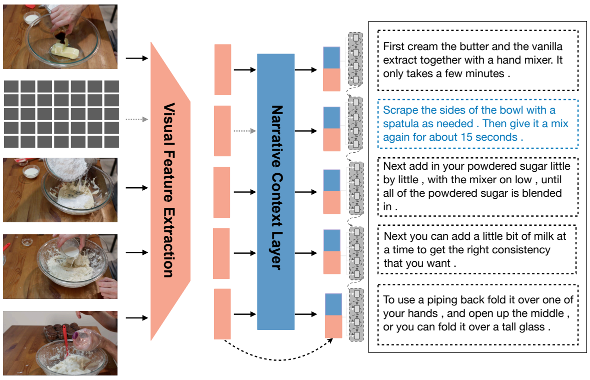
Abstract

Generating long form narratives such as stories and procedures from multiple modalities has been a long standing dream for artificial intelligence. In this regard, there is often crucial subtext that is derived from the surrounding contexts. The general seq2seq training methods render the models shorthanded while attempting to bridge the gap between these neighbouring contexts. In this paper, we tackle this problem by using *infilling* techniques involving prediction of missing steps in a narrative while generating textual descriptions from a sequence of images. We also present a new large scale *visual procedure telling* (ViPT) dataset with a total of 46,200 procedures and around 340k pairwise images and textual descriptions that is rich in such contextual dependencies. Generating steps using infilling technique demonstrates the effectiveness in visual procedures with more coherent texts. We conclusively show a METEOR score of 27.51 on procedures which is higher than the state-of-the-art on visual storytelling. We also demonstrate the effects of interposing new text with missing images during inference. The code and the dataset will be publicly available at https://visual-narratives.github.io/Visual-Narratives.

1 Introduction

Humans process information from their surrounding contexts from multiple modalities. These situated contexts are often derived from a modality (source) and expressed in another modality (target). Recent advances have seen a surge of interest in vision and language as source and target modalities respectively. One such widely studied task is image captioning (Hossain et al., 2019; Liu et al., 2019) which provides a textual description T given an image I. In contrast, visual storytelling (Huang et al., 2016) is the task of generating a sequence of textual descriptions ($\{T_1, T_2, ..., T_n\}$) from a sequence of images ($\{I_1, I_2, ..., I_n\}$).



First cream the butter and the vanilla extract together with a hand mixer. It only takes a few minutes .

Scrape the sides of the bowl with a spatula as needed . Then give it a mix again for about 15 seconds .

Next add in your powdered sugar little by little , with the mixer on low , until all of the powdered sugar is blended in .

Next you can add a little bit of milk at a time to get the right consistency that you want .

To use a piping back fold it over one of your hands , and open up the middle , or you can fold it over a tall glass .

Figure 1: Overview of infilling in visual procedures. Image in the second step is masked while the model generates the corresponding textual description from surrounding context.

A fundamental incongruity between how humans process information from multiple modalities and how we teach machines to do the same is that, humans are capable of bridging the information gap from surrounding contexts. Traditionally, the problem of missing context in long text generation is addressed using additional input such as entities, actions, etc., (Fan et al., 2019; Dong et al., 2019). In contrast, in the spirit of simplicity, we propose infilling techniques to interpolate the gap between surrounding contexts from a stream of images. We focus on two kinds of visual narratives namely, stories and procedures. We curated a large scale *ViPT* dataset with pairwise image and text descriptions comprising of 46k procedures and 340k images. The percentage of unique words in each step in comparison to the rest of the recipe is about 60% for ViST and 39% for ViPT. This implies that overlapping contexts are predominant in procedures than stories datasets. This is usually because stories are more creative and diverse while procedures are in-domain. For both these reasons, we hypothe-

Table 1: Details of the ViST and *Visual Procedure Telling* Dataset broken down into 10 categories

size that infilling technique is more effective in scenarios where it can leverage the vast context from the surrounding information to filling the missing pieces. To this end, we present our infilling based model to perform visual narrative generation and compare its effects on visual stories and procedures. The overview of the infilling bassed training procedure is presented in Figure 1. We conclusively observe that it is more effective in procedural texts with stronger contextual dependencies. Interpolating contexts to generate narrative descriptions has potential applications in fields such as digital education (Hollingshead, 2018), social media content (Gella et al., 2018), augmented reality (Dudley et al., 2018), video games (Kurihara et al., 2019; Ammanabrolu et al., 2019), etc,.

The main contributions of this paper are:

• We present a Visual Procedure Telling (ViPT) dataset similar to the Visual Storytelling (ViST) dataset with 46k procedures on various domains.

• We demonstrate the efficacy of our visual infilling technique on narratives that have stronger contextual dependencies on the rest of the sentences.

2 Related Work

Multimodal Language: Language generation from visual modality has seen a steep rise in interest with the introduction of several large scale tasks such as image captioning (Hossain et al., 2019), visual question answering (Antol et al., 2015) and visual dialog (Das et al., 2017; Mostafazadeh et al., 2017; De Vries et al., 2017).

Visual Storytelling: Huang et al. (2016) ventured into sequential step wise generation of stories by introducing visual storytelling (ViST). Chandu et al. (2019) also proposed a dataset of 16k recipes in a similar form. Recent methods have tackled ViST using adversarial learning, reinforcement learning (Wang et al., 2018; Huang et al., 2019; Hu et al., 2019), modality-fusion (Smilevski et al., 2018), traditional seq2seq models (Kim et al., 2018; Jung et al., 2020; Hsu et al., 2018) and explicit structures (Bosselut et al., 2016; Bisk et al., 2019). Though the stories in ViST demonstrate a sense of continuity, the overarching sequential context is feeble. Procedures such as cooking recipes (Salvador et al., 2019; Wang et al., 2019) on the other hand, demonstrate this characteristic inviolably. Hence, we present a large scale ViPT dataset to encourage research in this direction.

Infilling and Masking: The idea is motivated by cloze tasks (Taylor, 1953) that addresses readability and understanding. However, recent advances in learning a masked language model (Devlin et al., 2019) paved way for a new trend in exploring masked contexts (Song et al., 2019; Lewis et al., 2019). Generation of meaning patches with missing portions of text is experimented by Zhu et al. (2019); Donahue et al. (2020); Fedus et al. (2018) to generate meaningful patches.Similarly, Ippolito et al. (2019) proposed a hierarchical model to generate middle span using a bag of predicted words from left and right contexts. In a similar spirit, this paper studies the effects of infilling techniques for visual narrative generation. An alternate stream of work to improve the context in stories include providing supporting information such as entities (Clark et al., 2018; Xu et al., 2018), latent templates (Wiseman et al., 2018), knowledge graphs (Yang et al., 2019), etc., explicitly. In contrast to this, infilling provides an opportune platform to implicitly learn the contextual information. Our work is positioned in the intersection of infilling and multimodal language generation.

3 Dataset Description

This section describes our new ViPT dataset and highlights the differences with ViST.

Procedures vs Stories: Narrative properties such as content and structure in these forms are sufficiently contrastive (Gatt and Krahmer, 2018). Content in stories include characters and events while procedures include ingredients, materials and actions. While stories start from setting an era to characterizing participants, procedures start by listing ingredients followed by a step by step description.

Dataset	Stories				Recipes			
Model	XE	V-Infill	V-InfillR	INet	XE	V-Infill	V-InfillR	INet
BLEU-1	62.05	61.58	61.84	**63.31**	28.61	**29.73**	28.61	25.10
BLEU-2	38.31	37.27	37.81	**39.60**	16.89	**17.50**	17.01	13.36
BLEU-3	22.68	21.70	22.42	**23.62**	10.50	**10.83**	10.59	6.51
BLEU-4	13.74	12.96	13.69	**14.30**	5.68	**5.81**	5.71	3.60
METEOR	35.01	34.53	35.08	**35.57**	26.72	27.26	**27.51**	25.62
ROUGE_L	29.66	29.12	29.65	**30.14**	21.64	**22.02**	18.66	20.43

Table 2: Performance of different models on stories (from ViST) and recipes (from ViPT) datasets

ViPT dataset: Though stories have the potential to exhibit the properties listed above, it is challenging to observe them in ViST dataset (Huang et al., 2016) owing to the shorter sequence lengths. To facilitate multi-domain research with stronger interleaved contexts between surrounding steps, we present a large scale *visual procedure telling* dataset with 46k procedures comprising of 340k pairwise images and textual descriptions. It is carefully curated from a number of *how-to* blogging websites. Our dataset comprises of pairwise images and textual descriptions of the corresponding images, typiccally describing a step in a procedure. This means that each description of the step is tethered to an image. We categorized the dataset into 10 distinct domains including recipes, crafts, outdoors, lifestyle, technology, styling, fitness, hobbies, pets and miscellaneous. The category wise details of the dataset are presented in Table 1.

Differences between ViPT and ViST datasets: As observed in Table 1, the average number of steps in ViPT is higher than ViST. The average number of words per step in ViPT is also much higher, thereby presenting a more challenging long form text generation task. Typically, each step in the ViPT dataset comprises of multiple sentences as opposed to ViST which is a single sentence. These long sequences also present a case for dealing with larger vocabularies as well. The recipes category alone has a vocabulary of 109k tokens while the same for stories is 25k. We also compared the diversity in vocabulary of each step by computing the average percentage of unique words in a step with respect to the rest of the narrative. While this number is a high 60% for ViST, it is 39% for ViPT. This reveals the stronger cohesive and overlapping contexts in the ViPT dataset, as compared to the ViST datasets. These overlapping contexts motivates the idea of generating a sentence by bridging the contexts from surrounding sentences. Hence it forms a suitable test bed to learn interpolation with infilling technique.

4 Models Description

We present infilling based techniques for learning missing visual contexts to generate narrative text from a sequence of images. As the ViST and recipes category in ViPT are of comparable sizes (both in terms of data size and the average number of steps per instance), we perform comparative experimentation on these two categories. For our ViPT category, We use 80% for training, 10% for validation and 10% for testing. An overview of infilling based training is depicted in Figure 1. The underlying encoding and decoding stages are described here.

Encoding: Models 1, 2 and 3 here show different variants of encoding with and without infilling.

1. XE (baseline): We choose a strong performing baseline model based on sequence to sequence modeling with cross entropy (XE) loss inspired from Wang et al. (2018). The visual features are extracted from the penultimate layer of ResNet-152 by passing the resized images ($\{I_1, I_2, ..., I_n\}$) of size 224 X 224. These represent the image specific local features ($\{l_1, l_2, ..., l_n\}$). These features are then passed through a bidirectional GRU layer to attain narrative level global features ($\{g_1, g_2, ..., g_n\}$) constituting the narrative context layer in Figure 1.

2. V-Infill: We introduce an infilling indicator function on the underlying XE model by randomly sampling an infilling index (in_{idx}). This is used to construct the final infilled local features as follows.

$$l_k(\forall k, s.t. 0 < k \leq n) = \begin{cases} zero\_tensor & \text{if k=}in_{idx} \\ l_k & \text{otherwise} \end{cases}$$

Other than the sampled in_{idx}, the rest of the local features for other indices remain the same. The local features for in_{idx} are all masked to a zero tensor. The dropout of an entire set of local features from an image forces the model to learn to bridge the context from the left and the right images of in_{idx}. In this way, the infilling mechanism encourages our underlying seq2seq model to learn the local

Infill Index	0		1		2		3		4		5

representation from contextual global features in the narrative context layer.

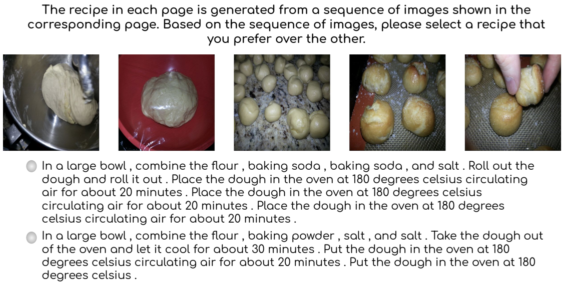
3. V-InfillR: This model varies the **R**ates in which local features are masked as training proceeds based on the indicator function above in the V-Infill model. Scheduling the number of missing features itself is a hyperparameter and we used the following setting. In the first quarter of training epochs, none are masked, then increasing it to 1 local feature for the next quarter and leaving it at 2 for the last two quarters.

Decoding: In all the above models, g_k are fed into a GRU decoder to predict each word ($\hat{\boldsymbol{w}}_t$) of the step (k). We perform beam search with a beam size of 3 during inference.Here τ is the number of words in each step and t is the current time step.

$$\hat{\boldsymbol{w}}_t \sim \prod_{\tau} Pr(\hat{\boldsymbol{w}}_t^{\tau} | \hat{\boldsymbol{w}}_t^{<\tau}, \boldsymbol{g}_k)$$

4. INet: We reimplemented the model achieving the state of the art results (Hu et al., 2019) on the visual storytelling dataset. Additionally, they use a relational embedding layer that captures relations across spatio-temporal sub-spaces. Our replication of their model is close, achieving a 35.5 METEOR and 63.3 BLEU-1 in comparison to the scores reported in their paper which are 35.6 and 64.4.

Hyperparameter Setup: We use a GRU with hidden dimension of 256 for encoder and 512 for decoder. The word embedding dimension is 512. The learning rate is 4e-4 optimized with Adam and smoothing of 1e-8. We use a dropout of 0.2 and momentum of 0.9 with a gradient clipping of 10.



The recipe in each page is generated from a sequence of images shown in the corresponding page. Based on the sequence of images, please select a recipe that you prefer over the other.

○ In a large bowl , combine the flour , baking soda , baking soda , and salt . Roll out the dough and roll it out . Place the dough in the oven at 180 degrees celsius circulating air for about 20 minutes . Place the dough in the oven at 180 degrees celsius circulating air for about 20 minutes . Place the dough in the oven at 180 degrees celsius circulating air for about 20 minutes .

○ In a large bowl , combine the flour , baking powder , salt , and salt . Take the dough out of the oven and let it cool for about 30 minutes . Put the dough in the oven at 180 degrees celsius circulating air for about 20 minutes . Put the dough in the oven at 180 degrees celsius .

Figure 2: Human Evaluation Interface for an example of generated recipes with both techniques.

The performance when experimented with a transformer based encoder along with autoregressive decoding is comparatively lesser and hence we proceed with a GRU based model. Based on the average number of steps in recipes from Table 1 which is 5.96, we truncate the recipes to 6 steps.

5 Results and Discussion

In this section, we present the effects of infilling both during both training and inference on ViST and ViPT datasets.

Infilling during training: The overall performance of the models is presented in Table 2. Both the infilling model variants achieve higher scores on the recipes while not decreasing their performances on stories. We also observed that increasing the number of masked local features beyond 2 drastically decreases the performance on both datasets.

Infilling during inference: Acquiring parallel pairwise image and narrative data in the wild is

		0 	1 	2 	3 	4 	5 	***Analysis***
GT		**There are only a few components necessary to sear meat and make a pan sauce.**	**Trim the fat around the meat until almost none is left .**	**Dry the meat by blotting it with paper towels .**	**Heat a little oil on a stainless steel or cast iron skillet on high heat and wait for the oil to start smoking .**	**After 3-5 minutes pass , use a spatula to check the meat.**	**Once the meat is to your desired temperature , rest on a plate and cover with foil , 5-10 minutes .**	
XE	0	Cut the chicken into small pieces .	The first thing you will need to do is put the meat in the pan .	Heat the oil in a pan and add the olive oil .	Add the salt and pepper to the pan .	Once the chicken is cooked , remove the chicken from the oven and let it cool for about 10 minutes .	Now that you have a hot pan , it 's time to cook the chicken .	- The content step 1 is being copied to step 0. - Recovering from incorrect steps until step 2.
	4	For this recipe you will need the following ingredients : - 1 cup of water , salt and pepper	Cut the chicken breast into small pieces .	The first thing you need to do is put the meat in the pan and let it cool for about 10 minutes .	Place the pan on the stove and heat the pan on medium heat .	Make sure it is properly cooked.	Once the chicken is done , remove the chicken from the oven and let it cool for a few minutes	- The infilled sentence at step 4 is generic and underspecified
V-Infill	0	You will need the following ingredients	Cut the chicken breast into small pieces .	Add the chicken to the pan .	Heat the oil in a frying pan over medium heat .	Once the chicken is done , add the chicken to the pan and stir it up .	Now that you have a little bit , you will need to put the meat in the oven at 180 degrees celsius circulating air for about 20 minutes .	+ Step 0 talks about ingredients. - The ingredients are still underspecified.
	4	You will need the following ingredients : - meat , 1 cup of butter and salt	Cut the onion into small pieces .	Cut the chicken breast into small pieces .	Heat the oil in a frying pan over medium heat .	Once the chicken is ready , add the chicken to the pan .	Once the chicken is done , remove the pan from the pan and let it sit for about 10 minutes .	+ Step 0 talks about ingredients. - Phrase from step 5 copied to step 4

Figure 3: Comparison of V-Infill and XE dealing with infilling context during inference (for making *chicken roast*). GT corresponds to the ground truth step. The index in each row corresponds to the index of the missing image.

often not feasible. Hence, we perform infilling not only at train time but also at inference time to evaluate the ability of the model to bridge contexts when the corresponding image is absent and deal with real world data imputation scenarios. Figure 3 demonstrates an example of generated samples by infilling different indices. As observed, the XE model either generates generic sentences to infill content or copies the content from the surrounding contexts. In contrast, the V-Infill model is able to generate new sentences with small phrases of sentences being copied. Underspecification of content is an issue in both these models where there is a room for improvement.

Lengths of generated sequences : We compare infilling during inference between baseline XE model and our V-Infill model in Table 3. While the METEOR scores remain comparable, the BLEU scores steadily increase as we move the in_{idx} to the right. Specifically, these jumps are bigger after step 3. Quantitatively, this is the result of the model being able to produce longer sequences as we move to the right as BLEU gets penalized for short sentences. Qualitatively, this implies that the initial steps like specifying the ingredients are more crucial as compared to later ones. A similar observation emerges by analyzing the effects of infilling during training. The average length of generated recipes by XE is 71.26 and by V-Infill is 76.49. A similar trend is observed for stories in Table 4.

Human Evaluation: We also conducted human evaluation (interface in Figure 2) in the form of preference testing comparing our V-Infill model with XE by randomly sampling 10 recipes. Among 20 evaluators, our V-Infill model is preferred 64% of the times over the XE model on an average.

6 Conclusions and Future Work

We demonstrate that infilling is a simple yet effective technique and a step towards maximizing the utilization of surrounding contexts in visual narratives. Infilling is the strategy of enabling the model to learn surrounding contextual information by masking spans of input while the decoding attempts in generating the entire text. To experimentally support our hypothesis, we collect a new large scale ViPT dataset of 46k procedures comprising 10 categories. We compare the performance of our model and conclusively show the higher significance of infilling based techniques in visual procedures compared to visual stories. In future, we plan to explore the following two directions: (1) interpolating the contexts between consecutive steps by introducing a new infilled image, and (2) addressing the underspecification problem by controlling the content in infilled image with explicit guidance. These infilling techniques are also immensely useful when dealing with data imputation with missing contexts and collaborative authoring in real world scenarios.

7 Supplemental Material

1. Human Evaluation: Figure 2 depicts a screenshot of our human evaluation interface. A sequence of images are presented on top of the screen. This evaluation is conducted to compare between XE and V-Infill model. The generated sentences from the 2 models, in this case XE and V-Infill are presented after the images. Note that the generated outputs are presented in arbitrarily random order for each example to ensure there is no bias while performing preference testing. Human subjects are asked to pick one of the generated recipes for the given sequence of images. 10 such recipes are presented for each user and we avergaed the preference scores among 20 users.

2. Data Collection Process: We manually examined around 10 blogging websites with various user written text on several *how-to* activities. Among these we found that *snapguide* and *instructables* are consistent in the form of pairs of textual descriptions along with their images. We are going to release the scripts used to collect this data as well as preprocess them. We removed all the procedures in which atleast one image in each step is absent. Once all this preprocessing is done, the data contained the following categories in both the websites. These categories are based on the tags given by the bloggers to the articles they have written from among the categories that each website offers. These categories for each of these websites are:

- *snapguide:* recipes, games-tricks, sports-fitness, gardening, style, lifestyle, outdoors, beauty, arts-crafts, home, music, photography, pets, automotive, technology
- *instructables:* crafts, cooking, teachers, circuits, living, workshop, outside

In union, they are a total of 18 categories. We manually examined a few procedures in each of the categories and regrouped them into 10 broad categories that are presented in Table 1. A list of urls corresponding to the data is submitted along with the paper.

3. Visualization of topics: Each of the categories in our Visual Procedure Telling (ViPT) are analyzed for the topics present in them. A screenshot highlighting one of the topics in recipes category is presented in Figure 4. To get a more detailed understanding of these topics in the dataset, we hosted the topic visualizations here: visual-narratives.github.io/Visual-Narratives/.

category	snapguide	instructables
recipes	desserts, food	cooking
crafts	arts-crafts	craft
outdoors	outdoors, gardening	outside
lifestyle	lifestyle, home	living
technology	technology, automotive	circuits
styling	style, beauty	
fitness	sports-fitness	
hobbies	music, photography	
pets	pets	
misc	games-tricks	teachers, workshop

Table 5: Regrouping the categories in ViPT dataset

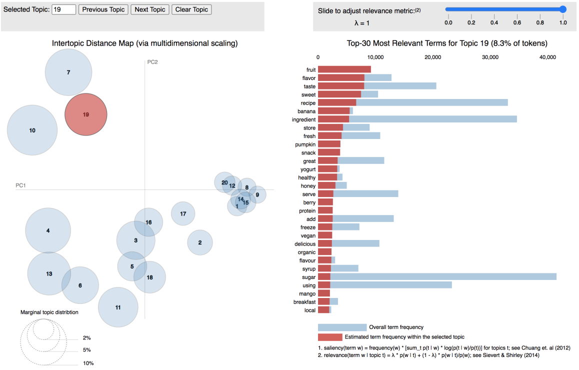

Figure 4: Visualization of topic model for recipes category

4. Performance of infilling during inference for Visual Story Telling: Table 4 demonstrates the effects of infilling various indices during inference. This table is analogous to Table 3 for stories. As we can see, a similar trend in the increase in all the automatic metrics are present as we move the infill index to the right of the story. While that is still the case, a very interesting observation is that the difference between the performance of XE and Infill models for any given index is much higher for recipes compared to stories. The infilling technique is bringing much more value to the task when the nature of the text is procedural and dependent more on the surrounding contexts.

5. Reproducibility Checklist:

1. **For all reported experimental results:**
   (a) *A clear description of the mathematical setting, algorithm, and/or model:* Yes. There are two important definitions to understand in the paper. The first is the task definition which is outlined in Section 1. The second is the infilling technique definition which is presented in Section

Hyperparameter	Value
Num of Epochs	100
Batch size	64
Learning rate	4e-4

Optimizer	Adam
alpha for Adam	0.8
beta for Adam	0.99
Adam smoothing	1e-8
Word Embedding dim	512
Visual feature dim (ResNet)	2048
Num of GRU layers	1
GRU Hidden dim	512
Beam width	3

Table 6: Hyperparameters of the best performing model

4.

(b) *Submission of a zip file containing source code, with specification of all dependencies, including external libraries, or a link to such resources (while still anonymized):* No. Though they are not submitted along with the paper, we plan to release both the code and the data along with the scripts to preprocess the data here: visual-narratives.github.io/Visual-Narratives/

(c) *Description of computing infrastructure used:* The models are trained on a GPU with driver version 430.26 and CUDA version 10.2. The GPU RAM being used have a maximum size of 8GB and 12 GB for different experiments. A few of the experiments are run on GeForce GTX 1070 with 1920 cores and GeForce GTX 1080 Ti with 3584 cores.

(d) *Average runtime for each approach:* On an average the experiments on the visual procedure telling dataset took around 8 hours and the same on the visual story telling dataset took around 11 hours. These numbers are the averages of the 4 different models on each dataset comprising of XE, V-Infill, V-InfillR and INet.

(e) *Number of parameters in each model:* For the models pertaining to XE, V-Infill and V-InfillR, the number of parameters are listed below. For the ViPT dataset, the number of trainable parameters are 15,665,896. For the ViST dataset, the number of trainable parameters are 14,390,894. The INet model for the ViPT dataset has 19,345,128 and on the stories data is 18,070,126. As we can see, the infilling variants are able to achieve better performance on procedural texts with comparatively fewer parameters. This justifies our hypothesis that infilling is a simple yet effective technique to perform text generation where there are strong contextual dependencies.

(f) *Explanation of evaluation metrics used, with links to code:* The automatic metrics are evaluated using BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and ROUGE_L (Lin and Och, 2004). The scripts used to evaluate will be released along with the code. We adapted the standard code that computes the aforementioned metrics for the task of MS COCO image captioning challenging for our task. The code for the metrics can be found here: github.com/microsoft/DialoGPT/tree/master/pycocoevalcap. The code in the above repository is not ours. We simply used their evaluation scripts for our task.

2. **For all experiments with hyperparameter search:**

(a) *Bounds for each hyperparameter:* For the scheduling of the infilling, we tried the following settings. We experimented with the following settings. The first setting is: (i) 0 images for first quarter (ii) 1 image for second quarter (iii) 2 images for the last half number of epochs. The second setting is: (i) 0 images for first quarter (ii) 1 image for 2 quarters (iii) 2 images for the last quarter number of epochs. The third setting is: (i) 1 images for first quarter (ii) 2 image for second quarter (iii) 3 images for the last half number of epochs. The fourth setting is: (i) 0 images for first quarter (ii) 1 image for second quarter (iii) 2 images for the third quarter (iv) 3 images for the last quarter number of epochs. For the rest of the hyperparameters, we used the same as the baseline. We contacted the authors of the INet model, which is the state-of-the-art on visual storytelling for the hyperparameter values they have used and used the same in our work to replicate their results and perform reliable comparisons.

   (b) *Hyperparameter configurations for best-performing models:* The hyperparameters for the best performing model are descibed in Section 4. A more detailed set of the hyperparameters are presented in Table 6.
   (c) *Number of hyperparameter search trials:* The important hyperparameter that we tuned is the scheduling of infilling. The hyperparam that performed best is described in Section 4. In total, we have tried 4 settings to arrive pick the best setting.
   (d) *The method of choosing hyperparameter values (e.g., uniform sampling, manual tuning, etc.) and the criterion used to select among them (e.g., accuracy):* We performed manual tuning in various settings for the rate of infilling in the V-InfillR model. The criterion used to select the best model is METEOR score, which is the automatic metric to evaluate our model.
   (e) *Expected validation performance, or the mean and variance as a function of the number of hyperparameter trials:*

3. **For all datasets used:**
   (a) *Relevant statistics such as number of examples:* The statistics of the ViPT dataset along with category wise distribution for the number of procedures, number of steps, average number of steps and average number of words per step are presented in Table 1. The same table also compares these distributions with the ViST dataset.
   (b) *Details of train/validation/test splits:* The splits to perform training, validation and testing are readily available for ViST dataset. For our newly collected ViPT dataset, we conduct experiments on the recipes category. These splits are done for this dataset as 80% for training, 10% for validation and 10% for testing.
   (c) *Explanation of any data that were excluded, and all pre-processing steps:* The data is cleaned of any html tags as they are collected from the blogging websites.
   (d) *A link to a downloadable version of the data:* We plan to release the preprocessed data along with visual features. It will be avaialable for download here: visual-narratives.github.io/Visual-Narratives/
   (e) *For new data collected, a complete description of the data collection process, such as instructions to annotators and methods for quality control:* We collected the data from *how-to* blogging websites. From the collected procedures, we perform an additional step of removing the ones that do not have any images. We keep the procedures in the final dataset that have at least one image per step. Additionally, we manually inspected the different types of procedures and categorized them into the 10 categories as mentioned in the paper.

Acrostic Poem Generation

Abstract

We propose a new task in the area of computational creativity: acrostic poem generation in English. Acrostic poems are poems that contain a hidden message; typically, the first letter of each line spells out a word or short phrase. We define the task as a generation task with multiple constraints: given an input word, 1) the initial letters of each line should spell out the provided word, 2) the poem's semantics should also relate to it, and 3) the poem should conform to a rhyming scheme. We further provide a baseline model for the task, which consists of a conditional neural language model in combination with a neural rhyming model. Since no dedicated datasets for acrostic poem generation exist, we create training data for our task by first training a separate topic prediction model on a small set of topic-annotated poems and then predicting topics for additional poems. Our experiments show that the acrostic poems generated by our baseline are received well by humans and do not lose much quality due to the additional constraints. Last, we confirm that poems generated by our model are indeed closely related to the provided prompts, and that pretraining on Wikipedia can boost performance.

1 Introduction

Poetry, derived from the Greek word *poiesis* (”making”), is the art of combining rhythmic and aesthetic properties of a language to convey a specific message. Its creation is a manifestation of creativity, and, as such, hard to automate. However, since the development of creative machines is a crucial step towards real artificial intelligence, automatic poem generation is an important task at the intersection of computational creativity and natural language generation, and earliest attempts date back several decades; see Gonçalo Oliveira (2017) for an overview.

Translated kings.

Figure 1: An acrostic poem generated by our proposed baseline model for the word *poet*.

With this paper, we add a new task to this research area: acrostic poem generation in English. Acrostic poems, or simply *acrostics*, are a special type of poetry, in which typically the first letter of each line spells out a word or message, as in the example in Figure 1. While this is the only formal characteristic of an acrostic, we here define the task of acrostic poem generation as generating poems such that, additionally, poems should also both rhyme and relate to the topic of their hidden word, e.g., the content of the poem in Figure 1 should be related to the word ”poet”. As far as meter is concerned, we are interested in free verse poems. Acrostic poem generation, as we define it, is a challenging *constrained generation* task with multiple constraints: semantic ones (the content of the poem should follow a given topic), and structural ones (the poem should rhyme, and the first letters should spell out a given word).

We further propose a baseline model for the task, which we call the *neural poet*. It is a generative model, which consists of two components: a conditional neural language model, which generates an acrostic poem based on a given word, and a rhyming model, trained on sonnets, which generates rhyming words for the last position in each line. Furthermore, two acrostic-specific challenges need to be solved: (i) generating such that the first letters of all lines spell out the defined word, and (ii) making sure that the resulting poem relates to

Table 1: Number of poems in our datasets used for training, listed by the number of lines they contain.

the topic of that word. We address the first challenge by limiting the choices in the output softmax during sampling from the language model. For the second challenge, we feed the word embedding of the topic to the language model at each time step. Since no large datasets for the task are available, we scrape poems for given key words from the web and train a separate discriminative model to predict topics, which we then use to predict silver standard topics for a larger poem dataset. Our final model is trained on a combination of poems with predicted and gold topics.

Human evaluation on *fluency*, *meaningfulness*, and *poeticness* (Manurung, 2003) shows that our additional constraints hardly reduce performance as compared to unconstrained generation. Further, our poems relate to the acrostic word, even if the topic does not appear in the training set. Finally, we show that model performance—in terms of perplexity on a held-out validation set—can be improved by pretraining on Wikipedia.

2 Datasets

To train the baseline model for our new task, we make use of 4 datasets, which we will describe here, before explaining the actual model in the next section.

KnownTopicPoems. We scrape poems from the web[1] in order to create our first dataset (KnownTopicPoems). The poems on this site are a good match for our task, since they are sorted by topics. Our resulting dataset contains 144 topics, and a total of 32,786 poems. These poems are all of different lengths, but we aim at generating poems of up to 8 lines.[2] Thus, we split all longer poems such that they contain at least 4 and a maximum of 8 lines in the following way: First, we split poems on empty lines, since those usually mark the end of a semantic unit. Second, if any of the resulting partial poems are still too long, we split them at full stops, but only use the beginning, since not every new sentence makes for a meaningful start of a poem. We add all possible options. This step increases the number of poems to 53,972, belonging to 144 topics. This dataset is used to train the language model of our neural poet, and to train the topic prediction model which is used to create additional training data for poem generation. We use 80%, 10%, and 10% of the data for training, development, and test, respectively.

We tokenize all poems with the NLTK WordTreeBank tokenizer package (Loper and Bird, 2002).

UnknownTopicPoems. We further make use of another poem dataset taken from Liu et al. (2018)[3] (UnknownTopicPoems), since it is larger than KnownTopicPoems. However, this dataset does not explicitly state the topics of individual poems. Thus, we automatically predict a topic for each poem with the help of our topic prediction model, which will be described in Subsection 3.3. The poems in UnknownTopicPoems are again broken down into poems with 4 to 8 lines, and, for our main experiments, this dataset is combined with KnownTopicPoems, increasing the number of samples to 119,252 poems for 144 topics. Table 1 shows detailed statistics for both datasets. All poems are tokenized with the help of NLTK.

Sonnets. The last poem dataset we make use of is the sonnet poem dataset introduced by Lau et al. (2018). This dataset consists of Shakespearean sonnets. Since those differ significantly in style from the poems in KnownTopicPoems and UnknownTopicPoems, we do not train our language model directly on them. However, we make use of the fact that sonnets follow a known rhyming scheme, and leverage them to train a neural model to produce rhymes, which will be explained in detail in Subsection 3.2. As for the previous two datasets, poems are tokenized using NLTK.

---

[1] `https://poemhunter.com/poem-topics`

[2] Extending our method to longer poems is straightforward.

[3] `https://github.com/researchmm/img2poem/blob/master/data/unim_poem.json`

Wikipedia. Finally, we utilize a large English Wikipedia corpus[4] for pretraining. While this corpus does not consist of poems, we expect pretraining a language model on English text to help the overall coherence of the generated output. Again, we tokenize all sentences using NLTK.

3 The Neural Poet

We now describe all models that are either part of our baseline for acrostic poem generation or used for data preprocessing. An overview of our final neural poet is shown in Figure 2.

3.1 Neural Poem Language Model

We model the probability of a poem x, which consists of the word sequence $x_1 x_2 ... x_n$, as:

$$p(x) = \prod_{i=1}^{n} p(x_i | \{x_0, ... x_{i-1}\}, u, v, w) \qquad (1)$$

x_0 is a start-of-sequence token, u is a given topic, v is the acrostic word, and w is the number of lines the poem should consist of. We then model the conditional probability as

$$\begin{aligned} & p_{LM}(x_i | \{x_0, ... x_{i-1}\}, u, v, w) \\ =& g(\{x_0, ... x_{i-1}\}, u, v, w) \end{aligned} \qquad (2)$$

for all but the first word in each line, since, for each first word, the probability depends on the acrostic word as described at the end of this subsection. The non-linear function g is parameterized as a 3-layer uni-directional long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997) language model. For generation – but not during training –, u and v correspond to the same word.

At each time step, the model is given the last generated word, the topic of the poem, the characters of the acrostic word, and the number of lines to generate as input. Each letter of the acrostic word v is represented as a one-hot vector of size 27.[5] Our language model is trained to generate poems with up to 8 lines. Hence, the input matrix for the acrostic word is of size $8 * 27$, where, for poems corresponding to words with less than 8 letters, we make use of a padding token. All word-level input is represented by pretrained GloVe embeddings (Pennington et al., 2014). The number of lines is represented in the model by a single-digit tensor.

The first word of each line. The task of English acrostic poem generation as we define it demands that each line starts with a predefined letter. We want to enforce this constraint, while, at the same time, using the first word to guide the poem's content to stay close to the acrostic word. In order to achieve this with our baseline and still ensure coherent poem generation, we generate the initial words of each line as follows.

First, from all words in our vocabulary which start with the indicated character, we compute the $k = 5$ nearest neighbors $n_1, \ldots, n_k$ to the topic word u, using cosine similarity and our pretrained embeddings:

$$\text{sim}(x, u) = \frac{\text{emb}(x) \cdot \text{emb}(u)}{\|\text{emb}(x)\| \cdot \|\text{emb}(u)\|}$$

Then, we select our output with a probability of $m_1 = 0.7$ as

$$\text{argmax}_i \left(p_{LM}(n_1), p_{LM}(n_2), \ldots, p_{LM}(n_k)\right) \qquad (3)$$

However, this can cause the output to frequently become incoherent. Thus, we sample the first word from the language model, masking out all words that start with a wrong letter, with a probability of $m_2 = 0.3$.[6]

The last symbol of each line. Since the number of lines we want to generate is defined by the acrostic word, besides feeding an embedding which represents the number of lines to our model, we further enforce the right poem length by substituting each end-of-sentence symbol by end-of-line, if the number of lines is still too small. We do the same the other way around. Whenever this would lead to the last symbol of a poem being "," or ";", we substitute it by ".".

Thus, while our intuition is that having knowledge of the target number of lines will help our model for planning during generation, we do not require it to learn something that is already known.

3.2 Rhyming Model

We further make use of a separate neural model to generate rhyming words for the last position in each line. We aim at generating the following rhyming schemes. 4 lines: ABAB; 5 lines:

---

[4] Version from 2018/10/01; downloaded from `https://linguatools.org/tools/corpora/wikipedia-monolingual-corpora/`

[5] We represent letters from $A - Z$, ignoring case, and add an additional padding token.

[6] When sampling from the nearest neighbors, we find it necessary to not permit end-of-line tokens as the second word in the line, since those are generated with a high frequency.

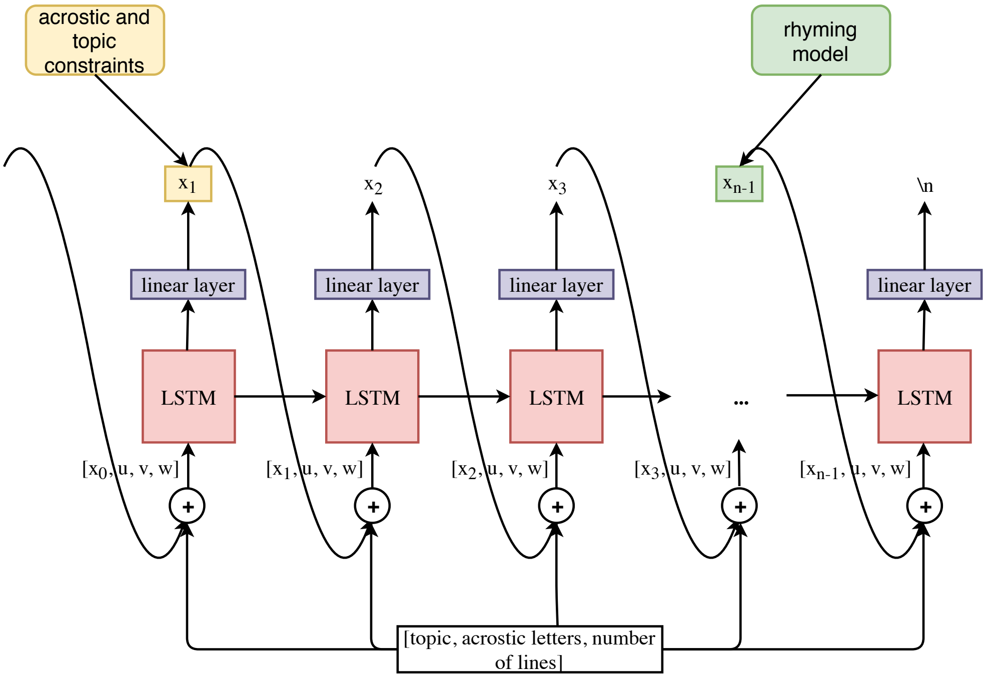

Figure 2: Overview of the baseline model we introduce together with the task of acrostic poem generation.

ABABC; 6 lines: ABABCC; 7 lines: ABABCDC; 8 lines: ABABCDCD.

Whenever a rhyming word is required, our rhyming model computes the probability of an output word c, consisting of a character sequence $c_1c_2...c_l$, as:

$$p(c) = \prod_{i=1}^{l} p(c_i|\{c_0, ...c_{i-1}\}, a, b) \tag{4}$$

a is the first word of the rhyme pair, i.e., the word c should rhyme with, and b denotes the poem up to c. a is represented as an encoding produced by concatenating the two last hidden states of a bidirectional character-level LSTM. b is the last hidden state of a uni-directional character-level LSTM, which encodes the poem.

Training and hyperparameters. Our rhyming model is trained on sonnet data (cf. Section 2), since sonnets follow a known rhyming scheme. The LSTM which encodes the word to rhyme with has 1 hidden layer and 256-dimensional hidden states. The LSTM which encodes the poem also has 1 hidden layer, but 512-dimensional hidden states. Character embeddings are randomly initialized. The rhyming model is trained with Adam (Kingma and Ba, 2014) with an initial learning rate of 0.0005, and a batch size of 64.

Generation. The words generated by the rhyming model substitute the last word in lines which are second in a rhyming pair. For instance, considering a 4-line poem which follows the scheme ABAB, the rhyming model would provide the last word of the third and fourth line, taking the last words of the first and, respectively, second line as input. During generation, we use beam search with width 5 to generate 5 candidates. Similarly to the line starts described above, we choose the candidate word with the highest language model probability as our final output.

3.3 Topic Prediction Model

Since our poem generator expects the topic of each poem, but the UnknownTopicPoems dataset does not provide any, we train a topic prediction model to create silver standard topic annotations.

We model the probability of poem x, consisting of the word sequence $x_1x_2...x_n$, belonging to topic y as:

$$p(y) = d(\{x_0, x_1, ..., x_n, x_{n+1}\}) \tag{5}$$

where x_0 is a start-of-sequence token, x_{n+1} is an end-of-sequence token, and d is a bidirectional word-level LSTM.

Training and hyperparameters. Our topic prediction LSTM has 1 hidden layer and a hidden size

Model	Perplexity

of 1024. It is trained on the KnownTopicPoems dataset. We use Adam with an initial learning rate of 0.0005 and a batch size of 128.

4 Experiments

4.1 Language Model Evaluation

Experimental setup.

Models. We train multiple language models to select the best basis for our neural poet:

- **GOLD+ and GOLD-.** Our first networks are only trained on gold poems, i.e., our KnownTopicPoems dataset. ”+” and ”-” indicate if topics are fed into the model (+) or substituted by zero vectors (-).
- **PRED/GOLD+ and PRED/GOLD-.** We further train language models on both the KnownTopicPoems dataset and the UnknownTopicPoem dataset. ”+” and ”-” indicate if topics are fed into the model (+) or substituted by zero vectors (-).
- **WIKI+ and WIKI-.** Finally, we pretrain two language models on Wikipedia and finetune them on a combination of KnownTopicPoems and UnknownTopicPoem. Again, ”+” and ”-” indicate if topics are fed into the model (+) or substituted by zero vectors (-).

Hyperparameters. All language models have 3 hidden layers and hidden states of size 1024 in all layers. Dropout (Srivastava et al., 2014) of 0.4 is applied between layers for regularization. 100-dimensional GloVe embeddings are used to encode the input. The number of tokens in the GloVe embeddings are reduced to the 50,000 most frequently occurring tokens in the dataset. We keep the GloVe and character embeddings fixed and do not update them during training. All models are trained with early stopping with patience 25 on the development split from KnownTopicPoems.

Results. Results on the test split of KnownTopicPoems are shown in Table 2 . WIKI+ and WIKI- obtain the lowest perplexity scores. Thus, we use them as the basis of our neural poet for the remaining experiments in this paper.

4.2 Human Evaluation Of Poems

Experimental setup. In order to get an idea of the difficulty of our proposed task, we need to assess the quality of the poems generated by our baseline. Following previous work (Manurung, 2003; Zhang and Lapata, 2014; Loller-Andersen and Gambäck, 2018), we ask human annotators to evaluate 40 poems generated for the words in Table 4 for *readability* (lexical and syntactic coherence), *meaningfulness* (if the poem can be interpreted as conveying a message to its reader), and *poeticness* (if the poem rhymes and looks like a poem) on a scale from 1 (worst) to 5 (best). Additionally, we also ask for an overall score. We collect a minimum of 2 and a maximum of 5 ratings for each aspect of each poem. All annotators are fluent in English: they either are or have in the past been working or studying at an English-speaking institution.

Models. In order to further obtain insight into the effect of the different components of our model, we perform an ablation study: we evaluate our final neural poet including the rhyming model, a given topic, and acrostic forcing against versions of the model without selected components. We evaluate the following models:

- **NeuralPoet.** This is our final model with all components. It has been pretrained on Wikipedia and fine-tuned on both KnownTopicPoems and UnknownTopicPoems.
- **NeuralPoet-ST.** This is NeuralPoet, but we do not choose the first word of each line from the nearest neighbors of the topic, i.e., we set $m_1 = 0$ and $m_2 = 1$ in the notation from Section 3.1.
- **NeuralPoet-ST-AC.** Next, we additionally switch off acrostic forcing, i.e., we do not enforce that the first letters spell out the acrostic word. Since the language model receives embeddings of the characters as input, we observe that NeuralPoet-ST-AC still largely produces the acrostic word, but the language

Table 4: The acrostic words used to generate poems in our experiments, corresponding to known or unknown topics.

model has more freedom to generate coherent and fluent text.

- **NeuralPoet-ST-RH.** This is NeuralPoet-ST, but we switch off the rhyming model, i.e., the last words are generated directly from the language model. We expect this to also be more fluent and coherent, but less poem-like.
- **NeuralPoet-ST-TP.** This version of NeuralPoet-ST does not receive the topic as input. To achieve this, we set the topic vector to zero during both training and generation.

We further collect ratings for human poems from our training set for comparison; some of them are partial poems as used for training.

Results. All ratings are displayed in Table 3. We can see that human poems obtain the highest scores overall; they serve as a rough upper bound on the scores of our models. We then compare the different versions of our neural poet on the basis of our four criteria. We observe the following:

- **NeuralPoet.** This model performs well in most evaluations, and it has the highest performance among all models for fluency and poeticness for *Known*. For *All*, NeuralPoet obtains the best poeticness score. This shows the effectiveness of our proposed baseline.
- **NeuralPoet-ST.** We only notice small differences in the scores for poems generated by this model and the previous one. However, differences in poeticness are relatively large: 0.41, 0.46, and 0.36 for *All*, *Known*, and *Unknown*, respectively. We hypothesize that a reason for this might be that the generated words are not always closely related to the given topic. Thus, the poems loose context and cohesiveness more often, leading to a worse overall impression.
- **NeuralPoet-ST-AC.** Without enforcement of the acrostic constraints, the language model has more autonomy in selecting words. As expected, the results show that the poems generated are more fluent than those of most other

models: it obtains the highest fluency scores for *All* and *Unknown*. However, differences to NeuralPoet are relatively small, showing that we do not lose much quality by enforcing acrostics. Another effect of fewer constraints is that the poems are more coherent: they get the highest meaningfulness scores for *Known*, and the second highest for *All*.

- **NeuralPoet-ST-RH.** This version of our model gets scores in the lower half for all individual evaluations. This clearly shows that rhyming seems to be evaluated highly by human annotators and that the rhyming model is an important component of our neural poet.

Correct	9	12	21
Disagreement	8	7	15
Incorrect	3	1	4

Table 6: Number of poems correctly or incorrectly identified by human annotators as belonging to the given topic. *Disagreement* denotes examples where the annotators selected different poems.

- **NeuralPoet-ST-TP.** This version of the model, which is not given a topic, obtains highest or close-to-highest scores for most individual evaluations. In particular, the generated poems seem to be more fluent and coherent than the alternatives. However, they do not relate to any specific topic, which probably causes the drop in quality for poeticness, where this model always performs worse than NeuralPoet.

4.3 Human Evaluation Of Topicality

Experimental setup. Besides the first characters of all lines forming the input prompt, our acrostic poem generation task further requires that the content of the poem should relate to the input word. In order to gain insight if we succeed with the latter, we further conduct the following evaluation: we create poems with (i) our final neural poet and (ii) a version of the poet that only sees zero vectors as topic vectors during training and generation. Both models are forced to generate acrostics. We then show poems generated by both models together with the acrostic word to human evaluators and ask which poem is more closely related to the topic.

Models. We compare poems generated by the following two models:

- **NeuralPoet.** Our final baseline model with all components. It is pretrained on Wikipedia and fine-tuned on a combination of KnownTopicPoems and UnknownTopicPoems.

- **NeuralPoet-ST-TP.** This version of our model, as described in the last subsection, has no component which takes the topic as input: the first word of the line is generated exclusively by the language model, and the topic vector is set to zero. It, thus, makes it possible to evaluate if the topic is indeed being reflected in our poems.

Results. As shown in Table 6, our annotators agree on the poem generated by NeuralPoet to be closer related to its topic for 21 out of 40 poems. In 15 cases, the two annotators disagree, and only in 4 cases they find the poem generated by NeuralPoet-ST-TP, i.e., the model that does in fact not know about the topic, to be more similar to it. This indicates that our poems indeed confirm with the topic given by the acrostic word.

Considering poems for known and unknown topics separately, we get a similar picture. Suprisingly, however, 12 out of 20 and 9 out of 20 poems are recognized correctly for know and unknown words, respectively. Thus, our model works well even for topics it has not seen during training.

5 Related Work

Automated poetry generation has long been getting attention from researchers at the intersection of artificial intelligence and computational creativity. Even before the advent of deep learning, researchers used stochastic models and algorithms to generate poems (Queneau, 1961; Oulipo (Association), 1981; Gervás, 2000; Manurung, 2003). With the advancements in deep learning, more and more researchers are exploring possibilities of training neural networks to generate poems which mimic human creativity. The authors of Lau et al. (2018) trained a model on generating Shakespearean sonnets. They used a hybrid word-character LSTM-based recurrent neural network to generate poems, and used separate rhythmic and rhyming models to enforce sonnet structure on the poems generated. All three component were trained in a multi-task fashion. Their crowd-work and expert evaluations suggested that the generated poems conformed to the sonnet structure, however lacked readability and coherent meaning. We make use of explicit representations of topics to address the poem coherence and readability concern: as our poems are generated based on a topic, we expect them to be more coherent.

Authors of Wang et al. (2018) generated Chinese poems based on images, rather than topic words. They used a combination of a convolutional neural network (CNN) and a gated recurrent unit (GRU) to generate poems which related to the target image. They also generated acrostic poems, but used character-level modelling to achieve this – which was simpler than in our case, since they worked with Chinese text where characters often correspond to entire words. Our preliminary experiments on English showed that character-level models learn easily to generate acrostics by themselves, however do not follow the topic as coherently as word-level models. Zhang and Lapata (2014); Zhang et al. (2017); Yang et al. (2017); Yi et al. (2018a,c); Yang et al. (2019) are other examples of work on generating Chinese poems, but did not focus on acrostics.

Ghazvininejad et al. (2016, 2017) built a model to generate poems based on topics in a similar fashion to ours. However, they chose words related to a given topic to be the *last* words in each line – and to rhyme. For this, they built rhyming classes for an input topic first, from which rhyming pairs were chosen. The most obvious differences to our work are, however, that they produced poems following predefined stress patterns, while we are interested in free verse poems and that we generate acrostic poems, while they did not.

Finally, some additional work on poem generation includes Yi et al. (2018b), who applied reinforcement learning to the problem, in order to overcome the mismatch of training loss and evaluation metric.

6 Conclusion

We introduce a new task in the area of computational creativity: acrostic poem generation in English. The task consists of creating poems with the following constraints: 1) the first letters of all lines should spell out a given word, 2) the poem's content should also be related to that word, and 3) the poem should conform to a rhyming scheme. We further present a baseline for the task, based on a neural language model which has been pretrained on Wikipedia and fine-tuned on a combination of poems with gold standard and automatically predicted topics. A separate rhyming model is responsible for generating rhymes.

We perform a manual evaluation of the generated poems and find that, while human poets still outperform automatic approaches, poems written by our neural poet obtain good ratings. Our additional constraints only slightly decrease fluency and meaningfulness and, in fact, even increase the poeticness of the generated poems. Furthermore, our model's poems are indeed topic-wise closely related to the acrostic word. Our neural poet is available at `https://nala-cub.github.io/resources` as a baseline for future research on the task.

Acknowledgments

We would like to thank the members of NYU's ML^2 group for their help with the human evaluation and their feedback on our paper! We are also grateful to the anonymous reviewers for their insightful comments.

Abstract

Named Entity Recognition (NER) is one of the first stages in deep language understanding yet current NER models heavily rely on human-annotated data. In this work, to alleviate the dependence on labeled data, we propose a **L**ocal **A**dditivity based **D**ata **A**ugmentation (LADA) method for semi-supervised NER, in which we create virtual samples by interpolating sequences *close* to each other. Our approach has two variations: Intra-LADA and Inter-LADA, where Intra-LADA performs interpolations among tokens within one sentence, and Inter-LADA samples different sentences to interpolate. Through linear additions between sampled training data, LADA creates an infinite amount of labeled data and improves both entity and context learning. We further extend LADA to the semi-supervised setting by designing a novel consistency loss for unlabeled data. Experiments conducted on two NER benchmarks demonstrate the effectiveness of our methods over several strong baselines. We have publicly released our code at `https://github.com/GT-SALT/LADA`.

1 Introduction

Named Entity Recognition (NER) that aims to detect the semantic category of entities (e.g., persons, locations, organizations) in unstructured text (Nadeau and Sekine, 2007), is an essential prerequisite for many NLP applications. Being one of the most fundamental and classic sequence labeling tasks in NLP, there have been extensive research from traditional statistical models like Hidden Markov Models (Zhou and Su, 2002) and Conditional Random Fields (Lafferty et al., 2001a), to neural network based models such as LSTM-CRF (Lample et al., 2016a) and BLSTM-CNN-CRF (Ma and Hovy, 2016), and to recent pre-training and fine-tuning methods like ELMO (Peters et al., 2018a), Flair (Akbik et al., 2018) and BERT (Devlin et al., 2019). However, most of those models still heavily rely on *abundant annotated data* to yield the state-of-the-art results (Lin et al., 2020), making them hard to be applied into new domains (e.g., social media, medical context or low-resourced languages) that lack labeled data.

Different kinds of data augmentation approaches have been designed to alleviate the dependency on labeled data for many NLP tasks, and can be categorized into two broad classes: (1) adversarial attacks at token-levels such as word substitutions (Kobayashi, 2018; Wei and Zou, 2019) or adding noise (Lakshmi Narayan et al., 2019), (2) paraphrasing at sentence-levels such as back translations (Xie et al., 2019) or submodular optimized models (Kumar et al., 2019). The former has already been used for NER but struggles to create diverse augmented samples with very few word replacements. Despite being widely utilized in many NLP tasks like text classification, the latter often fails to maintain the labels at the token-level in those paraphrased sentences, thus making it difficult to be applied to NER.

We focus on another type of data augmentations called mixup (Zhang et al., 2018), which was originally proposed in computer vision and performed linear interpolations between randomly sampled image pairs to create virtual training data. Miao et al. (2020); Chen et al. (2020b) adapted the idea to textual domains and have applied it to the preliminary task of text classification. However, unlike classifications where each sentence only has one label, sequence labeling tasks such as NER usually involve multiple interrelated labels in a single sentence. As we found in empirical experiments, it is challenging to directly apply such mixup technique to sequence labeling, and improper interpolations may mislead the model. For instance, *random sam-*

November 16–20, 2020. ©2020 Association for Computational Linguistics

pling in mixup may inject too much noise by interpolating data points far away from each other, hence making it fail on sequence labeling.

To fill this gap, we propose a novel method called **L**ocal **A**dditivity based **D**ata **A**ugmentation **(LADA)**, in which we constrain the samples to mixup to be *close* to each other. Our method has two variations: **Intra-LADA** and **Inter-LADA**. Intra-LADA interpolates each token's hidden representation with other tokens from the same sentence, which could increase the robustness towards word orderings. Inter-LADA interpolates each token's hidden representation in a sentence with each token from other sentences sampled from a weighted combination of k-nearest neighbors sampling and random sampling, the weight of which controls the delicate trade-off between noise and regularization. To further enhance the performance of learning with limited labeled data, we extend LADA to the semi-supervised setting, i.e., **Semi-LADA**, by designing a novel consistency loss between unlabeled data and its local augmentations. We conduct experiments on two NER datasets to demonstrate the effectiveness of our LADA based models over state-of-the-art baselines.

2 Background

Zhang et al. (2018) proposed a data augmentation technique called *mixup*, which trained an image classifier on linear interpolations of randomly sampled image data. Given a pair of data points $(\mathbf{x}, \mathbf{y})$ and $(\mathbf{x}', \mathbf{y}')$, where $\mathbf{x}$ denotes an image in raw pixel space, and $\mathbf{y}$ is the label in a one-hot representation, *mixup* creates a new sample by interpolating images and their corresponding labels:

$$\tilde{\mathbf{x}} = \lambda\mathbf{x} + (1-\lambda)\mathbf{x}',$$
$$\tilde{\mathbf{y}} = \lambda\mathbf{y} + (1-\lambda)\mathbf{y}',$$

where λ is drawn from a Beta distribution. *mixup* trains the neural network for image classification by minimizing the loss on the virtual examples. In experiments, the pairs of images data points $(\mathbf{x}, \mathbf{y})$ and $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}})$ are *randomly* sampled. By assuming all the images are mapped to a low dimension manifold through a neural network, linearly interpolating them creates a virtual vicinity distribution around the original data space, thus improving the generalization performance of the classifier trained on the interpolated samples.

Prior work like Snippext (Miao et al., 2020), MixText (Chen et al., 2020b) and AdvAug (Cheng et al., 2020) generalized the idea to the textual domain by proposing to interpolate in output space (Miao et al., 2020), embedding space (Cheng et al., 2020), or general hidden space (Chen et al., 2020b) of textual data and applied the technique to NLP tasks such as text classifications and machine translations and achieved significant improvements.

3 Method

Based on the above interpolation based data augmentation techniques, in Section 3.1, we introduced a **L**ocal **A**dditivity based **D**ata **A**ugmentation **(LADA)** for sequence labeling, where creating augmented samples is much more challenging. We continue to describe how to utilize unlabeled data with LADA for semi-supervised NER in Section 3.4.

3.1 LADA

For a given sentence with n tokens $\mathbf{x} = \{x_1, ..., x_n\}$, denote the corresponding sequence label as $\mathbf{y} = \{y_1, ..., y_n\}$. In this paper, we use NER as the working example to introduce our model, in which the labels are the entities types. We randomly sample a pair of sentences from the corpus, $(\mathbf{x}, \mathbf{y})$ and $(\mathbf{x}', \mathbf{y}')$, and then compute the interpolations in the hidden space using a L-layer encoder $\mathbf{F}(.;\theta)$. The hidden representations of $\mathbf{x}$ and $\mathbf{x}'$ up to the m-th layer are given by:

$$\mathbf{h}^l = \mathbf{F}^l(\mathbf{h}^{l-1};\theta), l \in [1, m],$$
$$\mathbf{h}'^l = \mathbf{F}^l(\mathbf{h}'^{l-1};\theta), l \in [1, m],$$

Here $\mathbf{h}^l = \{h_1, ..., h_n\}$ refer to the hidden representations at the l-th layer and is the concatenation of token representations at all positions. We use $\mathbf{h}^0, \mathbf{h}'^0$ to denote the word embedding of $\mathbf{x}$ and $\mathbf{x}'$ respectively. At the m-th layer, the hidden representations for each token in $\mathbf{x}$ are linearly interpolated with each token in $\mathbf{x}'$ by a ratio λ:

$$\tilde{\mathbf{h}}^m = \lambda\mathbf{h}^m + (1-\lambda)\mathbf{h}'^m,$$

where the mixing parameter λ is sampled from a Beta distribution, i.e., $\lambda \sim \text{Beta}(\alpha, \alpha)$. Then $\tilde{\mathbf{h}}^m$ is fed to the upper layers:

$$\tilde{\mathbf{h}}^l = \mathbf{F}^l(\tilde{\mathbf{h}}^{l-1};\theta), l \in [m+1, L].$$

$\tilde{\mathbf{h}}^L$ can be treated as the hidden representations of a *virtual sample* $\tilde{\mathbf{x}}$, i.e., $\tilde{\mathbf{h}}^L = \mathbf{F}(\tilde{\mathbf{x}};\theta)$.

In the meanwhile, their corresponding labels are linearly added with the same ratio:

$$\tilde{y}_i = \lambda y_i + (1-\lambda)y_i'$$
$$\tilde{\mathbf{y}} = \{\tilde{y}_1, ..., \tilde{y}_n\}.$$

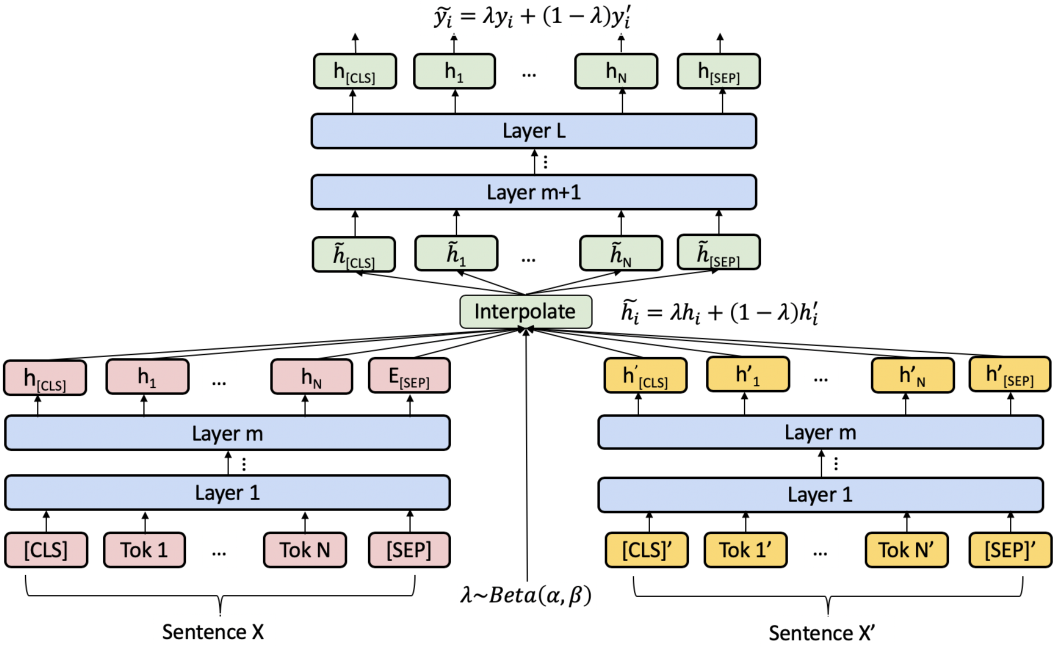

Figure 1: Overall Architecture of LADA. LADA takes in two sentences, linearly interpolates their hidden states h_i and h'_i at layer m with weight λ into $\tilde{h}_i$, and then continues forward passing to get encoded representations $\tilde{h}_i$, which are utilized in downstream tasks where the labels in each task are also mixed with weight λ.

The hidden representations $\tilde{\mathbf{h}}^L$ are then fed into a classifier $p(:, \phi)$ and the loss over all positions is minimized to train the model:

$$L = \mathop{\mathbb{E}}_{\mathbf{x}' \sim P_{\text{mix}}(\mathbf{x}'|\mathbf{x})} [\sum_{i=1}^{n} \text{KL}(\tilde{y}_i; p(\tilde{h}_i^L; \phi))]. \quad (1)$$

Here $P_{\text{mix}}(\mathbf{x}'|\mathbf{x})$ defines the probability of sampling $(\mathbf{x}', \mathbf{y}')$ to mix with $(\mathbf{x}, \mathbf{y})$. The overall diagram is shown in Figure 1.

Let $\mathbf{S} = \{(\mathbf{x}, \mathbf{y})\}$ be the corpus of data samples, then according to Chen et al. (2020b),

$$P_{\text{mix}}(\mathbf{x}'|\mathbf{x}) = \frac{1}{|\mathbf{S}|}, \qquad (\mathbf{x}', \mathbf{y}') \in \mathbf{S}. \quad (2)$$

Note that $P_{\text{mix}}(\mathbf{x}'|\mathbf{x})$ is a uniform distribution that is independent of $\mathbf{x}$. Even though $\mathbf{x}'$ can be far away from $\mathbf{x}$ in the Euclidean space, they are mapped into a low-dimension manifold through a neural network. Interpolating them in the hidden space regularizes the model to perform linearly in the low-dimensional manifold, hence greatly improves tasks such as classification.

However, we found empirically in experiments that the above *random sampling* strategy failed on sequence labeling like NER, leading to worse modeling results than purely supervised learning. Intuitively, sequence labeling is more complicated than sentence classification as it requires learning much more fine-grained information. Labeling a token depends on not only the token itself but also the *context*. We hypothesize that mixing the sequence $\mathbf{x}$ with $\mathbf{x}'$ changes the context for all tokens and injects too much noise, hence making learning the labels for the tokens challenging. In other words, the relative distance between $\mathbf{x}$ and $\mathbf{x}'$ in the manifold mapped by neural networks is further in sequence labeling than sentence classification (demonstrated in Figure 2), which is intuitively understandable as every data point in sentence classification is the pooling over all the tokens in one sentence while every token is a single data point in sequence labeling. Randomly mixing data points far away from each other introduces more noise for sequence labeling. To overcome this problem, we introduce a *local* additivity based data augmentation approach with two variations, in which we constrain $\mathbf{x}'$ to be close to $\mathbf{x}$:

3.2 Intra-LADA

As stated above, mixing two sequences not only changes the local token representations but also affects the context required to label tokens. To reduce the noises from unrelated sentences, the most direct way is to construct $\mathbf{x}'$ using the same tokens from $\mathbf{x}$ but changing the orders and perform interpolations between them.

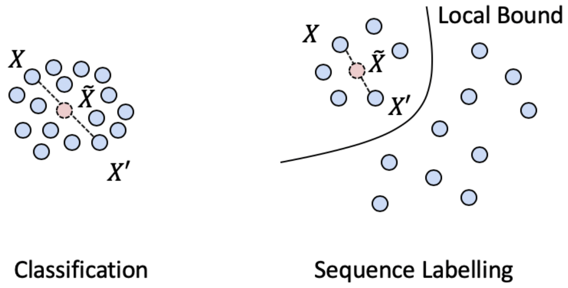

Figure 2: Data manifold for sentence classification and sequence labeling. The dimension of data manifold for sequence labeling is higher than sentence classification, hence the distance between data samples is larger. We constraint $\mathbf{x}'$ to be close to $\mathbf{x}$ in creating interpolated data in LADA.

Let $\mathbf{Q} = \text{Permutations}((\mathbf{x}, \mathbf{y}))$ be the set including all possible permutations of $\mathbf{x}$, then

$$P_{\text{Intra}}(\mathbf{x}'|\mathbf{x}) = \frac{1}{n!}, \qquad (\mathbf{x}', \mathbf{y}') \in \mathbf{Q}. \quad (3)$$

In this case, each token x_i in $\mathbf{x}$ is actually interpolated with another token x_j in $\mathbf{x}$, while the context is unaltered. By sampling from P_{Intra}, we are essentially turning sequence level interpolation to token level interpolation, thus greatly reducing the complexity of the problem. From another perspective, Intra-LADA generates augmentations with different sentence structures using the same word set, which could potentially increase the model's robustness towards word orderings.

Intra-LADA restraints the context from changing, which could be limited in generating diverse augmented data. To overcome that, we propose Inter-LADA, where we sample a different sentence from the training set to perform interpolations.

3.3 Inter-LADA

Instead of interpolating within one sentence, Intra-LADA samples a different sentence $\mathbf{x}'$ from the training set to interpolate with $\mathbf{x}$. To achieve a trade-off between noise and regularization, we sample $\mathbf{x}'$ through a weighted combination of two strategies: k-nearest neighbors (kNNs) sampling and random sampling:

$$P_{\text{Inter}}(\mathbf{x}'|\mathbf{x}) = \begin{cases} \frac{\mu}{k}, & \mathbf{x}' \in \text{Neighbor}_k(\mathbf{x}), \\ \frac{1-\mu}{|S|}, & (\mathbf{x}', \mathbf{y}') \in \mathbf{S}, \end{cases} \quad (4)$$

where μ is the weight of combining two distributions. To get the kNNs, we use sentence-BERT (Reimers and Gurevych, 2019) to map each sentence $\mathbf{x}$ into a hidden space, then collect each sentence's kNNs using l^2 distance. For each sentence $\mathbf{x}$, we sample $\mathbf{x}'$ to mix up from the kNNs with probability μ and the whole training corpus with a probability $1 - \mu$. When $\mathbf{x}'$ is sampled from the whole training corpus, it may be unrelated to $\mathbf{x}$, introducing large noise but also strong regularization on the model. When $\mathbf{x}'$ is sampled from the kNNs, $\mathbf{x}'$ shares similar, albeit different, context with $\mathbf{x}$, thus achieving good signal to noise ratio. By treating μ as a hyper-parameter, we can control the delicate trade-off between noise and diversity in regularizing the model.

To examine why sampling sentences from kNNs decreases the noise and provides meaningful signals to training, we analyze an example with its kNNs in Table 1: (1) As it shows, kNNs may contain the same entity words as the original sentence, but in different contexts. The entity types in the neighbor sentences are also changed corresponding to contexts. For example, entity *Israel* in the third neighbor becomes an organization when surrounded by *Radio* while it is a location in the original sentence. (2) Contexts from neighbor sentences can help detect the entities of the same type in a given sentence. For example, *Lebanon* in the second neighbor shares the same type as *Israel* in the original sentence. *Lebanon* can resort to the context of the original sentence to detect its entity type. (3) Neighbor sentences may contain the same words but in different forms. For example, the *Israeli* in the first neighbor sentence is a different form of *Israel*, which is miscellaneous while *Israel* is a location in the example sentence. Interpolation with such an example can improve models' ability to recognize words of different forms and their corresponding types.

In summary, Inter-LADA can improve both entity learning and context learning by interpolating more diverse data. Note that although we use NER as a working example , LADA can be applied to any sequence labeling models.

3.4 Semi-supervised LADA

To further improve the performance of learning with less labeled data, we propose a novel LADA-based approach specifically for unlabeled data. Instead of looking for nearest neighbors, we use back-translation techniques to generate paraphrases of an unlabeled sentence $\mathbf{x}_u$ in constructing $\mathbf{x}'_u$. The paraphrase $\mathbf{x}'_u$, generated via translating $\mathbf{x}_u$ to an intermediate language and then translating it back, describes the same content as $\mathbf{x}_u$ and should be close to $\mathbf{x}_u$ semantically. However, there is no

Sentence	Israel plays down fears of war with Syria.

	Parliament Speaker Berri: Israel is preparing for war against Syria and Lebanon .
	Itamar Rabinovich , who as Israel's ambassador to Washington conducted unfruitful negotiations with Syria , told Israel Radio looked like Damascus wanted to talk rather than fight .

Table 1: kNNs of an example sentence. Entities in sentences are colored. Green means locations , red means persons , blue means organizations and yellow means miscellaneous.

guarantee that the same entity would appear in the same position in $\mathbf{x}_u$ and $\mathbf{x}'_u$. In fact, the number of tokens in $\mathbf{x}_u$ and $\mathbf{x}'_u$ may not even be the same. For instance, for the sentence "*Rare **Hendrix** song draft sells for almost $17,000*" and its paraphrased sentence "*A rare **Hendrix** song design is selling for just under $17,000*", although some words are different, the entity *Hendrix* keeps unchanged, and there are no extra entities added. That is, both contain one and only one entity (*Hendrix*) of the same type (*Person*). Nevertheless, we empirically found that most paraphrases contain the same number of entities (for any specific type) as the original sentence. Inspired by the observation, we propose a new consistency loss to leverage unlabeled data: $\mathbf{x}_u$ and $\mathbf{x}'_u$ should have the same number of entities for any given entity type.

Specifically, for an unlabeled sentence $\mathbf{x}_u$ and its paraphrase $\mathbf{x}'_u$, we first guess their token labels with the current model:

$$\mathbf{y}_u = p(\mathbf{F}(\mathbf{x}_u; \theta); \phi).$$

To avoid predictions being too uniform at the early stage, we sharpen every token prediction $y_{u,i} \in \mathbf{y}_u$ with a temperature T:

$$\hat{y}_{u,i} = \frac{(y_{u,i})^{\frac{1}{T}}}{\left\| (y_{u,i})^{\frac{1}{T}} \right\|_1},$$

where $||.||_1$ denotes the $l1$-norm. We then add the prediction $\hat{y}_{u,i}$ over all tokens in the sentence to denote its total number of entities for each type:

$$\hat{y}_{u,\text{ num}} = \sum_{i=1}^{n} \hat{y}_{u,i}.$$

Note that $\hat{y}_{u,\text{num}}$ is the guessed label vector with C-dimensions, where C is the total number of entity types. The i-th element in the $\hat{y}_{u,\text{num}}$ denotes the total number i-type entity in the sentence.

Dataset	**CoNLL**	**GermEval**
Train	14,987	24,000
Dev	3,466	2,200
Test	3,684	5,100
Entity Types	4	12
Max Sent Length	142	84

Table 2: Data statistics and our data split following Benikova et al. (2014).

During training, we use the same procedure to get the number of entities for original and each paraphrase sentence (without sharpening). Assume there are K paraphrases, denote the entity number vector for the k-the paraphrase as $\hat{y}'^{k}_{u,\text{num}}$. The consistency objective for unlabeled sentence $\mathbf{x}$ and its paraphrases is:

$$L_u = ||\hat{y}_{u,\text{num}} - \hat{y}'^{k}_{u,\text{num}}||^2. \tag{5}$$

Here we treat $\hat{y}_{u,\text{num}}$ as fixed and back-propagate only through $\hat{y}'_{u,\text{num}}$ to train the model.

Taking into account the loss objectives for both labeled and unlabeled data (Equation 1 and Equation 5), our **Semi-LADA** training objective is:

$$L_{semi} = L + \gamma L_u$$

where γ controls the trade-off between the supervised loss term and the unsupervised loss term.

4 Experiments

4.1 Datasets and Pre-processing

We performed experiments on two datasets in different languages: **CoNLL** 2003 (Tjong Kim Sang and De Meulder, 2003) in English and **GermEval** 2014 (Benikova et al., 2014) in German. The data statistics are shown in Table 2. We used the BIO labeling scheme and reported the F1 score. In order to make LADA possible in recent transformer-based models like BERT, we assigned labels to

Model	Unlabeled data	CoNLL			GermEval		
		5%	10%	30%	5%	10%	30%
Flair (Akbik et al., 2019)	no	79.32	86.31	89.96	66.54	67.92	74.11
Flair + Intra-LADA†	no	-	-	-	-	-	-
Flair + Inter-LADA†	no	80.84	86.33	**90.61**	67.40	70.02	74.63
BERT (Devlin et al., 2019)	no	83.28	86.85	89.28	79.64	80.92	82.87
BERT + Intra-LADA†	no	83.52	87.54	89.31	79.93	81.10	82.92
BERT + Inter-LADA†	no	84.60	87.81	89.68	80.13	**81.28**	83.63
BERT + Intra&Inter-LADA†	no	**84.85**	**87.85**	89.87	**80.17**	81.23	**83.65**
VSL-GG-Hier (Chen et al., 2018)	yes	83.38	84.71	85.52	-	-	-
MT + Noise (Lakshmi Narayan et al., 2019)	yes	82.60	83.47	84.88	-	-	-
BERT + Semi-Intra-LADA†	yes	**87.15**	88.70	89.69	80.95	81.52	83.46
BERT + Semi-Inter-LADA†	yes	86.51	88.53	90.00	**81.20**	81.70	83.53
BERT + Semi-Intra&Inter-LADA†	yes	86.33	**88.78**	**90.25**	81.07	**81.77**	**83.63**

Table 3: The F1 scores on CoNLL 2003 and GermEval 2014 training with varying amounts of the labeled training data (5%, 10%, and 30% of the original training set). There were 10,000 unlabeled data for each dataset which was randomly sampled from the original training set. All the results were averaged over 5 runs. † denotes our methods.

special tokens [SEP], [CLS], and [PAD]. Since BERT tokenized a token into one or multiple sub-tokens, we not only assigned labels to the first sub-token but also to the remaining sub-tokens following the rules: (1) O word: Oxx→OOO, (2) I word: Ixx→III,(3) B word: Bxx→BII, as such kind of assignment will not harm the performance (ablation study was conducted in Section 4.4). During the evaluation, we ignored special tokens and non-first sub-tokens for fair comparisons.

In the fully supervised setting, we followed the standard data splits shown in Table 2. In the semi-supervised setting, we sampled 10,000 sentences in the training set as the unlabeled training data. We adopted FairSeq[1] to implement the back translation. For CoNLL dataset, we utilized German as the intermediate language and English as the intermediate language for GermEval.

4.2 Baselines & Model Settings

Our LADA can be applied to any models in standard sequence labeling frameworks. In this work, we applied LADA to two state-of-the-art pre-trained models to show the effectiveness:

- **Flair** (Akbik et al., 2019): We used the pre-trained Flair embeddings[2], and a multi-layer BiLSTM-CRF (Ma and Hovy, 2016) as the encoder to detect the entities.
- **BERT** (Devlin et al., 2019): We loaded the BERT-base-multilingual-cased[3] as the encoder and a linear layer to predict token labels.

To demonstrate whether our Semi-LADA works with unlabeled data, we compared it with two recent state-of-the-art semi-supervised NER models:

- **VSL-GG-Hier** (Chen et al., 2018) introduced a hierarchical latent variables models into semi-supervised NER learning.
- **MT + Noise** (Lakshmi Narayan et al., 2019) explored different noise strategies including word-dropout, synonym-replace, Gaussian noise and network-dropout in a mean-teacher framework.

We also compared our models with another two recent state-of-the-art NER models trained on the whole training set:

- **CVT** (Clark et al., 2018) performed multi-task learning and made use of 1 Billion Word Language Model Benchmark as the source of unlabeled data.
- **BERT-MRC** (Li et al., 2020) formulated the NER as a machine reading comprehension task instead of a sequence labeling problem.

For **Intra-LADA**, as it broke the sentence structures, it cannot be applied to Flair that was based on LSTM-CRF. Thus we only combined it with BERT and only used the labeled data. The mix layer set was $\{12\}$. For **Inter-LADA**, we applied it to Flair and BERT trained with only the labeled data. The mix layer set was $\{8,9,10\}$, k in kNNs was 3, and 0.5 was a good start point for tuning μ. **Semi-LADA** utilized unlabeled data as well. The model was built on BERT. The weight γ to balance the supervised loss and unsupervised loss was 1.

4.3 Main Results

We evaluated the baselines and our methods using F1-scores on the test set.

Utilizing Limited Labeled Data We varied the number of labeled data (made use of 5%, 10%, 30% of labeled sentences in each dataset, which were 700, 1400, 4200 in CoNLL and 1200, 2400, 7200 in GermEval) and the results were shown in Table 3. Compared to purely Flair and BERT, applying *Intra-LADA* and *Inter-LADA* consistently boosted performances significantly, indicating the effectiveness of creating augmented training data through local linear interpolations. When unlabeled data was introduced, VSL-GG-Hier and MT + Noise performed slightly better than Flair and BERT with 5% labeled data in CoNLL, but pre-trained models (Flair, BERT) still got higher F1 scores when there were more labeled data. Both kinds of *BERT + Semi-LADA* significantly boosted the F1 scores on CoNLL and GermEval compared to baselines, as Semi-LADA not only utilized LADA on labeled data to avoid overfitting but also combined back translation based data augmentations on unlabeled data for consistent training, which made full use of both labeled data and unlabeled data.

Utilizing All the Labeled data Table 4 summarized the experimental results on the full training sets (14,987 on CoNLL 2003 and 24,000 on GermEval 2014). Compared to pre-trained Flair and BERT[4], there were still significant performance gains from utilizing our LADA, which indicated that our proposed data augmentation methods work well even with a large amount of labeled training data (full datasets). We also showed two state-of-the-art NER models' results with different settings, they had better performance mainly due to the multi-task learning with more unlabeled data (CVT) or formulating the NER as reading comprehension problems (BERT + MRC). Note that our LADA was orthogonal to these two models.

Loss on the Development Set To illustrate that our LADA could also help the overfitting problem, we plotted the loss on the development set of BERT, *BERT + Inter-LADA* and *BERT + Semi-Inter-LADA* on CoNLL and GermEval training with 5% labeled data in Figure 3. After applying LADA, the loss curve was more stable with training epoch increased, while the loss curve of BERT started increasing after about 10 epochs, indicating that the model might overfit the training data. Such property made LADA a suitable method, especially for semi-supervised learning.

Combining Intra&Inter-LADA We further combined Intra-LADA and Inter-LADA with a ratio π, i.e. data point would be augmented through Intra-LADA with a probability π and Inter-LADA with a probability $1 - \pi$. In practice, we set the probability 0.3, and kept the settings for each kind of LADA the same. The results are shown in Table 3. Through combining two variations, *BERT + Intra&Inter-LADA* further boosted model performance on both datasets, with an increase of 0.25, 0.04 and 0.19 on CoNLL over *BERT + Inter-LADA* trained with 5%, 10% and 30% labeled data. We obtained consistent improvement in semi-supervised settings: *BERT + Semi-Intra&Inter-LADA* improved over *BERT*

---

[4] Note that for the discrepancy between our BERT results and results published in the BERT paper, it has been discussed in the official repo `https://github.com/google-research/bert/issues/223`, where the best performance one can replicate on CoNLL was around 91.3 based on the given scripts. For our experiments, we followed the provided scripts, and kept model settings identical as baselines for fair comparison.

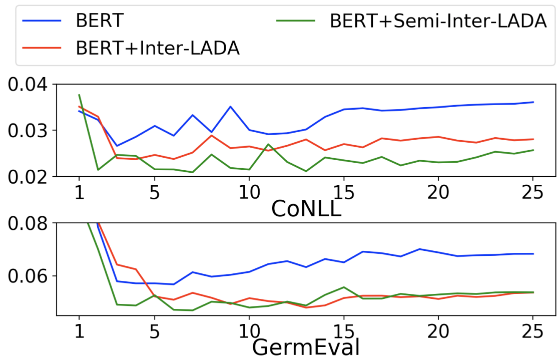

Figure 3: Loss (Y axis) on development set, trained with 5% labeled data, over different epochs (X axis).

+ *Semi-Inter-LADA* trained with 5%, 10% and 30% labeled data on GermEval by +0.05, +0.07 and +0.10. This showed that our Intra-LADA and Inter-LADA can be easily combined by future work to create diverse augmented data to help sequence labeling tasks.

4.4 Ablation Study

Different Sub-token Labeling Strategies To prove that our pre-processing of labeling sub-tokens for training was reasonable, we compared BERT training with different sub-token labeling strategies in Table 5."**None**" strategy was used in original BERT-Tagger where sub-tokens are ignored during learning. "**Real**" strategy was used in our Inter-LADA where O words' sub-tokens were assigned O (Oxx→OOO), I and B words' sub-tokens were assigned I (Ixx→III, Bxx→BII). "**Repeat**" referred to assigning the original label to each sub-token (Oxx→OOO, Ixx→III, Bxx→BBB). "O" means we assigned O to each sub-token (Oxx→OOO, Ixx→IOO, Bxx→BOO). "Real" strategy received comparable performances with original BERT models while the other two strategies decreased F1 scores, indicating our strategy mitigated the sub-token labeling issue.

Influence of μ in Inter-LADA We varied the μ in *BERT + Inter-LADA* from 0 to 1 to validate that combining kNNs sampling and random sampling in Inter-LADA could achieve the best performance, and the results were plotted in Figure 4. Note that when $\mu = 0$, Inter-LADA only did random sampling and it barely improved over BERT largely due to too much noise from interpolations between unrelated sentences. And when $\mu = 1$, Inter-LADA only did kNNs sampling, and it could get a better F1 score over BERT because of providing meaningful signals to training. BERT + Inter-LADA got the best F1 score with $\mu = 0.7$ on CoNLL and $\mu = 0.5$ on GermEval, which indicated the trade-off between noise and diversity (kNNs sampling with lower noise and random sampling with higher diversity) was necessary for Inter-LADA.

Tag Strategy	CoNLL	GermEval
None	83.28	79.64
Real	84.15	79.59
Repeat	82.67	78.27
O	83.13	78.48

5 Related Work

5.1 Named Entity Recognition

Conditional random fields (CRFs) (Lafferty et al., 2001b; Sutton et al., 2004) have been widely used for NER, until recently they have been outperformed by neural networks. Hammerton (2003) and Collobert et al. (2011) are among the first several studies to model sequence labeling using neural networks. Specifically Hammerton (2003) encoded the input sequence using a unidirectional LSTM (Hochreiter and Schmidhuber, 1997) while (Collobert et al., 2011) instead used a CNN with character level embedding to encode sentences. Ma and Hovy (2016); Lample et al. (2016b) proposed LSTM-CRFs to combine neural networks with CRFs that aim to leverage both the representation learning capabilities of neural network and structured loss from CRFs. Instead of modeling NER as a sequence modeling problem, Li et al. (2020) converted NER into a reading comprehension task with an input sentence and a query sentence based on the entity types and achieved competitive performance.

5.2 Semi-supervised Learning for NER

There has been extensive previous work (Altun et al., 2005; Søgaard, 2011; Mann and McCallum, 2010) that utilized semi-supervised learning for NER. For instance, (Zhang et al., 2017; Chen et al., 2018) applied variational autoencoders (VAEs) to semi-supervised sequence labeling; (Zhang et al., 2017) proposed to use discrete labeling sequence as latent variables while (Chen et al., 2018) used continuous latent variables in their models. Recently, contextual representations such as ELMO (Peters

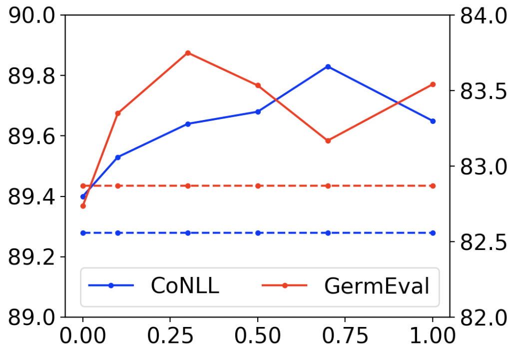

Figure 4: F1 score on test set training with 30% labeled data with different μ in BERT + Inter-LADA. The left Y axis is for CoNLL, and the right Y axis is for GermEval. Dashed lines are the F1 scores of BERT model.

et al., 2018b) and BERT (Devlin et al., 2019) trained on a large amount of unlabeled data have been applied to NER and achieved reasonable performances. Our work is related to research that introduces different data augmentation techniques for NER. For example, Lakshmi Narayan et al. (2019) applied noise injection and word dropout and obtained a performance boost, Bodapati et al. (2019) varied the capitalization of words to increase the robustness to capitalization errors, Liu et al. (2019) augmented traditional models with pretraining on external knowledge bases. In contrast, our work can be viewed as data augmentation in the continuous hidden space without external resources.

5.3 Mixup-based Data Augmentation

Mixup (Zhang et al., 2018) was originally proposed for image classification (Verma et al., 2018; Yun et al., 2019) as a data augmentation and regularization method , building on which Miao et al. (2020) proposed to interpolate sentences' encoded representations with augmented sentences by token-substitutions for text classification. Similarly, Chen et al. (2020a) designed a linguistically informed interpolation of hidden space and demonstrated significant performance increases on several text classification benchmarks. Cheng et al. (2020) performed interpolations at the embedding space in sequence-to-sequence learning for machine translations. Different from these previous studies, we sample sentences based on *local* additivity and utilize mixup for the task of sequence labeling.

6 Conclusion

This paper introduced a local additivity based data augmentation (LADA) methods for Named Entity Recognition (NER) with two different interpolation strategies. To utilize unlabeled data, we introduced a novel consistent training objective combined with LADA. Experiments have been conducted and proved our proposed methods' effectiveness through comparing with several state-of-the-art models on two NER benchmarks.

Abstract

Language models have emerged as a central component across NLP, and a great deal of progress depends on the ability to cheaply adapt them (e.g., through finetuning) to new domains and tasks. A language model's *vocabulary*—typically selected before training and permanently fixed later—affects its size and is part of what makes it resistant to such adaptation. Prior work has used compositional input embeddings based on surface forms to ameliorate this issue. In this work, we go one step beyond and propose a fully compositional output embedding layer for language models, which is further grounded in information from a structured lexicon (WordNet), namely semantically related words and free-text definitions. To our knowledge, the result is the first word-level language model with a size that does not depend on the training vocabulary. We evaluate the model on conventional language modeling as well as challenging cross-domain settings with an open vocabulary, finding that it matches or outperforms previous state-of-the-art output embedding methods and adaptation approaches. Our analysis attributes the improvements to sample efficiency: our model is more accurate for low-frequency words.

1 Introduction

Language models (LMs) are at the heart of natural language processing, especially following their recent success in the pretraining paradigm (Dai and Le, 2015; Peters et al., 2018; Devlin et al., 2019; Radford et al., 2019, *inter alia*). Continued advances in NLP rely on the adaptability of LMs to domains beyond their training data and to new domains and tasks, e.g., through domain adaptive pretraining followed by finetuning (Gururangan et al., 2020). Here, we focus on an important component of LMs, namely the **output vocabulary**—over which a LM's probability distribution over the "next word" (given the history) ranges—and investigate the impact of the type of its representation on the adaptability of neural LMs.

Today, LMs are typically trained with a closed output vocabulary derived from the training data; the vocabulary is not modified when the language model is adapted or deployed. This makes large pretrained language models struggle with rare words, despite being able to produce contextualized representations for them (Schick and Schütze, 2020). More importantly, this means a generative LM can never give nonzero probability to a specific word it did not see in training. This is a longstanding challenge of language modeling (Jelinek, 1997), but it becomes especially important when we adapt to new domains and tasks.

One way to "open up" the vocabulary is to model sequences of bytes, characters, or "wordpieces" rather than the conventional word tokens (Sennrich et al., 2016; Radford et al., 2018; Ponti et al., 2019). While effective, this approach requires the LM to memorize subsequences if it is to treat them as words. These models appear to require greater network depth and show slower convergence than word-based alternatives (Cherry et al., 2018; Al-Rfou et al., 2019); the extra work comes at a cost. This is one of the reasons why the area of word-level language modeling is still very active (Baevski and Auli, 2019; Sukhbaatar et al., 2019; Khandelwal et al., 2020; Press et al., 2020).

Interpolations between word- and character- or morphology-based LMs represent another class of solutions (Mielke and Eisner, 2018; Gerz et al., 2018; Ataman et al., 2020). These "hybrid" approaches combine benefits from both model types. However, they introduce complexity which makes them potentially more difficult to train, maintain, and analyze. Notable for enabling adaptability are interpolated LMs based on copy mechanisms (Merity et al., 2017), dynamic evaluation (Krause et al.,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1252–1267,
November 16–20, 2020.

2018), and neural caches (Grave et al., 2017c,a); the last provides state-of-the-art adaptation performance and, unlike the rest, it does not require additional training.

We propose a new word-level Grounded Compositional output LM (GroC) that applies a compositional representation to the output vocabulary (Section 3). Each word's output embedding is built from its surface character sequence and (if available) those of semantically related words and a free-text definition of from WordNet (Fellbaum, 1998). This parameterization offers two chief advantages. First, GroC can assign probability to words not seen during training. This means that a vocabulary different from the training vocabulary—e.g., one associated with a different text domain, crucial in adaptive settings—can be considered at inference time. Second, because there are no word type-specific parameters, the number of model parameters in GroC does not depend on the training vocabulary or its size.

We evaluate GroC on language modeling with both fixed and open vocabularies in English. On standard language modeling (Section 4) we observe that our model has superior perplexity and is more sample efficient than a variety of existing output embedding approaches, including the recent adaptive embedding of Baevski and Auli (2019). The open-vocabulary settings include a cross-domain setting and finetuning (Section 5). We find that GroC also outperforms strong interpolated baselines, including the unbounded neural cache model of Grave et al. (2017a) on "near" domains and performs competitively on "far" domains.

Our analysis shows that our approach has improved sharing across words in the output vocabulary. We show experimentally that the perplexity gains are strongest for low-frequency words, implying improved **sample efficiency** relative to baselines: compositional output representations allow us to predict words from fewer training examples.

2 Preliminaries on Language Modeling

Language models assign probability to sequences of tokens; the task is usually framed as learning the conditional probability distributions over individual tokens given their histories of tokens to the left (Bahl et al., 1983). Training requires a sequence of T tokens $\boldsymbol{x} = \langle x_1, \ldots, x_T \rangle$, each x_t a member of a preselected vocabulary $\mathcal{V}$. We let $\mathbf{x}_t \in \{0,1\}^{|\mathcal{V}|}$ denote the one-hot encoding of x_t. The probability of the sequence $\boldsymbol{x}$ is factored using the chain rule of probability:

$$p(\boldsymbol{x}) = \prod_{t=1}^{T} p(x_t \mid x_1, \ldots, x_{t-1}). \qquad (1)$$

To approximate this joint distribution, researchers have fit parametric families based on relative frequencies (Bahl et al., 1983; Kneser and Ney, 1995; Goodman, 2001) and neural networks (Bengio et al., 2003; Mikolov et al., 2010). Here, we focus on the latter due to their established effectiveness (Merity et al., 2018; Baevski and Auli, 2019). Tokens in this work correspond to words but they can also correspond to individual characters (Al-Rfou et al., 2019) or byte pairs (Radford et al., 2019).

2.1 Neural Language Models

To make clear this paper's contributions, we describe neural language models by decomposing them into several abstract parts.

In most neural language models, the first layer of computation obtains an input embedding of each history word x_j using a lookup function. In our notation, this corresponds to selecting the word type's row in a fixed **input embedding matrix**, $\mathbf{E}^{in}$: $\mathbf{x}_j^\top \mathbf{E}^{in}$, which we denote $\mathbf{e}^{in}_{x_j}$. Importantly, however, input embeddings need not be lookups; for example, they can be built compositionally from the characters in the surface form of the word (Ling et al., 2015), an idea central to this work.

Next, the history or "prefix" words $\boldsymbol{x}_{<t} = \langle x_1, \ldots, x_{t-1} \rangle$ is encoded into a fixed, d-dimensional vector $\mathbf{h}_{t-1}$ using a **prefix function** $f : \mathcal{V}^* \to \mathbb{R}^d$. f can be a recurrent or feedforward network; we will experiment with LSTMs (Hochreiter and Schmidhuber, 1997) in Section 4, but our method is agnostic to the prefix function design. In general, each history encoding is defined as

$$\mathbf{h}_{t-1} = f(\mathbf{e}^{in}_{x_1}, \ldots, \mathbf{e}^{in}_{x_{t-1}}). \qquad (2)$$

Finally, the distribution over the next word (random variable X_t) is given by

$$p(X_t = x_t \mid \mathbf{h}_{t-1}) \propto \exp\left(\mathbf{E}^{out}\mathbf{h}_{t-1} + \mathbf{b}\right), \qquad (3)$$

where $\mathbf{E}^{out} \in \mathbb{R}^{|\mathcal{V}| \times d}$ is the **output embedding matrix** and $\mathbf{b} \in \mathbb{R}^{|\mathcal{V}|}$ is the bias vector (corresponding roughly to unigram log-frequencies of words in the vocabulary).

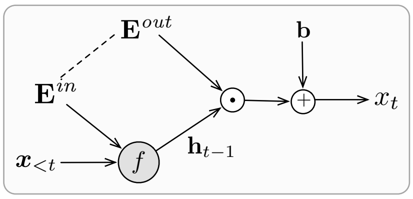
The parameters of the model—including all parameters of the prefix function f, $\mathbf{E}^{in}$, $\mathbf{E}^{out}$, and b—are all chosen by maximizing the likelihood of the training sequence $\boldsymbol{x}$ under the model (Eq. 1). Note that, though we focus on an autoregressive (left-to-right) language model objective, our analysis below is applicable to other language model pretraining objectives such as masked language modeling (Devlin et al., 2019) and replaced token detection (Clark et al., 2020).

2.2 Choice of Output Representations

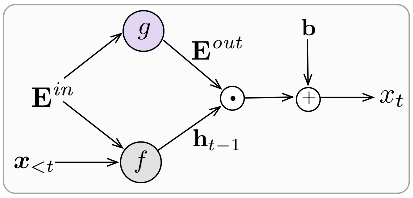
Above we assumed an output embedding matrix $\mathbf{E}^{out}$ that independently parameterizes each word in the vocabulary with a separate d-dimensional vector. This approach requires $d \times |\mathcal{V}|$ parameters, leading to concerns about cost and overparameterization. Prior work addressed this issue by tying parameters between the input and output embedding matrices (i.e., $\mathbf{E}^{out} = \mathbf{E}^{in}$; Inan et al., 2017; Press and Wolf, 2017). However, the parameters for each word are still independent from each other, as displayed in Figure 1(a).

An alternative, also considered here, is to share output parameters across words as well as with the input embeddings. Specifically, this involves making the output embedding a function of the input embedding using a shared parameterization across words, $\mathbf{E}^{out} = g(\mathbf{E}^{in})$, as displayed in Figure 1(b). For example, Gulordava et al. (2018) used a linear transformation, while Baevski and Auli (2019) used a linear transformation for each frequency bin to dedicate parameters to words proportional to their frequencies. Pappas and Henderson (2019) used a deep residual transformation as g, demonstrating that shared parameterizations perform better than independent ones. The two latter studies also provided evidence that models with shared parameterization are more *sample efficient* than independent parameterizations since they perform better on low-frequency words.

Limitations We argue that dependence of a model's parameterization on the size of the vocabulary leads to several limitations shared by current word-level language models. First, the output embedding methods above have terms that scale with the vocabulary size, such as the lookup table for the input embedding or the bias vector, which is a concern for the parameterization of infrequent words. Second, handling of words *unseen* in the training data leads us to the convention of uninformative "out-of-vocabulary" word types or linguistically naïve, data-driven vocabulary transformations that aggressively decompose words into smaller units (Sennrich et al., 2016). Finally, when pretrained language models are adapted on a downstream task, they do not allow graceful modifications to the vocabulary as required by the task or its data domain. Decoupling the training vocabulary from the target vocabulary that a model can use during inference or finetuning will simplify sequential training and enable open vocabularies.



(a) Independent



(b) Shared

Figure 1: Existing output layer parameterizations.

Building on encouraging results with compositional *input* embeddings (Ling et al., 2015; Józefowicz et al., 2016; Peters et al., 2018), we introduce a language model with shared compositional embeddings for input as well as for *output* word representations. Further, we go beyond past work based on surface forms, making optional use of relations and natural language definitions from structured lexicons like WordNet (Fellbaum, 1998). To our knowledge, this is the first word-level language model whose parameters do not depend on the vocabulary size and which is grounded to an external structured lexicon. Our experiments show that our models are more sample efficient (Section 4) on closed vocabularies and perform competitively on cross-domain settings (Section 5).

3 GroC: Grounded Compositional Output Language Models

We present our grounded compositional output language model (Figure 2).[1] Following the decomposition of neural language models in Section 2 (Equations 2–3), we consider each part of the model in turn: input embeddings (Section 3.1), output embeddings (Section 3.2), and bias (Section 3.3). As noted above, our approach is agnostic to the

---

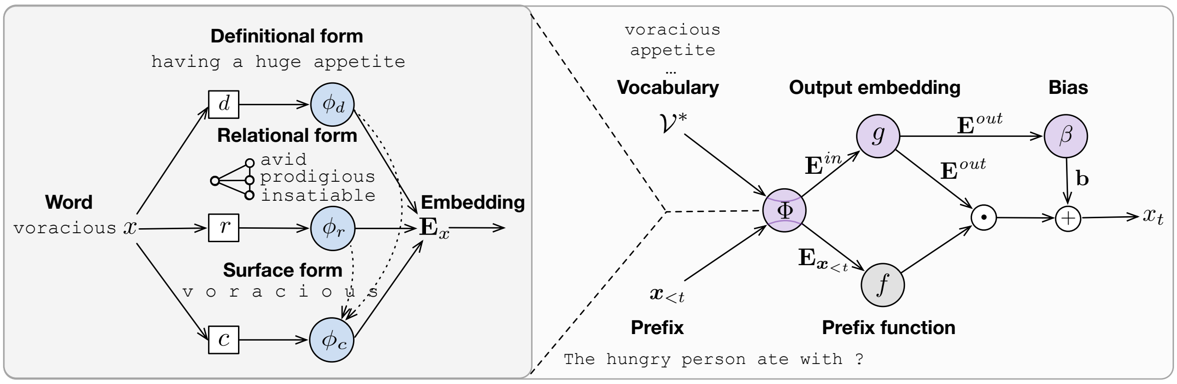

Figure 2: Grounded compositional output language modeling. (*Left*) The compositional input embedding is grounded in surface, relational, and definitional word forms from an external structured lexicon. (*Right*) The encoded prefix words are given as input to the prefix function and the words in an arbitrary vocabulary are given as input to the output embedding function and the bias function to predict the next word.

training vocabulary ($\mathcal{V}$) and to the prefix encoder (f) that has been the focus of most innovations in neural language model design.

3.1 Compositional Input Embeddings

We build on the compositional model of Ling et al. (2015), which encodes a word using its surface string (i.e., character sequence), adding two more sources of information. Peters et al. (2019) enhanced word representations with information from external relational knowledge bases, specifically for words that refer to entitites. Like them, we use a structured lexicon (WordNet); we encode every word in the lexicon using its neighbors. The second follows Bahdanau et al. (2017), who used **definitions** to represent out-of-vocabulary words; we encode definitions for all words (regardless of training-set frequency).

We begin by replacing the matrix $\mathbf{E}^{in} \in \mathbb{R}^{|\mathcal{V}|\times d}$ with a neural network that defines a word's embedding compositionally from its surface form, its position relative to other words in a structured lexicon, and a natural language definition. For each word x, we refer to these, respectively, as the word type's surface embedding $\mathbf{c}_x$, relational embedding $\mathbf{r}_x$, and definitional embedding $\mathbf{d}_x$. We assume each has a dimensionality of d. The last two are optional (if missing, they are set to zero), and we redefine $\mathbf{e}_x$ as the concatenation of the three, namely $\mathbf{e}_x = \langle \mathbf{c}_x, \mathbf{r}_x, \mathbf{d}_x \rangle$. For $\mathbf{r}_x$ and $\mathbf{d}_x$, we used the structured relations (synonyms and hyponyms) and free-text definitions in WordNet (Fellbaum, 1998).

In this study, we focus on simple, computationally efficient options for the three encoders. A word x's character sequence is encoded as surface encoding $\mathbf{c}_x$ using a convolutional network followed by a highway network (Józefowicz et al., 2016; Peters et al., 2018). Its relational encoding $\mathbf{r}_x$ is given by an average of $\mathbf{c}_{x'}$ across WordNet synonyms and hyponyms x'. The definitional encoding of x, $\mathbf{d}_x$, we similarly take an average of the surface encodings $\mathbf{c}_{x'}$ over words x' appearing in the definition. For computational efficiency, we set a maximum limit to the number of words to be used for both relations and definitions (see Appendix B.1).

If a word's information is not in WordNet, we set $\mathbf{r}_x$ and/or $\mathbf{d}_x$ to $\mathbf{0}$. In future work, additional encodings could be appended, such as contextualized examples (Khandelwal et al., 2020).

A notable property of these input embeddings is that their parameter count does not depend on the vocabulary size $|\mathcal{V}|$. Further, the vocabulary used in training need not be identical to the one used during finetuning, evaluation, or deployment. For example, during training we can use the full vocabulary combined with a softmax approximation method (e.g., Grave et al., 2017b), or by dynamically narrowing the choice of x_t based on its history using co-occurrence statistics (L'Hostis et al., 2016). During finetuning or evaluation, one can use the same vocabulary (required for traditional perplexity evaluations) or a different one chosen statically or dynamically, since any word's input embedding can be calculated compositionally.

3.2 Compositional Output Embeddings

One straightforward option for vocabulary size-independent output embeddings is to reuse the compositional input embeddings from Section 3.1, along the lines of Press and Wolf (2017). Concretely, at timestep t, we take the set $\mathcal{V}'_t$ of output word types allowed, embed each word type $v \in \mathcal{V}'_t$

as in Section 3.1, and stack these into a matrix $\mathbf{E}_t^{in}$ which serves directly as $\mathbf{E}^{out}$.

Though these compositional representations do enable extensive sharing across the vocabulary, we suspect that the features they capture may require additional processing before capturing "output" distributional similarity, especially when another domain is the real target use case for the language model. This follows prior work discussed in Section 2.2, which showed that making the output embedding a function of the input embeddings with shared parameters improves over simple tying.[2]

We therefore adopt a depth-k residual network for the output embedding function g (from Section 2.2) that consists of a feedforward function g_i at each layer j with d-dimensions each and apply it to the input embedding at timestep t:

$$\forall j : 1 \leq j \leq k, \mathbf{E}_t^{out(j)} = g_j\left(\mathbf{E}_t^{out(j-1)}\right) + \mathbf{E}_t^{in}$$
$$\mathbf{E}_t^{out(0)} = \mathbf{E}_t^{in}. \qquad (4)$$

Hence, we use $\mathbf{E}_t^{out(k)}$ as the output embedding at timestep t. To avoid overfitting, we apply variational dropout in between the layers, following Pappas and Henderson (2019). In contrast to that work, our resulting output embeddings are compositional. The depth k and the dropout rate are hyperparameters to be tuned on development data. The number of parameters is proportional to k times the number of parameters in the feedforward network ($O(d^2)$); it does not depend on the vocabulary size.

3.3 Bias

In conventional language models, each word in the vocabulary is assigned a bias parameter that roughly captures its log-frequency under a unigram distribution. This is the last part of a neural language model whose parameters depend on the vocabulary size. Instead of a dedicated, independent bias parameter for each word $v \in \mathcal{V}$, we define

$$b_v = \sigma\left(\mathbf{w} \cdot \mathbf{e}_v^{out} + a\right), \qquad (5)$$

where σ is the activation function and we introduce parameters $\mathbf{w} \in \mathbb{R}^d$ and $a \in \mathbb{R}$. The bias values b_v are stacked to form $\mathbf{b}$ and used in Equation 3.

3.4 Training

Since all components are differentiable with respect to their parameters, the entire model can be trained to maximize training-data likelihood as described earlier (Section 2.1). Parameters include:

- Input character embeddings, the convolutional network for $\mathbf{c}_*$, and $3d^2$ parameters for projection (Section 3.1);
- Output embedding transformation, including the depth-k feedforward network for output embeddings (Section 3.2) and the bias parameters (Section 3.3); and
- Prefix encoder f, an orthogonal design choice to our method (an LSTM in our experiments).

The model size can be adjusted by changing output embedding hyperparameters to fit a given memory requirement — this is the same as any other neural network. Note that despite our vocabulary-size independent parameterization, we still need to process all the words in the supplied vocabulary leading to increased training times despite the model's sample efficiency. This can be prohibitive for very large vocabularies ($\geq 100K$), where we recommend using softmax approximation methods and making sparse updates of the output embedding parameters (see Appendix 1.3). During inference, $\mathbf{E}^{out}$ can be cached for fast access; there is no need to execute a forward pass more than once.

4 Conventional Language Modeling

We first establish the performance of GroC in the conventional closed-vocabulary setting, considering two datasets. We consider out-of-sample generalization (measured by test-set perplexity) and also analyze fit across the vocabulary by frequency bin.

4.1 Experimental Setup

Datasets. We evaluate our methods on two English datasets: `penn` (Marcus et al., 1993) and `wikitext2` (Merity et al., 2017). We report test perplexity using the provided training/dev./test splits (see details in Appendix B.3). Table 1 also quantifies the percentage of each dataset's vocabulary that is covered by WordNet (used to derive relational and definitional encodings).

Dataset	genre	$\lvert\mathcal{V}\rvert$	# tokens	WNet cov.	
`penn`	news	10K	929K	78	86
`wikitext2`	Wikip.	33K	2M	73	76

Table 1: Language modeling dataset statistics.

---

[2] Note that the input embeddings are passed through the prefix encoder f, which uses additional parameters to create the hidden state $\mathbf{h}_{t-1}$.

Models. All of the models compared use the same prefix encoder: a vanilla recurrent neural network based on the implementation by Merity et al. (2017) with 2 layers and 1024 LSTM units, regularized with hidden unit dropout of 0.65 along the lines of Grave et al. (2017a). More details are given in Appendix B.4. The following output embedding approaches are compared:

- **Lookup table**: trains a full output embedding lookup table that corresponds to the vocabulary as defined in Eq. 3.
- **Convolutional** (Józefowicz et al., 2016): an alternative to a lookup table that uses a character-level convolutional neural network followed by a highway network plus a linear "correction" for each vocabulary element to represent the outputs.[3]
- **Tied** (Press and Wolf, 2017): avoids training separate input and output embedding matrices by tying their parameters. This is a common technique that mitigates the overparameterization issue of the lookup table.
- **Bilinear** (Gulordava et al., 2018): performs a simple linear transformation of the input embedding to produce the output embedding that effectively shares parameters across outputs.
- **Deep residual** (Pappas and Henderson, 2019): performs a deep residual transformation of the input embedding with variational dropout in between its layers, which is more expressive than the bilinear one.
- **Adaptive** (Baevski and Auli, 2019): uses a bilinear transformation of the input and output embedding with parameters proportional to the word frequencies, to assign more capacity to frequent words and less capacity to infrequent ones. This is considered to be a state-of-the-art output embedding method.
- **GroC** (ours): the grounded compositional output embedding described in Section 3.2.

For fair comparison, we apply variational dropout to all output embeddings. Hyperparameter selection of dropout rates, output network depth and activation, linear "correction," and adaptive frequency cutoffs was conducted by grid search on validation data. Details are given in Appendix B.2.

	`penn`		`wikitext2`	
Output embedding	$\|\Theta\|$	test	$\|\Theta\|$	test
Lookup table	13M	90.8	23M	108.3
Convolutional [J16]	13M	101.6	23M	116.6
Tied [PW17]	10M	86.2	15M	97.3
Bilinear [G18]	10M	83.7	15M	95.9
Deep residual [PH19]	10M	80.5	15M	94.7
Adaptive [AM19]	8M	79.3	9M	90.7
GroC (ours)	9M	69.5	9M	82.5

Table 2: Perplexity scores on conventional language modeling benchmarks with closed vocabulary. $|\Theta|$ denotes the total number of model parameters.

4.2 Results

Table 2 reports perplexities achieved by all seven models. The main finding is that GroC achieves lower perplexity than the previous models, on both datasets. Note that GroC outperforms the state-of-the-art output embedding method of Baevski and Auli (2019); specifically, by -9.8 and -8.2 points on `penn` and `wikitext-2`, respectively. The difference with the other methods is even larger. We also confirm the findings of Pappas and Henderson (2019), that output parameter sharing methods outperform tied output embedding and the lookup table, and, of Józefowicz et al. (2016), that convolutional output embeddings lag behind full softmax (lookup table). Notably, GroC outperforms the best reported scores by Merity et al. (2017) and Grave et al. (2017a) on `penn`, using about 11M fewer parameters and a similar prefix network to the latter. See Appendix B.5 for a more detailed comparison with state-of-the-art models of similar size.

Nevertheless, GroC is about $1.3\times$ slower than the convolutional method on `penn`; with sparse updates ($p > 0.3$) we can make it $2.1\times$ faster than that method, which is comparable to the speed of the bilinear method, while maintaining a perplexity improvement of -26 points (see detailed speed comparisons in Table 10 in Appendix B.4).

4.3 Analysis

The experiment above establishes that our approach achieves improved perplexity relative to alternative output embeddings. We next decompose its performance in various ways to understand why.

Word frequency effects. We conjecture that GroC's main benefit comes from words that are rare in the training data, since the core contribution is to share representations across the vocabulary. To evaluate this hypothesis, we consider the difference in test loss (cross entropy) between GroC and a

---

[3] Note that we chose not to use a linear "correction" with GroCince it deviates from our goal of having a vocabulary-independent parameterization, but it could be applied to GroCn the future for additional improvements.

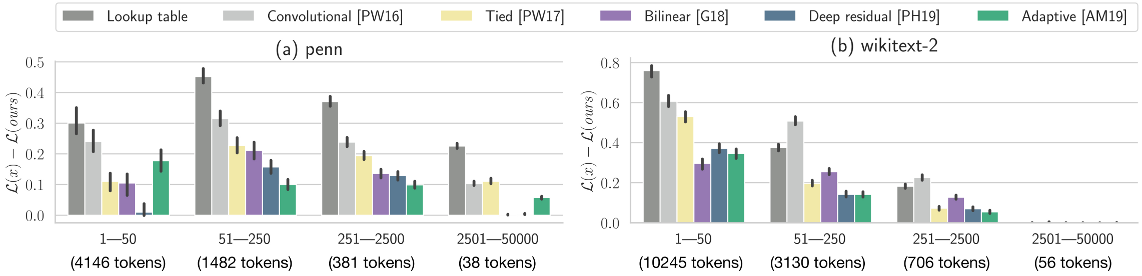

Figure 3: Median loss difference between each baseline and GroC over different word frequency intervals on `penn` (a) and `wikitext2` (b). The biggest differences are mostly observed on words with low training frequencies.

baseline model, following Baevski and Auli (2019) but computing the median instead of the average to reduce the effect of outliers. We decompose this score by data frequency bins (e.g., words occurring 1–50 times in the training dataset). Figure 3 is displayed for the `penn` and `wikitext2` datasets. The trend we observe is that GroC has the greatest relative benefit for words in lower frequency bins, compared to each model. The lowest-frequency bin on `penn` deviates from this pattern, which we take as an indication that generalizing to infrequent words with only 1M training tokens and a small 10K vocabulary is inherently challenging.

Ablations. To assess the contributions of GroC's components, we performed ablation tests on `penn` and `wikitext2` (Table 3). These include removing relational and/or definitional forms, either with or without a deep residual output network. For fairness, we tune the hyperparameters of the ablated model variants as above. Overall, removing the relational and definitional forms from the main model with or without output network on top increases the perplexity. The largest drop in perplexity happens when we remove both forms, which highlights their notable contribution to the full model. Lastly, the results on `wikitext2` highlight the importance of capturing the output similarity with an output network (out) for datasets with a larger vocabulary as opposed to merely reusing the grounded compositional embeddings as output embeddings.

	`penn`		`wikitext2`	
Model	dev.	test	dev.	test
GroC + out	75.0	71.4 -	87.0	82.5 -
– relations	77.1	72.7 ↑	90.2	85.3 ↑
– definitions	75.6	72.0 ↑	88.6	84.3 ↑
– both	79.8	75.8 ↑	94.3	89.8 ↑
GroC	72.5	69.5 -	88.7	84.1 -
– relations	74.2	70.8 ↑	93.0	88.0 ↑
– definitions	74.4	71.1 ↑	87.6	83.1 ↓
– both	76.3	73.2 ↑	94.5	89.5 ↑

Table 3: Ablated model variants on `penn` and `wikitext-2`. *out*: the deep residual output network.

Lexicon coverage. To measure the effect of lexicon coverage on model performance in a controlled setting, we artificially remove words from WordNet, making them unavailable for relational and definitional encodings. In this experiment, we consider the `penn` dataset, where WordNet's coverage over the (relatively small) vocabulary is highest to begin with. Table 4 shows the resulting test perplexity of a pretrained model (inference) and a model trained from scratch (train) when such controlled manipulation is applied to them from 0% up to the maximum of 82% coverage (Table 1) . Note that we treat relational independently of definitional forms since they are not always co-present. Overall, the results indicate that the model is sensitive to changes in the forms of words that have been seen during training but it is robust to changes if it is trained from scratch. In the next section, we investigate what happens when we add forms for words which the model has never seen before.

Coverage	surf.	0%	16%	32%	48%	64%	82%
inference	73.1	187.8	159.3	128.5	102.6	83.5	69.5
train	–	72.4	70.0	70.4	69.6	70.7	69.5

5 Cross-Domain Language Modeling

To demonstrate our model's ability to generalize beyond its training data, we evaluate it across domains with an open vocabulary, in two settings: zero-resource, where it is first trained on one domain and then tested on a new target domain, and low-resource, in which the model is further exposed to training data in the new domain.

5.1 Experimental Setup

Data. Following Grave et al. (2017a), we create English datasets from News Crawl (Bojar et al.,

	Model		near domains				far domains

	GroC + finetuning	–	**153.7**	**162.2**	**167.0**	**170.6**	239.5	**216.9**

Table 5: Results on *near* and *far* cross-domain language modeling with an open vocabulary with a zero-resource or a low-resource setting. Top four rows display scores from Grave et al. (2017a), while the next three are from our re-implementation with a stronger base model. Boldface marks the best perplexity on each test set.

Dataset	source	train $\vert V \vert$	test $\vert V \vert$	OOV%
`2007`	News Crawl	81K	188K	2.0
`2008`		82K	197K	2.3
`2009`		81K	195K	2.5
`2010`		78K	181K	2.4
`2011`		80K	184K	2.5
`web`	Common Crawl	75K	174K	5.8
`wiki`	WikiText-103	67K	109K	5.4

Table 6: Dataset statistics for cross-domain experiments. OOV% gives the percentage of tokens in the test set not present in the `2007` train vocabulary.

2014), Common Crawl,[4] and WikiText-103 (Merity et al., 2017). Dataset statistics are given in Table 6. All models are trained on 2M tokens from the `2007` dataset and evaluated on 10M tokens; finetuning is done on an additional 2M tokens from the target domain. We consider the domain of the `2008-2011` datasets to be similar ("near") to that of the training set, `2007`, as they contain news from different time periods. In comparison, `web` and `wiki` are more different ("far") from `2007`.

Models. We compare GroC to the tied output embedding model described in Section 4.1 when combined with the following adaptation methods:

- **Unigram**: we interpolate the model's distribution with a unigram cache, which assigns probabilities based on the counts of words in the test data observed so far during evaluation.
- **Local cache**: we interpolate the model's distribution with a neural cache (Grave et al., 2017c), which assigns probabilities based on the similarity of the current hidden state to previous hidden states during evaluation.
- **Finetuning**: the model is finetuned on 2M tokens from the target domain.

(We also compare to the reported unbounded cache results from Grave et al., 2017a.) Cache models provide effective adaptation without training by using recent history to develop an auxiliary distribution during evaluation, informing predictions of unseen or rarely-seen words. However, as GroC already assigns non-negligible weight to new words not seen prior to evaluation, the cache has less effect by default, even if its predictions are more accurate, an effect we observed in validation. To address this, we down-weighted the model's predictions for new words prior to cache interpolation by 0.1. For finetuning, both tied and GroC models were trained for an additional 3 epochs on the target domain, allowing them to adapt to the new domain. See Appendix C.4 for hyperparameter details.

Vocabulary setting. For a fair comparison, all models are evaluated on the union of the training and test vocabularies. Tied models are interpolated with the uniform distribution at test time to prevent infinite perplexities on unseen words, prior to cache interpolation if applicable. Words present in the finetuning data but not in the original training data are given random embeddings prior to finetuning.

---

[4] We used the version from WMT 2014 (Bojar et al., 2014).

5.2 Results

The results for the cross-domain experiments are shown in Table 5. Standalone GroC improves perplexity relative to the tied model in every domain by up to −30 points, including the local neural cache and the unbounded neural cache model in the near-domain, even when the former is applied to our own stronger tied-embedding baseline model. In addition, finetuned GroC outperforms all previous baselines by a wide margin including the unbounded cache by about −40 and −132 points on near and far domains, respectively. Here, GroC outperforms the finetuned tied model by up to −25 points except in `web` domain, and reaches lower validation scores with fewer iterations in 5 out of 6 domains (see Appendix C.1). For the `web` domain, caches and finetuning are more effective than in any other domain, indicating unique domain dynamics worthy of further study.

6 Conclusion

We proposed an adaptive language model based on grounded compositional outputs. We demonstrated that it reduces the number of parameters and increases sample efficiency, outperforming strong output embedding methods and adaptation baselines on both in-domain and open-vocabulary settings respectively. In principle, our results should be applicable to word-piece language models which are currently based on lookup tables to improve their sample efficiency and compactness. In future work, it would be interesting to investigate to what extent pretrained language models benefit from GroC on such zero-resource or low-resource adaptation settings. This work indicates several other future directions for language modeling in low-resource domains: extension to other languages, scaling training to even larger vocabularies, and applying GroC in a large pretraining setting to expand its zero-shot generalization.

A Supplementary Material for "Grounded Compositional Outputs for Adaptive Language Modeling"

We report here the computer infrastructure, experimental details, including hyperparameter bounds, hyperparameter optimal values, training speed, development scores, for both of the experiments where applicable. We also provide a comparison with state of the art by taking into account the number of model parameters and guide the reader through the replication effort we did to reproduce the neural cache by Grave et al. (2017a).

B Conventional Language Modeling

For the experiments with a closed vocabulary on `penn`[5] and `wikitext-2`,[6] we used the following computing infrastructure: 5 GeForce RTX 2080 Ti gpu cards. Our codebase is based on Pytorch[7] and is publicly available on Github.[8]

B.1 Model Configuration

The prefix network used by all output embedding methods is a vanilla recurrent neural network based on the implementation by Merity et al. (2017)[9] with 2 layers and 1024 LSTM units, regularized with hidden unit dropout of 0.65 along the lines of Grave et al. (2017a). The maximum length of the relational and definitional forms from Wordnet is set to 3 and 10 without search based on our computational budget.[10] The embedding size is set to 300 for `penn` and 256 for `wikitext2`. For optimization we use Adam with a learning rate of 0.001, initial weight uniformly sampled in the range $[-0.05, 0.05]$, and a batch size of 20 for `penn` and `wikitext2`. We clip the norm of the gradient to 0.1 and unroll the network for 35 steps. The learning rate is multiplied by 0.1 if the development loss does not decrease for 4 consecutive epochs and we perform early stopping if there is no improvement for 8 consecutive epochs.

Hyperparameter	abbrev.	range	trials
Output dropout	r	$\{0, 0.1, \ldots, 1.0\}$	10
Linear correction	cor	$\{32, 64, 128\}$	3
Adaptive cutoffs	cut	$\{253, 721, 118, 226, 424, 334\}$	6
Output net depth	k	$\{0, 1, 2, 3, 4\}$	4
Output net activation	act	$\{relu, selu, tanh\}$	3

Table 7: Hyperparameters, range of values, and, number of trials required to search them. Adaptive cutoffs are read as follows: e.g. for 253 the cutoff array contains $[0.2 * n, 0.5 * n, 0.3 * n], n = |\mathcal{V}|$ words per bin.

B.2 Hyperparameter Optimization

For all methods, the hyperparameter selection of output embedding dropout rate (r), output network depth (k) and activation (act), linear "correction", and adaptive frequency cutoffs was conducted by grid search over specific range of values given in Table 7 on development data. Note that not all the hyperparameters apply to all methods, as can be seen in Table 8 where we report the optimal hyperparameter values for each of the methods. For all the baselines we performed exhaustive grid search on both datasets, but for our method we performed grid search only on `penn` and searched manually on `wikitext-2` by selecting values of hyperparameters that were ranked high based on the grid search on `penn` to avoid the increased cost that comes with training our method (see speed comparison in Appendix B.4). The total number of trials for all methods including our ablations were 204 and 67 respectively for `penn` and `wikitext-2` respectively. Note that the reduced number of trials is due to not performing exhaustive search for our method and its ablations as explained above. The number of trials per method can be derived by

multiplying the non-zero columns per row with the number of trials required for each column.

B.3 Development Scores

Table 9 displays the development scores and number of parameters along with the test perplexities for our model and all the baseline output embedding methods for our main experiment. The development scores for the models of the ablation study and for the base models of the coverage experiment have already been given in Table 3 in the main paper (Section 4.3). Overall, we can observe that in most cases the ranking based on the development scores is indicative of the ranking of the methods according to the test scores.

Table 9: Development and test scores on conventional language modeling benchmarks with closed vocabulary. $|\Theta|$ denotes the total number of model parameters.

B.4 Training Speed

Table 10 displays the average training speed per epoch in seconds for each of the methods. This experiment was run on a single, dedicated[11] GeForce RTX 2080 Ti. As we mentioned in Section 3.1, even though our model has vocabulary-size independent parameterization it is not independent of the computation that is required to encode the vocabulary. This has a negative impact on the training speed of GroC, making it a bit slower than the Convolutional method, namely 1.3× slower.

To mitigate this problem we recommend training GroC with sparse updates for the output embedding parameters as described in the main paper (Section 3.4). Concretely, at each training iteration with probability p we make a full update and keep the output embedding frozen otherwise. The rest of the network is trained with full updates as before. We can observe that this optimization strategy makes GroC nearly as efficient as the baselines with $p = 0.1$ or $p = 0.3$. In particular, it becomes even faster than the convolutional baseline by $2.1\times$. Furthermore, our best model with $p = 0.3$ which is much faster reaches 75.3 perplexity on `penn` without additional hyperparameter optimization which is still -4 points lower than the second best, adaptive output embedding; tuning the model from scratch should likely lead to even better results. This is quite encouraging because it means that the benefits of our model need not come with a large computational cost. In future work, the training speed could be optimized even further by devising specialized efficient training methods for compositional outputs.

– 90% updates	46.0	299.0

Table 10: Training speed for each method. We report the average time in seconds to complete one epoch.

B.5 Comparison with State-of-the-Art Models

Table 11 displays several state-of-the-art models which have number of parameters ranging from 9M to 20M on Penn Treebank. We can observe that our model which has only 9.7M parameters achieves better performance than all the models that have lower than or equal to 21M parameters and even the model by Inan et al. (2017) which has 24M parameters. Note that our model has lower perplexity than the pointer sentinel mixture model by Merity et al. (2017) and the neural cache model by Grave et al. (2017a) while having 11M less parameters than them.

Moreover, it is very close to the other models which have around 23-25M parameters without being highly regularized (weight dropout, input dropout) or having advanced optimization strategies (SGD + ASGD, finetuning) like AWD-LSTM (Merity et al., 2017). Training larger models and

---

[11] By dedicated GPU card here we mean that no other processes were using the GPU card when we performed the experiments for each of the methods.

Table 11: Comparison with state-of-the-art models of comparable size to that of Grave et al. (2017a) and Merity et al. (2017) on the `penn` dataset.

investigating the potential of competing with even higher capacity models is an interesting direction which we hope will be explored in future studies.

C Cross-Domain Language Modeling

For the experiment in cross-domain language modeling, we used the following computing infrastructure: 2 GeForce RTX 2080 Ti and 2 TITAN RTX GPUs to train and finetune our GroC models, and 2 Tesla P100 GPUs to train and finetune the baselines and to perform hyperparameter search.

C.1 Finetuning Dynamics

Figures 4 and 5 show the loss on the training and validation data for the target domain during finetuning. GroC generalizes better from the training to the validation data than the tied model, consistently having lower validation loss. The training loss for GroC consistently starts out lower than that the of the tied model, showing that it has less difficulty adapting to the new data, and ends up higher, indicating greater regularization vs the tied model.

The `web` dataset is a clear outlier, in which the tied model improves much more dramatically than in any other domain. The difference in validation performance here is reflected in the test perplexity (Table 5) but does not have a clear explanation.

C.2 Data

As described in Section 5, the choice of data and preprocessing used for the cross-domain experiments are based on Grave et al. (2017a). News Crawl and Common Crawl can be downloaded from the WMT 2014 website.[12] WikiText-103 was downloaded from Salesforce website[13]. For the News Crawl datasets, the first 2M tokens of the English data for each year were used as the train

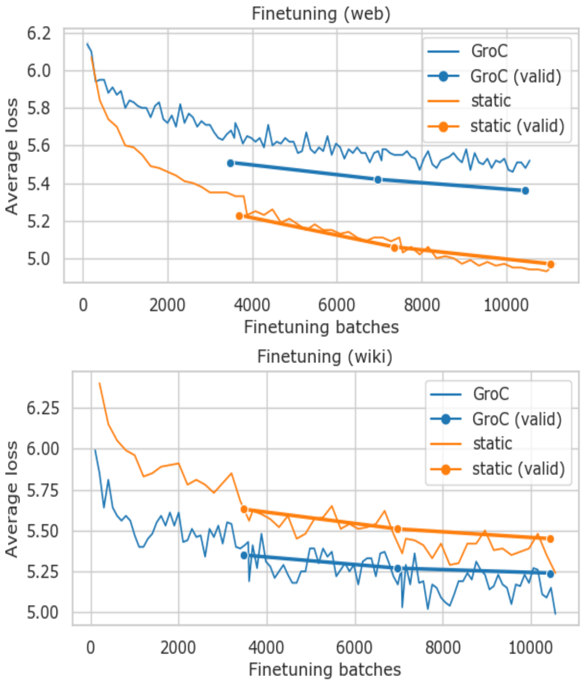

Figure 5: Training and validation loss for GroC and the tied model during finetuning, on far domains.

set, the next 2M tokens as the validation set, and the next 10M tokens as the test set. The same procedure was used for `web` (Common Crawl), for which we used the English portion of the English-German aligned data. While Grave et al. (2017a) describes the Common Crawl data as shuffled at the sentence level, we found that most sentences seemed closely related to adjacent sentences, so after creating train/valid/test splits for this dataset we re-shuffled each file. WikiText-103 comes divided into train/valid/test splits, so we used the first 2M/2M/10M tokens of each split respectively for our dataset. All data was then tokenized using the Europarl tokenizer[14] and lowercased.

Our data preprocessing can be replicated with the script `create-data.sh`, available with the code for GroC.[15]

C.3 Finetuning Validation Results

Because no target-domain training is required for most of our cross-domain experiments, validation scores were not computed for most model-domain combinations; however, we report the validation perplexity for the finetuned models in Table 12, to aid in replication.

C.4 Hyperparameter Selection

Cache hyperparameters were selected via grid search, with θ, the flattening hyperparameter described in Grave et al. (2017c), ranging over 5 values from 0 to 1, and λ ranging over 5 values from 0.833 to 0.966 (bounds which were selected based on the optimal hyperparameter ranges in (Grave et al., 2017c)). Perplexity of a model trained on `2007` and evaluated on the `2008` validation set was the metric used to select the optimal hyperparameters: $\lambda = 0.966$ for unigram and neural cache and $\theta = 0.5$ for neural cache. Because the cache is only used during evaluation, this hyperparameter search was quite efficient to carry out using the tied model, requiring no additional training, only 25 evaluation runs on the validation set. This hyperparameter search is illustrated in Figure 6.

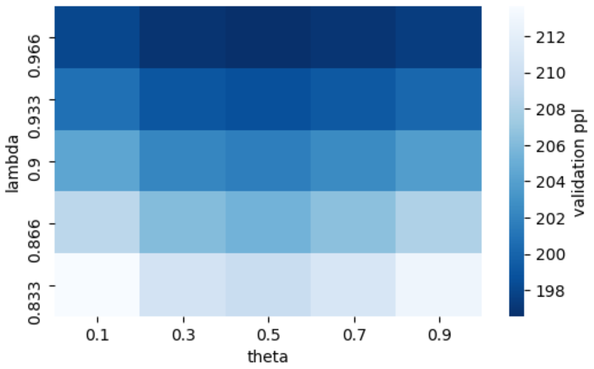

Figure 6: Validation accuracy for various hyperparameter settings on the `2008` validation set.

We then used the same hyperparameters for all cache models. This provides a slight advantage to the tied model, as the optimal hyperparameters for GroC might be different from those selected with the tied model. A cache size of 5,000 was used

---

[14] `statmt.org/europarl/v7/tools.tgz`

[15] `github.com/<anon>/groc`

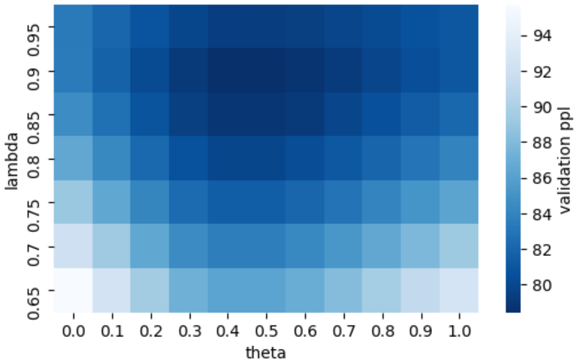

Figure 7: Validation accuracy for various hyperparameter settings on the `penn` validation set.

during hyperparameter tuning, but at test time we used 10,000 for all experiments based on its use in Grave17. Figure 7 shows a separate hyperparameter search performed over the `penn` validation set to confirm the accuracy of our neural cache reimplementation. Compare to Figure 2a in Grave et al. (2017c); note their λ is 1 minus ours.

For GroC, we also selected a downweighting hyperparameter dw, based on validation performance on the `wiki` dataset only. We searched over 5 values (0.1, 0.3, 0.5, 0.7, and 0.9) using GroC with the neural cache, and selected $dw = 0.1$ as the best value with a validation ppl of 154.01.

SSMBA: Self-Supervised Manifold Based Data Augmentation for Improving Out-of-Domain Robustness

New York University

Marzyeh Ghassemi
University of Toronto
Vector Institute

Abstract

Models that perform well on a training domain often fail to generalize to out-of-domain (OOD) examples. Data augmentation is a common method used to prevent overfitting and improve OOD generalization. However, in natural language, it is difficult to generate new examples that stay on the underlying data manifold. We introduce **SSMBA**, a data augmentation method for generating synthetic training examples by using a pair of corruption and reconstruction functions to move randomly on a data manifold. We investigate the use of SSMBA in the natural language domain, leveraging the manifold assumption to reconstruct corrupted text with masked language models. In experiments on robustness benchmarks across 3 tasks and 9 datasets, SSMBA consistently outperforms existing data augmentation methods and baseline models on both in-domain and OOD data, achieving gains of 0.8% accuracy on OOD Amazon reviews, 1.8% accuracy on OOD MNLI, and 1.4 BLEU on in-domain IWSLT14 German-English. [1]

1 Introduction

Training distributions often do not cover all of the test distributions we would like a supervised classifier or model to perform well on. Often, this is caused by biased dataset collection (Torralba and Efros, 2011) or test distribution drift over time (Quionero-Candela et al., 2009). Therefore, a key challenge in training machine learning models in these settings is ensuring they are robust to unseen examples. Since it is impossible to generalize to the entire distribution, methods often focus on the adjacent goal of *out-of-domain robustness*.

Data augmentation is a common technique used to improve out-of-domain (OOD) robustness by synthetically generating new training examples (Simard et al., 1998), often by perturbing existing examples in the input space (Perez and Wang, 2017). If data concentrates on a low-dimensional manifold (Chapelle et al., 2006), then these synthetic examples should lie in a manifold neighborhood of the original examples (Chapelle et al., 2000). Training models to be robust to such local perturbations has been shown to be effective in improving performance and generalization in semi-supervised and self-supervised settings (Bachman et al., 2014; Szegedy et al., 2014; Sajjadi et al., 2016). When the underlying data manifold exhibits easy-to-characterize properties, as in natural images, simple transformations such as translation and rotation can quickly generate local training examples. However, in domains such as natural language, it is much more difficult to find a set of invariances that preserves meaning or semantics.

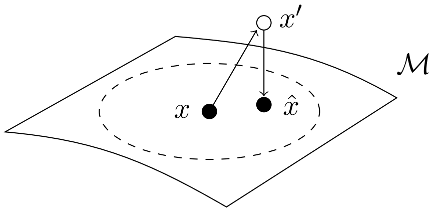

Figure 1: SSMBA moves along the data manifold $\mathcal{M}$ by using a corruption function to perturb an example x off the data manifold, then using a reconstruction function to project it back on.

In this paper we propose **S**elf-**S**upervised **M**anifold **B**ased Data **A**ugmentation (**SSMBA**): a data augmentation method for generating synthetic examples in domains where the data manifold is difficult to heuristically characterize. Motivated by the use of denoising auto-encoders as generative models (Bengio et al., 2013), we use a corruption function to stochastically perturb examples *off* the data manifold, then use a reconstruction function to project them *back on* (Figure 1). This ensures new

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1268–1283,
November 16–20, 2020.

examples lie within the manifold neighborhood of the original example. SSMBA is applicable to any supervised task, requires no task-specific knowledge, and does not rely on class- or dataset-specific fine-tuning.

We investigate the use of SSMBA in the natural language domain on 3 diverse tasks spanning both classification and sequence modelling: sentiment analysis, natural language inference, and machine translation. In experiments across 9 datasets and 4 model types, we show SSMBA consistently outperforms baseline models and other data augmentation methods on both in-domain and OOD data.

2 Background and Related Work

2.1 Data Augmentation in NLP

The problem of domain adaptation and OOD robustness is well established in NLP (Blitzer et al., 2007; Daumé III, 2007; Hendrycks et al., 2020). Existing work on improving generalization has focused on data augmentation, where synthetically generated training examples are used to augment an existing dataset. It is hypothesized that these examples induce robustness to local perturbations, which has been shown to be effective in semi-supervised and self-supervised settings (Bachman et al., 2014; Szegedy et al., 2014; Sajjadi et al., 2016).

Existing task-specific methods (Kafle et al., 2017) and word-level methods (Zhang et al., 2015; Xie et al., 2017; Wei and Zou, 2019) are based on human-designed heuristics. Back-translation from or through another language has been applied in the context of machine translation (Rico Sennrich, 2016), question answering (Yu et al., 2018), and consistency training (Xie et al., 2019). More recent work has used word embeddings (Wang and Yang, 2015) and LSTM language models (Fadaee et al., 2017) to perform word replacement. Other methods focus on fine-tuning contextual language models (Kobayashi, 2018; Wu et al., 2019b; Kumar et al., 2020) or large generative models (Anaby-Tavor et al., 2020; Yang et al., 2020; Kumar et al., 2020) to generate synthetic examples.

2.2 VRM and the Manifold Assumption

Vicinal Risk Minimization (VRM) (Chapelle et al., 2000) formalizes data augmentation as enlarging the training set support by drawing samples from a *vicinity* of existing training examples. Typically the vicinity of a training example is defined using dataset-dependent heuristics. For example, in computer vision, examples are generated using scale augmentation (Simonyan and Zisserman, 2015), color augmentation (Krizhevsky et al., 2012), and translation and rotation (Simard et al., 1998).

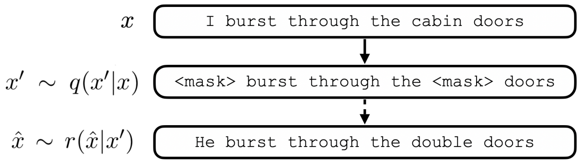

Figure 2: To sample from an MLM DAE, we apply the MLM corruption q to the original sentence then reconstruct the corrupted sentence using our DAE r.

The *manifold assumption* states that high dimensional data concentrates around a low-dimensional manifold (Chapelle et al., 2006). This assumption allows us to define the vicinity of a training example as its *manifold neighborhood*, the portion of the neighborhood that lies on the data manifold. Recent methods have used the manifold assumption to improve robustness by moving examples towards a decision boundary (Kanbak et al., 2018), generating adversarial examples (Szegedy et al., 2014; Miyato et al., 2017), interpolating between pairs of examples (Zhang et al., 2018), or finding affine transforms (Paschali et al., 2019).

2.3 Sampling from Denoising Autoencoders

A denoising autoencoder (DAE) is an autoencoder trained to reconstruct a clean input x from a stochastically corrupted one $x' \sim q(x'|x)$ by learning a conditional distribution $P_\theta(x|x')$ (Vincent et al., 2008). We can sample from a DAE by successively corrupting and reconstructing an input using the following pseudo-Gibbs Markov chain: $x'_t \sim q(x'|x_{t-1})$, $x_t \sim P_\theta(x|x'_t)$. As the number of training examples increases, the asymptotic distribution $\pi_n(x)$ of the generated samples approximate the true data-generating distribution $P(x)$ (Bengio et al., 2013). This corruption-reconstruction process allows for sampling directly along the manifold that $P(x)$ concentrates on.

2.4 Masked Language Models

Recent advances in unsupervised representation learning for natural language have relied on pretraining models on a *masked language modeling* (MLM) objective (Devlin et al., 2018; Liu et al., 2019). In the MLM objective, a percentage of the input tokens are randomly corrupted and the model is asked to reconstruct the original token given its

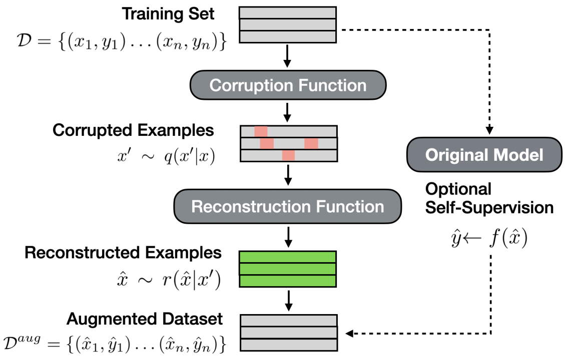

Figure 3: SSMBA generates synthetic examples by corrupting then reconstructing the original training inputs. To form the augmented dataset, corresponding outputs are preserved from the original data or generated from a supervised model f trained on the original data.

left and right context in the corrupted sentence. We use MLMs as DAEs (Lewis et al., 2019) to sample from the underlying natural language distribution by corrupting and reconstructing inputs (Figure 2).

3 SSMBA: Self-Supervised Manifold Based Augmentation

Algorithm 1 SSMBA

```
Require: perturbation function $q$
         reconstruction function $r$
Input: Dataset $\mathcal{D} = \{(x_1, y_1) \dots (x_n, y_n)\}$
       number of augmented examples $m$
function SSMBA($\mathcal{D}$, $m$)
    train a model $f$ on $\mathcal{D}$
    for $(x_i, y_i) \in \mathcal{D}$ do
        for $j \in 1 \dots m$ do
            sample perturbed $x'_{ij} \sim q(x'|x_i)$
            sample reconstructed $\hat{x}_{ij} \sim r(\hat{x}|x'_{ij})$
            generate $\hat{y}_{ij} \leftarrow f(\hat{x}_{ij})$ or preserve
            the original $y_i$
        end for
    end for
    let $\mathcal{D}^{aug} = \{(\hat{x}_{ij}, \hat{y}_{ij})\}_{i=1 \dots n, j=1 \dots m}$
    augment $\mathcal{D}' \leftarrow \mathcal{D} \cup \mathcal{D}^{aug}$
    return $\mathcal{D}'$
end function
```

We now describe **S**elf-**S**upervised **M**anifold **B**ased Data **A**ugmentation. Let our original dataset $\mathcal{D}$ consist of pairs of input and output vectors $\mathcal{D} = \{(x_1, y_1) \dots (x_n, y_n)\}$. We assume the input points concentrate around an underlying lower dimensional data manifold $\mathcal{M}$. Let q be a corruption function from which we can draw a sample $x' \sim q(x'|x)$ such that x' no longer lies on $\mathcal{M}$. Let r be a reconstruction function from which we can draw a sample $\hat{x} \sim r(\hat{x}|x')$ such that $\hat{x}$ lies on $\mathcal{M}$.

To generate an augmented dataset, we take each pair $(x_i, y_i) \in \mathcal{D}$ and sample a perturbed $x'_i \sim q(x'|x_i)$. We then sample a reconstructed $\hat{x}_{ij} \sim r(\hat{x}|x'_i)$. A corresponding vector $\hat{y}_{ij}$ can be generated by preserving y_i, or, since examples in the manifold neighborhood may cross decision boundaries on more sensitive tasks, by using a teacher model trained on the original data. This operation can be repeated to generate multiple augmented examples for each input example. These new examples form a dataset that we can augment the original training set with. We can then train an augmented model on the new augmented dataset.

In this paper we investigate SSMBA's use on natural language tasks, using the MLM training corruption function as our corruption function q and a pre-trained BERT model as our reconstruction model r. Different from other data augmentation methods, SSMBA does not rely on task-specific knowledge, requires no dataset-specific fine-tuning, and is applicable to any supervised natural language task. SSMBA requires only a pair of functions q and r used to generate data.

4 Datasets

To empirically evaluate our proposed algorithm, we select 9 datasets – 4 sentiment analysis datasets, 2 natural language inference (NLI) datasets, and 3 machine translation (MT) datasets. Table 1 and Appendix A provide dataset summary statistics. All datasets either contain metadata that can be used to split the samples into separate domains or similar datasets that are treated as separate domains.

4.1 Sentiment Analysis

The Amazon Review Dataset (Jianmo Ni, 2019) contains product reviews from Amazon. Following Hendrycks et al. 2020, we form two datasets: **AR-Full** contains reviews from the 10 largest categories, and **AR-Clothing** contains reviews in the clothing category separated into subcategories by metadata. Since the reviews in AR-Clothing come from the same top-level category, the amount of domain shift is much less than that of AR-Full. Models predict a review's 1 to 5 star rating.

SST2 (Socher et al., 2013) contains movie review excerpts. Following Hendrycks et al. 2020 we pair this dataset with the IMDb dataset (Maas et al.,

Dataset	Domain	n	l	Train	Test
AR-Clothing	*	4	35	25k†	2k
AR-Full	*	10	67	25k†	2k
Yelp	*	4	138	25k†	2k
Movies	SST2	-	11	66k	1k
	IMDb	-	296	46k	2k
MNLI	*	10	36	80k	1k
ANLI	R1	-	92	17k	1k
	R2	-	90	46k	1k
	R3	-	82	100k	1k
IWSLT	-	1	24	160k	7k
OPUS	Medical	5	15	1.1m	2k
de-rm	Law	-	22	100k	2k
	Blogs	-	25	-	2k

Table 1: Dataset summary statistics. n: number of domains. l: average tokenized input length. A * in the domain column indicates that the statistics are identical across domains within that dataset. Training sets marked with a † are sampled randomly from a larger dataset. Refer to Appendix A for more information.

2011), which contains full length movie reviews. We call this pair the **Movies** dataset. Models predict a movie review's binary sentiment.

The **Yelp Review Dataset** contains restaurant reviews with associated business metadata which we preprocess following Hendrycks et al. 2020. Models predict a review's 1 to 5 star rating.

4.2 Natural Language Inference

MNLI (Williams et al., 2018) is a corpus of NLI data from 10 distinct genres of written and spoken English. We train on the 5 genres with training data and test on all 10 genres. Since the dataset does not include labeled test data, we use the validation set as our test set and sample 2000 examples from each training set for validation.

ANLI (Nie et al., 2019) is a corpus of NLI data designed adversarially by humans such that state-of-the-art models fail to classify examples correctly. The dataset consists of three different levels of difficulty which we treat as separate textual domains.

4.3 Machine Translation

Following Müller et al. 2019, we consider two translation directions, German→English (de→en) and German→Romansh (de→rm). Romansh is a low-resource language with an estimated 40,000 native speakers where OOD robustness is of practical relevance (Müller et al., 2019).

In the de→en direction, we use **IWSLT14 de→en** (Cettolo et al., 2014) as a widely-used benchmark to test in-domain performance. We also use the **OPUS** (Tiedemann, 2012) dataset to test OOD generalization. We train on highly specific in-domain data (medical texts) and disparate out-of-domain data (Koran text, Ubuntu localization files, movie subtitles, and legal text). Since domains share very little similarities in language, generalization to out-of-domain text is extremely difficult. In the **de→rm** direction, we use a training set consisting of the Allegra corpus (Scherrer and Cartoni, 2012) and Swiss press releases. We use blog posts from Convivenza as a test domain.

5 Experimental Setup

5.1 Model Types

For sentiment analysis tasks, we investigate LSTMs (Hochreiter and Schmidhuber, 1997) and convolutional neural networks (CNNs). For NLI tasks, we investigate fine-tuned RoBERTa$_{\text{BASE}}$ models (Liu et al., 2019), which are pretrained bidirectional transformers (Vaswani et al., 2017). On both tasks, representations from the encoder are fed into an feed-forward neural network for classification. For MT tasks, we train transformers (Vaswani et al., 2017). For all models, word embeddings are initialized randomly and trained end-to-end with the model. We do not initialize with pre-trained word embeddings to maintain consistency across all models and tasks. Model hyperparameters are tuned to maximize performance on in-domain validation data. Training details and hyperparameters for all models are provided in Appendix C.

5.2 SSMBA Settings

For all experiments we use the MLM corruption function as our corruption function q. We tune tune the total percentage of tokens corrupted, leaving the percentages of specific corruption operations (80% masked, 10% random, 10% unmasked) the same. For sentiment analysis and NLI experiments we use a pre-trained RoBERTa$_{\text{BASE}}$ model as our reconstruction function r, and for translation experiments we use a pre-trained German BERT model (Chan et al., 2020). For each input example, we generate 5 augmented examples using unrestricted sampling. For translation experiments, target side translations are generated with beam search with width 5. SSMBA hyperparameters, including augmented example labelling method and corruption percentage, are chosen based on in-domain validation performance. Hyperparameters for each dataset are provided in Appendix D.

5.3 Baselines

On sentiment analysis and NLI tasks, we compare against 3 data augmentation methods. Easy Data Augmentation (EDA) (Wei and Zou, 2019) is a heuristic method that randomly replaces synonyms and inserts, swaps, and deletes words. Conditional Bert Contextual Augmentation (CBERT) (Wu et al., 2019b) finetunes a class-conditional BERT model and uses it to generate sentences in a process similar to our own. Unsupervised Data Augmentation (UDA) (Xie et al., 2020) translates data to and from a pivot language to generate paraphrases. We adapt UDA for supervised classification tasks by training directly on the backtranslated data.

On translation tasks, we compare only against methods which do not require additional target side monolingual data. Word dropout (Sennrich et al., 2016) randomly chooses words in the source sentence to set to zero embeddings. Reward Augmented Maximum Likelihood (RAML) (Norouzi et al., 2016) samples noisy target sentences based on an exponential of their Hamming distance from the original sentence. SwitchOut (Wang et al., 2018) applies a noise function similar to RAML to both the source and target side. We use publicly available implementations for all methods.

5.4 Evaluation Method

We train LSTM and CNN models with 10 random seeds, RoBERTa models with 5 random seeds, and transformer models with 3 random seeds. Models are trained separately on each domain then evaluated on all domains, and performance is averaged across seeds and test domains. We report the average in-domain (ID) and OOD performance across all train domains. On sentiment analysis and NLI tasks we report accuracy, and on translation we report uncased tokenized BLEU (Papineni et al., 2002) for IWSLT and cased, detokenized BLEU with SacreBLEU[2] (Post, 2018) for all others. Statistical testing details are in Appendix E.

6 Results

6.1 Sentiment Analysis

Table 2 present results on sentiment analysis. Across all datasets, models trained with SSMBA outperform baseline models and all other data augmentation methods on OOD data. On ID data, SSMBA outperforms baseline models and other data augmentation methods on all datasets for CNN models, and 3/4 datasets for RNN models. On average, SSMBA improves OOD performance by 1.1% for RNN models and 0.7% for CNN models, and ID performance by 0.8% for RNN models and 0.4% for CNN model. Other methods achieve much smaller OOD generalization gains and perform worse than baseline models on multiple datasets.

On the AR-Full dataset, RNNs trained with SSMBA demonstrate improvements in OOD accuracy of 1.1% over baseline models. On the AR-Clothing dataset, which exhibits less domain shift than AR-Full, RNNs trained with SSMBA exhibit slightly lower OOD improvement. CNN models exhibit about the same boost in OOD accuracy across both Amazon review datasets.

On the Movies dataset where we observe a large difference in average sentence length between the two domains, SSMBA still manages to present considerable gains in OOD performance. Although RNNs trained with SSMBA fail to improve ID performance, their OOD performance in this setting still beats other data augmentation methods.

On the Yelp dataset, we observe large performance gains on both ID and OOD data for RNN models. The improvements on CNN models are more modest, but notably our method is the only one that improves OOD generalization.

6.2 Natural Language Inference

Table 3 presents results on NLI tasks. Models trained with SSMBA outperform or match baseline models and data augmentation methods on both ID and OOD data. Even with a more difficult task and stronger baseline model, SSMBA still confers large accuracy gains. On MNLI, SSMBA improves OOD accuracy by 1.8%, while the best performing baseline achieves only 0.3% improvement. Our method also improves ID accuracy by 1.4%. All other baseline methods hurt both ID and OOD accuracy, or confer negligible improvements.

On the intentionally difficult ANLI, SSMBA maintains baseline OOD accuracy while conferring a large 6% improvement on ID data. Other augmentation methods improve ID accuracy by a much smaller margin while degrading OOD accuracy. Surprisingly, pseudo-labelling augmented examples in the R2 and R3 domains produced the

best results, even when the labelling model had poor in-domain performance.

6.3 Machine Translation

Table 4 presents results on IWSLT14 de→en. We compare our results with convolutional models (Edunov et al., 2018) and strong baseline transformer and dynamic convolution models (Wu et al., 2019a). SSMBA improves BLEU by almost 1.5 points, outperforming all other baseline and comparison models. Compared to SSMBA, other augmentation methods offer much smaller improvements or even degrade performance.

Table 5 presents results on OPUS and de→rm. On OPUS, where the training domain contains highly specialized language and differs significantly both from other domains and the learned MLM manifold, SSMBA offers a small boost in OOD BLEU but degrades ID performance. All other augmentation methods degrade both ID and OOD performance. On de→rm, SSMBA improves OOD BLEU by a large margin of 2.4 points, and ID BLEU by 0.4 points. Other augmentation methods offer much smaller OOD improvements while degrading ID performance.

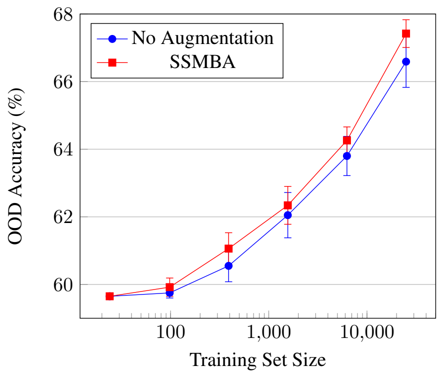

Figure 4: OOD accuracy of models trained on successively subsampled datasets. The full training set contains 25k examples. Error bars show standard deviation in OOD accuracy across models.

7 Analysis and Discussion

In this section, we analyze the factors that influence SSMBA's performance. Due to its relatively small size (25k sentences), number of OOD domains (3), and amount of domain shift, we focus our analysis on the Baby domain within the AR-Clothing dataset. Ablations are performed on a single domain rather than all domains, so error bars correspond to variance in models trained with different seeds and results are not comparable with those in Table 2. Unless otherwise stated, we train CNN models and augment with SSMBA, corrupting 45% of tokens, performing unrestricted sampling when reconstructing, and using self-supervised soft labelling, generating 5 synthetic examples for each training example.

7.1 Training Set Size

We first investigate how the size of the initial dataset affects SSMBA's effectiveness. Since a smaller dataset covers less of the training distribution, we might expect the data generated by SSMBA to explore less of the data manifold and reduce its effectiveness. We subsample 25% of the original dataset to form a new training set, then repeat this process successively to form exponentially smaller and smaller datasets. The smallest dataset contains only 24 examples. For each dataset fraction, we train 10 models and average performance, tuning a set of SSMBA hyperparameters on the same ID validation data. Figure 4 shows that SSMBA offers OOD performance gains across almost all dataset sizes, even in low resource settings with less than 100 training examples.

	Distil	Base	Large
OOD Accuracy Boost (%)	0.73	0.78	0.78

Table 6: Boost in OOD accuracy (%) of models trained with SSMBA augmented data generated with different reconstruction functions.

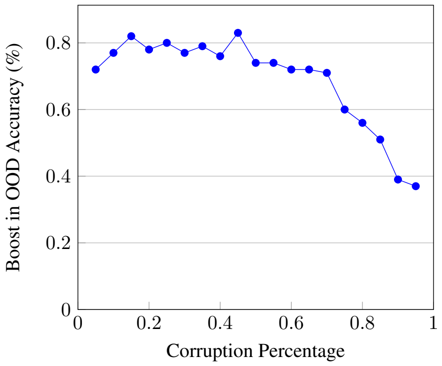

Figure 5: Boost in OOD accuracy (%) of models trained with SSMBA augmentation applied with different percentages of corrupted tokens.

7.2 Reconstruction Model Capacity

Since SSMBA relies on a reconstruction function that approximates the underlying data manifold, we might expect a larger and more expressive model to generate higher quality examples. We investigate three models of varying size: DistilRoBERTa (Sanh et al., 2019) with 82M parameters, RoBERTa$_{\text{BASE}}$ with 125M parameters, and RoBERTa$_{\text{LARGE}}$ with 355M parameters. For each reconstruction model, we generate a set of 10 augmented datasets and train a set of 10 models on each augmented dataset. We average performance across models and datasests. Table 6 shows that SSMBA displays robustness to the choice of reconstruction model, with all models conferring similar improvements to OOD accuracy. Using the smaller DistilRoBERTa model only degrades performance by a small margin.

7.3 Corruption Amount

How sensitive is SSMBA to the particular amount of corruption applied? Empirically, tasks that were more sensitive to input noise, like sentiment analysis, required less corruption than those that were more robust, like NLI. To analyze the effect of tuning the corruption amount, we generate 10 sets of augmented data with varying percentages of corruption, then train 10 models on each dataset, averaging performance across all 100 models. Figure 5 shows that for corruption percentages below 50%,

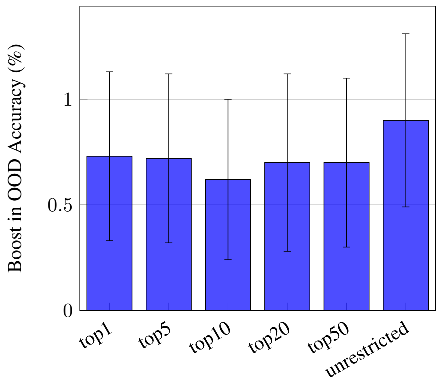

Figure 6: Boost in OOD accuracy (%) of models trained with SSMBA augmentation using different sampling methods. Error bars show standard deviation in OOD accuracy across models.

our algorithm is relatively robust to the specific amount of corruption applied. OOD performance peaks at 45% corruption, decreasing thereafter as corruption increases. Very large amounts of corruption tend to degrade performance, although surprisingly all augmented models still outperform unaugmented models, even when 95% of tokens are corrupted. In experiments on the more input sensitive NLI task, large amounts of noise degraded performance below baselines.

7.4 Sample Generation Methods

Next we investigate methods for generating the reconstructed examples $\hat{x} \sim r(\hat{x}|x')$. Top-k sampling draws samples from the MLM distribution on the top-k most probable tokens, leading to augmented data that explores higher probability regions of the manifold. We investigate top1, top5, top10, top20, and top50 sampling. Unrestricted sampling draws samples from the full probability distribution of tokens. This method explores a larger area of the underlying data distribution but can often lead to augmented data in low probability regions.

For each sample generation method, we generate 5 sets of augmented data and train 10 models on each dataset. OOD accuracy is averaged across all models for a given sampling method. Figure 6 shows that unrestricted sampling provides the greatest increase in OOD accuracy, with top-k sampling methods all performing similarly. This suggests that SSMBA works best when it is able to explore the manifold without any restrictions.

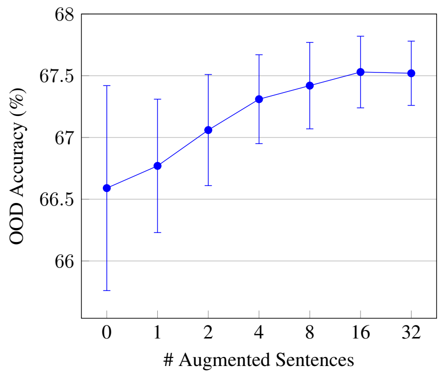

Figure 7: OOD accuracy (%) of models trained with different amounts of SSMBA augmentation. 0 augmentation corresponds to a baseline model. Error bars show standard deviation in OOD accuracy across models.

7.5 Amount of Augmentation

How does OOD accuracy change as we generate more sentences and explore more of the manifold neighborhood? To investigate we select various augmentation amounts and generate 5 datasets for each amount, training 10 models on each dataset and averaging OOD accuracy across all 50 models. Figure 7 shows that increasing the amount of augmentation increases the amount by which SSMBA improves OOD accuracy, as well as decreasing the variance in the OOD accuracy of trained models.

7.6 Label Generation

We investigate 3 methods to generate a label $\hat{y}_{ij}$ for a synthetic example $\hat{x}_{ij}$. *Label preservation* preserves the original label y_i. Since the manifold neighborhood of an example may cross a decision boundary, we also investigate using a supervised model f trained on the original set of unaugmented data for *hard labelling* of a one-hot class label $\hat{y}_{ij}$ and *soft labelling* of a class distribution $\hat{y}_{ij}$.

We train a CNN model to varying levels of convergence and validation accuracy, then label a set of 5 augmented datasets with each labelling method. When training with soft labels, we optimize the KL-divergence between the output distribution and soft label distribution. For each dataset we train 10 models and average performance across all models and datasets. Results are shown in Figure 8.

Unsurprisingly, soft and hard labelling with a low accuracy model degrades performance. As our supervision classifier improves, so does the performance of models trained with soft and hard labelled data. Once we pass a certain accuracy threshold, models trained with soft labels begin

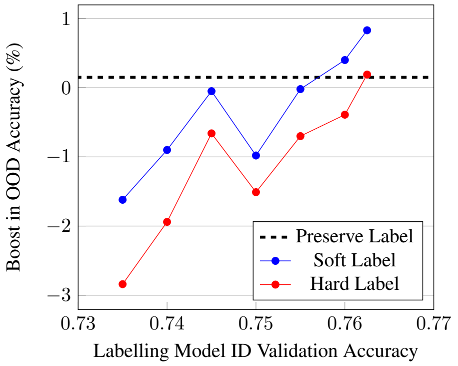

Figure 8: Boost in OOD accuracy (%) of models trained with augmented data labelled with different supervision models and label generation methods.

outperforming all other models. This threshold varies depending on the difficulty of the dataset and task. In ANLI experiments, labelling augmented examples even with a poor performing model still improved downstream accuracy.

8 Conclusion

In this paper, we introduce SSMBA, a method for generating synthetic data in settings where the underlying data manifold is difficult to characterize. In contrast to other data augmentation methods, SSMBA is applicable to any supervised task, requires no task-specific knowledge, and does not rely on dataset-specific fine-tuning. We demonstrate SSMBA's effectiveness on three NLP tasks spanning classification and sequence modeling: sentiment analysis, natural language inference, and machine translation. We achieve gains of 0.8% accuracy on OOD Amazon reviews, 1.8% accuracy on OOD MNLI, and 1.4 BLEU on in-domain IWSLT14 de→en. Our analysis shows that SSMBA is robust to the initial dataset size, reconstruction model choice, and corruption amount, offering OOD robustness improvements in most settings. Future work will explore applying SSMBA to the target side manifold in structured prediction tasks, as well as other natural language tasks and settings where data augmentation is difficult.

Acknowledgements

Resources used in preparing this research were provided, in part, by the Province of Ontario, the Government of Canada through CIFAR, and companies sponsoring the Vector Institute `www.vectorinstitute.ai/#partners`. This work was partly supported by Samsung Advanced Institute of Technology (Next Generation Deep Learning: from pattern recognition to AI) and Samsung Research (Improving Deep Learning using Latent Structure). We thank Julian McAuley, Vishaal Prasad, Taylor Killian, Victoria Cheng, and Aparna Balagopalan for helpful comments and discussion.

A Datasets

Full dataset statistics and details are provided in table 7. All data splits for all tasks can be downloaded at `https://nyu.box.com/s/henvmy17tkyr6npl7e1ltw8j46baxsml`.

B Data Preprocessing

We use the same preprocessing steps across all sentiment analysis and NLI experiments. All data is first tokenized using a GPT-2 style tokenizer and BPE vocabulary provided by `fairseq` (Ott et al., 2019). This BPE vocabulary consists of 50263 types. Corresponding labels are encoded using a label dictionary consisting of as many types as there are classes. Input text and labels are then binarized for model training. Although all models share the same vocabulary, we randomly initialize each model's embeddings and train the entire model end-to-end. For machine translation experiments, we follow Müller et al. 2019 and learn a 16k BPE on OPUS and a 32k BPE on de→rm. On IWSLT14 we learn a 10k BPE. We use a separate vocabulary for the source and target side.

C Model Architecture and Training Hyperparameters

All models are written and trained within the `fairseq` framework (Ott et al., 2019) with T4 GPUs. LSTM and CNN models were trained on a single GPU, RoBERTa models were trained with 4 GPUs, and tranfsormer models were trained with 2 GPUs. On average, when trained on augmented data, LSTM and CNN models took an hour to train to convergence, RoBERTa models took 12 hours to train to convergence, and transformer models took 24 hours to train to convergence. Models trained on unaugmented data took roughly 20% of the time of models trained on augmented data to reach convergence. For each model we investigate, we present first the model architecture and then the training hyperparameters.

C.1 LSTM

Our LSTM models are a single layer of 512 nodes. Input embeddings are 512 dimensions. The output embedding from the last time step is fed into a MLP classifier with a single hidden layer of 512 dimensions. Models contain 28M parameters. Dropout of 0.3 is applied to the input and output of our encoder, and dropout of 0.1 is applied to the MLP classifier.

We train with Adam optimizer (Kingma and Ba, 2014) with $\beta = (0.9, 0.98)$ and $\epsilon = 1\text{e}{-6}$. Our learning rate is set to $1\text{e}{-4}$ and is first warmed up for 2 epochs before it is decayed using an inverse square root scheduler.

C.2 CNN

Our CNN models are based on the architecture in (Kim, 2014). As in our LSTM models, our input embeddings are 512 dimensional, which we treat as our channel dimension. We apply three convolutions of kernel size 3, 4, and 5, with 256 output channels. Models contain 27M parameters. Convolutional outputs are max-pooled over time then concatenated to a 768-dimensional encoded representation. Again, we feed this representation into a MLP classifier with a single hidden layer of 512 dimensions. We apply dropout of 0.2 to our inputs and MLP classifier.

We train with Adam optimizer (Kingma and Ba, 2014) with $\beta = (0.9, 0.98)$ and $\epsilon = 1\text{e}{-6}$. Our learning rate is set to $1\text{e}{-3}$ and is first warmed up for 2 epochs before it is decayed using an inverse square root scheduler.

C.3 RoBERTa

Our RoBERTa models use a pre-trained RoBERTa$_{\text{BASE}}$ model provided by `fairseq`. As in other models, classification token embeddings are fed into an MLP classifier with a single hidden layer of 512 dimensions. Models contain 125M parameters. We follow the MNLI fine-tuning procedures in `fairseq`, training with learning rate $1\text{e}{-5}$ with Adam optimizer (Kingma and Ba, 2014) with $\beta = (0.9, 0.98)$ and $\epsilon = 1\text{e}{-6}$. We warmup the learning rate for 2 epochs before decaying with an inverse square root scheduler.

C.4 Transformer

Transformer models are trained with label-smoothed cross-entropy and label smoothing 0.1. Due to the dataset sizes, we use a slightly smaller transformer architecture with embedding dimension 512, feed forward embedding dimension 1024, 4 encoder heads, and 6 encoder and decoder layers. Models contain 52M parameters. We also apply dropout of 0.3 and weight decay of 0.0001. All other hyperparameters follow the base architecture in Vaswani et al. 2017.

As in other models, we train with Adam optimizer (Kingma and Ba, 2014) with $\beta = (0.9, 0.98)$ and $\epsilon = 1\text{e}{-6}$. Our learning rate is set to $5\text{e}{-4}$

and is first warmed up for 4000 updates before it is decayed using an inverse square root scheduler.

D SSMBA Hyperparameters

SSMBA hyperparameters for each dataset and domain are provided in table 8. Hyperparameters are chosen based on in-domain validation performance. A detailed analysis of hyperparameter tuning is provided in section 7.

E Statistical Testing

For the statistical tests on sentiment analysis and NLI tasks, we use a Wilcoxon ranked-sum test. Specifically, we compare averages of model performances on pairs of training and test domains. For example, in a dataset with 3 domains, D1, D2, and D3, we have 3 in-domain train-test pairs (D1-D1, D2-D2, D3-D3), and 6 out-of-domain train-test pairs (D1-D2, D1-D3, D2-D1, D2-D3, D3-D1, D3-D2). We calculate the average performance for each model on each pair, then compare the matched in-domain and out-of-domain pairs. Since the number of samples we can compare depends on the total number of domains in the dataset, a larger number of datasets gives us a better sense of our statistical significance.

For the statistical tests on machine translation tasks, we use a paired bootstrap resampling approach (Koehn, 2004). Since the test works only on a single system's output, we run the test on every pairing of seeds and test domains for the two comparison models. We report the significance level only if all tests result in a small enough probability.

Abstract

For many real-world classification problems, e.g., sentiment classification, most existing machine learning methods are biased towards the majority class when the Imbalance Ratio (IR) is high. To address this problem, we propose a set convolution (SetConv) operation and an episodic training strategy to extract a single representative for each class, so that classifiers can later be trained on a balanced class distribution. We prove that our proposed algorithm is permutation-invariant despite the order of inputs, and experiments on multiple large-scale benchmark text datasets show the superiority of our proposed framework when compared to other SOTA methods.

1 Introduction

In many real-world NLP applications, the collected data follow a skewed distribution (Deng et al., 2009; Fernández et al., 2013; Yan et al., 2017), i.e., data from a few classes appear much more frequently than those of other classes. For example, tweets related to incidents such as shooting or fire are usually rarer compared to those about sports or entertainments. These data instances often represent objects of interest as their rareness may carry important and useful knowledge (He and Garcia, 2009; Sun et al., 2007; Chen and Shyu, 2011). However, most learning algorithms tend to inefficiently utilize them due to their disadvantage in the population (Krawczyk, 2016). Hence, learning discriminative models with imbalanced class distribution is an important and challenging task to the machine learning community.

Solutions proposed in previous literature can be generally divided into three categories (Krawczyk, 2016): (1) *Data-level methods* that employ under-sampling or over-sampling technique to balance the class distributions (Barua et al., 2014; Smith et al., 2014; Sobhani et al., 2014; Zheng et al., 2015). (2) *Algorithm-level methods* that modify existing learners to alleviate their bias towards the majority classes. The most popular branch is the *cost-sensitive* algorithms, which assign a higher cost on misclassifying the minority class instances. (Díaz-Vico et al., 2018). (3) *Ensemble-based methods* that combine advantages of data-level and algorithm-level methods by merging data-level solutions with classifier ensembles, resulting in robust and efficient learners (Galar et al., 2012; Wang et al., 2015).

Despite the success of these approaches on many applications, some of their drawbacks have been observed. Resampling-based methods need to either remove lots of samples from the majority class or introduce a large amount of synthetic samples to the minority class, which may respectively lose important information or significantly increase the adverse correlation among samples (Wu et al., 2017). It is difficult to set the actual cost value in cost-sensitive approaches and they are often not given by expert before hand (Krawczyk, 2016). Also, how to guarantee and utilize the diversity of classification ensembles is still an open problem in ensemble-based methods (Wu et al., 2017; Huo et al., 2016).

In this paper, we propose a novel *set convolution* (SetConv) operation and a new training strategy named as *episodic training* to assist learning from imbalanced class distributions. The proposed solution naturally addresses the drawbacks of existing methods. Specifically, SetConv explicitly learns the weights of convolution kernels based on the intra-class and inter-class correlations, and uses the learned kernels to extract discriminative features from data of each class. It then compresses these features into a single class representative. These representatives are later applied for classification. Thus, SetConv helps the model to *ignore sample-specific noisy information*, and *focuses on the la-*

Figure 1: Overview of the proposed approach. (a) The training procedure of SetConv. At each iteration, SetConv is fed with an episode to evaluate the classification loss for model update. Each episode consists of a support set and a query set. The support set is formed by a group of samples where the imbalance ratio is preserved. The query set contains only one sample from each class. (b) The post training step of SetConv, which is performed only once after the main training procedure. In this step, we extract a representative for each class from the training data and will later use them for inference. Here we only perform inference using the trained model and do not update it. (c) The inference procedure of SetConv. Each query data is compared with every class representative to determine its label.

tent concept not only common to different samples of the same class but also discriminative to other classes. On the other hand, in episodic training, we assign equal weights to different classes and do not perform resampling on data. Moreover, at each iteration during training, the model is fed with an episode formed by a set of samples where the class imbalance ratio is preserved. It encourages the model learning to *extract discriminative features even when class distribution is highly unbalanced.*

Building models with SetConv and episodic training has several additional benefits:

(1) *Data-Sensitive Convolution.* By utilizing SetConv, each input sample is associated with a set of weights that are estimated based on its relation to the minority class. This data-sensitive convolution helps the model to customize the feature extraction process for each input sample, which potentially improves the model performance.

(2) *Automatic Class Balancing.* At each iteration, no matter how many data of a class is fed into the model, SetConv always extracts the most discriminative information from them and compress it into a single distributed representation. Thus, the subsequent classifier, which takes these class representatives as input, always perceives a balanced class distribution.

(3) *No dependence on unknown prior knowledge.* The only prior knowledge needed in episodic training is the class imbalance ratio, which can be easily obtained from data in real-world applications.

2 Related Work

2.1 Data-level Methods

The data-level methods modifies the collection of examples by resampling techniques to balance class distributions. Existing data-level methods can be roughly classified into two categories: (1) *Undersampling based methods*: this type of methods balances the distributions between the majority and minority classes by reducing majority-class samples. IHT (Smith et al., 2014) propose to performs undersampling based on instance hardness. On the other hand, EUS (Triguero et al., 2015) introduce evolutionary undersampling methods to deal with large-scale classification problems. (2) *Over-sampling based methods*: these methods balance the class distribution by adding samples to the minority class. SMOTE (Chawla et al., 2002) is the first synthetic minority oversampling technique. MWMOTE (Barua et al., 2014) first identifies the hard-to-learn informative minority class samples and then uses the weighted version of these samples to generate synthetic samples. Recently, based on k-means clustering and SMOTE, KMEANS-SMOTE (Last et al., 2017) is introduced to eliminate inter-class imbalance while at the same time avoiding the generation of noisy samples. However, for highly unbalanced data, resampling methods either discard a large amount of samples from the majority class or introduce many synthetic samples into the minority class. It leads to either the loss of important information (undersampling) or the improper increase of the adverse correlation among samples (oversampling), which will degrade the model performance (Wu et al., 2017).

2.2 Algorithm-level Methods

Algorithm-level methods focus on modifying existing learners to alleviate their bias towards the majority classes. The most popular branch is the cost-sensitive approaches that attempt to assign a higher cost on misclassifying the minority class instances. Cost-sensitive multilayer perceptron (CS-MLP) (Castro and de Pádua Braga, 2013) utilizes a single cost parameter to distinguish the importance of class errors. CLEMS (Huang and Lin, 2017) introduces a cost-sensitive label embedding technique that takes the cost function of interest into account. CS-DMLP (Díaz-Vico et al., 2018) is a deep multi-layer percetron model utilizing cost-sensitive learning to regularize the posterior probability distribution predicted for a given sample. This type of methods normally requires domain knowledge to define the actual cost value, which is often hard in real-world scenarios (Krawczyk, 2016).

2.3 Ensemble-based Methods

Ensemble-based methods usually combine advantages of data-level and algorithm-level methods by merging data-level solutions with classifier ensembles. A typical example is an ensemble model named as WEOB2 (Wang et al., 2015) which utilizes undersampling based online bagging with adaptive weight adjustment to effectively adjust the learning bias from the majority class to the minority class. Unfortunately, how to guarantee and utilize the diversity of classification ensembles is still an open problem in ensemble-based methods (Wu et al., 2017).

3 Model

3.1 Overview

Our goal is to develop a classification model that works well when the class distribution is highly unbalanced. For simplicity, we first consider a binary classification problem and later extend it to the multi-class scenario. As shown in Fig. 1a, our model is composed of a SetConv layer and a classification layer. At each iteration during training, the model is fed with an *episode* sampled from the training data, which is composed of a support set and a query set. The support set preserves the imbalance ratio of training data, and the query set contains only one sample from each class. Once the SetConv layer receives an episode, it extracts features for every sample in the episode and produces a representative for each class in the support set. Then, each sample in the query set is compared with these class representatives in classification layer to determine its label and evaluate the classification loss for model update. We refer this training procedure as *episodic training*.

We choose episodic training due to following reasons: (1) It encourages the SetConv layer learning to extract discriminative features even when the class distribution of the input data is highly unbalanced. (2) Since the episodes are randomly sampled from data with significantly different configuration of support and query sets (i.e., data forming these sets vary from iteration to iteration), it requires the SetConv layer to capture the underlying class concepts that are common among different episodes.

After training, a post training step is performed only once to extract a representative for each class from the training data, which will later be used for inference (Fig. 1b). It is conducted by randomly sampling a large subset of training data (referred as S_{post}) and feeding them to the SetConv layer. *Note that we only perform inference using the trained model and do not update it in this step.* We can conduct this operation because the SetConv layer has learned to capture the class concepts, which are insensitive to the episode configuration during training. We demonstrate it in experiments and the result is shown in Section 4.6.

The inference procedure of the proposed ap-

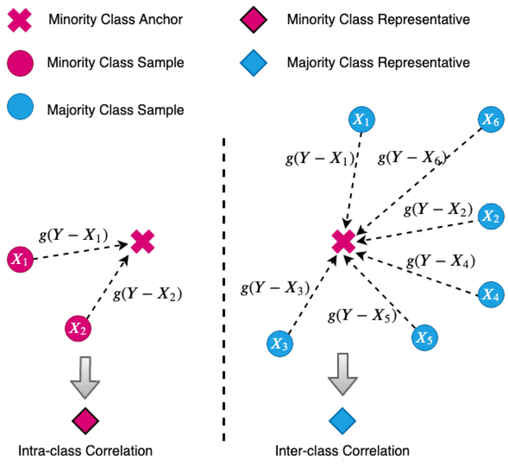

Figure 2: Relations between the input samples and a pre-selected minority class anchor are used by SetConv to estimate both intra-class correlations and inter-class correlations.

proach is straightforward (Fig. 1c). For each query sample, we extract its feature via the SetConv layer and then compare it with those class representatives obtained in post training step. The class that is most similar to the query is assigned as the predicted label.

3.2 SetConv Layer

In many real-world applications, the minority class instances often carry important and useful knowledge that need intensive attention by the machine learning models (He and Garcia, 2009; Sun et al., 2007; Chen and Shyu, 2011).

Based on this prior knowledge, we choose to design the SetConv layer in a way such that the *feature extraction process focuses on the minority class*. We achieve it by estimating the weights of the SetConv layer based on the relation between the input samples and a pre-selected minority class anchor. This anchor can be freely determined by the user. In this paper, we adopt a simple option, i.e., *average-pooling* of the minority class samples. Specifically, for each input variable, we compute its mean value across all the minority class samples in the training data. It is executable because the minority-class samples are usually limited in real-world applications[1]. As shown in Figure 2, this weight estimation method assists the SetConv layer in capturing not only the intra-class correlation of the minority class, but also the inter-class correlation between the majority and minority classes.

Suppose $\mathcal{E}_t = \{\mathcal{S}_t, \mathcal{Q}_t\}$ is the episode sent to the SetConv layer at iteration t, where $\mathcal{S}_t = \big(X_{maj} \in \mathcal{R}^{N_1 \times d}, X_{min} \in \mathcal{R}^{N_2 \times d}\big)$ is the support set and $\mathcal{Q}_t = \big(q_{maj} \in \mathcal{R}^{1 \times d}, q_{min} \in \mathcal{R}^{1 \times d}\big)$ is the query set. In general, X_{maj}, X_{min}, q_{maj} and q_{min} can be considered as a sample set of size N_1, N_2, 1 and 1 respectively. For simplicity, we abstract this sample set into $X \in \mathcal{R}^{N \times d}, N \in \{N_1, N_2, 1\}$.

Remind that the standard discrete convolution is:

$$h[n] = (f \star g)[n] = \sum_{m=-M}^{m=M} f[m]g[n-m] \quad (1)$$

Here, f and g denote the feature map and kernel weights respectively.

Similarly, in our case, we define the set convolution (SetConv) operation as:

$$\begin{aligned} h[Y] &= \frac{1}{N} \sum_{i=1}^{N} X_i \cdot g(Y - X_i) \\ &= \frac{1}{N} \Big(X \circ g(Y - X) \Big) \end{aligned} \quad (2)$$

where $Y \in \mathcal{R}^{1 \times d}$, $g(Y-X) \in \mathcal{R}^{N \times d \times d_o}$ and $h[Y] \in \mathcal{R}^{1 \times d_o}$ denote the minority class anchor, kernel weights and the output embedding respectively. Here, $\circ$ is the tensor dot product operator, i.e., for every $i \in \{1, 2, \ldots, d_o\}$, we compute the dot product of X and $g(Y-X)[:, :, i]$.

Unfortunately, directly learning $g(Y-X)$ is memory intensive and computationally expensive, especially for large-scale high-dimensional data. To overcome this issue, we introduce an efficient method to approximate these kernel weights. Instead of taking X as a set of d-dimensional samples, we stack these samples and consider it as a giant dummy sample $X' = Concat(X) \in \mathcal{R}^{1 \times Nd}$. Then, Eq. 2 is rewritten as

$$h[Y] = \frac{1}{N} \Big(X' \cdot g'(Y - X) \Big) \quad (3)$$

where $g'(Y-X) \in \mathcal{R}^{Nd \times d_o}$ is the transformed kernel weights. To efficiently compute $g'(Y-X)$, we propose to approximate it as the *Khatri-Rao* product[2] (Rabanser et al., 2017) of two individual components, i.e.,

$$\begin{aligned} g'(Y-X) &= g_1(Y-X) \circledast g_2(W) \\ &= \mathrm{MLP}(Y-X; \theta) \circledast \mathrm{SoftMax}(W, 0) \end{aligned} \quad (4)$$

---

[1] Otherwise, we may sample a subset from the minority class samples to compute the anchor.

[2] https://en.wikipedia.org/wiki/Kronecker_product

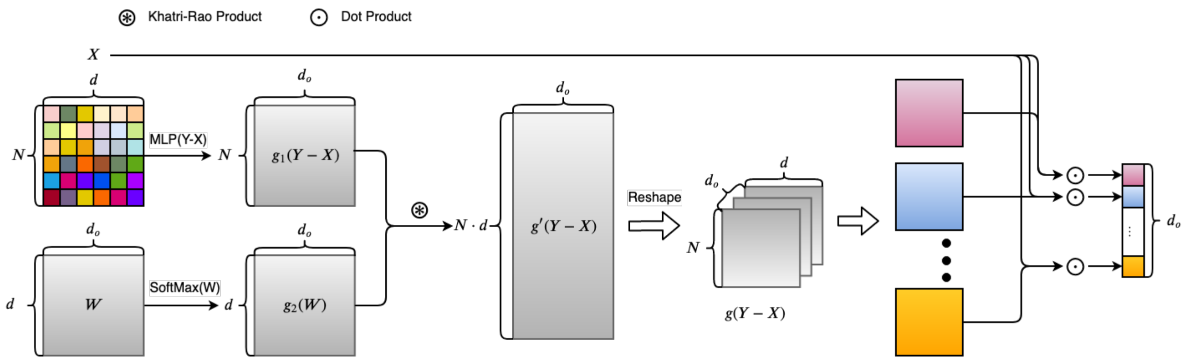

Figure 3: The computation graph of the SetConv layer. Here Y is a minority class anchor. $W \in \mathcal{R}^{d \times d_o}$ is a weight matrix to learn that records the correlation between the input and output variables. Specifically, the i_{th} column of $g_2(W)$ gives the weight distribution over input features for the i_{th} output feature. It is indeed a feature-level attention matrix. In addition, we estimate another data-sensitive weight matrix $g_1(Y-X)$ from the input data. The final convolution weight tensor is simply the Khatri-Rao product of $g_1(Y-X)$ and $g_2(W)$.

where $W \in \mathcal{R}^{d \times d_o}$ is a weight matrix that represents the correlation between input and output variables. $g_2(W)$ takes softmax over the first dimension of W, and is indeed a *feature-level attention* matrix. The i_{th} column of $g_2(W)$ provides the weight distribution over input features for the i_{th} output feature. On the other hand, $g_1(Y-X)$ is a *data-sensitive* weight matrix estimated from input data via a MLP by considering their relation to the minority class anchor. Similar to data-level attention, $g_1(Y-X)$ helps the model customize the feature extraction process for input samples, which potentially improves the model performance. Figure 3 shows the detailed computation graph of the SetConv layer.

Discussion: An important property of the SetConv layer is ***permutation-invariant***, i.e., it is insensitive to the order of input samples. As long as the input samples are same, no matter in which order they are sent to the model, the SetConv layer always produces the same feature representation. Mathematically, let π denote an arbitrary permutation matrix, we have $SetConv(\pi X) = SetConv(X)$. The detailed proof of this property is provided in the supplementary material.

3.3 Classification

Suppose the feature representation obtained from the SetConv layer for X_{maj}, X_{min}, q_{maj} and q_{min} in the episode are denoted by v^s_{maj}, v^s_{min}, v^q_{maj} and v^q_{min} respectively. The probability of predicting v^q_{maj} or v^q_{min} as the majority class is given by

$$P(c=0|x) = \frac{\exp(x \odot v^s_{maj})}{\exp(x \odot v^s_{maj}) + \exp(x \odot v^s_{min})} \tag{5}$$

where $\odot$ represents the dot product operation and $x \in \{v^q_{maj}, v^q_{min}\}$.

Similarly, the probability of predicting v^q_{maj} or v^q_{min} as the minority class is

$$P(c=1|x) = \frac{\exp(x \odot v^s_{min})}{\exp(x \odot v^s_{maj}) + \exp(x \odot v^s_{min})} \tag{6}$$

where $x \in \{v^q_{maj}, v^q_{min}\}$.

We adopt the well-known cross-entropy loss for error estimation and use the Adam optimizer to update model.

3.4 Extension to Multi-Class Scenario

Extending SetConv for multi-class imbalance learning is straightforward. We translate the multi-class classification problem into multiple binary classification problems, i.e., we create a one-vs-all classifier for each of the N classes. Specifically, for a class c, we treat those instances with label $y = c$ as positive and those with $y \neq c$ as negative. The anchor is hence computed based on the smaller one of the positive and negative classes. The prediction probability $P(y = c|x)$ for a given instance x is computed in a similar way as Eq. 5,

$$P(y=c|x) = \frac{\exp(x \odot v^s_{y=c})}{\exp(x \odot v^s_{y\neq c}) + \exp(x \odot v^s_{y=c})} \tag{7}$$

Therefore, the predicted label of the instance x is $\text{argmax}_c P(y = c|x)$.

4 Experiment

We evaluate SetConv on two typical tasks, including *incident detection on social media* and *sentiment classification*.

Table 2: Class distribution in Amazon Review and SemiEval Datasets.

Dataset	Negative	Positive	IR
Amazon-Books	72039	7389	9.75
Amazon-Electronics	13560	1908	7.11
Amazon-Movies	12896	2066	6.24
SemiEval	39123	7273	5.38

4.1 Benchmark Dataset

4.1.1 Incident Detection on Social Media

We conduct experiments on a real-world benchmark *Incident-Related Tweet*[3] (Schulz et al., 2017) (**IRT**) dataset. It contains $22,170$ tweets collected from 10 cities, and allows us to evaluate our approach against geographical variations. The IRT dataset supports two different problem settings: binary classification and multi-class classification. In binary classification, each tweet is either "incident-related" or "not incident-related". In multi-class classification, each tweet belongs to one of the four categories including "crash", "fire", "shooting" and a neutral class "not incident related". The details of this dataset are shown in Table 1.

4.1.2 Sentiment Classification

We conduct experiments on two large-scale benchmark datasets, including *Amazon Review*[4] (He and McAuley, 2016) and *SemiEval*[5] (Rosenthal et al., 2017), which have been widely used for sentiment classification. Similar to MSDA (Li et al., 2019) and SCL-MI (Blitzer et al., 2007), we treat the amazon reviews with rating > 3 as positive examples, those with rating < 3 as negative examples, and discard the rest because their polarities are ambiguous. In addition, due to the tremendous size of Amazon Review dataset, we choose its 3 largest categories, i.e., "Books", "Electronics", and "Movies and TV", and uniformly sample from these categories to form a subset that contains $109,858$ reviews. This subset is sufficiently large to evaluate the effectiveness of our method. More importantly, the imbalance ratio of each category in this subset is exactly same as that in the original dataset. Details of Amazon Review and SemiEval datasets are listed in Table 2.

4.2 Baseline

We compare our algorithm with several state-of-the-art imbalance learning methods.

- **IHT** (Smith et al., 2014) (*under-sampling*) is a model that performs undersampling based on instance hardness.
- **WEOB2** (Wang et al., 2015) (*ensemble*) is an undersampling based ensemble model that effectively adjusts the learning bias from the majority class to the minority class via adaptive weight adjustment. It only supports binary classification.
- **KMeans-SMOTE** (Last et al., 2017) (*over-sampling*) is an oversampling technique that avoids the generation of noisy samples and effectively overcomes the imbalance between classes.
- **IML** (Wang et al., 2018) (*metric learning*) is a method that utilizes metric learning to explore the correlations among imbalance data and constructs an effective data space for classification.
- **CS-DMLP** (Díaz-Vico et al., 2018) (*cost-sensitive*) is a deep MLP model that utilizes cost-sensitive learning to regularize the posterior probability distribution predicted for a given sample.

4.3 Evaluation Metric

We use the Specificity (*Spec*), Sensitivity (*Sens*), F_1-measure (F_1), Geometric-Mean (*G-Mean*), and the Area Under the receiver operating characteristic Curve (*AUC*) to evaluate the model performance, since they are widely used in previous imbalance learning research (Wang et al., 2018; Díaz-Vico et al., 2018; Last et al., 2017). The confusion matrix for multi-class classification is shown in Table 3. In the multi-class scenario, we report the model performance for each of the minority classes because: (1) the minority classes are usually more important than the majority class in most imbalance learning

[4] http://jmcauley.ucsd.edu/data/amazon/

[5] http://alt.qcri.org/semeval2017/task4/index.php?id=data-and-tools

Table 3: Confusion matrix for multi-class classification problem, where c denotes the class to evaluate.

	Predict Label $= c$	Predict Label $\neq c$
True Label $= c$	True Positive (TP)	False Negative (FN)
True Label $\neq c$	False Positive (FP)	True Negative (TN)

problems (He and Garcia, 2009; Chen and Shyu, 2011). (2) simply averaging model performance on different classes may cover model defects, especially when the class distribution is unbalanced.

(1) Class-specific performance measure:

- $Spec = \frac{TN}{TN+FP}$. Spec measures the model's capability to avoid false positive and finds all negative samples.
- $Sens = \frac{TP}{TP+FN}$. Sens measures the model's capability to avoid false negative and finds all positive samples.

(2) Overall performance measure:

- $F_1 = 2 \cdot \frac{precision \cdot recall}{precision + recall}$ is the harmonic mean of *precision* $= \frac{TP}{TP+FP}$ and *recall* $= \frac{TP}{TP+FN}$.
- *G-Mean* $= \sqrt{Spec \cdot Sens}$. G-Mean receives a higher value only when both Spec and Sens stay at a higher level. Thus, *G-Mean* can be considered as a trade-off between *Spec* and *Sens*.
- *AUC* computes the area under the ROC curve. It measures the model's capability to distinguish positive and negative classes.

In general, the model that gives higher values on these metrics is the one with better performance.

4.4 Experiment Setup

For all text datasets, we first pre-process each data instance via a pretrained Bert[6] (Devlin et al., 2019) model to produce a 1024-dimension feature vector, which is utilized for subsequent experiments. Note that this step does not lead to any ground-truth information leakage, because Bert is trained on Wikipedia corpus in an unsupervised manner.

Specifically, we choose the *BERT-Large, Cased (Whole Word Masking)*[7] model provided by Google Research team, and take the final hidden state of the special classification token [CLS] as the embedding for any input text sequence. This process is described in Figure 4.

```
'''Please install transformers via pip install transformers'''
from transformers import BertModel, BertTokenizer
import torch

# create model
tokenizer = BertTokenizer.from_pretrained('bert-large-cased')
model = BertModel.from_pretrained('bert-large-cased')

input = 'Here is some text to encode'
tokens = tokenizer.encode(input, add_special_tokens=True, max_length=512)
input_ids = torch.tensor([tokens])
with torch.no_grad():
    last_hidden_state = model(input_ids)[0]
# we take the final hidden state of the special classification token [CLS]
# as the embedding for input sentences
embedding = last_hidden_state[:, 0, :]
```

Figure 4: Implementation code used to extract sentence embedding via Bert.

After data pre-processing, we uniformly shuffle each dataset, and then divide it into development and test sets with the split ratio of 7:3. Thus, the class distribution in both development and test sets is same as that in the original dataset. To avoid any influence of random division, we repeat the experiments 10 times and report the average classification results.

We implement our algorithm using Python 3.7.3 and PyTorch 1.2.0 library. All baseline methods are based on code released by corresponding authors. Hyper-parameters of these baselines were set based on values reported by the authors and fine-tuned via 10-fold cross-validation on the development set. In our approach, we set the output dimension of the SetConv layer $d_o = 128$, the size of support set $||S_{support}|| = N_1 + N_2 = 64$, the size of post-training subset $||S_{post}|| = 1000$, learning rate $r = 0.01$, $\beta_1 = 0.9$ (Adam), and $\beta_2 = 0.999$ (Adam). The input dimension d of the SetConv layer is set to be the same as the dimension of input data for each dataset. The sensitivity analysis of $||S_{post}||$ is shown in Section 4.6.

4.5 Result

4.5.1 Binary Classification

The binary classification performance of competing methods for incident detection and sentiment classification tasks are shown in Figure 5 and Figure 7 respectively. The results demonstrate that the proposed algorithm *significantly outperforms* the competing methods in most cases and achieves the *best* classification performance. Moreover, as shown in Figure 6, in contrast to baselines that are biased towards either the majority or minority class, the *high values of specificity and sensitivity* indicate that our algorithm performs almost *equally well* on

---

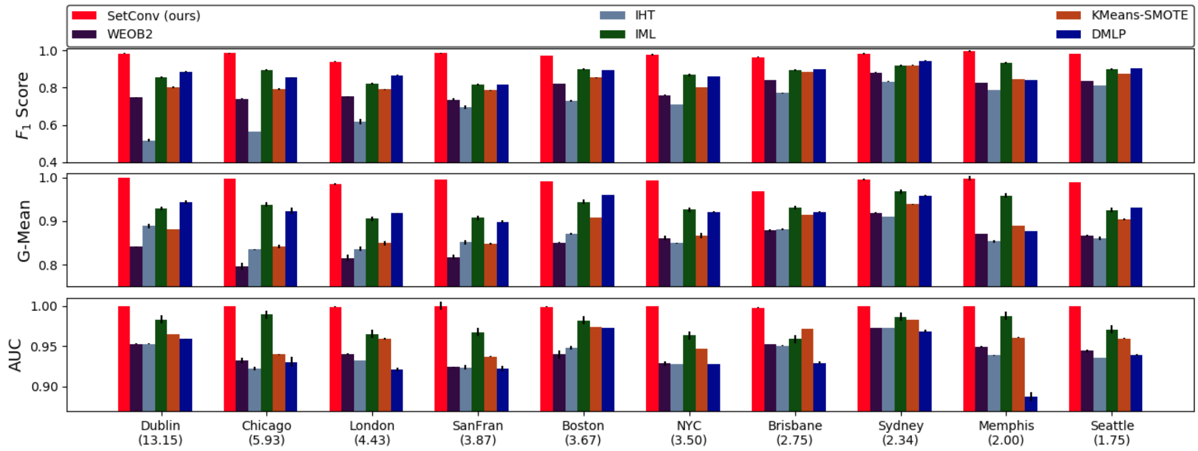

Figure 5: Binary classification (incident detection) performance of competing methods on the IRT dataset. The value in the bracket indicates the imbalance ratio (IR).

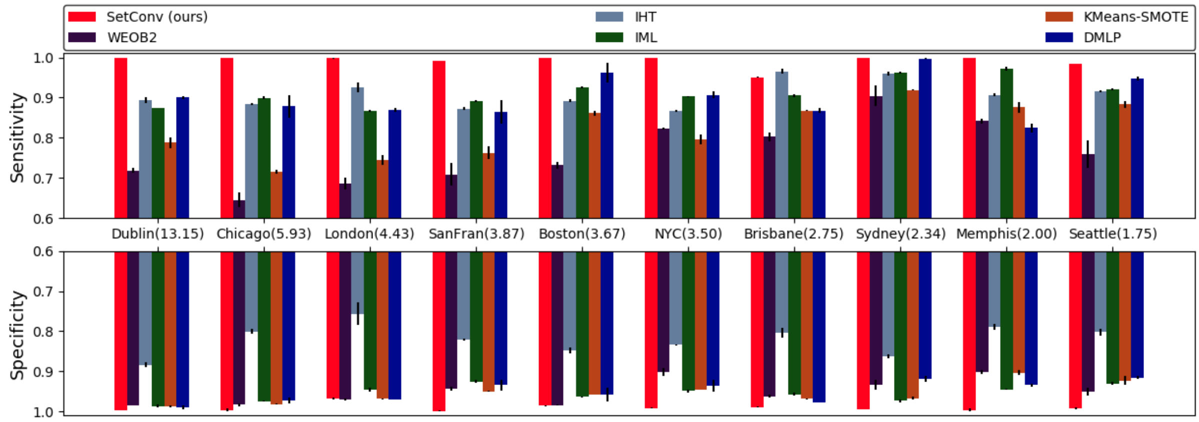

Figure 6: The performance diagnosis of competing methods for binary classification. The value in the bracket indicates the imbalance ratio (IR). In contrast to baselines that are biased towards either the majority or minority class, SetConv performs almost equally well on both classes.

both classes. That is, it not only makes few false positive predictions, but also produces few false negative predictions. It is also observed that our method is insensitive to geographical variations.

Our approach performs better because (1) compared to resampling based approaches, e.g., IHT and WEOB2, it makes full utilization of data via episodic training and set convolution operation, which avoids removing lot of samples from the majority class and losing important information. (2) compared to IML, SetConv enhances the feature extraction process by learning to extract discriminative features from a set of samples and compressing it into a single representation. It helps model to ignore sample-specific noisy information and focuses only on the latent concept common to different samples. (3) Compared to cost-sensitive approaches, e.g., CS-DMLP, episodic training assigns equal weights to both the majority and minority classes and eliminates the overhead of finding suitable cost values for different datasets. The model is forced to address class imbalance by learning to extract discriminative features during training.

4.5.2 Multi-Class Classification

To verify the effectiveness of the proposed algorithm in the multi-class classification scenario, we first compare it with competing methods on the IRT dataset (incident detection) and report their performance on the three minority classes, i.e., “Fire”, “Shooting”, and “Crash”. Due to space limitation, we only show the results of New York City (NYC) in Table 4, although similar results have been observed for other cities. We observe that our approach significantly outperforms baseline methods by providing much higher F_1, G-Mean and AUC metrics. Moreover, in contrast to baseline methods, it performs almost equally well on all the three

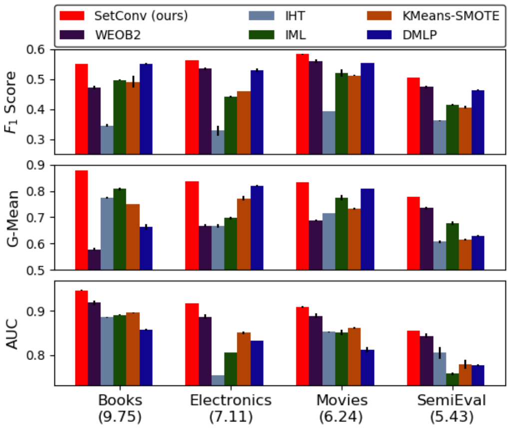

Figure 7: Binary sentiment classification performance of competing methods on the Amazon Review and SemiEval datasets. The value in the bracket indicates the imbalance ratio (IR).

</table>

minority classes.

In most cases, the overall classification performance of our method is superior to that of competing methods in terms of F_1, G-Mean and AUC metrics. Although CS-DMLP may provide better overall performance than our method in few cases, it achieves that by making many false negative predictions and missing lots of minority class samples, which is undesired in practical applications.

4.6 Sensitivity Analysis

The main parameter in our algorithm is the size of post training subset, i.e., $||S_{post}||$. We vary $||S_{post}||$ from 1000 to 4000 to study its effect on the classification performance. As shown in Figure 8, our method performs stably with respect to different values of $||S_{post}||$. It demonstrates that the SetConv layer has learned to capture the class concepts that are common across different data samples. Thus, as long as $||S_{post}||$ is large enough, e.g., 1000, varying $||S_{post}||$ has little effect on model performance.

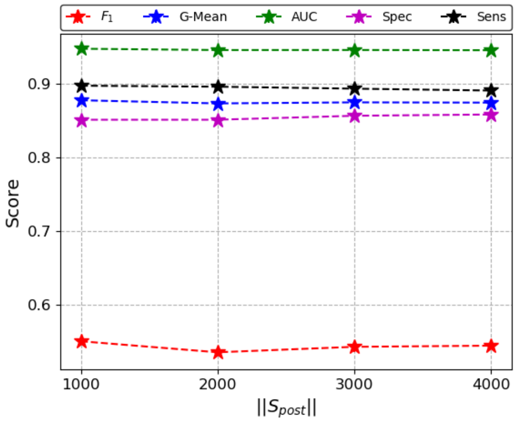

Figure 8: Effect of post-training subset size ($||S_{post}||$) on classification performance.

5 Conclusion

In this paper, we propose a novel permutation-invariant SetConv operation and a new training strategy named as episodic training for learning from imbalanced class distributions. The combined utilization of them enables extracting the most discriminative features from data and automatically balancing the class distribution for the subsequent classifier. Experiment results demonstrates the superiority of our approach when compared to SOTA methods. Moreover, the proposed method can be easily migrated and applied to data of other types (e.g., images) with few modifications.

Although the performance of SetConv shows its advantage in classification, it may not be appropriate for high-dimensional sparse data. It is because the large amount of 0s in these data may lead to close-to-zero convolution kernels and limit the model's capacity for classification. Combining sparse deep learning techniques with SetConv is a potential solution to this issue. We leave it for future work.

Appendix

Hardware Configuration

All experiments are performed on a server with the following hardware configuration: (1) 1 Intel Core i9-7920X 2.90 GHZ CPU with a total of 24 physical CPU cores (2) 4 GeForce GTX 2080 TI GPU with 11 GB video memory (3) 126 GB RAM. (4) Ubuntu 16.04 and a 4.15.0-39-generic Linux kernel.

Proof of Permutation Invariant Property

An important property of the SetConv layer is permutation-invariant, i.e., it is insensitive to the order of input samples. As long as the input samples are same, no matter in which order they are sent to the model, the SetConv layer always produces the same feature representation.

To prove it, let's consider an arbitrary permutation matrix π. Our goal is to show that $SetConv(\pi X) = SetConv(X)$.

$$\begin{aligned}
&SetConv(\pi X)\\
&= \frac{1}{N}\Big(Concat(\pi X)\cdot\big[g_1(Y-\pi X)\circledast g_2(W)\big]\Big)\\
&= \frac{1}{N}\cdot\\
&\Big(Concat(X)E(\pi)\cdot\big[(\pi\cdot g_1(Y-X))\circledast g_2(W)\big]\Big)\\
&= \frac{1}{N}\Big(X'E(\pi)\cdot E[\pi]^T\big[g_1(Y-X)\circledast g_2(W)\big]\Big)\\
&= \frac{1}{N}\Big(X'\cdot I\cdot\big[g_1(Y-X)\circledast g_2(W)\big]\Big)\\
&= SetConv(X)
\end{aligned} \tag{8}$$

Here $Concat$ is the concatenation operation which transforms a N-by-d matrix into a Nd-dimensional row vector. $E(\pi)$ is the expansion operator for the permutation matrix π. For example, considering a 2-by-2 permutation matrix,

$$\pi = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

$E(\pi)$ is given by:

$$E(\pi) = \begin{bmatrix} 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \end{bmatrix}$$

For a toy example, $Concat(\pi X)$ is computed as below:

$$\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}\begin{bmatrix} a & a \\ b & b \end{bmatrix} = \begin{bmatrix} b & b \\ a & a \end{bmatrix} \rightarrow \begin{bmatrix} b & b & a & a \end{bmatrix}$$

On the other hand, $Concat(X)E(\pi)$ is given by

$$\begin{aligned}
&Concat(X)E(\pi)\\
&= \begin{bmatrix} a & a & b & b \end{bmatrix}\begin{bmatrix} 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \end{bmatrix}\\
&= \begin{bmatrix} b & b & a & a \end{bmatrix}\\
&= Concat(\pi X)
\end{aligned}$$

Scalable Multi-Hop Relational Reasoning for Knowledge-Aware Question Answering

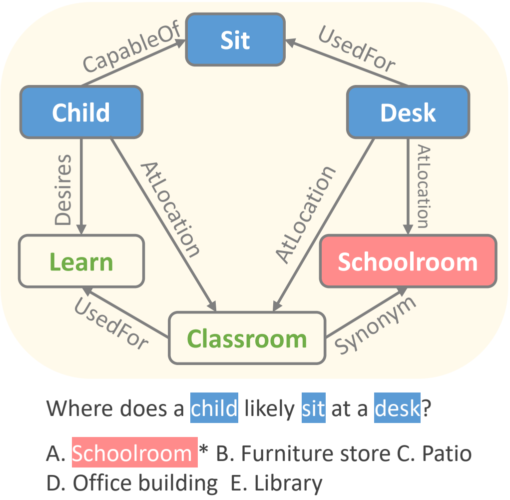
Abstract

Existing work that augment question answering (QA) models with external knowledge (e.g., knowledge graphs) either struggle to model multi-hop relations efficiently, or lack transparency into the model's prediction rationale. In this paper, we propose a novel knowledge-aware approach that equips pre-trained language models (PTLMs) with a *multi-hop relational reasoning module*, named multi-hop graph relation network (MHGRN). It performs multi-hop, multi-relational reasoning over subgraphs extracted from external knowledge graphs. The proposed reasoning module unifies path-based reasoning methods and graph neural networks and results in better interpretability and scalability. We also empirically show its effectiveness and scalability on CommonsenseQA and OpenbookQA datasets, and interpret its behaviors with case studies, with the code for experiments released[1].

1 Introduction

Many recently proposed question answering tasks require not only machine comprehension of the question and context, but also *relational reasoning* over entities (concepts) and their relationships by referencing external knowledge (Talmor et al., 2019; Sap et al., 2019; Clark et al., 2018; Mihaylov et al., 2018). For example, the question in Fig. 1 requires a model to perform relational reasoning over mentioned entities, *i.e.*, to infer latent relations among the concepts: {CHILD, SIT, DESK, SCHOOLROOM}. Background knowledge such as *"a child is likely to appear in a schoolroom"* may not be readily contained in the questions themselves, but are commonsensical to humans.



Where does a child likely sit at a desk?
A. Schoolroom * B. Furniture store C. Patio
D. Office building E. Library

Figure 1: **Illustration of knowledge-aware QA.** A sample question from CommonsenseQA can be better answered if a relevant subgraph of ConceptNet is provided as evidence. **Blue nodes** correspond to entities mentioned in the question, and **pink nodes** correspond to those in the answer. The other nodes are associated entities introduced in subgraph extraction. ⋆ indicates the correct answer.

Despite the success of large-scale pre-trained language models (PTLMs) (Devlin et al., 2019; Liu et al., 2019b), these models fall short of providing interpretable predictions, as the knowledge in their pre-training corpus is not explicitly stated, but rather is implicitly learned. It is thus difficult to recover the evidence used in the reasoning process.

This has led many to leverage knowledge graphs (KGs) (Mihaylov and Frank, 2018; Lin et al., 2019; Wang et al., 2019; Yang et al., 2019). KGs represent relational knowledge between entities with multi-relational edges for models to acquire. Incorporating KGs brings the potential of interpretable and trustworthy predictions, as the knowledge is now explicitly stated. For example, in Fig. 1, the relational path (CHILD → `AtLocation` → CLASSROOM → `Synonym` → SCHOOLROOM) naturally provides evidence for

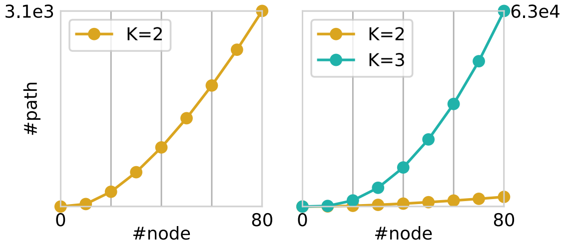

Figure 2: **Number of K-hop relational paths w.r.t. the node count in extracted graphs on CommonsenseQA. Left**: The path count is polynomial w.r.t. the number of nodes. **Right**: The path count is exponential w.r.t. the number of hops.

the answer SCHOOLROOM.

A straightforward approach to leveraging a knowledge graph is to directly model these relational paths. KagNet (Lin et al., 2019) and MHPGM (Bauer et al., 2018) extract multi-hop relational paths from KG and encode them with sequence models. Application of attention mechanisms upon these relational paths can further offer good interpretability. However, these models are hardly scalable because the number of possible paths in a graph is (1) *polynomial* w.r.t. the number of nodes (2) *exponential* w.r.t. the path length (see Fig. 2). Therefore, some (Weissenborn et al., 2017; Mihaylov and Frank, 2018) resort to only using one-hop paths, namely, triples, to balance scalability and reasoning capacities.

Graph neural networks (GNNs), in contrast, enjoy better scalability via their message passing formulation, but usually lack transparency. The most commonly used GNN variant, Graph Convolutional Networks (GCNs) (Kipf and Welling, 2017), perform message passing by aggregating neighborhood information for each node, but ignore the relation types. RGCNs (Schlichtkrull et al., 2018) generalize GCNs by performing relation-specific aggregation, making it applicable to multi-relational graphs. However, these models do not distinguish the importance of different neighbors or relation types and thus cannot provide explicit relational paths for model behavior interpretation.

In this paper, we propose a novel graph encoding architecture, *Multi-hop Graph Relation Network* (MHGRN), which combines the strengths of path-based models and GNNs. Our model inherits scalability from GNNs by preserving the message passing formulation. It also enjoys interpretability of path-based models by incorporating structured relational attention mechanism. Towards multi-hop relational reasoning, our key motivation is to allow each node to directly attend to its multi-hop neighbors by performing *multi-hop* message passing within a *single* layer. We outline the desired merits of knowledge-aware QA models in Table 1 and compare MHGRN with them.

	GCN	RGCN	KagNet	MHGRN
Multi-Relational Encoding	✗	✓	✓	✓
Interpretable	✗	✗	✓	✓
Scalable w.r.t. #node	✓	✓	✗	✓
Scalable w.r.t. #hop	✓	✓	✗	✓

Table 1: **Properties** of our MHGRN and other representative models for graph encoding.

We summarize the main contributions of this work as follows: 1) We propose MHGRN, a novel model architecture tailored to multi-hop relational reasoning, which explicitly models multi-hop relational paths at scale. 2) We propose a structured relational attention mechanism for efficient and interpretable modeling of multi-hop reasoning paths, along with its training and inference algorithms. 3) We conduct extensive experiments on two question answering datasets and show that our models bring significant improvements compared to knowledge-agnostic PTLMs, and outperform other graph encoding methods by a large margin.

2 Problem Formulation and Overview

In this paper, we limit the scope to the task of multiple-choice question answering, although the formulation can be easily generalized to other knowledge-guided tasks (*e.g.*, natural language inference). The overall paradigm of knowledge-aware QA is illustrated in Fig. 3. Formally, given a question q and an external knowledge graph (KG) as the knowledge source, our goal is to identify the correct answer from a set $\mathcal{C}$ of given options. We turn this problem into measuring the plausibility score between q and each option $a \in \mathcal{C}$, after which we select the option with the highest plausibility score.

To measure the score for q and a, we first concatenate q and a to form a statement $s = [q; a]$ and encode the statement s into the statement representation $\boldsymbol{s}$. Then we extract from the external KG a subgraph $\mathcal{G}$ (*i.e.*, schema graph in KagNet (Lin et al., 2019)), with the guidance of $\boldsymbol{s}$ (detailed in §5.1). This contextualized subgraph is defined as a multi-relational graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \phi)$. Here $\mathcal{V}$

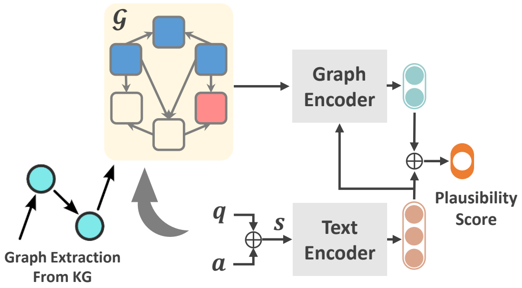

Figure 3: **Overview of the knowledge-aware QA framework.** It integrates the output from graph encoder (for relational reasoning over contextual subgraphs) and text encoder (for textual understanding) to generate the plausibility score for an answer option.

is a subset of entities in the external KG, containing only those relevant to $\boldsymbol{s}$. $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{R} \times \mathcal{V}$ is the set of edges that connect nodes in $\mathcal{V}$, where $\mathcal{R} = \{1, \cdots, m\}$ are the ids of all pre-defined relation types. The mapping function $\phi(i) : \mathcal{V} \rightarrow \mathcal{T} = \{\mathbf{E}_q, \mathbf{E}_a, \mathbf{E}_o\}$ takes node $i \in V$ as input, and outputs $\mathbf{E}_q$ if i is an entity mentioned in q, $\mathbf{E}_a$ if it is mentioned in a, and $\mathbf{E}_o$ otherwise[2]. Finally, we encode $\mathcal{G}$ into $\boldsymbol{g}$, and concatenate $\boldsymbol{s}$ and $\boldsymbol{g}$ to calculate the plausibility score.

3 Background: Multi-Relational Graph Encoding Methods

We leave encoding of s to pre-trained language models and focus on the challenge of encoding graph $\mathcal{G}$ to capture latent relations between entities. Current methods for encoding multi-relational graphs mainly fall into two categories: GNNs and path-based models. GNNs encode structured information by passing messages between nodes, directly operating on the graph structure, while path-based methods first decompose the graph into paths and then pool their representations to form a graph representation.

Graph Encoding with GNNs. For a graph with n nodes, a graph neural network (GNN) takes a set of node features $\{\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_n\}$ as input, and computes their corresponding node embeddings $\{\boldsymbol{h}'_1, \boldsymbol{h}'_2, \ldots, \boldsymbol{h}'_n\}$ via message passing (Gilmer et al., 2017). A compact graph representation for $\mathcal{G}$ can thus be obtained by pooling the node embeddings $\{\boldsymbol{h}'_i\}$:

$$\text{GNN}(\mathcal{G}) = \text{Pool}(\{\boldsymbol{h}'_1, \boldsymbol{h}'_2, \ldots, \boldsymbol{h}'_n\}). \quad (1)$$

As a notable variant of GNNs, graph convolutional networks (GCNs) (Kipf and Welling, 2017) additionally update node embeddings by aggregating messages from its direct neighbors. RGCNs (Schlichtkrull et al., 2018) extend GCNs to encode multi-relational graphs by defining relation-specific weight matrix $\boldsymbol{W}_r$ for each edge type:

$$\boldsymbol{h}'_i = \sigma\left(\left(\sum_{r\in\mathcal{R}} |\mathcal{N}_i^r|\right)^{-1} \sum_{r\in\mathcal{R}} \sum_{j\in\mathcal{N}_i^r} \boldsymbol{W}_r \boldsymbol{h}_j\right), \quad (2)$$

where $\mathcal{N}_i^r$ denotes neighbors of node i under relation r.[3]

While GNNs have proved to have good scalability, their reasoning is done at the node level, and are therefore incompatible with path modeling. This property also hinders path-level interpretation of the model's decisions.

Graph Encoding with Path-Based Models. In addition to directly modeling the graph with GNNs, a graph can also be viewed as a set of relational paths connecting pairs of entities.

Relation Networks (RNs) (Santoro et al., 2017) can be adapted to multi-relational graph encoding under QA settings. RNs use MLPs to encode all triples (one-hop paths) in $\mathcal{G}$ whose head entity is in $\mathcal{Q} = \{j \mid \phi(j) = \mathbf{E}_q\}$ and tail entity is in $\mathcal{A} = \{i \mid \phi(i) = \mathbf{E}_a\}$. It then pools the triple embeddings to generate a vector for $\mathcal{G}$ as follows,

$$\begin{aligned}\text{RN}(\mathcal{G}) = \text{Pool}\Big(\{&\text{MLP}(\boldsymbol{h}_j \oplus \boldsymbol{e}_r \oplus \\ &\boldsymbol{h}_i) \mid j \in \mathcal{Q}, i \in \mathcal{A}, (j,r,i) \in \mathcal{E}\}\Big). \quad (3)\end{aligned}$$

Here $\boldsymbol{h}_j$ and $\boldsymbol{h}_i$ are features for nodes j and i, $\boldsymbol{e}_r$ is the embedding of relation $r \in \mathcal{R}$, $\oplus$ denotes vector concatenation.

To further equip RN with the ability to model nondegenerate paths, KagNet (Lin et al., 2019) adopts LSTMs to encode all paths connecting question entities and answer entities with lengths no more than K. It then aggregates all path embeddings via the attention mechanism:

$$\begin{aligned}&\textsc{KagNet}(\mathcal{G}) = \text{Pool}\Big(\{\text{LSTM}(j, r_1, j_1, \ldots, r_k, i) \mid \\ &(j, r_1, j_1), \cdots, (j_{k-1}, r_k, i) \in \mathcal{E}, 1 \le k \le K\}\Big). \quad (4)\end{aligned}$$

---

[2] It is plausible to accordingly re-design mapping functions for this paradigm to work in other NLP tasks.

[3] For simplicity, we assume a single graph convolutional layer. In practice, multiple layers are stacked to enable message passing from multi-hop neighbors.

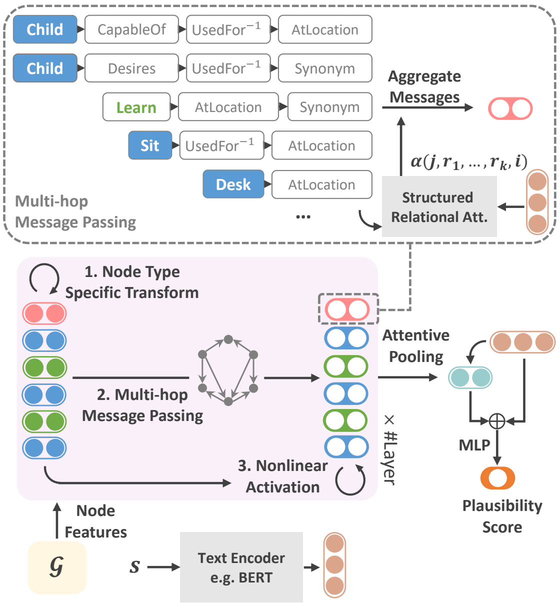

Figure 4: **Our proposed MHGRN architecture for relational reasoning.** MHGRN takes a multi-relational graph $\mathcal{G}$ and a (question-answer) statement vector $\boldsymbol{s}$ as input, and outputs a scalar that represent the plausibility score of this statement.

4 Proposed Method: Multi-Hop Graph Relation Network (MHGRN)

This section presents *Multi-hop Graph Relation Network* (MHGRN), a novel GNN architecture that unifies both GNNs and path-based models. MHGRN inherits path-level reasoning and interpretabilty from path-based models, while preserving good scalability of GNNs.

4.1 MHGRN: Model Architecture

We follow the GNN framework introduced in §3, where node features can be initialized with pre-trained weights (details in Appendix B). Here we focus on the computation of node embeddings.

Type-Specific Transformation. To make our model aware of the node type ϕ, we first perform node type specific linear transformation on the input node features:

$$\boldsymbol{x}_i = \boldsymbol{U}_{\phi(i)} \boldsymbol{h}_i + \boldsymbol{b}_{\phi(i)}, \qquad (5)$$

where the learnable parameters $\boldsymbol{U}$ and $\boldsymbol{b}$ are specific to the type of node i.

Multi-Hop Message Passing. As mentioned before, our motivation is to endow GNNs with the capability of *directly modeling paths*. To this end, we propose to pass messages directly over all the relational paths of lengths up to K. The set of valid k-hop relational paths is defined as:

$$\Phi_k = \{(j, r_1, \dots, r_k, i) \mid (j, r_1, j_1), \\ \cdots, (j_{k-1}, r_k, i) \in \mathcal{E}\} \quad (1 \le k \le K). \quad (6)$$

We perform k-hop ($1 \le k \le K$) message passing over these paths, which is a generalization of the single-hop message passing in RGCNs (see Eq. 2):

$$\boldsymbol{z}_i^k = \sum_{(j, r_1, \dots, r_k, i) \in \Phi_k} \alpha(j, r_1, \dots, r_k, i) / d_i^k \cdot \boldsymbol{W}_0^K \\ \cdots \boldsymbol{W}_0^{k+1} \boldsymbol{W}_{r_k}^k \cdots \boldsymbol{W}_{r_1}^1 \boldsymbol{x}_j \quad (1 \le k \le K), \quad (7)$$

where the $\boldsymbol{W}_r^t (1 \le t \le K, 0 \le r \le m)$ matrices are learnable[4], $\alpha(j, r_1, \dots, r_k, i)$ is an attention score elaborated in §4.2 and $d_i^k = \sum_{(j \cdots i) \in \Phi_k} \alpha(j \cdots i)$ is the normalization factor. The $\{\boldsymbol{W}_{r_k}^k \cdots \boldsymbol{W}_{r_1}^1 \mid 1 \le r_1, \dots, r_k \le m\}$ matrices can be interpreted as the low rank approximation of a $\{m \times \cdots \times m\}_k \times d \times d$ tensor that assigns a separate transformation for each k-hop relation, where d is the dimension of $\boldsymbol{x}_i$.

Incoming messages from paths of different lengths are aggregated via attention mechanism (Vaswani et al., 2017):

$$\boldsymbol{z}_i = \sum_{k=1}^{K} \text{softmax}\big(\text{bilinear}\big(\boldsymbol{s}, \boldsymbol{z}_i^k\big)\big) \cdot \boldsymbol{z}_i^k. \qquad (8)$$

Non-linear Activation. Finally, we apply shortcut connection and nonlinear activation to obtain the output node embeddings.

$$\boldsymbol{h}_i' = \sigma\left(\boldsymbol{V} \boldsymbol{h}_i + \boldsymbol{V}' \boldsymbol{z}_i\right), \qquad (9)$$

where $\boldsymbol{V}$ and $\boldsymbol{V}'$ are learnable model parameters, and σ is a non-linear activation function.

4.2 Structured Relational Attention

Naive parameterization of the attention score $\alpha(j, r_1, \dots, r_k, i)$ in Eq. 7 would require $\mathcal{O}(m^k)$ parameters for k-hop paths. Towards efficiency, we first regard it as the probability of a relation sequence $(\phi(j), r_1, \dots, r_k, \phi(i))$ conditioned on $\boldsymbol{s}$:

$$\alpha(j, r_1, \dots, r_k, i) = p\left(\phi(j), r_1, \dots, r_k, \phi(i) \mid \boldsymbol{s}\right), \qquad (10)$$

---

[4] $\boldsymbol{W}_0^t (0 \le t \le K)$ are introduced as padding matrices so that K transformations are applied regardless of k, thus ensuring comparable scale of $\boldsymbol{z}_i^k$ across different k.

which can naturally be modeled by a probabilistic graphical model, such as conditional random field (Lafferty et al., 2001):

$$\begin{aligned} p(\cdots \mid \boldsymbol{s}) &\propto \exp\Bigg(f(\phi(j), \boldsymbol{s}) + \sum_{t=1}^{k} \delta(r_t, \boldsymbol{s}) \\ &\quad + \sum_{t=1}^{k-1} \tau(r_t, r_{t+1}) + g(\phi(i), \boldsymbol{s}) \Bigg) \\ &\triangleq \underbrace{\beta(r_1, \ldots, r_k, \boldsymbol{s})}_{\text{Relation Type Attention}} \cdot \underbrace{\gamma(\phi(j), \phi(i), \boldsymbol{s})}_{\text{Node Type Attention}}, \end{aligned} \tag{11}$$

where $f(\cdot)$, $\delta(\cdot)$ and $g(\cdot)$ are parameterized by two-layer MLPs and $\tau(\cdot)$ by a transition matrix of shape $m \times m$. Intuitively, $\beta(\cdot)$ models the importance of a k-hop relation while $\gamma(\cdot)$ models the importance of messages from node type $\phi(j)$ to $\phi(i)$ (*e.g.*, the model can learn to pass messages only from question entities to answer entities).

Our model scores a k-hop relation by decomposing it into both context-aware single-hop relations (modeled by δ) and two-hop relations (modeled by τ). We argue that τ is indispensable, without which the model may assign high importance to illogical multi-hop relations (*e.g.*, [`AtLocation`, `CapableOf`]) or noisy relations (*e.g.*, [`RelatedTo`, `RelatedTo`]).

4.3 Computation Complexity Analysis

Although the message passing process in Eq. 7 and the attention module in Eq.11 handle potentially exponential number of paths, computation can be done in linear time with the help of dynamic programming (see Appendix C). As summarized in Table 2, both the time complexity and space complexity of MHGRN on a sparse graph are linear w.r.t. the maximum path length K or the number of nodes n.

4.4 Expressive Power of MHGRN

In addition to efficiency and scalability, we now discuss the modeling capacity of MHGRN. With the message passing formulation and relation-specific transformations, MHGRN is by nature the generalization of RGCN. It is also capable of directly modeling paths, making it interpretable as are path-based models such as RN and KagNet. To show this, we first generalize RN (Eq. 3) to the multi-hop setting and introduce K-hop RN (formal definition in Appendix D), which models multi-hop relation as the composition of single-hop relations. We can show that MHGRN is capable of representing K-hop RN (proof in Appendix E).

Model	**Time**	**Space**
$\mathcal{G}$ is a dense graph		
K-hop KagNet	$\mathcal{O}\left(m^K n^{K+1} K\right)$	$\mathcal{O}\left(m^K n^{K+1} K\right)$
K-layer RGCN	$\mathcal{O}\left(mn^2 K\right)$	$\mathcal{O}\left(mnK\right)$
MHGRN	$\mathcal{O}\left(m^2 n^2 K\right)$	$\mathcal{O}\left(mnK\right)$
$\mathcal{G}$ is a sparse graph with maximum node degree $\Delta \ll n$		
K-hop KagNet	$\mathcal{O}\left(m^K nK\Delta^K\right)$	$\mathcal{O}\left(m^K nK\Delta^K\right)$
K-layer RGCN	$\mathcal{O}\left(mnK\Delta\right)$	$\mathcal{O}\left(mnK\right)$
MHGRN	$\mathcal{O}\left(m^2 nK\Delta\right)$	$\mathcal{O}\left(mnK\right)$

Table 2: **Computation complexity** of different K-hop reasoning models on a dense/sparse multi-relational graph with n nodes and m relation types. Despite the quadratic complexity w.r.t. m, MHGRN's time cost is similar to RGCN on GPUs with parallelizable matrix multiplications (cf. Fig. 7).

4.5 Learning, Inference and Path Decoding

We now discuss the learning and inference process of MHGRN instantiated for QA tasks. Following the problem formulation in §2, we aim to determine the plausibility of an answer option $a \in \mathcal{C}$ given the question q with the information from both text s and graph $\mathcal{G}$. We first obtain the graph representation $\boldsymbol{g}$ by performing attentive pooling over the output node embeddings of answer entities $\{\boldsymbol{h}_i' \mid i \in \mathcal{A}\}$. Next we concatenate it with the text representation $\boldsymbol{s}$ and compute the plausibility score by $\rho(q, a) = \texttt{MLP}(\boldsymbol{s} \oplus \boldsymbol{g})$.

During training, we maximize the plausibility score of the correct answer $\hat{a}$ by minimizing the *cross-entropy* loss:

$$\mathcal{L} = \mathbb{E}_{q,\hat{a},\mathcal{C}}\left[-\log \frac{\exp(\rho(q, a))}{\sum_{a \in \mathcal{C}} \exp(\rho(q, a))} \right]. \tag{12}$$

The whole model is trained **end-to-end** jointly with the text encoder (e.g., RoBERTa).

During inference, we predict the most plausible answer by $\text{argmax}_{a \in \mathcal{C}}\ \rho(q, a)$. Additionally, we can decode a reasoning path as evidence for model predictions, endowing our model with the interpretability enjoyed by path-based models. Specifically, we first determine the answer entity i^* with the highest score in the pooling layer and the path length k^* with the highest score in Eq. 8. Then the reasoning path is decoded by $\text{argmax}\ \alpha(j, r_1, \ldots, r_{k^*}, i^*)$, which can be computed in linear time using dynamic programming.

5 Experimental Setup

We introduce how we construct $\mathcal{G}$ (§5.1), the datasets (§5.2), as well as the baseline methods (§5.3). Appendix B shows more implementation and experimental details for reproducibility.

5.1 Extracting $\mathcal{G}$ from External KG

We use *ConceptNet* (Speer et al., 2017), a general-domain knowledge graph as our external KG to test models' ability to harness structured knowledge source. Following KagNet (Lin et al., 2019), we merge relation types to increase graph density and add reverse relations to construct a multi-relational graph with 34 relation types (details in Appendix A). To extract an informative contextualized graph $\mathcal{G}$ from KG, we recognize entity mentions in s and link them to entities in *ConceptNet*, with which we initialize our node set $\mathcal{V}$. We then add to $\mathcal{V}$ all the entities that appear in any two-hop paths between pairs of mentioned entities. Unlike KagNet, we do not perform any pruning but instead reserve all the edges between nodes in $\mathcal{V}$, forming our $\mathcal{G}$.

5.2 Datasets

We evaluate models on two multiple-choice question answering datasets, CommonsenseQA and OpenbookQA. Both require world knowledge beyond textual understanding to perform well.

CommonsenseQA (Talmor et al., 2019) necessitates various commonsense reasoning skills. The questions are created with entities from *ConceptNet*. It is noteworthy that although CommonsenseQA is built upon *ConceptNet*, its questions are designed to probe multi-hop/compositional relations between entities that cannot be directly read from, or are even absent from *ConceptNet*. This design prevents short-cutting the reasoning by taking advantage of the graph structure.

Methods	Single	Ensemble
UnifiedQA† (Khashabi et al., 2020)	**79.1**	-

OpenBookQA (Mihaylov et al., 2018) provides elementary science questions together with an open book of science facts. This dataset also probes general common sense beyond the provided facts.

Dataset split specifications. CommonsenseQA [6] and OpenbookQA [7] all have their leaderboards, with training and development set publicly available. As the ground truth labels for CommonsenseQA are not readily available, for model anal-

---

[5] Models based on ConceptNet are no longer shown on the leaderboard, and we got our results from the organizers.

[6] `https://www.tau-nlp.org/commonsenseqa`

[7] `https://leaderboard.allenai.org/open_book_qa/submissions/public`

ysis, we follow Lin et al. (2019) and take 1,241 examples from official training examples as our in-house test examples and regard the remaining 8,500 ones as our in-house training examples, forming CommonsenseQA (IH). We also make use of the official split of CommonsenseQA, denoted as CommonsenseQA (OF). The numbers of instances in different dataset splits are listed in Table 5.

5.3 Compared Methods

We implement both knowledge-agnostic fine-tuning of pre-trained LMs and models that incorporate external KG as our baselines. Additionally, we directly compare our model with the results from corresponding leaderboard. These methods typically leverage textual knowledge or extra training data, as opposed to external KG. In all our *implemented* models, we use pre-trained LMs as text encoders for s for fair comparison. We do compare our models with those (Ma et al., 2019; Lv et al., 2019; Khashabi et al., 2020) augmented by other text-form external knowledge (*e.g.*, Wikipedia), although we stick to our focus of encoding *structured* KG.

Specifically, we fine-tune BERT-BASE, BERT-LARGE (Devlin et al., 2019), and ROBERTA (Liu et al., 2019b) for multiple-choice questions. We take `RGCN` (Eq. 2 in §3), `RN`[8] (Eq. 3 in §3), `KagNet` (Eq. 4 in §3) and `GconAttn` (Wang et al., 2019) as baselines. `GconAttn` generalizes match-LSTM (Wang and Jiang, 2016) and achieves success in language inference tasks.

6 Results and Discussions

In this section, we present the results of our models in comparison with baselines as well as methods on the leaderboards for both CommonsenseQA and OpenbookQA. We also provide analysis of models' components and characteristics.

6.1 Main Results

For CommonsenseQA (Table 3), we first use the in-house data split (IH) (see §5.2) to compare our models with implemented baselines. This is **different from the official split** used in the leaderboard methods. Almost all KG-augmented models achieve performance gain over vanilla pre-trained LMs, demonstrating the value of external knowledge on this dataset. Additionally, we evaluate our MHGRN (with text encoder being ROBERTA-LARGE) on **official split**, OF (Table 4) for fair comparison with other methods on leaderboard, in both single-model setting and ensemble-model setting. With backbone being T5 (Raffel et al., 2019), UnifiedQA (Khashabi et al., 2020) tops the leaderboard[9]. Considering its training cost, we do not intend to compare our ROBERTA-based model with it. We achieve the best performances among the other models.

Methods	Dev (%)	Test (%)
T5-3B† (Raffel et al., 2019)	-	83.20
UnifiedQA† (Khashabi et al., 2020)	-	**87.20**
RoBERTa-Large (w/o KG)	66.76 (±1.14)	64.80 (±2.37)
+ RGCN	64.65 (±1.96)	62.45 (±1.57)
+ GconAttn	64.30 (±0.99)	61.90 (±2.44)
+ RN (1-hop)	64.85 (±1.11)	63.65 (±2.31)
+ RN (2-hop)	67.00 (±0.71)	65.20 (±1.18)
+ MHGRN (K = 3)	68.10 (±1.02)	**66.85** (±1.19)
AristoRoBERTaV7†	79.2	77.8
+ MHGRN (K = 3)	78.6	**80.6**

Table 6: **Performance comparison on OpenbookQA.** † indicates reported results on leaderboard. T5-3B is 8 times larger than our models. UnifiedQA is 30x larger.

For OpenbookQA (Table 6), we use official split and build models with ROBERTA-LARGE as text encoder. MHGRN surpasses all implemented baselines, with an absolute increase of ~2% on Test. Also, as our approach is naturally compatible with the methods that utilize textual knowledge or extra data, because in our paradigm the encoding of textual statement and graph are structurally-decoupled (Fig. 3). To empirically show MHGRN can bring gain over textual-knowledge empowered systems, we replace our text encoder with AristoRoBERTaV7[10], and fine-tune our MHGRN upon OpenbookQA. Empirically, MHGRN continues to bring benefits to strong-performing textual-knowledge empowered systems. One takeaway is that textual knowledge and structured knowledge are potentially complementary.

6.2 Performance Analysis

Ablation Study on Model Components. As shown in Table 7, disabling type-specific transformation results in ~ 1.3% drop in performance, demonstrating the need for distinguishing node types for QA tasks. Our structured relational attention mechanism is also critical, with its two

---

[8] We use mean pooling for 1-hop RN and attentive pooling for 2-hop RN (detailed in Appendix D).

[9] The leaderboard in August, 2020.

[10] `https://leaderboard.allenai.org/open_book_qa/submission/blcp1tu91i4gm0vf484g`

Methods	IHdev-Acc. (%)
MHGRN (K = 3)	**74.45** (±0.10)
- Type-specific transformation (§4.1)	73.16 (±0.28)
- Structured relational attention (§4.2)	73.26 (±0.31)
- Relation type attention (§4.2)	73.55 (±0.68)
- Node type attention (§4.2)	73.92 (±0.65)

Table 7: **Ablation study on model components** (removing one component each time) using ROBERTA-LARGE as the text encoder. We report the IHdev accuracy on CommonsenseQA.

sub-components contributing almost equally.

Impact of the Amount of Training Data. We use different fractions of training data of CommonsenseQA and report results of fine-tuning text encoders alone and jointly training text encoder and graph encoder in Fig. 5. Regardless of training data fraction, our model shows consistently more performance improvement over knowledge-agnostic fine-tuning compared with the other graph encoding methods, indicating MHGRN's complementary strengths to text encoders.

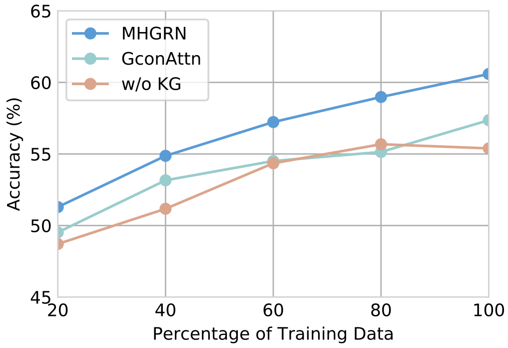

Figure 5: Performance change (accuracy in %) w.r.t. the amounts of training data on CommonsenseQA IHTest set (same as Lin et al. (2019)).

Impact of Number of Hops (K). We investigate the impact of hyperparameter K for MHGRN with experiments on CommonsenseQA (Fig. 6). The increase of K continues to bring benefits until K = 4. However, performance begins to drop when $K > 3$. This might be attributed to exponential noise in longer relational paths in the knowledge graph.

6.3 Model Scalability

Fig. 7 presents the computation cost of MHGRN and RGCN (measured by training time) with the text encoder removed. Both grow linearly w.r.t. K. Although the theoretical complexity of MHGRN is m times that of RGCN, the ratio of their empirical cost only approaches 2, demonstrating that our model can be better parallelized. It is noteworthy that the text encoder part actually dominates the overall cost. Therefore, the gap between our model and the RGCN are further narrowed if we consider the cost of the entire model.

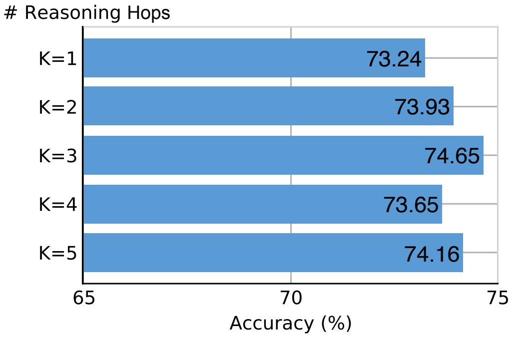

Figure 6: **Effect of K in MHGRN**. We show IHDev accuracy of MHGRN on CommonsenseQA w.r.t. # hops.

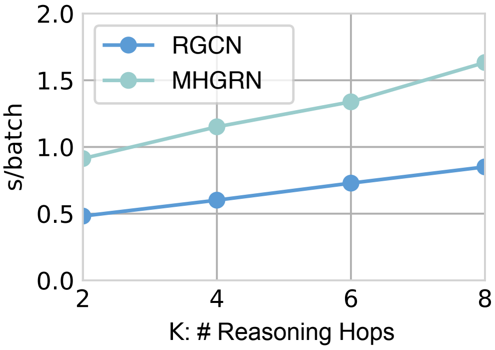

Figure 7: **Analysis of model scalability**. Comparison of per-batch training efficiency w.r.t. # hops K.

6.4 Model Interpretability

We can analyze our model's reasoning process by decoding the reasoning path using the method described in §4.5. Fig. 8 shows two examples from CommonsenseQA, where our model correctly answers the questions and provides reasonable path evidences. In the example on the left, the model links question entities and answer entity in a chain to support reasoning, while the example on the right provides a case where our model leverage unmentioned entities to bridge the reasoning gap between question entity and answer entities, in a way that is coherent with the latent relation between CHAPEL and the desired answer in the question.

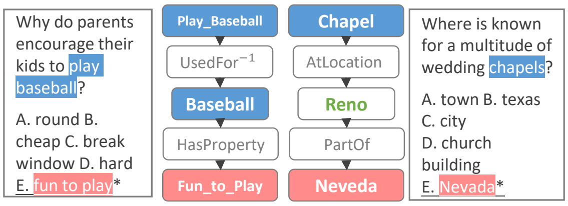

Figure 8: **Case study on model interpretability.** We present two sample questions from CommonsenseQA with the reasoning paths output by MHGRN.

7 Related Work

Knowledge-Aware Methods for NLP Various work have investigated the potential to empower NLP models with external knowledge. Many attempt to extract *structured* knowledge, either in the form of nodes (Yang and Mitchell, 2017; Wang et al., 2019), triples (Weissenborn et al., 2017; Mihaylov and Frank, 2018), paths (Bauer et al., 2018; Kundu et al., 2019; Lin et al., 2019), or subgraphs (Li and Clark, 2015), and encode them to augment textual understanding.

Recent success of pre-trained LMs motivates many (Pan et al., 2019; Ye et al., 2019; Zhang et al., 2018; Li et al., 2019; Banerjee et al., 2019) to probe LMs' potential as latent knowledge bases. This line of work turn to *textual* knowledge (*e.g.* Wikipedia) to directly impart knowledge to pre-trained LMs. They generally fall into two paradigms: 1) Fine-tuning LMs on large-scale general-domain datasets (*e.g.* RACE (Lai et al., 2017)) or on knowledge-rich text. 2) Providing LMs with evidence via information retrieval techniques. However, these models cannot provide explicit reasoning and evidence, thus hardly trustworthy. They are also subject to the availability of in-domain datasets and maximum input token of pre-trained LMs.

Neural Graph Encoding Graph Attention Networks (GAT) (Velickovic et al., 2018) incorporates attention mechanism in feature aggregation, RGCN (Schlichtkrull et al., 2018) proposes relational message passing which makes it applicable to multi-relational graphs. However they only perform single-hop message passing and cannot be interpreted at path level. Other work (Abu-El-Haija et al., 2019; Nikolentzos et al., 2019) aggregate for a node its K-hop neighbors based on node-wise distances, but they are designed for non-relational graphs. MHGRN addresses these issues by reasoning on multi-relational graphs and being interpretable via maintaining paths as reasoning chains.

8 Conclusion

We present a principled, scalable method, MHGRN, that can leverage general knowledge via multi-hop reasoning over interpretable structures (e.g. ConceptNet). The proposed MHGRN generalizes and combines the advantages of GNNs and path-based reasoning models. It explicitly performs multi-hop relational reasoning and is empirically shown to outperform existing methods with superior scalablility and interpretability.

B Implementation Details

	CommonsenseQA	OpenbookQA
BERT-BASE	3×10^{-5}	-
BERT-LARGE	2×10^{-5}	-
ROBERTA-LARGE	1×10^{-5}	1×10^{-5}

Table 9: Learning rate for text encoders on different datasets.

Our models are implemented in *PyTorch*. We use *cross-entropy* loss and *RAdam* (Liu et al., 2019a) optimizer. We find it beneficial to use separate learning rates for the text encoder and the graph encoder. We tune learning rates for text encoders and graph encoders on two datasets. We first fine-tune ROBERTA-LARGE, BERT-LARGE, BERT-BASE on *CommonsenseQA* and ROBERTA-LARGE on *OpenbookQA* respectively, and choose a dataset-specific learning rate from $\{1\times10^{-5}, 2\times10^{-5}, 3\times10^{-5}, 6\times10^{-5}, 1\times10^{-4}\}$ for each text encoder, based on the best performance on development set, as listed in Table 9. We report the performance of these fine-tuned text encoders and also adopt their dataset-specific optimal learning rates in joint training with graph encoders. For models that involve KG, the learning rate of their graph encoders are chosen from $\{1\times10^{-4}, 3\times10^{-4}, 1\times10^{-3}, 3\times10^{-3}\}$, based on their best development set performance with ROBERTA-LARGE as the text encoder. We report the optimal learning rates for graph encoders in Table 10. In training, we set the maximum input sequence length to text encoders to 64, batch size to 32, and perform early stopping. AristoRoBERTaV7+MHGRN is the only exception. In order to host fair comparison, we follow AristoRoBERTaV7 and set the batch size to 16, max input sequence length to 128, and choose a decoder learning rate from $\{1\times10^{-3}, 2\times10^{-5}\}$.

	CommonsenseQA	OpenbookQA
RN	3×10^{-4}	3×10^{-4}
RGCN	1×10^{-3}	1×10^{-3}
GconAttn	3×10^{-4}	1×10^{-4}
MHGRN	1×10^{-3}	1×10^{-3}

Table 10: Learning rate for graph encoders on different datasets.

	#Param
RN	$399K$
RGCN	$365K$
GconAttn	$453K$
MHGRN	$544K$

Table 11: Numbers of parameters of different graph encoders.

For the input node features, we first use templates to turn knowledge triples in *ConceptNet* into sentences and feed them into pre-trained BERT-LARGE, obtaining a sequence of token embeddings from the last layer of BERT-LARGE for each triple. For each entity in *ConceptNet*, we perform mean pooling over the tokens of the entity's occurrences across all the sentences to form a $1024d$ vector as its corresponding node feature. We use this set of features for all our implemented models.

We use 2-layer RGCN and single-layer MHGRN across our experiments.

The numbers of parameter for each graph encoder are listed in Table 11.

C Dynamic Programming Algorithm for Eq. 7

To show that multi-hop message passing can be computed in linear time, we observe that Eq. 7 can be re-written in matrix form:

$$
\begin{aligned}
\boldsymbol{Z}^k = (\boldsymbol{D}^k)^{-1} & \sum_{(r_1,\dots,r_k)\in\mathcal{R}^k} \beta(r_1,\dots,r_k,\boldsymbol{s}) \\
& \cdot \boldsymbol{G}\boldsymbol{A}_{r_k}\cdots\boldsymbol{A}_{r_1}\boldsymbol{F}\boldsymbol{X}{\boldsymbol{W}_{r_1}^{1}}^{\top}\cdots{\boldsymbol{W}_{r_k}^{k}}^{\top} \\
& \cdot {\boldsymbol{W}_0^{k+1}}^{\top}\cdots{\boldsymbol{W}_0^{K}}^{\top} \quad (1 \le k \le K), \quad (13)
\end{aligned}
$$

where $\boldsymbol{G} = \mathrm{diag}(\exp([g(\phi(v_1),\boldsymbol{s}),\dots,g(\phi(v_n),\boldsymbol{s})])$ ($\boldsymbol{F}$ is similarly defined), $\boldsymbol{A}_r$ is the adjacency matrix for relation r and $\boldsymbol{D}^k$ is defined as follows:

$$
\begin{aligned}
\boldsymbol{D}^k = \mathrm{diag}\Bigg(& \sum_{(r_1,\dots,r_k)\in\mathcal{R}^k} \beta(r_1,\dots,r_k,\boldsymbol{s}) \\
& \cdot \boldsymbol{G}\boldsymbol{A}_{r_k}\cdots\boldsymbol{A}_{r_1}\boldsymbol{F}\boldsymbol{X}\boldsymbol{1}\Bigg) \quad (1 \le k \le K) \quad (14)
\end{aligned}
$$

Using this matrix formulation, we can compute Eq. 7 using dynamic programming:

D Formal Definition of K-hop RN

Definition 1 *(K-hop Relation Network) A multi-hop relation network is a function that maps a multi-relational graph to a fixed size vector:*

$$
\textit{KHopRN}(\mathcal{G};\tilde{\boldsymbol{W}},\tilde{\boldsymbol{E}},\tilde{\boldsymbol{H}}) = \sum_{k=1}^{K} \sum_{\substack{(j,r_1,\dots,r_k,i)\in\Phi_k \\ j\in\mathcal{Q} \;\; i\in\mathcal{A}}} \tilde{\beta}(j,r_1,\dots,r_k,i)\cdot\tilde{\boldsymbol{W}}(\tilde{\boldsymbol{h}}_j \oplus (\tilde{\boldsymbol{e}}_{r_1}\circ\cdots\circ\tilde{\boldsymbol{e}}_{r_k}) \oplus \tilde{\boldsymbol{h}}_i), \quad (15)
$$

where $\circ$ denotes element-wise product and $\tilde{\beta}(\cdots) = 1/(K|\mathcal{A}| \cdot |\{(j',\dots,i) \in \mathcal{G} \mid j' \in \mathcal{Q}\}|)$ defines the pooling weights.

E Expressing K-hop RN with MultiGRN

Theorem 1 *Given any $\tilde{\boldsymbol{W}},\tilde{\boldsymbol{E}},\tilde{\boldsymbol{H}}$, there exists a parameter setting such that the output of the model becomes $\textit{KHopRN}(\mathcal{G};\tilde{\boldsymbol{W}},\tilde{\boldsymbol{E}},\tilde{\boldsymbol{H}})$ for arbitrary $\mathcal{G}$.*

Algorithm 1 Dynamic programming algorithm for multi-hop message passing.

```
Input: $\mathrm{s}, \boldsymbol{X}, \boldsymbol{A}_r (1 \le r \le m), \boldsymbol{W}_r^t (r \in \mathcal{R}, 1 \le t \le k), \boldsymbol{F}, \boldsymbol{G}, \delta, \tau$
Output: $\boldsymbol{Z}$

 1: $\hat{\boldsymbol{W}}^K \leftarrow \boldsymbol{I}$
 2: for $k \leftarrow K-1$ to $1$ do
 3:     $\hat{\boldsymbol{W}}^k \leftarrow \boldsymbol{W}_0^{k+1}\hat{\boldsymbol{W}}^{k+1}$
 4: end for
 5: for $r \in \mathcal{R}$ do
 6:     $\boldsymbol{M}_r \leftarrow \boldsymbol{F}\boldsymbol{X}$
 7: end for
 8: for $k \leftarrow 1$ to $K$ do
 9:     if $k > 1$ then
10:         for $r \in \mathcal{R}$ do
11:             $\boldsymbol{M}'_r \leftarrow e^{\delta(r,\mathrm{s})}\boldsymbol{A}_r \sum_{r'\in\mathcal{R}} e^{\tau(r',r,\mathrm{s})}\boldsymbol{M}_{r'}{\boldsymbol{W}_r^k}^{\top}$
12:         end for
13:         for $r \in \mathcal{R}$ do
14:             $\boldsymbol{M}_r \leftarrow \boldsymbol{M}'_r$
15:         end for
16:     else
17:         for $r \in \mathcal{R}$ do
18:             $\boldsymbol{M}_r \leftarrow e^{\delta(r,\mathrm{s})} \cdot \boldsymbol{A}_r\boldsymbol{M}_r{\boldsymbol{W}_r^k}^{\top}$
19:         end for
20:     end if
21:     $\boldsymbol{Z}^k \leftarrow \boldsymbol{G}\sum_{r\in\mathcal{R}} \boldsymbol{M}_r\hat{\boldsymbol{W}}^k$
22: end for
23: Replace $\boldsymbol{W}_r^t (0 \le r \le m, 1 \le t \le k)$ with identity
    matrices and $\boldsymbol{X}$ with $\boldsymbol{1}$ and re-run line 1 - line 19 to
    compute $\boldsymbol{d}^1, \dots, \boldsymbol{d}^K$
24: for $k \leftarrow 1$ to $K$ do
25:     $\boldsymbol{Z}^k \leftarrow (\mathrm{diag}(\boldsymbol{d}^k))^{-1}\boldsymbol{Z}^k$
26: end for
27: return $\boldsymbol{Z}^1, \boldsymbol{Z}^2, \dots, \boldsymbol{Z}^k$
```

Proof. Suppose $\tilde{\boldsymbol{W}} = [\tilde{\boldsymbol{W}}_1, \tilde{\boldsymbol{W}}_2, \tilde{\boldsymbol{W}}_3]$, where $\tilde{\boldsymbol{W}}_1, \tilde{\boldsymbol{W}}_3 \in \mathbb{R}^{d_3 \times d_1}, \tilde{\boldsymbol{W}}_2 \in \mathbb{R}^{d_3 \times d_2}$. For *MHRGN*, we set the parameters as follows: $\boldsymbol{H} = \tilde{\boldsymbol{H}}, \boldsymbol{U}_* = [\boldsymbol{I}; \boldsymbol{0}] \in \mathbb{R}^{(d_1+d_2) \times d_1}, \boldsymbol{b}_* = [\boldsymbol{0}, \boldsymbol{1}]^\top \in \mathbb{R}^{d_1+d_2}, \boldsymbol{W}_r^t = \text{diag}(\boldsymbol{1} \oplus \tilde{\boldsymbol{e}}_r) \in \mathbb{R}^{(d_1+d_2) \times (d_1+d_2)} (r \in \mathcal{R}, 1 \le t \le K), \boldsymbol{V} = \tilde{\boldsymbol{W}}_3 \in \mathbb{R}^{d_3 \times d_1}, \boldsymbol{V}' = [\tilde{\boldsymbol{W}}_1, \tilde{\boldsymbol{W}}_2] \in \mathbb{R}^{d_3 \times (d_1+d_2)}$. We disable the relation type attention module and enable message passing only from $\mathcal{Q}$ to $\mathcal{A}$. By further choosing σ as the identity function and performing pooling over $\mathcal{A}$, we observe that the output of *MultiGRN* becomes:

$$
\begin{aligned}
&\frac{1}{|\mathcal{A}|} \sum_{i \in \mathcal{A}} \boldsymbol{h}_i' \\
&= \frac{1}{|\mathcal{A}|} \left(\boldsymbol{V} \boldsymbol{h}_i + \boldsymbol{V}' \boldsymbol{z}_i \right) \\
&= \frac{1}{K|\mathcal{A}|} \sum_{k=1}^{K} \left(\boldsymbol{V} \boldsymbol{h}_i + \boldsymbol{V}' \boldsymbol{z}_i^k \right) \\
&= \sum_{k=1}^{K} \sum_{\substack{(j, r_1, \ldots, r_k, i) \in \Phi_k \\ j \in \mathcal{Q},\ i \in \mathcal{A}}} \tilde{\beta}(j, r_1, \ldots, r_k, i) \Big(\boldsymbol{V} \boldsymbol{h}_i + \\
&\quad \boldsymbol{V}' \boldsymbol{W}_{r_k}^k \cdots \boldsymbol{W}_{r_1}^1 \boldsymbol{x}_j \Big) \\
&= \sum_{k=1}^{K} \sum_{\substack{(j, r_1, \ldots, r_k, i) \in \Phi_k \\ j \in \mathcal{Q}}} \tilde{\beta}(\cdots) \Big(\boldsymbol{V} \boldsymbol{h}_i + \boldsymbol{V}' \boldsymbol{W}_{r_k}^k \\
&\quad \cdots \boldsymbol{W}_{r_1}^1 \boldsymbol{U}_{\phi(j)} \boldsymbol{h}_j + \boldsymbol{V}' \boldsymbol{W}_{r_k}^k \cdots \boldsymbol{W}_{r_1}^1 \boldsymbol{b}_{\phi(j)} \Big) \\
&= \sum_{k=1}^{K} \sum_{\substack{(j, r_1, \ldots, r_k, i) \in \Phi_k \\ j \in \mathcal{Q},\ i \in \mathcal{A}}} \tilde{\beta}(\cdots) \Big(\tilde{\boldsymbol{W}}_3 \boldsymbol{h}_i + \tilde{\boldsymbol{W}}_1 \boldsymbol{h}_j \\
&\quad + \tilde{\boldsymbol{W}}_2 (\tilde{\boldsymbol{e}}_{r_1} \circ \cdots \circ \tilde{\boldsymbol{e}}_{r_k}) \Big) \\
&= \sum_{k=1}^{K} \sum_{\substack{(j, r_1, \ldots, r_k, i) \in \Phi_k \\ j \in \mathcal{Q},\ i \in \mathcal{A}}} \tilde{\beta}(\cdots) \tilde{\boldsymbol{W}} \Big(\tilde{\boldsymbol{h}}_j \oplus \\
&\quad (\tilde{\boldsymbol{e}}_{r_1} \circ \cdots \circ \tilde{\boldsymbol{e}}_{r_k}) \oplus \tilde{\boldsymbol{h}}_i \Big) \\
&= \mathit{RN}(\mathcal{G}; \tilde{\boldsymbol{W}}, \tilde{\boldsymbol{E}}, \tilde{\boldsymbol{H}})
\end{aligned}
\tag{16}

Improving Bilingual Lexicon Induction for Low Frequency Words

Jiaji Huang **Xingyu Cai** **Kenneth Church**
Baidu Research, 1195 Bordeaux Dr, Sunnyvale, CA, USA, 94089
{huangjiaji, xingyucai, kennethchurch}@baidu.com

Abstract

This paper designs a *Monolingual Lexicon Induction* task and observes that two factors accompany the degraded accuracy of bilingual lexicon induction for rare words. First, a diminishing *margin* between similarities in low frequency regime, and secondly, exacerbated *hubness* at low frequency. Based on the observation, we further propose two methods to address these two factors, respectively. The larger issue is hubness. Addressing that improves induction accuracy significantly, especially for low-frequency words.

1 Introduction

Bilingual Lexicon Induction (BLI) studies how to generate word-level translations from non-parallel corpora in two languages. Recently, Irvine and Callison-Burch (2017) observe that rarer words are harder to translate than frequent ones. But their BLI method is based on various "hand-crafted" features. We show that the same phenomenon occurs as well in BLI methods that are based on word embeddings. This type of methods have become especially popular in recent years (Mikolov et al., 2013; Faruqui and Dyer, 2014; Artetxe et al., 2016, 2018) and achieved state-of-art accuracies (Conneau et al., 2018).

We briefly review BLI methods that are based on word embeddings. Without loss of generality, in this paper, we focus on "supervised" BLI, which assumes that a seeding dictionary is available. Unsupervised BLI (Artetxe et al., 2018; Conneau et al., 2018) often alternates between inducing a seeding dictionary and using that to refine generated translations. Therefore, to some extent, "supervised" BLI is a key step in its "unsupervised" counterpart, and a more basic prototype to study.

Let the source space be $\mathbf{X} \triangleq [\mathbf{x}_1, \ldots, \mathbf{x}_m]$, where $\mathbf{x}_i \in \mathbb{R}^d$ is the embedding vector for the i-th source word. Similarly, let the target space be $\mathbf{Y} \triangleq [\mathbf{y}_1, \ldots, \mathbf{y}_n]$ where $\mathbf{y}_j$ is the embedding vector for the j-th target word. Here m and n are the vocabulary sizes for the two spaces. The seeding dictionary is made up of subsets of $\mathbf{X}$ and $\mathbf{Y}$, denoted as $\mathbf{X}^s = [\mathbf{x}^s_1, \ldots, \mathbf{x}^s_S]$ and $\mathbf{Y}^s = [\mathbf{y}^s_1, \ldots, \mathbf{y}^s_S]$ respectively, where $\mathbf{x}^s_k$ and $\mathbf{y}^s_k$ are the word embeddings of a pair of translations. S is the size of seeding dictionary.

The typical supervised BLI works by first learning a transformation $\mathbf{W}$ that minimizes the discrepancy between $\mathbf{X}^s$ and $\mathbf{Y}^s$,

$$\mathbf{W} = \arg\min_{\mathbf{W} \in \mathcal{W}} \|\mathbf{W}\mathbf{X}^s - \mathbf{Y}^s\|_F^2, \tag{1}$$

where $\|\cdot\|_F$ is Frobenius norm, and $\mathcal{W}$ is a constraint set of $\mathbf{W}$. The easiest choice of $\mathcal{W}$ may be $\mathbb{R}^{d\times d}$, seen in (Mikolov et al., 2013). On the other hand, Xing et al. (2015) has observed substantial gain by letting $\mathcal{W} = \mathcal{O}(d)$, the set of orthogonal matrices. In this case, (1) is also called a *Procrustes problem*.

Once the transformation $\mathbf{W}$ is learned, translation can be induced for a word $\mathbf{x}_i$, by retrieving the Nearest Neighbor (NN) of $\mathbf{W}\mathbf{x}_i$ in $\mathbf{Y}$. Cosine distance is often adopted in the retrieval. Solving the Procrustes problem (Eq. (1)), followed by NN search is a representative framework. We use it as a baseline of this paper.

Despite the existing success in word embedding based BLI, understanding of its performance against word frequency is still lacking. This paper observes that BLI's accuracy significantly degrades for low-frequency words. Then, two factors are identified that may explain the observation. Motivated by them, we propose two methods that address each of the two factors, both improving BLI's performance in low-frequency regime.

2 Lexicon Induction at Low Frequency

We study how induction accuracies vary for words of different frequencies. Before we start, it should be emphasized that the frequency ranking of a source word and its translation(s) can differ a lot in their respective language. We term this fact as *frequency mismatch*, and the extent of mismatch also depends on the language pair. To simplify the problem, we design a "Monolingual Lexicon Induction" (MLI) task.

2.1 Monolingual Lexicon Induction (MLI)

MLI works with two sets of word embeddings for a single language. Given a word to be translated, the induction is supposed to retrieve the same word. The embeddings are trained respectively from two pieces of monolingual corpora (in the same language). While frequency mismatch still exists due to the differences in the two corpora, it is however reduced significantly. Compared with BLI, the induction task is also much simplified as the ground-truth is an one-to-one mapping.

We take the fasttext wiki and crawl[1] embeddings, and build a shared vocabulary of 500K words. The words are sorted from the most to least frequent according to the crawl corpora, and the order is more or less preserved in the wiki corpora. We split the 500K words into 50 frequency bins. That is, the first bin includes the 10K most frequent words. The second bin includes the next 10K most frequent words, and so on.

In each frequency bin, we randomly hold out 4K words as test words. The rest 6K are used to build seeding dictionary. To see how the size of seeds may impact induction accuracy, we vary the number of seeds sampled from the 6K words. In particular, we sample 0.02K, 0.2K and all the 6K in each frequency bin, resulting in seeding dictionaries of size 1K, 10K and 300K respectively. We ensure that any smaller seeding set is a subset of a bigger one.

An orthogonal transformation is learned using the seeds. Then, for the transformed source embeddings, nearest neighbors are retrieved in the target space. Figure 1a shows the accuracies of retrievals in each frequency bin. The accuracies drop significantly at low frequency. One may wonder if adding more seeds can help. It helps but is not very effective, as the gain diminishes quickly. Indeed, the improvement is tiny from a seeding size of 10K to 300K. In the next two subsections, we look into two statistics as diagnostics of the observation.

2.2 Cosine Similarities and Margin

Consider a source word $\mathbf{x}_i$, when we apply NN retrieval, it is supposed that its true translation $\text{trans}(\mathbf{x}_i)$ is the closest to $\mathbf{W}\mathbf{x}_i$, among all the candidates in $\mathbf{Y}$. In other words, we want

$$\cos(\mathbf{W}\mathbf{x}_i, \text{trans}(\mathbf{x}_i)) \geq \cos(\mathbf{W}\mathbf{x}_i, \mathbf{y}_j),$$

for $\mathbf{y}_j \neq \text{trans}(\mathbf{x}_i)$. Further define the difference between $\cos(\mathbf{W}\mathbf{x}_i, \text{trans}(\mathbf{x}_i))$ and $\max_j \cos(\mathbf{W}\mathbf{x}_i, \mathbf{y}_j)$ as a *margin* associated with $\mathbf{x}_i$, *i.e.*,

$$\begin{aligned} M(\mathbf{x}_i) &\triangleq \cos(\mathbf{W}\mathbf{x}_i, \text{trans}(\mathbf{x}_i)) \\ &\quad - \max_j \cos(\mathbf{W}\mathbf{x}_i, \mathbf{y}_j), \;\; \mathbf{y}_j \neq \text{trans}(\mathbf{x}_i). \end{aligned} \tag{2}$$

When $M(\mathbf{x}_i) < 0$, a translation error occurs. Figure 1b plots the (averaged) $M(\mathbf{x})$ values within each frequency bin. We observe that the margin decreases in low frequency regime, leading to the degraded accuracies. Again, when the seeding size increases, the margin can be enlarged, but it also saturates quickly.

2.3 Hubness and Tail of k-occurrence

Hubness is a tendency in high dimensional space that some data points, called hubs, appear to be suspiciously close to many others (Radovanovic et al., 2010). Hubness is detrimental as NN search may retrieve these hubs more often than should be.

A variable to measure the degree of hubness is k-occurrence. k-occurrence, N_k, is defined for any one item in the target space. It is the number of times the item being retrieved as a k-nearest neighbor against a query set $\mathcal{Q}$. Formally,

$$N_k(\mathbf{y}; \mathcal{Q}) = |\{\mathbf{x} \in \mathcal{Q} : \mathbf{y} \in k\text{-NN}(\mathbf{x})\}|.$$

To see the degree of hubness, one makes a histogram of $N_k(\mathbf{y}; \mathcal{Q})$ for all the $\mathbf{y}$'s in the target space. A long tail of the histogram is an indication of strong hubness. The "*tailness*" can be measured by the number of times the N_k values being bigger than a threshold n, formally defined as

$$T_n(N_k) \triangleq |\mathbf{y} : \{N_k(\mathbf{y}; \mathcal{Q}) > n\}|. \tag{3}$$

A bigger $T_n(N_k)$ indicates longer tail of the distribution of N_k, hence more hubness.

---

[1] https://fasttext.cc/docs/en/english-vectors.html

In our MLI case, the ground-truth translation is one-to-one. Therefore if a target word $\mathbf{y}$ has a big value of $N_1(\mathbf{y})$, it is a "hub" that is incorrectly retrieved for at least $N_1(\mathbf{y}_j) - 1$ times. Note that N_k and $T_n(N_k)$ both depend on the query set $\mathcal{Q}$. We vary the $\mathcal{Q}$ from the most frequent to the least words, and plot $T_2(N_1)$ values in figure 1c. For all seeding sizes, hubness becomes more prominent for low-frequency words, implying that some "hubby" target words are being retrieved more often than should be.

Summarizing this section, we have identified two statistics that may explain the inferior accuracy for low-frequency words. Moreover, adding more seeds is not very effective for improving the accuracy.

3 Two Methods

Motivated by the two diagnostics in the last section, we introduce two methods, each individually improving the accuracy in low frequency regime.

3.1 Hinge Loss for Learning Transformation

We first design a learning objective that enlarges the *margin*, as follows,

$$\min_{\mathbf{W}\in\mathcal{O}(d)} \sum_i \sum_{j:\mathbf{y}_j\neq\text{trans}(\mathbf{x}_i^s)} \max\{0, \gamma - \cos(\mathbf{W}\mathbf{x}_i^s, \mathbf{y}_i^s) + \cos(\mathbf{W}\mathbf{x}_i^s, \mathbf{y}_j)\}, \tag{4}$$

where $\gamma > 0$ is a threshold. The objective encourages the margin $\cos(\mathbf{W}\mathbf{x}_i^s, \mathbf{y}_i^s) - \cos(\mathbf{W}\mathbf{x}_i^s, \mathbf{y}_j)$ to be bigger than γ.

It should be noticed that using hinge loss to learn the transformation is not a new idea. Examples are seen not only for BLI (Lazaridou et al., 2015), but also zero-shot image classification (Frome et al., 2013). Our difference with (Lazaridou et al., 2015) is that $\mathcal{W}$ is set to $\mathcal{O}(d)$ instead of $\mathbb{R}^{d\times d}$, as empirically we observe some gain. This is consistent with the discovery in (Xing et al., 2015), although they experiment with the Procrustes loss (Eq. (1)) instead.

We apply the hinge loss to train the orthogonal transformation, using a seeding dictionary of 10K. Accuracy is reported as the green line in figure 2a. A notable gain is observed over the Procrustes loss (blue line), especially in low frequency regime. Figure 2b validates that the margins (for low-frequency words) are indeed enlarged by adopting a hinge loss.

3.2 Hubless Nearest Neighbor (HNN) Search

To motivate, let us first consider a case where the translation is an one-to-one mapping. We should be able to take advantage of this strong prior, so that each target word is retrieved exactly only once. To this end, we introduce an assignment matrix $\mathbf{P} \in [0,1]^{m\times n}$ such that $P_{i,j}$ is the probability of assigning $\mathbf{y}_j$ as a translation of $\mathbf{x}_i$. By this definition,

$$\sum_j P_{i,j} = 1.$$

On the other hand, $\sum_i P_{i,j}$ measures how each $\mathbf{y}_j$ is likely to be retrieved. We want them to be equally preferred, so we constrain $\sum_i P_{i,j}$ to be uniform over all j. In other words,

$$\sum_i P_{i,j} = m/n.$$

Observe that m does not necessarily equal n, so in fact we do not constrain the mapping to be one-to-one. The $\mathbf{P}$ is such that $\sum_{i,j} P_{i,j}\cos(\mathbf{W}\mathbf{x}_i, \mathbf{y}_j)$ is minimized, which can be considered as the "cost" of translation. In summary, we want to solve the following optimization problem,

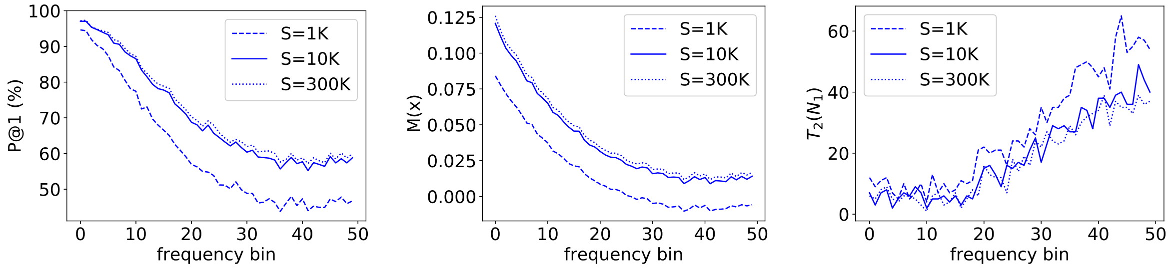
$$\begin{aligned} &\min_{\mathbf{P}\in[0,1]^{m\times n}} \sum_{i,j} P_{i,j}\cos(\mathbf{W}\mathbf{x}_i, \mathbf{y}_j) \\ &s.t. \sum_j P_{i,j} = 1, \sum_i P_{i,j} = m/n \end{aligned}. \tag{5}$$

(5) is a linear assignment problem. It can be solved by Hungarian algorithm (Jonker and Volgenant, 1987) with cubic complexity. Recently, a more efficient solver is rediscovered in (Cuturi, 2013) by regularizing the entropy of $\mathbf{P}$,

$$\begin{aligned} &\min_{\mathbf{P}\in[0,1]^{m\times n}} \sum_{i,j} P_{i,j}\cos(\mathbf{W}\mathbf{x}_i, \mathbf{y}_j) - \epsilon H(\mathbf{P}) \\ &s.t. \sum_j P_{i,j} = 1, \sum_i P_{i,j} = m/n \end{aligned}, \tag{6}$$

where $H(\mathbf{P}) = -\sum_{i,j} P_{i,j}\log P_{i,j}$ is entropy of $\mathbf{P}$. It is known that as $\epsilon \to 0$, the solution of problem (6) converges to that of problem (5).

Now a key challenge in solving (6) is its expensive computational cost, when m and n are huge. One way to circumvent that is by solving a dual problem (Genevay et al., 2016) of (6) instead. Since the math is lengthy and less relevant, we refer interested readers to a sister paper, (Huang et al., 2019), for all details. Our implementation

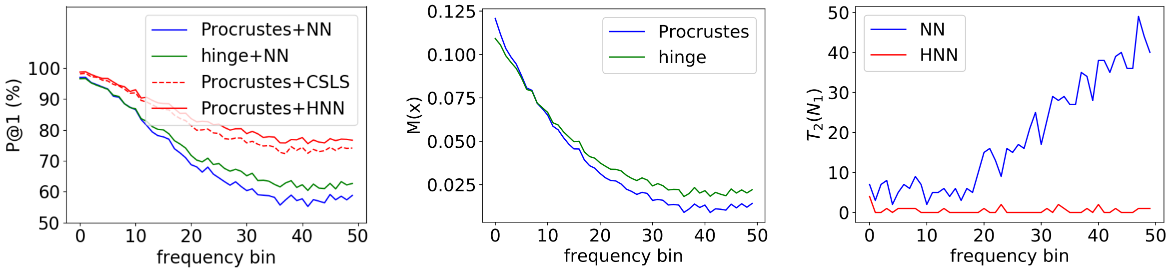


(a) Induction accuracies

(b) margins

(c) tailness of N_1

Figure 1: Applying the Procrustes + NN pipeline for MLI: In each plot, the x-axis are frequency bins of words, from the most (left) to least (right) frequent. All statistics are averaged within each bin. (a) Accuracy is inferior in low-frequency regime. The accuracies saturate though more seeds are used. (b) Margin decays for low-frequency words, resulting in lower accuracy. (c) *Tailness* of N_1 values. Hubness exacerbates in low frequency regime.



(a) Induction accuracies

can be found at github[2]. Once we obtain the $\mathbf{P}$ by solving (6), translation of the $\mathbf{x}_i$ is induced as the $\mathbf{y}_j$ where $j = \arg\max_j P_{i,j}$.

We learn the transformation by solving the Procrustes problem (with 10K seeds) but replace NN with HNN search. The accuracies across all frequency bins are reported as the red line in figure 2a. It significantly outperforms Procrustes + NN, especially in the low-frequency regime. The reduced hubness is validated by the smaller $T_2(N_1)$ values in figure 2c. While HNN is effective, it is not the only method to reduce hubness. For example, CSLS (Conneau et al., 2018) is a recent state-of-art. Fig. 2a also compares our HNN (solid red line) against CSLS (dashed red line) across all frequency bins, and HNN outperforms CSLS for rare words.

3.3 Bilingual Experiments

We experiment with two language pairs, an easier pair (English, French) and a harder pair (En-

---

[2] code at https://github.com/baidu-research/HNN

glish, Finnish). The embeddings and ground-truth dictionaries are downloaded from MUSE repo[3]. We use a vocabulary of size 200K for both source and target languages. Following the same setup as in section 2.1, we create 30 frequency bins and a seeding dictionary of size 10K by uniformly sampling from each bin. The remaining words are used for test. Figure 3 shows accuracy as a function of frequency rank.

In all cases, the proposed two methods both improve upon the baseline (blue curve), and HNN shows more gain over hinge loss. However, compared with MLI (figure 2a), now the improvement seems to be more evenly distributed over all frequencies, especially on the harder language pair.

Moreover, HNN is on-par with or slightly better than CSLS for closer language pair. In contrast, en-fi (fig. 3c) is a case where CSLS works better than HNN notably. We think it is due to a strong morphology in Finnish.

4 Conclusion

Accuracy of bilingual lexicon induction decays for low-frequency words, as indicated by two factors: (1) diminishing *margin* between cosine similarities, and (2) exacerbated *hubness*. Two methods are proposed to address each factor. Experimental results validate their effectiveness.

Abstract

The introduction of VAE provides an efficient framework for the learning of generative models, including generative topic models. However, when the topic model is a Latent Dirichlet Allocation (LDA) model, a central technique of VAE, the reparameterization trick, fails to be applicable. This is because no reparameterization form of Dirichlet distributions is known to date that allows the use of the reparameterization trick. In this work, we propose a new method, which we call Rounded Reparameterization Trick (RRT), to reparameterize Dirichlet distributions for the learning of VAE-LDA models. This method, when applied to a VAE-LDA model, is shown experimentally to outperform the existing neural topic models on several benchmark datasets and on a synthetic dataset.

1 Introduction

Probabilistic generative models are widely used in topic modelling and have achieved great success in many applications (Deerwester et al., 1990)(Hofmann, 1999)(Blei et al., 2003)(Blei and Lafferty, 2006). A landmark of topic models is Latent Dirichlet Allocation (LDA) (Blei et al., 2003), where a document is treated as a bag of words and each word is modelled via a generative process. More specifically, in this generative process, a topic distribution is first drawn from a Dirichlet prior, then a topic is sampled from the topic distribution and a word is drawn subsequently from the word distribution corresponding to the drawn topic. Since its introduction, LDA has shown great power in a large varieties of natural language applications (Wei and Croft, 2006)(AlSumait et al., 2008)(Mehrotra et al., 2013). However, the classical methods of learning LDA, such as variational techniques and collapsed Gibbs sampling, entails high computation complexity in posterior inference(Blei et al., 2003)(Griffiths and Steyvers, 2004), which limits the ability of LDA on modelling large corpus.

Variational AutoEncoder (VAE) or AutoEncoding Variational Bayes (AEVB) (Kingma and Welling, 2013) provides another choice of learning a generative model. Under the VAE framework, a generative model is specified by first drawing a latent vector z from a prior distribution and then transforming this vector through a neural network, called decoder, which subsequently generates the observation x. Using a variational inference approach, VAE couples the decoder network with another network, called encoder, responsible for computing the posterior distribution of the latent variable z for each observation x. A key technique of VAE is its “reparameterization trick”, in which sampling from the posterior is performed by sampling a noise variable ϵ from some distribution $p(\epsilon)$ and then transforming ϵ to z using a differentiable function. This technique allows the model to be trained efficiently using back propagation.

The VAE framework significantly alleviates the computational burden of learning a generative model. Therefore, researchers interested in topic modelling are naturally motivated to consider VAE as an alternative approach to learn LDA, exploiting the power and efficiency of deep learning neural networks. This is also the interest of this paper. However, the key limitation in the application of VAE to Dirichlet-based topic models is that the original reparameterization trick in VAE is not applicable to Dirichlet distributions. In this sense, VAE cannot be directly used for learning any Dirichlet-based topic models. To cope with this, the NVDM model (Miao et al., 2016) discards the Dirichlet assumption and build neural topic models based on Gaussian prior. Although such a Gaussian-based topic model achieves a reasonably good performance on perplexity, the topic words they extracted appear to lack human-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1315–1325,
November 16–20, 2020.

interpretability. Additionally the use of Gaussian prior significantly deviates from the desired Dirichlet distribution and arguably has significant room for improvement.

The adoption of the Dirichlet prior plays a central role in topic modelling, since it nicely captures the intuition that a topic is sampled from a sparse topic distribution. Due to the importance of the Dirichlet assumption in topic modelling, ProdLDA (Srivastava and Sutton, 2017) attempts to apply VAE to LDA by constructing a Laplace approximation to the Dirichlet prior in the softmax basis. However, the Laplace approximation is only used to estimate the prior parameters and ProdLDA has essentially a Gaussian VAE architecture where the KL divergence is on Gaussian distributions. The work of (Joo et al., 2019) argues that the Laplace approximation in ProdLDA fails to capture the multimodality nature of Dirichlet distributions. They then propose DirVAE, in which an approximation of the inverse Gamma CDF (Knowles, 2015) is used to reparameterize Gamma distributions. The Dirichlet samples are then constructed by normalizing Gamma random variables. However, the approximation of inverse Gamma CDF is accurate only when the shape parameter of the Gamma distribution is much less than 1 (Knowles, 2015). This in turn limits the application scope of DirVAE.

In this work, we develop a technique, which we call the Rounded Reparameterization Trick (RRT), to reparameterize Dirichlet distributions. The use of RRT enables VAE as an efficient method for learning LDA, based on which we propose a new neural topic model, referred to as "RRT-VAE".[1] Experiments on several datasets show that RRT-VAE outperforms NVDM, ProdLDA, and DirVAE. The experimental results strongly demonstrate the applicability of RRT in topic modelling that utilizes VAE.

2 Preliminary

2.1 LDA

In this paper, we refer to LDA broadly as a generative model characterized by first drawing a distribution θ over k topics from a Dirichlet prior $\mathrm{Dir}\left(\theta|\hat{\alpha}\right)$ and then through a function f_{dec}, or a *decoder*, transforming θ to a distribution P over a vocabulary of n words. That is,

$$\theta \sim \mathrm{Dir}\left(\theta|\hat{\alpha}\right) \tag{1}$$

$$P := f_{\mathrm{dec}}(\theta;\beta) \tag{2}$$

where β is the parameter of the decoder and will be treated as a $k \times n$ matrix throughout this paper, although other options are also possible. Under this model, the words in a document is regarded as being drawn i.i.d from this distribution P.

In the classical LDA model (Blei et al., 2003), each row of β represents a word distribution, and the decoder can be written as

$$f_{\mathrm{dec}}(\theta;\beta) = \theta^T\beta \tag{3}$$

In the deep learning paradigm, the decoder may be constructed differently, for example,

$$f_{\mathrm{dec}}(\theta) = \theta^T\mathrm{Softmax}\left(\beta\right) \tag{4}$$

$$\text{and} \quad f_{\mathrm{dec}}(\theta) = \mathrm{Softmax}\left(\theta^T\beta\right) \tag{5}$$

where in both cases, the rows of β are unconstrained. Note that (4), presented in (Srivastava and Sutton, 2017) is merely a different parameterization of (3) and will be referred to as the "standard decoder" in this paper. The structure in (5), referred to as "product of experts" in (Srivastava and Sutton, 2017), will be called "prod decoder" for simplicity.

2.2 VAE-LDA

The difficulty in learning an LDA model lies in the exact inference of θ. In the classical LDA, exact inference is replaced by approximation methods using a symbolist variational method (Blei et al., 2003) or MCMC (Griffiths and Steyvers, 2004). In the deep learning era, the development of Variational AutoEncoder (Kingma and Welling, 2013), a connectionist counterpart of the symbolist variational methods, provides an alternative approach to handle this difficulty.

When applying VAE to an LDA model, the model is augmented with an *encoder* network f_{enc}. Specifically, the encoder takes as the input the bag-of-words (i.e., word histogram) representation x of a document and outputs a k-dimensional parameter α, and then the Dirichlet distribution with parameter α is taken as the posterior distribution $q(\cdot|\alpha)$ of θ:

$$\alpha := f_{\mathrm{enc}}(x;\Pi) \tag{6}$$

$$q(\cdot|\alpha) := \mathrm{Dir}(\cdot|\alpha) \tag{7}$$

---

[1] Code will be available at `https://github.com/rzTian/RRT-VAE/tree/main`

where Π denotes the parameters of the encoder.

Under the VAE framework, the parameters of the encoder and the decoder are jointly optimized by minimizing the negative Evidence Lower Bound (ELBO):

$$\mathcal{L}(\Pi, \beta; x) = \mathrm{KL}\left(q(\theta|\alpha)||p(\theta|\hat{\alpha})\right) - \mathbb{E}_{q(\theta|\alpha)}\left[J(\theta, x)\right] \tag{8}$$

where $p(\theta|\hat{\alpha}) := \mathrm{Dir}(\theta|\hat{\alpha})$, the Dirichlet prior; and

$$J(\theta, x) := x^{\mathrm{T}} \log f_{\mathrm{dec}}(\theta) \tag{9}$$

We refer to the model specified by the loss function (8) as VAE-LDA.

Note that the KL term in (8) has a closed-form expression

$$\begin{aligned} &\mathrm{KL}(q(\theta|\alpha)||p(\theta|\hat{\alpha})) = \log\Gamma\left(\sum \alpha_i\right) \\ &- \sum \log\Gamma(\alpha_i) - \log\Gamma\left(\sum \hat{\alpha}_i\right) + \sum \log\Gamma(\hat{\alpha}_i) \\ &+ \sum (\alpha_i - \hat{\alpha}_i)\left(\psi(\alpha_i) - \psi\left(\sum \alpha_i\right)\right) \end{aligned}$$

The gradient of this term can be obtained directly. The optimization of the second term in (8) is however challenging, since it has no closed-form expression. Additionally, when using a stochastic approximation, one must deal with back-propagating gradient signals through a sampling process.

One way to deal with this is to use a score function estimator (Williams, 1992)(Glynn, 1990). But such an approach is known to give rise to high variances in the gradient estimation, due to which a reliable estimate would require drawing a large number of θ from the posterior $q(\cdot|\alpha)$ and make learning inefficient. In the framework of VAE, a "reparameterization trick" is introduced as an elegant solution to such a problem, where the posterior is reparameterized as drawing a noise from another distribution and re-expressing the posterior as a differentiable function of the noise. However when the posterior distribution is a Dirichlet distribution (or a related distribution such as Beta and Gamma distributions), no such noise distribution and continuous functions are known to exist. Thus the standard reparameterization trick does not apply to learning VAE-LDA.

3 Rounded Reparameterization Trick

To tackle the limitation of the standard reparameterization trick, we propose a new reparameterization method, referred to as *rounded reparameterization trick* or RRT.

Given a real number Δ, we define a "Δ-rounding" function $\lfloor\cdot\rfloor_\Delta$ as follows: For any real number a,

$$\lfloor a \rfloor_\Delta = \left\lfloor \frac{a}{\Delta} \right\rfloor \cdot \Delta \tag{10}$$

where the operation $\lfloor\cdot\rfloor$ is the integer floor (or "rounding down") operation. For example, $\lfloor 3.14159265 \rfloor_{\Delta=0.001} = 3.141$. When the Δ-rounding operation applies to a vector, it acts on the vector component-wise.

In RRT, we draw an auxiliary variable $\hat{\theta}$ from a "rounded" posterior distribution $q\left(\hat{\theta}|\lfloor\alpha\rfloor_\Delta\right)$,

$$\hat{\theta} \sim q\left(\hat{\theta}|\lfloor\alpha\rfloor_\Delta\right) \tag{11}$$

and compute

$$\widetilde{\theta} = g(\hat{\theta}; \alpha) := \hat{\theta} + \lambda\left(\alpha - \lfloor\alpha\rfloor_\Delta\right) \tag{12}$$

Then $\widetilde{\theta}$ is used to approximate $\theta \sim q(\theta|\alpha)$. In (12), the parameter λ is a hyper parameter which will serve to adjust the strength of the gradient. Note that when choosing a very small rounding precision Δ, we expect that the distribution $\widetilde{q}(\cdot|\alpha)$ of $\widetilde{\theta}$ and the distribution $q(\cdot|\alpha)$ are nearly identical. As a consequence, $\mathbb{E}_{q(\theta|\alpha)}[J(\theta, x)]$ and its replacement $\mathbb{E}_{\widetilde{q}(\theta|\alpha)}[J(\theta, x)]$ are also very close to each other. Thus such a replacement keeps the loss function very close to the original loss in (8).

For shorter notations, we denote

$$\begin{aligned} A(\alpha) &:= \mathbb{E}_{q(\theta|\alpha)}[J(\theta, x)] \qquad (13) \\ \widetilde{A}(\alpha) &:= \mathbb{E}_{\widetilde{q}(\theta|\alpha)}[J(\theta, x)] \qquad (14) \end{aligned}$$

and

$$\widetilde{\mathcal{L}}(\Pi, \beta; x) := \mathrm{KL}\left(q(\theta|\alpha)||p(\theta|\hat{\alpha})\right) - \widetilde{A}(\alpha) \tag{15}$$

Constructing gradient estimator using RRT

The gradient $\nabla_\alpha \widetilde{A}(\alpha)$ can be expressed as a sum of two terms:

$$\begin{aligned} \nabla_\alpha \widetilde{A}(\alpha) =& \nabla_\alpha \mathbb{E}_{q(\hat{\theta}|\lfloor\alpha\rfloor_\Delta)}\left[J\left(g(\hat{\theta}, \alpha), x\right)\right] \\ =& \nabla_\alpha \int q\left(\hat{\theta}|\lfloor\alpha\rfloor_\Delta\right) J\left(g(\hat{\theta}; \alpha), x\right) d\hat{\theta} \\ =& \int \nabla_\alpha q\left(\hat{\theta}|\lfloor\alpha\rfloor_\Delta\right) J\left(g(\hat{\theta}; \alpha), x\right) d\hat{\theta} \\ &+ \int q\left(\hat{\theta}|\lfloor\alpha\rfloor_\Delta\right) \nabla_\alpha J\left(g(\hat{\theta}; \alpha), x\right) d\hat{\theta} \end{aligned}$$

The first term in sum is usually estimated through the score function estimator. But this is unnecessary in this case. To see this, note that $\nabla_\alpha \lfloor\alpha\rfloor_\Delta =$

0 *almost everywhere*. This implies that the first term is in fact 0 at every α for which the gradient exists. The next lemma then immediately follows.

Lemma 1 *For any* α *at which the gradient* $\nabla_\alpha \widetilde{A}(\alpha)$ *exists,*

$$\nabla_\alpha \widetilde{A}(\alpha) = \lambda \mathbb{E}_{q(\hat{\theta}|\lfloor\alpha\rfloor_\Delta)} \left[\nabla_\theta J(\theta, x)|_{\theta=g(\hat{\theta};\alpha)} \right]$$

The fact that the score function estimator is not needed for estimating the gradient $\nabla_\alpha \widetilde{A}(\alpha)$ allows RRT to enjoy a low variance and hence requires very few samples in Monte-Carlo estimation.

Using Lemma 1, one can directly express the stochastic (Monte Carlo) estimate of the gradient $\nabla_\alpha \widetilde{A}(\alpha)$ as

$$\nabla_\alpha \widetilde{A}(\alpha) \approx \frac{\lambda}{N} \sum_{i=1}^{N} \nabla_\theta J(\theta, x)|_{\theta=g(\hat{\theta}_i;\alpha)} \tag{16}$$

where $\hat{\theta} \sim q\left(\hat{\theta}|\lfloor\alpha\rfloor_\Delta\right)$. The fact that g is differentiable *almost everywhere* with respect to α allows the gradient signal to back propagate and can be implemented using automatic differentiation libraries.

Due to the low variance in this estimator, it is sufficient to sample only a single $\hat{\theta}$ from $q\left(\hat{\theta}|\lfloor\alpha\rfloor_\Delta\right)$, namely, take $N = 1$ in (16).

At this end, we conclude that the loss function $\widetilde{\mathcal{L}}$ obtained by replacing θ with $\widetilde{\theta}$ is very close to the original loss function $\mathcal{L}$, and a low-variance gradient estimator can be easily constructed from $\widetilde{\mathcal{L}}$. This completes the description of RRT.

On the discontinuities induced by RRT

Notably the Δ-rounding function in RRT induces discontinuities in the resulting loss function $\widetilde{\mathcal{L}}$. This is because $\widetilde{A}(\alpha)$ is discontinuous in α and countably many discontinuity points exist. One may be concerned with whether an update of α may "hop over" a discontinuity point of $\widetilde{A}(\alpha)$ and cause training unstable or diverge.

To that end, we have the following result.

Lemma 2 *Suppose that* J *is* ζ*-lipschitz in* θ *and* $A(\alpha)$ *is* γ*-lipschitz in* α*. Then for any integer* m*,*

$$\left|\widetilde{A}(m\Delta) - \widetilde{A}(m\Delta - \epsilon)\right| < (\gamma + \zeta\lambda)\Delta$$

when $\epsilon \to \Delta$.

We note that when $\epsilon \to \Delta$, the quantity $\left|\widetilde{A}(m\Delta) - \widetilde{A}(m\Delta - \epsilon)\right|$ measures the magnitude of a sudden rise or drop when an update hops over the discontinuity point $\alpha = m\Delta$. When this magnitude is small, the discontinuity causes little impact on the stability of training. The upper bound of this quantity given by this lemma suggests that as long as $J(\theta)$ and the objective function $A(\alpha)$ are reasonably smooth, one may control this magnitude to be small by choosing a relatively small Δ. On the other hand, in case one indeed chooses a relatively large Δ, the bound of this magnitude may become quite large. However in this case, the update will have much smaller chance of hopping over a discontinuity point, and one still expects no serious problem caused by these discontinuities.

We now present the proof.

Proof: Clearly, $\widetilde{A}(m\Delta) = A(m\Delta)$. And

$$\begin{aligned} &\widetilde{A}(m\Delta - \epsilon) \\ =&\mathbb{E}_{q(\theta|(m-1)\Delta)} J(\theta + \lambda(\Delta - \epsilon)) \\ \approx&\mathbb{E}_{q(\theta|(m-1)\Delta)} \left\{ J(\theta) + \lambda(\Delta - \epsilon) J'(\theta) \right\} \\ =&A((m-1)\Delta) + \lambda(\Delta - \epsilon) \cdot \mathbb{E}_{q(\theta|(m-1)\Delta)} J'(\theta) \end{aligned}$$

Since J is ζ-lipschitz,

$$\begin{aligned} &A((m-1)\Delta) - \zeta\lambda(\Delta - \epsilon) \\ &< \widetilde{A}(m\Delta - \epsilon) < A((m-1)\Delta) + \zeta\lambda(\Delta - \epsilon) \end{aligned}$$

It follows

$$\begin{aligned} &A(m\Delta) - A((m-1)\Delta) + \zeta\lambda(\Delta - \epsilon) \\ &> \widetilde{A}(m\Delta) - \widetilde{A}(m\Delta - \epsilon) \\ &> A(m\Delta) - A((m-1)\Delta) - \zeta\lambda(\Delta - \epsilon) \end{aligned}$$

Since $A(\cdot)$ is γ-lipschitz, then

$$\begin{aligned} &\gamma\Delta + \zeta\lambda(\Delta - \epsilon) \\ &> \widetilde{A}(m\Delta) - \widetilde{A}(m\Delta - \epsilon) > -\gamma\Delta - \zeta\lambda(\Delta - \epsilon) \end{aligned}$$

It follows

$$\left|\widetilde{A}(m\Delta) - \widetilde{A}(m\Delta - \epsilon)\right| < (\gamma + \zeta\lambda)\Delta$$

This proves the lemma. □

It is clear that when Δ is small, the discontinuity is not obvious and has small impact on the optimization of the model.

4 Related Work

Beyond topic modelling, another theme of research related to this work is the estimation of gradient in neural networks containing stochastic nodes or samplers. In this setting, one desires that the gradient signal is capable of back-propagating through the samplers. A classical method for this purpose is to construct a score function estimator, also known as the "log derivative trick" or REINFORCE (Williams, 1992)(Glynn, 1990). However, despite giving an unbiased estimate, the Monte-Carlo implementation of such an estimator typically suffers from a high variance, and thus relies on some additional variance-reduction techniques (Greensmith et al., 2004). Reparameterization trick(Kingma and Welling, 2013), as mentioned above, may also be used to back-propagate gradients through samples and enjoys a low-variance advantage. Unfortunately this technique is not applicable to many distributions such as Gamma, Beta and Dirichlet distributions. Various efforts have been spent on extending the applicability of reparameterization trick to a broader range. These works include, for example, G-REP (Ruiz et al., 2016), RSVI (Naesseth et al., 2016) and Implicit Reparameterization Gradients (Figurnov et al., 2018), etc. These methods usually involve complicated gradient derivations and are often difficult to implement in neural networks.

5 Experiments and Results

To quantitatively evaluate RRT-VAE, we conduct experiments on synthetic datasets and five real-world datasets. Our model is compared with several existing topic models: Online LDA (Hoffman et al., 2010), NVDM (Miao et al., 2016), ProdLDA (Srivastava and Sutton, 2017) and DirVAE (Joo et al., 2019).

In the experiments, we adopt three MLPs with ReLU activations as the encoder of RRT-VAE, where each hidden layer is set to 500 dimensions. We apply an exponential function on the outputs of the encoder, so that the outputs are positive values. The topic distribution vectors are sampled through RRT and then normalized before being passed to the decoder. For Online LDA, we use the standard implementation from scikit-learn (Pedregosa et al., 2011). The encoder structures of NVDM, ProdLDA and DirVAE are built according to (Miao et al., 2016), (Srivastava and Sutton, 2017) and (Joo et al., 2019), where in our experiments the dimension of each hidden layer is set to 500.

On the real-world datasets, we adopt the prod decoder, since the standard decoder appears to extract many repetitive topic words (see Appendix B.1).[2] On the synthetic datasets, we adopt the standard decoder, which is examined to be superior to the prod decoder on this learning task (see Appendix A.1).

5.1 Datasets

Synthetic datasets. We construct three synthetic datasets based on the LDA generative process: a 30×500 topic-word probability matrix β_g is generated as the ground truth; each dataset is then generated based on β_g using different Dirichlet priors $\alpha_g \cdot \mathbf{1} \in \mathbb{R}^{30}$, where $\mathbf{1}$ denotes the all-one vector. We set α_g to [0.01, 0.05, 0.1] for the three datasets and the vocabulary size to 500. Each dataset has 20000 training examples.

Real-world datasets. We use five real-world datasets in our experiments: 20NG, RCV1-v2, [3] AGNews[4], DBPeida (Lehmann et al., 2015), and Yelp review polarity (Zhang et al., 2015).

The 20NG and RCV1-v2 datasets are the same as (Miao et al., 2016). The other three datasets are preprocessed through tokenizing, stemming, lemmatizing and the removal of stop words. We keep the most frequent 2000 words in DBPedia and Yelp. For AGNews, we keep the words which are contained in no more than half the documents and are contained in at least 15 documents. The statistics of the cleaned datasets are summarized in Table 1.

	20NG	AGNews	RCV1-v2	DBpedia	Yelp
#Train	11258	120000	794414	560000	560000
#Test	7487	7600	10000	70000	38000
#Vocab	1995	10630	10000	20000	20000

Table 1: Summary of different datasets

5.2 Evaluation Methods

On the real-world datasets, we use perplexity and normalized pointwise mutual information (NPMI) (Lau et al., 2014) as the evaluation metrics. On synthetic datasets, we propose *topic words recovery accuracy* (or "recovery accuracy" in short) to evaluate the model performance.

Specifically, we extract the top-10 highest-probability word indexes from each row of β_g. The

---

[2] As reported in (Srivastava and Sutton, 2017), ProdLDA also appears to extract many repetitive words when using the standard decoder.

[3] For 20NG and RCV1-v2, we use the datasets provided by https://github.com/ysmiao/nvdm

[4] http://groups.di.unipi.it/ gulli/AG_corpus_of_news_articles.html

extracted word indexes constitute a 30×10 topic-word matrix T_g. Our goal is to use the topic models to recover this matrix. Denote by T_L, a matrix extracted from the learned β matrix of a model. Note that the rows of T_L are arbitrarily ordered. To count how many words in the ith row $t_g^{(i)}$ of T_g is recovered in a topic in T_L, we compare $t_g^{(i)}$ with each row in T_L. We count the number of common words in the compared two rows and keep the maximum count as the number of recovered words in $t_g^{(i)}$. The recovery accuracy is then defined as the total number of recovered words in all rows of T_L divided by the total number of words.

We note that after a row of T_g is compared with T_L as the target of coverage, the found best-matching row in T_L is not removed. This approach is better than the alternative approach of greedily removing the best-matching row, since the latter would give an accuracy result that depends on the row ordering in T_g. Additionally we note that the data generation process assures that the rows of T_g each contain 10 distinct words. For this reason, keeping the found best-matching row in T_L in each step entails no problem.

5.3 Influence of Parameter Settings

In this section, we run RRT-VAE on 20NG and the synthetic datasets to explore its performance under different parameter settings.

5.3.1 Results on 20NG

Prior settings. Prior settings are claimed to have a significant influence on model performance (Wallach et al., 2009). In this experiment, we run RRT-VAE on the 20NG dataset using four symmetric Dirichlet prior settings [0.02,0.2,1.0,2.0]. The number of topics is set to 50 and λ is set to 0.01 in all experiments. We use $\Delta = 10^{-10}$ as the rounding precision such that accurate Dirichlet samples can be drawn.

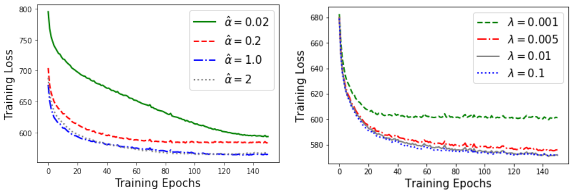

Figure 1: Training performance of RRT-VAE with different prior (left) and λ settings (right).

Prior Settings	0.02	0.2	1.0	2.0
Perplexity	1415	1130	951	875
NPMI	0.275	0.254	0.243	0.259
Sparsity	0.5353	0.1954	0.0868	0.0655

Table 2: Evaluation results on RRT-VAE with different prior settings. Perplexity: lower is better; NPMI: higher is better; Sparsity: higher means sparser.

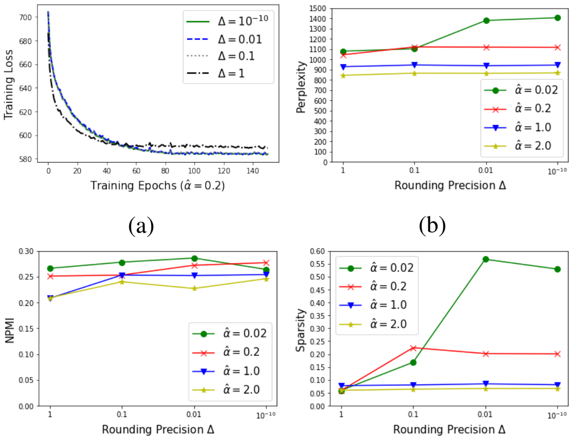
λ Settings	0.1	0.01	0.005	0.001
Perplexity	1004	951	978	1127
NPMI	0.221	0.243	0.271	0.160

Table 3: Evaluation results of RRT-VAE with different λ settings.

As shown in Figure 1 (left), when using a larger prior parameter (1 or larger), the training loss drops more rapidly and converges to a lower value. Table 2 reports the corresponding testing results. We found that when using a smaller prior setting, RRT-VAE tends to achieve a better topic coherence (NPMI) while sacrificing some performance on perplexity. One possible explanation of these phenomena is that a smaller prior setting (lower than 1) encourages the encoder network to sample a sparser topic distribution θ. The sparsity of θ in turn makes it easier for the model to assign a very small probability on some existing words in a document and thus increases the training loss and perplexity.

To verify this conjecture, we construct a simple method to measure sparsity: after the training, we randomly feed 1000 training samples into the encoder network and obtain 1000 topic distribution vectors $\{\theta_i\}_{i=1}^{1000}$. For each θ_i, we calculate the difference between its largest and smallest probability value and then average these differences over the 1000 samples. Clearly, a larger difference value indicates a sparser θ, e.g. the maximum difference 1 is achieved by a one-hot vector. From the sparsity measurements in Table 2, we see that a smaller prior setting causes the encoder to generate sparser topic distribution vectors, which in turn hinders the convergence of the training loss to a lower value and hence causes a higher perplexity. On the other hand, sparser topic distributions tend to improve NPMI, although this improvement is slight.

λ settings. The "gradient control" parameter λ in RRT adjusts the strength of the gradient signal back-propagated to the encoder while also influencing the variance of the Monte Carlo gradient estimator. Figure 1 (right) and Table 3 report the influence of different λ settings on the model performance, where the number of topics is set to 50 and the prior is set to 1. As shown, when λ is set too small (e.g. $\lambda = 0.001$), the training loss fails to converge to a lower value, resulting in a higher perplexity and worse NPMI. The best performance is achieved when λ is set between around 0.01 and 0.005. Different λ settings can bring similar training performances but different testing results. For example, when λ is set to 0.1 and 0.01, the corresponding training performances are very similar (see Figure 1 (right), blue and grey dash line), however, $\lambda = 0.01$ achieves a better perplexity and NPMI result.



(a) (b)

(c) (d)

Figure 2: (a) Training performance of RRT-VAE with different Δ settings; (b)-(d) perplexity, NPMI and sparsity of RRT-VAE with different Δ and prior $\hat{\alpha}$ settings. In these experiments, λ is set to 0.01, the number of topics is set to 50.

Influence of the rounding precision Δ. A main concern of RRT is that the induced discontinuities may cause training to be unstable. As proved in Section 3, this discontinuity actually causes little impact on the stability of training. We substantiate this conclusion in Figure 2 (a) by plotting the training loss curves of RRT-VAE under different Δ settings. As shown, all the training losses converge stably when using different Δ. This demonstrates that the precision of the rounding operation has little impact on the training stability. The influences of Δ on perplexity and NPMI are also modest. As shown in Figure 2 (b) and (c), the resulting perplexities and NPMIs are in general insensitive to the Δ settings.

From Figure 2 (b) and (d), it can also be observed that the perplexity of RRT-VAE has correlation with the sparsity. When Δ changes from 1 to 10^{-10}, the sparsity value of $\hat{\alpha} = 0.02$ (green line in Figure 2 (d)) jumps from 0.059 to around 0.55.[5] The corresponding perplexity value (green line in Figure 2 (b)) also increases from 1078 to around 1400. In contrast, the sparsity levels of $\hat{\alpha} = 1.0$ and $\hat{\alpha} = 2.0$ remain unchanged. Their corresponding perplexities also stay at the same levels.

5.3.2 Results on Synthetic datasets

Our experiments on the synthetic datasets again demonstrate that the rounding precision has little impact on the training stability. Figure 3 (left) exhibits how different Δ settings influence the training performance of RRT-VAE when $\alpha_g = 0.01$ (the results of $\alpha_g = 0.05$ and 0.1 are shown in Appendix A.2). As shown, all the training losses decrease stably, although a higher Δ setting hinders the loss converging to a lower value. Figure 3 (right) reports how different Δ settings influence the recovery accuracy of RRT-VAE on three synthetic datasets. It can be seen that a smaller Δ achieves a better performance. Specifically, when $\Delta = 1$, the training loss remains at a high value and the corresponding recovery accuracy is lower than 60%, indicating that RRT-VAE fails to fit the true data distribution. In contrast, when $\Delta = 10^{-10}$, RRT-VAE fits the data well: the training loss drops rapidly and converges to a much lower value; the resulting recovery accuracy reaches up to 90%.

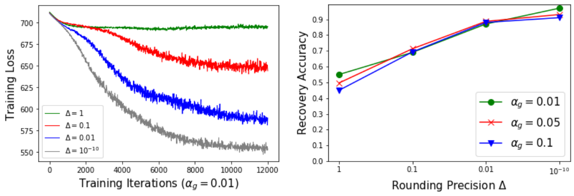


Figure 3: Training performances (left) and recovery accuracy (right) of RRT-VAE on a synthetic dataset ($\alpha_g = 0.01$) with different Δ settings.

Recall that on 20NG, both the training and testing performances are insensitive to the rounding precision. In contrast, on synthetic datasets, the rounding precision has a significant influence. This phenomenon is reasonable, since the synthetic data strictly satisfies the LDA generative process. A

---

[5] Since the sparsity we define is computed from the randomly sampled θ, it is inherently stochastic due to randomness in θ. Thus a small fluctuation of the computed sparsity value needs not to indicate a true difference of sparsity levels. For example, on the green line of Figure 2 (d), the sparsity values of $\Delta = 0.01$ and $\Delta = 10^{-10}$ are different, but the difference is not large enough to suggest that the two models have different sparsity levels; such a difference is primarily due to stochastic irregularity in our sparsity computation.

higher Δ setting causes the rounded distribution deviate the Dirichlet posterior, thereby interfering with the fitting of the data. On the other hand, the underlying distribution of the real-world data does not strictly conform to the LDA assumption. This deviation, therefore, has little impact on fitting the data.

5.4 Comparison with Other Models

In this section, we compare RRT-VAE with other existing topic models on both real-world datasets and synthetic datasets.

Real-world datasets

On real-world datasets, we do not compare Online LDA, since the training of Online LDA on large datasets is extremely time consuming and Online LDA fails to obtain any good results after being trained for a long time (results of Online LDA on 20NG are shown in Appendix B.2). For ProdLDA, DirVAE and RRT-VAE, we tune the prior parameter from [0.02,0.2,1.0]. The best λ settings of RRT-VAE for each dataset are shown in Table 4. All the compared models adopt the same prod decoder of (5) on the real-world datasets.

	20NG	AGNews	RCV1-v2	DBPedia	Yelp
50 topics	0.01	0.008	0.002	0.005	0.005
200 topics	0.005	0.005	0.002	0.003	0.003

Table 7: Topic words extracted from the Yelp dataset. From top to bottom, each cell is extracted by NVDM, ProdLDA, DirVAE and RRT-VAE. More examples are exhibited in Appendix B.3.

The experimental results are shown in Table 5 and 6. It can be seen that on the small and medium size datasets (20NG and AGNews), the performance of DirVAE levels with RRT-VAE, while on the large datasets (RCV1-v2, DBpedia and Yelp), the NPMI of RRT-VAE is significantly better than all the other compared models. Although the perplexity of NVDM is better than RRT-VAE, this gap is small. On the other hand, on NPMI, RRT-VAE outperforms NVDM by a very large margin. In fact, it has been demonstrated that perplexity is not necessarily a good metric for evaluating the quality of learned topics (Newman et al., 2010). Its correlation to the quality of the learned topics is questionable [6] (Chang et al., 2009). With these considerations, we argue that RRT-VAE is overall superior to other compared models.

Table 7 exhibits the extracted topic words of different models, where each line of the words corresponds to a certain topic. We see that the words extracted by RRT-VAE (the bottom cell of Table 7) are much more interpretable, from which it can

---

[6] In general, perplexity measures the goodness-of-fit of data to a learned model under the maximum likelihood principle. This makes it a valid metric for evaluation when the learning objective (as in the considered models) aims at maximizing the data likelihood. On the other hand, we note that traditionally in all VAE-LDA models (e.g., those compared in this paper) and also in this paper, perplexity is in fact approximately computed using the evidence lower bound (ELBO) of the data likelihood, since exact computation of the data likelihood is usually intractable. But the perplexity computed this way aggregates the overall effects of both the learned decoder (i.e., the β matrix) and the learned encoder. Therefore it does not provide a direct evaluation of the learned word distributions in the β matrix. This problem is overcome by the additional NPMI measure, which is computed directly from the β matrix and serves as a more indicative quality measurement of the learned topics.

be easily inferred that the corresponding topics are "trade", "Japanese food", "medical" and "fitness". But it is not the case for the other models.

Synthetic datasets

We compare RRT-VAE with Online LDA, ProdLDA and DirVAE on three synthetic datasets which are generated by different Dirichlet parameters. The compared three neural topic models adopt the same standard decoder of (4). Since NVDM is a pure Gaussian VAE model without any approximation of Dirichlet distributions, it is not compared in this experiment. Table 8 reports the recovery accuracy of the compared models. The experimental results strongly demonstrate the ability of RRT-VAE as an inference method to learn LDA. Specifically, RRT-VAE levels with Online LDA on recovery accuracy, while it enjoys a much higher computational efficiency. Among three neural topic models, RRT-VAE clearly outperforms the others. Appendix A.3 shows an example of the ground truth matrix T_g and the matrix recovered by RRT-VAE.

	Online LDA	ProdLDA	DirVAE	RRT-VAE
α_g=0.01	87.33%	84.0%	91.33%	**96.67%**
α_g=0.05	91.33%	83.0%	84.67%	**93.0%**
α_g=0.1	90.0%	55.67%	83.67%	**91.0%**

Table 8: Recovery accuracy of four topic models on synthetic datasets generated by three different α_g settings. For RRT-VAE, λ is set to 1; Δ is set to 10^{-10}.

6 Concluding Remarks

In this paper, rounded reparameterization trick, or RRT, is shown as an effective and efficient reparameterization method for Dirichlet distributions in the context of learning VAE based LDA models. In fact, the applicability of RRT can be generalized beyond Dirichlet distributions. This is because any distribution can be reparameterized to an "RRT form" as long as a sampling algorithm exists for that distribution. Thus it will be interesting to investigate the performance of RRT in other applications of VAE beyond topic modelling. Successes in these investigations will certainly extend the applicability of VAE to much broader application domains and model families.

A Additional Results on Synthetic Datasets

A.1 Topic recovery accuracy using prod decoder

	ProdLDA	DirVAE	RRT-VAE
α_g=0.01	50.33%	59.33%	61.33%
α_g=0.05	48.33%	64.67%	59.67%
α_g=0.1	43.0%	64.66%	62.33%

Table 9: Topic words recovery accuracy of three neural topic models on synthetic datasets generated with three different α_g settings. The models adopt the same prod decoder structure. For RRT-VAE, λ is set to 1; Δ is set to 10^{-10}.

Table 9 reports the topic recovery accuracy of three neural topic models using the prod decoder. Compared to Table 8, it can be seen that the standard decoder significantly outperforms the prod decoder on the synthetic datasets.

A.2 Training performance

Figure 4 plots the training loss curves of RRT-VAE with different Δ settings on two synthetic datasets ($\alpha = 0.05$ and $\alpha = 0.1$). The curves perform similarly to Figure 3 (left).

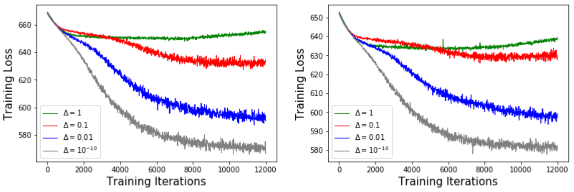

Figure 4: Training performances of RRT-VAE with different Δ settings. Left: $\alpha_g = 0.05$; right: $\alpha_g = 0.1$.

A.3 Recovered topic words

Table 10 exhibits an example of the ground truth topic word matrix T_g used in our experiments and the corresponding recovered matrix T_L learned by RRT-VAE. Note that the rows of T_L are arbitrarily ordered. The matching relation between T_L and T_g can be found using the evaluation method introduced in Section 5.2.

Calibrated Language Model Fine-Tuning for In- and Out-of-Distribution Data

Lingkai Kong, Haoming Jiang, Yuchen Zhuang, Jie Lyu, Tuo Zhao, Chao Zhang
Georgia Institute of Technology, Atlanta, USA
`{lkkong,jianghm,yczhuang,jie.lyu,tourzhao,chaozhang}@gatech.edu`

Abstract

Fine-tuned pre-trained language models can suffer from severe miscalibration for both in-distribution and out-of-distribution (OOD) data due to over-parameterization. To mitigate this issue, we propose a regularized fine-tuning method. Our method introduces two types of regularization for better calibration: (1) *On-manifold regularization*, which generates pseudo on-manifold samples through interpolation within the data manifold. Augmented training with these pseudo samples imposes a smoothness regularization to improve in-distribution calibration. (2) *Off-manifold regularization*, which encourages the model to output uniform distributions for pseudo off-manifold samples to address the over-confidence issue for OOD data. Our experiments demonstrate that the proposed method outperforms existing calibration methods for text classification in terms of expectation calibration error, misclassification detection, and OOD detection on six datasets. Our code can be found at `https://github.com/Lingkai-Kong/Calibrated-BERT-Fine-Tuning`.

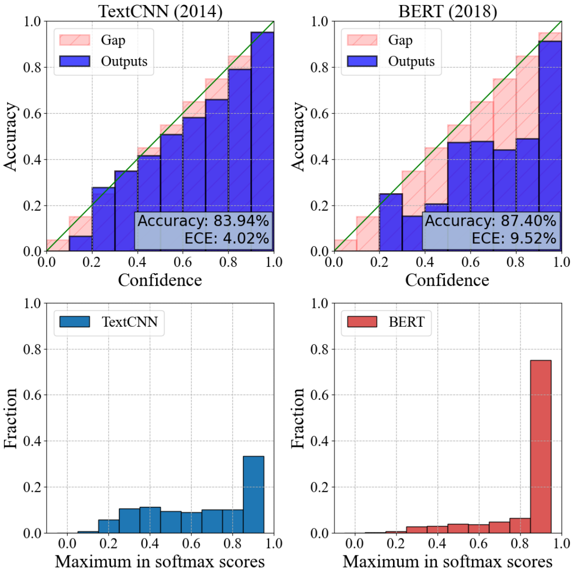

Figure 1: The reliability diagrams on in-distribution data (the first row) and the histograms of the model confidence on out-of-distribution (OOD) data (the second row) of CNN (Kim, 2014) and fine-tuned BERT-MLP classifier (Devlin et al., 2019). Though BERT improves classification accuracy, it makes over-confident predictions for both in-distribution and OOD data.

1 Introduction

Pre-trained language models have recently brought the natural language processing (NLP) community into the transfer learning era. The transfer learning framework consists of two stages, where we first pre-train a large-scale language model, (*e.g.*, BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020) and T5 (Raffel et al., 2019)) on a large text corpus and then fine-tune it on downstream tasks. Such a fine-tuning approach has achieved SOTA performance in many NLP benchmarks (Wang et al., 2018, 2019).

Many applications, however, require trustworthy predictions that need to be not only accurate but also well *calibrated*. In particular, a well-calibrated model should produce reliable confident estimates for both in-distribution and out-of-distribution (OOD) data: (1) For in-distribution data, a model should produce predictive probabilities close to the true likelihood for each class, *i.e.*, confidence $\approx$ true likelihood. (2) For OOD data, which do not belong to any class of the training data, the model output should produce high uncertainty to say 'I don't know', *i.e.*, confidence $\approx$ random guess, instead of producing absurdly wrong yet wildly confident predictions. Providing such calibrated output probabilities can help us to achieve better model robustness (Lee et al., 2018), model fairness (Chouldechova, 2017) and improve label efficiency via uncertainty driven learning (Gal et al., 2017; Siddhant and Lipton, 2018; Shen et al., 2018).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1326–1340,
November 16–20, 2020. ©2020 Association for Computational Linguistics

Unfortunately, Guo et al. (2017) have shown that due to over-parameterization, deep convolutional neural networks are often miscalibrated. Our experimental investigation further corroborates that fine-tuned language models can suffer from miscalibration even more for NLP tasks. As shown in Figure 1, we present the calibration of a BERT-MLP model for a text classification task on the 20NG dataset. Specifically, we train a TextCNN (Kim, 2014) and a BERT-MLP using $20NG_{15}$ (the first 15 categories of 20NG) and then evaluate them on both in-distribution and OOD data. The first row plots their reliability diagrams (Niculescu-Mizil and Caruana, 2005) on the test set of $20NG_{15}$. Though BERT improves the classification accuracy from 83.9% to 87.4%, it also increases the expected calibration error (ECE, see more details in Section 2) from 4.0% to 9.5%. This indicates that BERT-MLP is much more miscalibrated for in-distribution data. The second row plots the histograms of the model confidence, *i.e.*, the maximum output probability, on the test set of $20NG_5$ (the unseen 5 categories of 20NG). While it is desirable to produce low probabilities for these unseen classes, BERT-MLP produces wrong yet over-confident predictions for such OOD data.

Such an aggravation of miscalibration is due to the even more significant over-parameterization of these language models. At the pre-training stage, they are trained on a huge amount of unlabeled data in an unsupervised manner, *e.g.*, T5 is pre-trained on 745 GB text. To capture rich semantic and syntactic information from such a large corpus, the language models are designed to have enormous capacity, *e.g.*, T5 has about 11 billion parameters. At the fine-tuning stage, however, only limited labeled data are available in the downstream tasks. With the extremely high capacity, these models can easily overfit training data likelihood and be over-confident in their predictions.

To fight against miscalibration, a natural option is to apply a calibration method such as temperature scaling (Guo et al., 2017) in a post-processing step. However, temperature scaling only learns a single parameter to rescale all the logits, which is not flexible and insufficient. Moreover, it cannot improve out-of-distribution calibration. A second option is to mitigate miscalibration during training using regularization. For example, Pereyra et al. (2017) propose an entropy regularizer to prevent over-confidence, but it can needlessly hurt legitimate high confident predictions. A third option is to use Bayesian neural networks (Blundell et al., 2015; Louizos and Welling, 2017), which treat model parameters as probability distributions to represent model uncertainty explicitly. However, these Bayesian approaches are often prohibitive, as the priors of the model parameters are difficult to specify, and exact inference is intractable, which can also lead to unreliable uncertainty estimates.

We propose a regularization approach to addressing miscalibration for fine-tuning pre-trained language models from a data augmentation perspective. We propose two new regularizers using pseudo samples both *on* and *off* the data manifold to mitigate data scarcity and prevent over-confident predictions. Specifically, our method imposes two types of regularization for better calibration during fine-tuning: (1) **On-manifold regularization**: We first generate *on-manifold samples* by interpolating the training data and their corresponding labels along the direction learned from hidden feature space; training over such augmented on-manifold data introduces a smoothness constraint within the data manifold to improve the model calibration for in-distribution data. (2) **Off-manifold regularization**: We generate *off-manifold* samples by adding relatively large perturbations along the directions that point outward the data manifold; we penalize the negative entropy of the output distribution for such off-manifold samples to address the over-confidence issue for OOD data.

We evaluate our proposed model calibration method on six text classification datasets. For in-distribution data, we measure ECE and the performance of misclassification detection. For out-of-distribution data, we measure the performance of OOD detection. Our experiments show that our method outperforms existing state-of-the-art methods in both settings, and meanwhile maintains competitive classification accuracy.

We summarize our contribution as follows: (1) We propose a general calibration framework, which can be applied to pre-trained language model fine-tuning, as well as other deep neural network-based prediction problems. (2) The proposed method adopts on- and off-manifold regularization from a data augmentation perspective to improve calibration for both in-distribution and OOD data. (3) We conduct comprehensive experiments showing that our method outperforms existing calibration methods in terms of ECE, miscalssification detection and OOD detection on six text classification datasets.

2 Preliminaries

We describe model calibration for both in-distribution and out-of-distribution data.

Calibration for In-distribution Data: For in-distribution data, a well-calibrated model is expected to output prediction confidence comparable to its classification accuracy. For example, given 100 data points with their prediction confidence 0.6, we expect 60 of them to be correctly classified. More precisely, for a data point X, we denote by $Y(X)$ the ground truth label, $\hat{Y}(X)$ the label predicted by the model, and $\hat{P}(X)$ the output probability associated with the predicted label. The calibration error of the predictive model for a given confidence $p \in (0,1)$ is defined as:

$$\mathcal{E}_p = |\mathbb{P}(\hat{Y}(X) = Y(X) | \hat{P}(X) = p) - p|. \quad (1)$$

As (1) involves population quantities, we usually adopt empirical approximations (Guo, 2017) to estimate the calibration error. Specifically, we partition all data points into M bins of equal size according to their prediction confidences. Let $\mathcal{B}_m$ denote the bin with prediction confidences bounded between ℓ_m and u_m. Then, for any $p \in [\ell_m, u_m)$, we define the empirical calibration error as:

$$\hat{\mathcal{E}}_p = \hat{\mathcal{E}}_m = \frac{1}{|\mathcal{B}_m|} \Big| \sum_{i \in \mathcal{B}_m} \big[\mathbf{1}(\hat{y}_i = y_i) - \hat{p}_i\big] \Big|, \quad (2)$$

where y_i, $\hat{y}_i$ and $\hat{p}_i$ are the true label, predicted label and confidence for sample i.

To evaluate the overall calibration error of the predictive model, we can futher take a weighted average of the calibration errors of all bins, which is also known as the expected calibration error (ECE) (Naeini et al., 2015) defined as:

$$\text{ECE} = \sum_{m=1}^{M} \frac{|\mathcal{B}_m|}{n} \hat{\mathcal{E}}_m, \quad (3)$$

where n is the sample size.

We remark that the goal of calibration is to minimize the calibration error without significantly sacrificing prediction accuracy. Otherwise, a random guess classifier can achieve zero calibration error.

Calibration for Out-of-distribution Data: In real applications, a model can encounter test data that significantly differ from the training data. For example, they come from other unseen classes, or they are potential outliers. A well-calibrated model is expected to produce an output with high uncertainty for such out-of-distribution (OOD) data, formally,

$$P(Y = j) = 1/K \quad \forall j = 1, ..., K,$$

where K is the number of classes of the training data. As such, we can detect OOD data by setting up an uncertainty threshold.

3 Calibrated Fine-Tuning via Manifold Smoothing

We consider N data points of the target task $S = \{(\mathbf{x}_i, y_i)\}_{i=1}^{N}$, where $\mathbf{x}_i$'s denote the input embedding of the sentence and y_i's are the associated one-hot labels. Let $f(\cdot)$ denote the feature extraction layers (*e.g.*, BERT); let $g(\cdot)$ denote the task-specific layer; and let θ denote all parameters of f and g. We propose to optimize the following objective at the fine-tuning stage:

$$\begin{aligned} \min_{\theta} \mathcal{F}(\theta) &= \mathbb{E}_{\mathbf{x},y\sim S} \ell(g \circ f(\mathbf{x}), y) \\ &+ \lambda_{\text{on}} \mathcal{R}_{\text{on}}(g \circ f) + \lambda_{\text{off}} \mathcal{R}_{\text{off}}(g \circ f), \end{aligned} \quad (4)$$

where ℓ is the cross entropy loss, and $\lambda_{\text{on}}, \lambda_{\text{off}}$ are two hyper-parameters. The regularizers $\mathcal{R}_{\text{on}}$ and $\mathcal{R}_{\text{off}}$ are for on- and off-manifold calibration, respectively.

3.1 On-manifold Regularization

The on-manifold regularizer $\mathcal{R}_{\text{on}}$ exploits the interpolation of training data within the data manifold to improve the in-distribution calibration. Specifically, given two training samples $(\mathbf{x}, y)$ and $(\tilde{\mathbf{x}}, \tilde{y})$ and the feature extraction layers f, we generate an on-manifold pseudo sample $(\mathbf{x}', y')$ as follows:

$$\mathbf{x}'^{*} = \operatorname*{arg\,min}_{\mathbf{x}' \in \mathbb{B}(\mathbf{x}, \delta_{\text{on}})} D_x(f(\mathbf{x}'), f(\tilde{\mathbf{x}})), \quad (5)$$

$$y' = (1 - \delta_y) y + \delta_y \tilde{y}, \quad (6)$$

where δ_{on} and δ_y are small interpolation parameters for data and label, and D_x is a proper distance for features extracted by f such as cosine distance, *i.e.*, $D_x(\mathbf{a}, \mathbf{b}) = \langle \mathbf{a}/\|\mathbf{a}\|_2, \mathbf{b}/\|\mathbf{b}\|_2 \rangle$, and $\mathbb{B}(\mathbf{x}, \delta_{\text{on}})$ denotes an ℓ_∞ ball centered at $\mathbf{x}$ with a radius δ_{on}, *i.e.*,

$$\mathbb{B}(\mathbf{x}, \delta_{\text{on}}) = \{\mathbf{x}' \mid \|\mathbf{x}' - \mathbf{x}\|_\infty \le \delta_{\text{on}}\}.$$

As can be seen, $\mathbf{x}'^{*}$ is essentially interpolating between $\mathbf{x}$ and $\tilde{\mathbf{x}}$ on the data manifold, and $D_x(f(\cdot), f(\cdot))$ can be viewed as a metric over such a manifold. However, as $f(\cdot)$ is learnt from finite training data, it can recover the actual data manifold only up to a certain statistical error. Therefore,

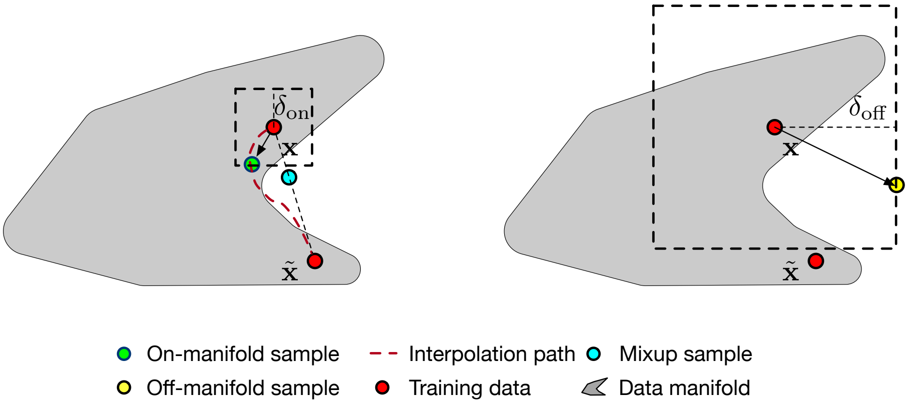

Figure 2: The on-manifold and off-manifold samples generated by our calibration procedure. Mixup adopts a coarse linear interpolation and the generated data point may deviate from the data manifold.

we constrain $\mathbf{x}'^*$ to stay in a small neighborhood of $\mathbf{x}$, which ensures $\mathbf{x}'^*$ to stay close to the actual data manifold.

This is different from existing interpolation methods such as Mixup (Zhang et al., 2018; Verma et al., 2019). These methods adopt coarse linear interpolations either in the input space or latent feature space, and the generated data may significantly deviate from the data manifold.

Note that our method not only interpolates $\mathbf{x}$ but also y. This can yield a soft label for $\mathbf{x}'^*$, when $\mathbf{x}$ and $\tilde{\mathbf{x}}$ belong to different classes. Such an interpolation is analogous to semi-supervised learning, where soft pseudo labels are generated for the unlabelled data. These soft-labelled data essentially induce a smoothing effect, and prevent the model from making overconfident predictions toward one single class.

We remark that our method is more adaptive than the label smoothing method (Müller et al., 2019). As each interpolated data point involves at most two classes, it is unnecessary to distribute probability mass to other classes in the soft label. In contrast, label smoothing is more rigid and enforces all classes to have equally nonzero probability mass in the soft label.

We then define the on-manifold regularizer as

$$\mathcal{R}_{\text{on}}(g \circ f) = \mathbb{E}_{(\mathbf{x}', y') \sim S_{\text{on}}} D_{\text{KL}}(y', g \circ f(\mathbf{x}')),$$

where S_{on} denotes the set of all pseudo labelled data generated by our interpolation method, and D_{KL} denotes the KL-divergence between two probability simplices.

Algorithm 1 Our Proposed Efficient Stochastic Optimization Algorithm for Solving (4). d is the dimension of features.

```
for # training iterations do
    Sample a mini-batch $B = \{\mathbf{x}_i, y_i\}$ from $S$.
    // Generate on-manifold samples:
    For each $\mathbf{x}_i \in B$, randomly select $\{\tilde{\mathbf{x}}_i, \tilde{y}_i\}$ from $B$, initialize $\mathbf{x}'_i \leftarrow \mathbf{x}_i + v_i$ with $v_i \sim \text{UNIF}[-\delta_{\text{on}}, \delta_{\text{on}}]^d$
    $\Delta'_i \leftarrow \text{sign}(\nabla_{\mathbf{x}'_i} D_x(f(\mathbf{x}'_i), f(\tilde{\mathbf{x}}_i)))$
    $\mathbf{x}'_i \leftarrow \Pi_{\|\mathbf{x}'_i - \mathbf{x}_i\|_\infty \leq \delta_{\text{on}}}(\mathbf{x}'_i - \delta_{\text{on}} \Delta'_i)$
    $y' \leftarrow (1 - \delta_y) y_i + \delta_y \tilde{y}_i$
    // Generate off-manifold samples:
    For each $\mathbf{x}_i \in B$, initialize $\mathbf{x}''_i \leftarrow \mathbf{x}_i + v'_i$ with $v'_i \sim \text{UNIF}[-\delta_{\text{off}}, \delta_{\text{off}}]^d$
    $\Delta''_i \leftarrow \text{sign}(\nabla_{\mathbf{x}''_i} \ell(g \circ f(\mathbf{x}''_i), y)$
    $\mathbf{x}''_i \leftarrow \Pi_{\|\mathbf{x}''_i - \mathbf{x}_i\|_\infty = \delta_{\text{off}}}(\mathbf{x}''_i + \delta_{\text{off}} \Delta''_i)$
    Update $\theta$ using ADAM
end for
```

3.2 Off-manifold Regularization

The off-manifold regularizer, $\mathcal{R}_2$, encourages the model to yield low confidence outputs for samples outside the data manifold, and thus mitigates the over-confidence issue for out-of-distribution (OOD) data. Specifically, given a training sample $(\mathbf{x}, y)$, we generate an off-manifold pseudo sample $\mathbf{x}''^*$ by:

$$\mathbf{x}''^* = \max_{\mathbf{x}'' \in \mathbb{S}(\mathbf{x}, \delta_{\text{off}})} \ell(g \circ f(\mathbf{x}''), y), \tag{7}$$

where $\mathbb{S}(\mathbf{x}, \delta_{\text{off}})$ denotes an ℓ_∞ sphere centered at $\mathbf{x}$ with a radius δ_{off}.

Since we expect $\mathbf{x}''^*$ to mimic OOD data, we first need to choose a relatively large δ_{off} such that the sphere $\mathbb{S}(\mathbf{x}, \delta_{\text{off}})$ can reach outside the data manifold. Then, we generate the pseudo off-manifold sample from the sphere along the adversarial direction. Existing literature (Stutz et al., 2019; Gilmer et al., 2018) has shown that such an adversarial direction points outward the data manifold.

By penalizing the prediction confidence for these off-manifold samples, we are able to encourage low prediction confidence for OOD data. Hence, we define the off-manifold regularizer as

$$\mathcal{R}_{\text{off}}(g \circ f) = \mathbb{E}_{\mathbf{x}'' \sim S_{\text{off}}} - \mathcal{H}(g \circ f(\mathbf{x}'')), \quad (8)$$

where S_{off} denotes the set of all generated off-manifold samples, and $\mathcal{H}(\cdot)$ denotes the entropy of the probability simplex.

3.3 Model Training

We can adopt stochastic gradient-type algorithms such as ADAM (Kingma and Ba, 2014) to optimize (4). At each iteration, we need to first solve two inner optimization problems in (5) and (7), and then plug $\mathbf{x}'$ and $\mathbf{x}''$ into (4) to compute the stochastic gradient. The two inner problems can be solved using the projected sign gradient update for multiple steps. In practice, we observe that one single update step with random initialization is already sufficient to efficiently optimize θ. Such a phenomenon has also been observed in existing literature on adversarial training (Wong et al., 2019). We summarize the overall training procedure in Algorithm 1.

4 Experiments

To evaluate calibration performance for in-distribution data, we measure the expected calibration error (ECE) and the misclassification detection score. For out-of-distribution data, we measure the OOD detection score.

We detect the misclassified and OOD samples by model confidence, which is the output probability associated with the predicted label $\hat{P}(X)$. Specifically, we setup a confidence threshold $\tau \in [0, 1]$, and take the samples with confidence below the threshold, *i.e.*, $\hat{P}(X) < \tau$, as the misclassified or OOD samples. We can compute the detection F_1 score for every τ: $F_1(\tau)$, and obtain a calibration curve ($F_1(\tau)$ vs. τ). Then, we set τ_{upper} as the upper bound of the confidence threshold, since a well calibrated model should provide probabilities that reflect the true likelihood and it is not reasonable to use a large τ to detect them. We use the empirical Normalized Bounded Area Under the Calibration Curve (NBAUCC) as the overall detection score:

$$\text{NBAUCC}_{\tau_{\text{upper}}} = \frac{1}{M} \sum_{i=1}^{M} F_1\left(\frac{\tau_{\text{upper}}}{M} i\right),$$

where M is the number of sub-intervals for the numerical integration. We set $M = 50$ throughout the following experiments. Note that the traditional binary classification metrics, *e.g.*, AUROC and AUPR, cannot measure the true calibration because the model can still achieve high scores even though it has high confidences for the misclassified and OOD samples. We provide more explanations of the metrics in Appendix C. We report the performance when $\tau_{\text{upper}} = 0.5$ here and the results when $\tau_{\text{upper}} = 0.7$ and 1 in Appendix D.

4.1 Datasets

For each dataset, we construct an in-distribution training set, an in-distribution testing set, and an OOD testing set. Specifically, we use the following datasets:

20NG[1]. The 20 Newsgroups dataset (20NG) contains news articles with 20 categories. We use Stanford Sentiment Treebank (SST-2) (Socher et al., 2012) as the OOD data.

$\mathbf{20NG_{15}}$. We take the first 15 categories of 20NG as the in-distribution data and the other 5 categories ($20NG_5$) as the OOD data.

WOS (Kowsari et al., 2017). Web of Science (WOS) dataset contains scientific articles with 134 categories. We use AGnews (Zhang et al., 2015) as the OOD data.

$\mathbf{WOS_{100}}$. We use the first 100 classes of WOS as the in-distribution data and the other 34 classes (WOS_{34}) as the OOD data.

Yahoo (Chang et al., 2008). This dataset contains questions with 10 categories posted to 'Yahoo! Answers'. We randomly draw 2000 from $140,000$ samples for each category as the training set. We use Yelp (Zhang et al., 2015) as the OOD data.

$\mathbf{Yahoo_8}$. We use the first 8 classes of Yahoo as the in-distribution data and the other 2 classes ($Yahoo_2$) as the OOD data.

The testing set of OOD detection consists of the in-distribution testing set and the OOD data. More dataset details can be found in Appendix A. We remark that $20NG_{15}$, WOS_{100}, and $Yahoo_8$ are included to make OOD detection more challenging, as the OOD data and the training data come from similar data sources.

4.2 Baselines

We consider the following baselines:

- **BERT** (Devlin et al., 2019) is a pre-trained base BERT model stacked with one linear layer.

---

[1] We use the 20 Newsgroups dataset from: `http://qwone.com/~jason/20Newsgroups/`

- **Temperature Scaling (TS)** (Guo, 2017) is a post-processing calibration method that learns a single parameter to rescale the logits on the development set after the model is fine-tuned.
- **Monte Carlo Dropout (MCDP)** (Gal and Ghahramani, 2016) applies dropout at testing time for multiple times and then averages the outputs.
- **Label Smoothing (LS)** (Müller et al., 2019) smoothes the one-hot label by distributing a certain probability mass to other non ground-truth classes.
- **Entropy Regularized Loss (ERL)** (Pereyra et al., 2017) adds a entropy penalty term to prevent DNNs from being over-confident.
- **Virtual Adversarial Training (VAT)** (Miyato et al., 2018) introduces a smoothness-inducing adversarial regularizer to encourage the local Lipschitz continuity of DNNs.
- **Mixup** (Zhang et al., 2018; Thulasidasan et al., 2019) augments training data by linearly interpolating training samples in the input space.
- **Manifold-mixup (M-mixup)** (Verma et al., 2019) is an extension of Mixup, which interpolates training samples in the hidden feature space.

4.3 Implementation Details

We use ADAM (Kingma and Ba, 2014) with $\beta_1 = 0.9$ and $\beta_2 = 0.999$ as the optimizer. For our method, we simply set $\lambda_{\text{on}} = \lambda_{\text{off}} = 1, \delta_{\text{on}} = 10^{-4}, \delta_{\text{off}} = 10^{-3}$, and $\delta_y = 0.1$ for all the experiments. We also conduct an extensive hyper-parameter search for the baselines. See more details in Appendix B.

4.4 Main Results

Our main results are summarized as follows:

Expected Calibration Error: Table 1 reports the ECE and predictive accuracy of all the methods. Our method outperforms all the baselines on all the datasets in terms of ECE except for Yahoo, where only ERL is slightly better. Meanwhile, our method does not sacrifice the predictive accuracy.

Misclassification Detection: Table 2 compares the $\text{NBAUCC}_{0.5}$ on misclassification detection of different methods. As shown, our method outperforms all the baselines on all the six datasets.

Out-of-distribution Detection: Table 2 reports the $\text{NBAUCC}_{0.5}$ on OOD detection of different methods. Again, our method achieves the best performance on all the six datasets. The improvement is particularly remarkable on the 20NG dataset, where $\text{NBAUCC}_{0.5}$ increases from 47.00 to 63.92 compared with the strongest baseline. We also find that detecting the unseen classes from the original dataset is much more challenging than detecting OOD samples from a totally different dataset.

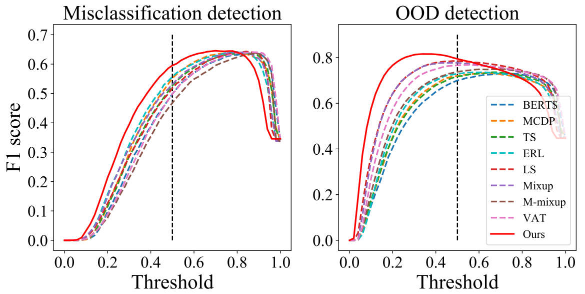

Figure 3: Calibration curves of OOD detection and misclassification detection on WOS. Our method can achieve high F_1 scores starting from a small threshold which indicates that it indeed provides low confidences for misclassified and OOD samples; the F_1 scores of the baselines peak at high thresholds which indicates that they are poorly calibrated.

Significance Test: We perform the Wilcoxon signed rank test (Wilcoxon, 1992) for significance test. For each dataset, we conduct experiments using 5 different random seeds with significance level $\alpha = 0.5$. We find that our model outperforms other baselines on all the datasets significantly, with only exceptions of ERL in ECE on Yahoo and ERL in misclassification detection on 20NG.

4.5 Parameter Study

We investigate the effects of the interpolation parameters for on-manifold data, *i.e.*, δ_{on} and δ_y, and the perturbation size for off-manifold samples, *i.e.*, δ_{off}. The default values are $\delta_{\text{on}} = 10^{-4}, \delta_{\text{off}} = 10^{-3}$ and $\delta_y = 0.1$. Figure 4 shows the reuslts on 20NG_{15}, 20NG, WOS_{100}, and WOS datasets. Our results are summarized as follows:

- The performance of all metrics versus δ_{on} is stable within a large range from 10^{-5} to 10^{-2}. When δ_{on} is larger than 10^{-1}, the predictive accuracy begins to drop.
- The performance versus δ_{off} is more sensitive: (1) when δ_{off} is too small, ECE increases dramatically becasue the generated off-manifold samples are too close to the manifold and make the model under-confident. (2) when δ_{off} is too large, the off-manifold regularization is too weak and OOD detection performance drops.
- In general, δ_{on} should be small to let $\mathbf{x}'$ stay on the data manifold while δ_{off} should be large to let $\mathbf{x}''$ leave the data manifold. However, the regularization effect of $\mathcal{R}_{\text{on}}$ ($\mathcal{R}_{\text{off}}$) depends on both λ_{on}

(λ_{off}) and δ_{on} (δ_{off}). Therefore, it is not necessary to let δ_{on} be smaller than δ_{off}. We can also tune λ_{on} and λ_{off} to achieve better performance.

- The performance versus δ_y is relatively stable except for the metric of ECE. When δ_y is larger than 0.2, ECE begins to increase.

4.6 Ablation Study

We investigate the effectiveness of the on-manifold regularizer $\mathcal{R}_{\text{on}}$ and the off-manifold regularizer $\mathcal{R}_{\text{off}}$ via ablation studies. Table 3 shows the results on the 20NG$_{15}$ and 20NG datasets.

- As expected, removing either component in our method would result in a performance drop. It demonstrates that these two components complement each other. All the ablation models outperform the BERT baseline model, which demonstrates the effectiveness of each module.
- We observe that the optimal δ_{on} is different when using only $\mathcal{R}_{\text{on}}$. This indicates that the hyperparameters of $\mathcal{R}_{\text{on}}$ and $\mathcal{R}_{\text{off}}$ should be jointly tuned, due to the joint effect of both components.
- By removing $\mathcal{R}_{\text{off}}$, we observe a severe OOD performance degradation on the 20NG dataset (from 63.92 to 43.87). This indicates that $\mathcal{R}_{\text{off}}$ is vital to out-of-distribution calibration. Meanwhile, the performance degradation is less severe on 20NG$_{15}$ (from 9.69 to 7.94). It is because $\mathcal{R}_{\text{on}}$ can also help detect the OOD samples from similar data sources. (20NG$_5$).
- By removing $\mathcal{R}_{\text{on}}$, the in-distribution calibration performance drops as expected.

5 Related Works and Discussion

Other Related Works: Lakshminarayanan et al. (2017) propose a model ensembling approach to improve model calibration. They first train multiple models with different initializations and then average their predictions. However, fine-tuning multiple language models requires extremely intensive computing resources.

Kumar et al. (2018) propose a differentiable surrogate for the expected calibration error, called

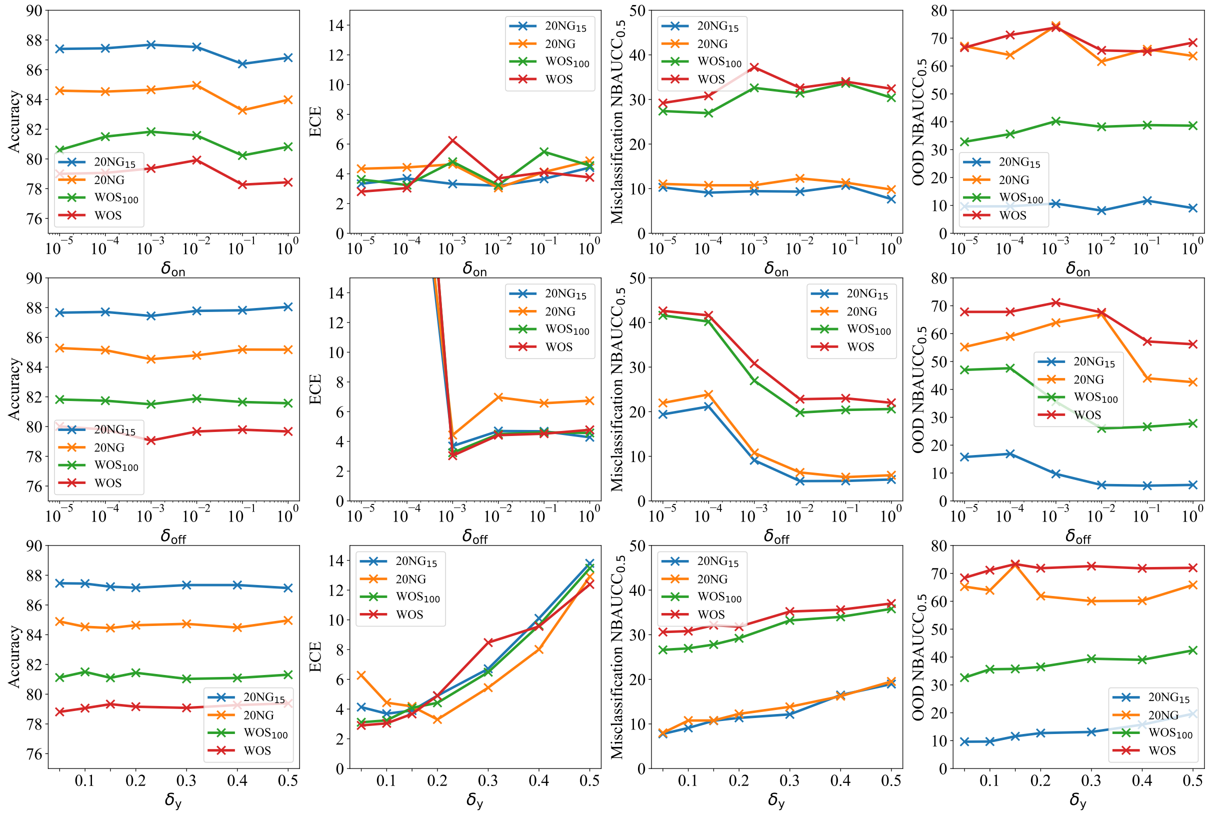

Figure 4: Parameter study of δ_{on}, δ_{off} and δ_y.

Table 3: Ablation study on the 20NG$_{15}$ and 20NG datasets. For OOD detection and misclassification detection, we report BAUCC$_{0.5}$. We set $\delta_y = 0.1$ and $\delta_{\text{off}} = 10^{-3}$.

maximum mean calibration error (MMCE), using kernel embedding. However, such a kernel embedding method is computationally expensive and not scalable to the large pre-trained language models.

Accelerating Optimization: To further improve the calibration performance of our method, we can leverage some recent minimax optimization techniques to better solve the two inner optimization problems in (5) and (7) without increasing the computational complexity. For example, Zhang et al. (2019) propose an efficient approximation algorithm based on Pontryagin's Maximal Principle to replace the multi-step projected gradient update for the inner optimization problem. Another option is the learning-to-learn framework (Jiang et al., 2018), where the inner problem is solved by a learnt optimizer. These techniques can help us obtain $\mathbf{x}'$ and $\mathbf{x}''$ more efficiently.

Connection to Robustness: The interpolated training samples can naturally promote the local Lipschitz continuity of our model. Such a local smoothness property has several advantages: (1) It makes the model more robust to the inherent noise in the data, *e.g.*, noisy labels; (2) it is particularly helpful to prevent overfitting and improve generalization, especially for low-resource tasks.

Extensions: Our method is quite general and can be applied to other deep neural network-based problems besides language model fine-tuning.

6 Conclusion

We have proposed a regularization method to mitigate miscalibration of fine-tuned language models from a data augmentation perspective. Our method imposes two new regularizers using generated on- and off- manifold samples to improve both in-distribution and out-of-distribution calibration. Extensive experiments on six datasets demonstrate that our method outperforms state-of-the-art calibration methods in terms of expected calibration error, misclassification detection and OOD detection.

6. Yelp: `https://github.com/yumeng5/WeSTClass`.

B Experiment Details

We use ADAM (Kingma and Ba, 2014) with $\beta_1 = 0.9$ and $\beta_2 = 0.999$ as the optimizer in all the datasets. We use the learning rate of 5×10^{-5} and batch size 32 except 1×10^{-5} and 16 for $Yahoo_8$ and Yahoo. We set the maximum number of epochs to 5 in $Yahoo_8$ and Yahoo and 10 in the other datasets. We use the dropout rate of 0.1 as in (Devlin et al., 2019). The documents are tokenized using wordpieces and are chopped to spans no longer than 150 tokens on $20NG_{15}$ and 20NG and 256 on other datasets..

Hyper-parameters: For our method, we use $\lambda_{\text{on}} = \lambda_{\text{off}} = 1$, $\delta_{\text{on}} = 10^{-4}$, $\delta_{\text{off}} = 10^{-3}$ and $\delta_y = 0.1$ for all the datasets. We then conduct an extensive hyper-parameter search for the baselines: for label smoothing, we search the smoothing parameter from $\{0.05, 0.1\}$ as in (Müller et al., 2019); for ERL, the penalty weight is chosen from $\{0.05, 0.1, 0.25, 0.5, 1, 2.5, 5\}$; for VAT, we search the perturbation size in $\{10^{-3}, 10^{-4}, 10^{-5}\}$ as in (Jiang et al., 2020); for Mixup, we search the interpolation parameter from $\{0.1, 0.2, 0.3, 0.4\}$ as suggested in (Zhang et al., 2018; Thulasidasan et al., 2019); for Manifold-mixup, we search from $\{0.2, 0.4, 1, 2, 4\}$. We perform 10 stochastic forward passes for MCDP at test time. For hyper-parameter tuning, we run all the methods 5 times and then take the average. The hyper-parameters are selected to get the best ECE on the development set of each dataset. The interpolation of Mixup is performed on the input embeddings obtained from the first layer of the language model; the interpolation of Manifold-mixup is performed on the features obtained from the last layer of the language model.

C Metrics of Misclassification and Out-of-distribution detection

Existing works on out-of-distribution (OOD) detection and misclassification detection (Hendrycks and Gimpel, 2016) use traditional binary classification metrics, *e.g.*, AUPR and AUROC. As we discussed in Section 1 and 2, the output probability of a calibrated model should reflect the true likelihood. However, AUROC and AUPR cannot reflect true model calibration because the model can still achieve high scores even though it has high confidences for misclassified and OOD samples. We argue that it is more reasonable to use the Normalized Bounded Area Under the Calibration Curve (NBAUCC) defined as in Section 4.

Table 5 shows an illustrative example. As can be seen, h_1 is better calibrated than h_2, since h_1 can detect OOD samples under a wide range of threshold ($0.15 < \tau < 0.9$) while h_2 requires an absurdly large threshold ($0.85 < \tau < 0.9$). However, if we use the traditional AUPR and AUROC metrics, we will conclude that h_1 is as well calibrated as h_2 since $\text{AUPR}^{h_1} = \text{AUPR}^{h_2} = 0.417$ and $\text{AUROC}^{h_1} = \text{AUROC}^{h_2} = 1$. On the

Model	Confidence				Optimal τ	AUPR	AUROC	NBAUCC_1	$\mathrm{NBAUCC}_{0.5}$
	$x_{\text{in},1}$	$x_{\text{in},2}$	$x_{\text{out},1}$	$x_{\text{out},2}$					
h_1 (Miscalibrated)	0.9	0.95	0.8	0.85	$(0.85, 0.9)$	0.417	1	0.145	0
h_2 (Well-calibraterd)	0.9	0.95	0.1	0.15	$(0.15, 0.9)$	0.417	1	0.845	0.773

Table 5: NBAUCC vs. AUROC/AUPR

other hand, if we use NBAUCC, we will have $\mathrm{NBAUCC}_1^{h_1} = 0.845 > \mathrm{NBAUCC}_1^{h_1} = 0.145$, or $\mathrm{NBAUCC}_{0.5}^{h_1} = 0.773 > \mathrm{NBAUCC}_{0.5}^{h_1} = 0$ which can reflect the true calibration of the two classifiers.

We remark that it is more appropriate to use $\mathrm{NBAUCC}_{0.5}$ than NBAUCC_1 since a calibrated model should provide low confidences for the misclassified and OOD samples and it is unreasonable to use a large threshold to detect them.

D Additional Results

Table 6 and 7 report the NBAUCCs of all the methods on misclassification and OOD detection when $\tau_{\text{upper}} = 0.7$ and $\tau_{\text{upper}} = 1$. Table 8 and 9 report the ablation study results of all the methods when $\tau_{\text{upper}} = 0.7$ and $\tau_{\text{upper}} = 1$. Figure 5 and 6 report the parameter study results of all the methods when $\tau_{\text{upper}} = 0.7$ and $\tau_{\text{upper}} = 1$.

Scaling Hidden Markov Language Models

Justin T. Chiu and **Alexander M. Rush**
Department of Computer Science
Cornell Tech
{jtc257,arush}@cornell.edu

Abstract

The hidden Markov model (HMM) is a fundamental tool for sequence modeling that cleanly separates the hidden state from the emission structure. However, this separation makes it difficult to fit HMMs to large datasets in modern NLP, and they have fallen out of use due to very poor performance compared to fully observed models. This work revisits the challenge of scaling HMMs to language modeling datasets, taking ideas from recent approaches to neural modeling. We propose methods for scaling HMMs to massive state spaces while maintaining efficient exact inference, a compact parameterization, and effective regularization. Experiments show that this approach leads to models that are more accurate than previous HMM and n-gram-based methods, making progress towards the performance of state-of-the-art neural models.

1 Introduction

Hidden Markov models (HMMs) are a fundamental latent-variable model for sequential data, with a rich history in NLP. They have been used extensively in tasks such as tagging (Merialdo, 1994), alignment (Vogel et al., 1996), and even, in a few cases, language modeling (Kuhn et al., 1994; Huang, 2011). Compared to other sequence models, HMMs are appealing since they fully separate the process of generating hidden states from observations, while allowing for exact posterior inference.

State-of-the-art systems in NLP have moved away from utilizing latent hidden states and toward deterministic deep neural models. We take several lessons from the success of neural models for NLP tasks: (a) model size is critical for accuracy, e.g. large LSTMs (Zaremba et al., 2014) show marked improvements in performance; (b) the right parameterization is critically important for representation learning, e.g. a feedforward model (Bengio et al., 2003) can have the same distributional assumptions as an n-gram model while performing significantly better; (c) dropout is key to achieving strong performance (Zaremba et al., 2014; Merity et al., 2017).

We revisit HMMs for language modeling as an alternative to modern neural models, while considering key empirical lessons from these approaches. Towards that goal, we introduce three techniques: a modeling constraint that allows us to use a large number of hidden states while maintaining efficient exact inference, a neural parameterization that improves generalization while remaining faithful to the probabilistic structure of the HMM, and a variant of dropout that both improves accuracy and halves the computational overhead during training.

Experiments employ HMMs on two language modeling datasets. Our approach allows us to train an HMM with tens of thousands of states while maintaining efficiency and significantly outperforming past HMMs as well as n-gram models.

2 Related Work

In order to improve the performance of HMMs on language modeling, several recent papers have combined HMMs with neural networks. Buys et al. (2018) develop an approach to relax HMMs, but their models either perform poorly or alter the probabilistic structure to resemble an RNN. Krakovna and Doshi-Velez (2016) utilize model combination with an RNN to connect both approaches in a small state-space model. Our method instead focuses on scaling pure HMMs to a large number of states.

Prior work has also considered neural parameterizations of HMMs. Tran et al. (2016) demonstrate

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1341–1349,
November 16–20, 2020.

improvements in POS induction with a neural parameterization of an HMM. They consider small state spaces, as the goal is tag induction rather than language modeling.[1]

Most similar to this work are the large HMM models of Dedieu et al. (2019). They introduce a sparsity constraint in order to train a 30K state non-neural HMM for character-level language modeling; however, their constraint precludes application to large vocabularies. We overcome this limitation and train models with neural parameterizations on word-level language modeling.

Finally, another approach for scaling state spaces is to grow from small to big via a split-merge process (Petrov et al., 2006; Huang, 2011). In particular, Huang (2011) learn an HMM for language modeling via this process. As fixed-size state spaces are amenable to batching on modern hardware, we leave split-merge procedures for future work.

3 Background: HMMs

We are interested in learning a distribution over observed tokens $\mathbf{x} = \langle x_1, \ldots, x_T \rangle$, with each token x_t an element of the finite vocabulary $\mathcal{X}$. Hidden Markov models (HMMs) specify a joint distribution over observed tokens $\mathbf{x}$ and discrete latent states $\mathbf{z} = \langle z_1, \ldots, z_T \rangle$, with each z_t from the finite set $\mathcal{Z}$. For notational convenience, we define the starting state $z_0 = \epsilon$. This yields the joint distribution,

$$p(\mathbf{x}, \mathbf{z}; \theta) = \prod_{t=1}^{T} p(x_t \mid z_t) p(z_t \mid z_{t-1}). \quad (1)$$

We refer to the transition and emission matrices as the distributional parameters of the HMM. Specifically, let $\mathbf{A} \in [0,1]^{|\mathcal{Z}| \times |\mathcal{Z}|}$ be the transition probabilities and $\mathbf{O} \in [0,1]^{|\mathcal{Z}| \times |\mathcal{X}|}$ the emission probabilities,

$$p(z_t \mid z_{t-1}) = A_{z_{t-1} z_t} \quad p(x_t \mid z_t) = O_{z_t x_t}. \quad (2)$$

We distinguish between two types of model parameterizations: *scalar* and *neural*, where the model parameters are given by θ. A scalar parameterization sets the model parameters equal to the distributional parameters, so that $\theta = \{\mathbf{A}, \mathbf{O}\}$, resulting in $O(|\mathcal{Z}|^2 + |\mathcal{Z}||\mathcal{X}|)$ model parameters. A neural parameterization instead generates the distributional parameters from a neural network (with parameters θ), decoupling the size of θ from $\mathbf{A}, \mathbf{O}$. This decoupling gives us the ability to choose between compact or overparameterized θ (relative to $\mathbf{A}, \mathbf{O}$). As we scale to large state spaces, we take advantage of compact neural parameterizations.

In order to fit an HMM to data $\mathbf{x}$, we must marginalize over the latent states to obtain the likelihood $p(\mathbf{x}) = \sum_{\mathbf{z}} p(\mathbf{x}, \mathbf{z})$. This sum can be computed in time $O(T|\mathcal{Z}|^2)$ via the forward algorithm, which becomes prohibitive if the number of latent states $|\mathcal{Z}|$ is large. We can then optimize the likelihood with gradient ascent (or alternative variants of expectation maximization).

HMMs and RNNs Although the forward algorithm resembles that of the forward pass in a recurrent neural network (RNN) (Buys et al., 2018), there are key representational differences. RNNs do not decouple the latent dynamics from the observed. This often leads to improved accuracy, but precludes posterior inference which is useful for interpretability. A further benefit of HMMs over RNNs is that their associative structure allows for parallel inference via the prefix-sum algorithm (Ladner and Fischer, 1980).[2] Finally, HMMs bottleneck information from every timestep through a discrete hidden state. NLP has a long history of utilizing discrete representations, and discrete representations may yield interesting results. For example, recent work has found that discrete latent variables work well in low-resource regimes (Jin et al., 2020).

4 Scaling HMMs

We propose three extensions to scale HMMs for better language modeling performance: blocked emissions, which allow for very large models; neural parameterization, which makes it easy for states to share model parameters; and state dropout, which encourages broader state usage.

Blocked Emissions Our main goal is to apply a HMM with a large number of hidden states to learn the underlying dynamics of language data. However, the $O(T|\mathcal{Z}|^2)$ complexity of marginal inference practically limits the number of HMM states. We can get around this limit by making an assump-

---

[1] Other work has used neural parameterization for structured models, such as dependency models (Han et al., 2017), hidden semi-Markov models (Wiseman et al., 2018), and context free grammars (Kim et al., 2019).

[2] Quasi-RNNs (Bradbury et al., 2016) also have a (parallel) logarithmic dependency on T by applying the same prefix-sum trick, but do not model uncertainty over latent dynamics.

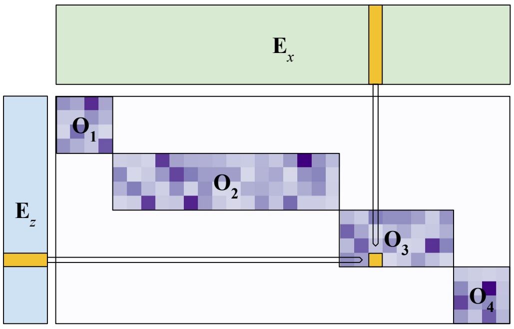

Figure 1: The emission matrix as a set of blocks $\mathbf{O}_1, \ldots, \mathbf{O}_4$ with fixed number of states k. The columns of each block may vary, as there is no constraint on the number of words a state can emit. Each non-zero cell is constructed from an MLP applied to word $\mathbf{E}_x$ and state $\mathbf{E}_z$ embeddings.

tion on the HMM emission matrix $\mathbf{O}$. As noted by Dedieu et al. (2019), restricting the number of states that can produce each word can improve inference complexity. We utilize a slightly stronger assumption on the model: a) states are partitioned into M equal sized groups each of which emit the same subset of words, and b) each word is only admitted by one group of $k = |\mathcal{Z}|/M$ states which we indicate as $\mathcal{Z}_x \subset \mathcal{Z}$.

We implement this group structure through a set of blocked emissions, each corresponding to one of the M state groups,

$$\mathbf{O} = \begin{bmatrix} \mathbf{O}_1 & 0 & 0 \\ 0 & \ldots & 0 \\ 0 & 0 & \mathbf{O}_M \end{bmatrix}$$

where $\mathbf{O}_m \in \mathbb{R}^{k \times |\mathcal{X}_m|}$. Figure 1 shows these emission blocks. Each block matrix $\mathbf{O}_m$ gives the probabilities for emitting tokens $\mathcal{X}_m$ for states in group m, i.e. states $(m-1)k$ through mk.

With this constraint, exact marginalization can be computed via

$$p(\mathbf{x}) = \sum_{z_1 \in \mathcal{Z}_{x_1}} p(z_1 \mid z_0) p(x_1 \mid z_1) \times \\ \cdots \sum_{z_T \in \mathcal{Z}_{x_T}} p(z_T \mid z_{T-1}) p(x_T \mid z_T) \tag{3}$$

Since there are only k states with nonzero probability of occurring at every timestep, we only need to consider transitioning from the $|\mathcal{Z}_{x_t}| = k$ previous states to the next $|\mathcal{Z}_{x_{t+1}}| = k$ states, resulting in $O(k^2)$ operations per timestep. This gives a serial complexity of $O(Tk^2)$.[3]

Algorithm 1 HMM Training (a single batch)

```
Given: block structure and model parameters
Sample block-wise dropout mask $\mathbf{b}$
Compute $\mathbf{A}, \mathbf{O}$ ignoring $b_z = 0$
for all examples $\mathbf{x}$ in batch do
    Compute $\log p(\mathbf{x}; \mathbf{A}, \mathbf{O})$
    Compute grad wrt parameters of $\log p(\mathbf{x})$
Update model parameters $\mathbf{E_z}, \mathbf{E_x}$ and MLP
```

Neural Parameterization A larger state space allows for longer HMM memory, but it also may require more parameters. Even with blocked emissions, the scalar model parameterization of an HMM grows as $O(|\mathcal{Z}|^2)$ due to the transition matrix. A neural parameterization allows us to share parameters between words and states to capture common structure.

Our parameterization uses an embedding for each state in $\mathcal{Z}$ ($\mathbf{E}_z \in \mathbb{R}^{|\mathcal{Z}| \times h}$) and each token in $\mathcal{X}$ ($\mathbf{E}_x \in \mathbb{R}^{|\mathcal{X}| \times h}$). From these we can create representations for leaving and entering a state, as well as emitting a word:

$$\mathbf{H}_{\text{out}}, \mathbf{H}_{\text{in}}, \mathbf{H}_{\text{emit}} = \text{MLP}(\mathbf{E}_z)$$

with all in $\mathbb{R}^{|\mathcal{Z}| \times h}$. The HMM distributional parameters are then computed as,[4]

$$\mathbf{O} \propto \exp(\mathbf{H}_{\text{emit}} \mathbf{E}_x^\top) \qquad \mathbf{A} \propto \exp(\mathbf{H}_{\text{in}} \mathbf{H}_{\text{out}}^\top) \tag{4}$$

The MLP architecture follows Kim et al. (2019), with details in the appendix. This factorized parameterization, shown in Figure 1, reduces the total parameters to $O(h^2 + h|\mathcal{Z}| + h|\mathcal{X}|)$.

Note that parameter computation is independent of inference and can be cached completely as the emission and transition matrices, $\mathbf{A}$ and $\mathbf{O}$, at test-time. For the training algorithm, shown in Algorithm 1, we compute $\mathbf{A}$ and $\mathbf{O}$ once per batch while RNNs and similar models recompute emissions every token.

Dropout as State Reduction Finally, to encourage full use of the large state space, we introduce dropout that prevents the model from favoring specific states. We propose a form of HMM state dropout that removes states from use entirely at each batch, which also has the added benefit of speeding up inference.

---

[3] This can be sped up on a parallel machine to $O(\log(T)k^2)$ via a binary reduction.

[4] As an optimization, one could only compute the nonzero emission matrix blocks saving space and time. In practice we compute the full matrix as in the equation.

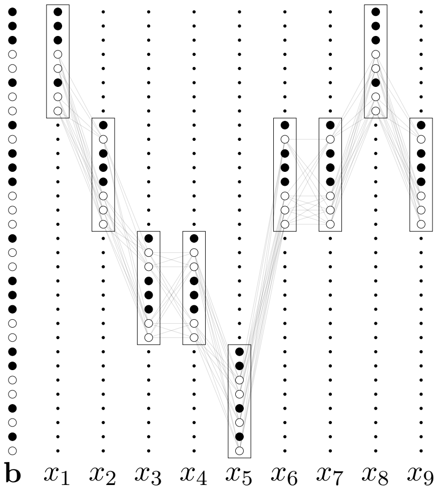

Figure 2: The computation of $p(\mathbf{x})$ is greatly reduced by blocked emissions and state dropout. In the above trellis, each row corresponds to a latent state and each column after the first to a timestep. Each edge between nodes corresponds to a nonzero transition probability. Blocked emissions result in a small subset of all states emitting a given word, as shown by the rectangles. State dropout (leftmost column) allows us to further reduce the number of states we consider, halving the number of (white) states that have nonzero probability in each rectangle. In experiments, the number of possible transitions may be as large as 2^{30} while the max number of non-zero transitions is 2^{16}.

State dropout acts on each emission block $\mathbf{O}_1, \dots, \mathbf{O}_M$ independently. For each block, we sample a binary dropout mask by sampling λk dropped row indices uniformly without replacement, where λ is the dropout rate. We concatenate these into a global vector $\mathbf{b} \in \{0,1\}^{|\mathcal{Z}|}$, which, along with the previous constraints, ensures,

$$\begin{aligned} p(z_t \mid z_{t-1}) &\propto b_{z_t} A_{z_{t-1} z_t} \\ p(x_t \mid z_t) &\propto b_{z_t} 1(z \in \mathcal{Z}_{x_t}) O_{z_t x_t} \end{aligned} \tag{5}$$

An example of the HMM lattice after state dropout is show in Figure 2.

In addition to accuracy improvements, state dropout gives a large practical speed up for both parameter computation and inference. For $\lambda = 0.5$ we get a $4\times$ speed improvement for both, due to the reduction in possible transitions. This structured dropout is also easy to exploit on GPU, as it maintains block structure.

5 Experimental Setup

Emission Blocks The model requires partitioning token types into blocks $\mathcal{X}_m$. While there are many partitioning methods, a natural choice is Brown clusters (Brown et al., 1992; Liang, 2005) which are also based on HMMs. Brown clusters are obtained by assigning every token type in $\mathcal{X}$ a state in an HMM, then merging states until a desired number of partitions M is reached. We construct the Brown clusters on the training portions of the datasets and assume the vocabulary remains identical at test time (with OOV words mapped to unk). We include more background on Brown Clusters in the appendix.

State Dropout We use a dropout rate of $\lambda = 0.5$ at training time. For each block of size $|\mathcal{X}_m|$, we sample $\lambda|\mathcal{X}_m|$ states to use in that block each batch. We draw states from each block from a multivariate hypergeometric distribution using the Gumbel Top-k trick for sampling without replacement (Vieira, 2014). At test time we do not use state dropout.

Datasets We evaluate on the PENN TREEBANK (Marcus et al., 1993) (929k train tokens, 10k vocab) and WIKITEXT2 (Merity et al., 2016) (2M train tokens, 33k vocab) datasets. For PENN TREEBANK we use the preprocessing from Mikolov et al. (2011), which lowercases all words and substitutes OOV words with unks. We insert EOS tokens after each sentence. For WIKITEXT2 casing is preserved, and all OOV words are unked. We insert EOS tokens after each paragraph. In both datasets OOV words were included in the perplexity (as unks), and EOS was included in the perplexity as well (Merity et al., 2017).

Baselines Baselines include both state-of-the-art language models and other alternative LM styles. These include AWD-LSTM (Merity et al., 2017); a 900-state scalar HMM and HMM+RNN extension, which discards the HMM assumptions (Buys et al., 2018); a traditional Kneser-Ney 5-gram model (Mikolov and Zweig, 2012; Heafield et al., 2013), a 256 dimension feedforward neural model, and a 2-layer 256 dimension LSTM.

We compare these with our approach: the very large neural HMM (VL-HMM). Unless otherwise noted, our model has $|\mathcal{Z}| = 2^{15}$ total states but only considers $k = 256$ states at every timestep at test time with $M = 128$ groups.[5] The state and word embeddings as well as the MLP have a hidden dimension of 256. We train with a state dropout rate of $\lambda = 0.5$. See the appendix for all hyperparameters.

---

[5] The 256 dim FF, LSTM, and VL-HMM in particular have comparable computational complexity: $O(256^2 T)$.

Model	Param	Val	Test
PENN TREEBANK			
KN 5-gram	2M	-	141.2
AWD-LSTM	24M	60.0	57.3
256 FF 5-gram	2.9M	159.9	152.0
2x256 dim LSTM	3.6M	93.6	88.8
HMM+RNN	10M	142.3	-
HMM $\|\mathcal{Z}\| = 900$	10M	284.6	-
VL-HMM $\|\mathcal{Z}\| = 2^{15}$	11.4M	125.0	116.0
WIKITEXT			
KN 5-gram	5.7M	248.7	234.3
AWD-LSTM	33M	68.6	65.8
256 FF 5-gram	8.8M	210.9	195.0
2x256 LSTM	9.6M	124.5	117.5
VL-HMM $\|\mathcal{Z}\| = 2^{15}$	17.3M	166.6	158.2

Table 1: Perplexities on PTB / WIKITEXT-2. The HMM+RNN and HMM of Buys et al. (2018) reported validation perplexity only for PTB.

6 Results

Table 1 gives the main results. On PTB, the VL-HMM is able to achieve 125.0 perplexity on the valid set, outperforming a FF baseline (159.9) and vastly outperforming the 900-state HMM from Buys et al. (2018) (284.6).[6] The VL-HMM also outperforms the HMM+RNN extension of Buys et al. (2018) (142.3). These results indicate that HMMs are a much stronger model on this benchmark than previously claimed. However, the VL-HMM is still outperformed by LSTMs which have been extensively studied for this task. This trend persists in WIKITEXT-2, with the VL-HMM outperforming the FF model but underperforming an LSTM.

Figure 3 examines the effect of state size: We find that performance continuously improves significantly as we grow to 2^{16} states, justifying the large state space. The marginal improvement does lower as the number of states increases, implying that the current approach may have limitations in scaling to even larger state spaces.

Table 2 considers other ablations: Although neural and scalar parameterizations reach similar training perplexity, the neural model generalizes better on validation with almost 100x fewer model parameters. We find that state dropout results in both an improvement in perplexity and a large improvement in computational speed. See the appendix for emission sparsity constraint ablations, as well as experiments on further reducing the number of parameters.

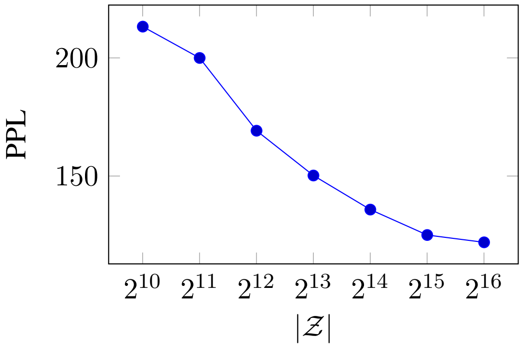

Figure 3: Perplexity on PTB by state size $|\mathcal{Z}|$ ($\lambda = 0.5$ and $M = 128$).

Model	Param	Train	Val	Time
VL-HMM (2^{14})	7.2M	115	134	40
- neural param	423M	119	169	14
- state dropout	7.2M	88	157	100

Table 2: Ablations on PTB ($\lambda = 0.5$ and $M = 128$) with a smaller model $|\mathcal{Z}| = 2^{14}$. Time is ms per eval batch (Run on RTX 2080). Ablations were performed independently, removing a single component per row. Removing the neural parameterization results in a scalar parameterization.

7 Conclusion

This work demonstrates methods for effectively scaling HMMs to large state spaces on parallel hardware, and shows that this approach results in accuracy gains compared to other HMM models. In order to scale, we introduce three techniques: a blocked emission constraint, a neural parameterization, and state dropout, which lead to an HMM that outperforms n-gram models and prior HMMs. Once scaled up to take advantage of modern hardware, very large HMMs demonstrate meaningful improvements over smaller HMMs. HMMs are a useful class of probabilistic models with different inductive biases, performance characteristics, and conditional independence structure than RNNs. Future work includes using these approaches to induce model structure, develop accurate models with better interpretability, and to apply these approaches in lower data regimes.

---

[6] Buys et al. (2018) only report validation perplexity for the HMM and HMM+RNN models, so we compare accordingly.

A Appendices

A.1 Brown Clustering

Brown clustering is an agglomerative clustering approach (Brown et al., 1992; Liang, 2005) that assigns every token type a single cluster. The Brown clustering model aims to find an HMM that maximizes the likelihood of an observed corpora under the constraint that every token type can only be emit by a single latent class. The cluster for the word is given by the latent class that emits that token type.

Clusters are initialized by assigning every token type a unique latent state in an HMM. States are then merged iteratively until a desired number M is reached. Liang (2005) propose an algorithm that chooses a pair of states to merge at every iteration based on state bigram statistics within a window.

A.2 Hyperparameters

For PENN TREEBANK and WIKITEXT-2, we trained the following baselines: a two layer FF 256-dim 5-gram model and a two layer 256-dim LSTM. The FF model is given by the following:

$$p(w_t \mid \mathbf{w}_{<t}) = W_x \text{ReLU}(W_h \mathbf{E}_w(\mathbf{w}_{t-4:t-1})) \tag{6}$$

where $\mathbf{E}_w$ gives the word embeddings, $W_h \in \mathbb{R}^{h \times 4h}$, and $W_x \in \mathbb{R}^{|\mathcal{X}| \times h}$ is weight-tied to the word embeddings. The LSTM model is given by:

$$p(w_t \mid \mathbf{w}_{<t}) = W_x \text{LSTM}(\mathbf{E}_w(\mathbf{w}_{<t})) \tag{7}$$

with a 2-layer LSTM that has weight-tied W_x and $\mathbf{E}_w$.

For the (5-gram) FF model we use a batch size of 128 and a bptt length of 64, as we found the model needed a larger batch size to achieve decent performance. For the LSTM, we use a batch size of 16 and a BPTT length of 32. For both baseline models we use AdamW (Loshchilov and Hutter, 2017) with a learning rate of 1e-3 and a dropout rate of 0.3 on the activations in the model. Both models use a hidden dimension of $h = 256$ throughout. These same hyperparameters were applied on both PENN TREEBANK and WIKITEXT-2.

For the HMMs we use a batch size of 16 and a BPTT length of 32. We use state dropout with rate $\lambda = 0.5$. We reset the state distribution to $p(z_1 \mid z_0)$ after encountering the EOS symbol. We use AdamW (Loshchilov and Hutter, 2017) with a learning rate of 1e-2 for PENN TREEBANK, and a learning rate of 1e-3 for WIKITEXT-2.

All weights are initialized with the Kaiming uniform initialization. The FF model was trained for 100 epochs, while all other models were trained for 50. Validation likelihood was checked 4 times per epoch, and learning rates were decayed by a factor of 4 if the validation performance did not improve after 8 consecutive checks.

Hyperparameter search was performed manually, using the best validation perplexity achieved in a run. Bounds:

1. Learning rate $\in \{0.0001, 0.001, 0.01, 0.1\}$
2. Dropout $\lambda \in \{0, 0.25, 0.5, 0.75\}$
3. Hidden dimension $h \in \{128, 256, 512\}$
4. Batch size $\in \{16, 32, 64, 128\}$

Experiments were run on RTX 2080 GPUs.

On PTB the FF model takes 3s per epoch, the LSTM 23s, and the VLHMM 2^{15} 433s. The inference for VLHMM was not heavily optimized, and uses a kernel produced by TVM (Chen et al., 2018) for computing gradients through marginal inference.

A.3 HMM Parameterization

Let $\mathbf{E}, \mathbf{D} \in \mathbb{R}^{v \times h}$ be an embedding matrix and a matrix of the same size, where v is the size of the vocab and h the hidden dimension. We use the following residual network as our MLP:

$$\begin{aligned} f_i(\mathbf{E}) &= g_i(\text{ReLU}(\mathbf{E}W_{i1})) \\ g_i(\mathbf{D}) &= \text{LayerNorm}(\text{ReLU}(\mathbf{D}W_{i2}) + \mathbf{D}) \end{aligned} \tag{8}$$

Constraint	$\lvert\mathcal{Z}\rvert$	k	M	Val PPL
Brown	16384	512	32	137
Brown	16384	256	64	138
Brown	16384	128	128	134
Brown	16384	64	256	136
None	1024	-	-	180
Brown	1024	256	4	182
Brown	1024	128	8	194
Uniform	8192	128	-	150
Brown	8192	128	64	142
Uniform	16384	128	-	146
Brown	16384	128	128	136

Table 3: Emission constraint ablations on PENN TREEBANK. $\lvert\mathcal{Z}\rvert$ is the size of the hidden space, k is the size number of hidden states in each block, and M is the number of blocks.

with $i \in \{\text{out}, \text{in}, \text{emit}\}$, $W_{i1}, W_{i2} \in \mathbb{R}^{h \times h}$. The state embeddings are then obtained by

$$\begin{aligned} \mathbf{H}_{\text{out}} &= f_{\text{out}}(\mathbf{E}_z) \\ \mathbf{H}_{\text{in}} &= f_{\text{in}}(\mathbf{E}_z) \\ \mathbf{H}_{\text{emit}} &= f_{\text{emit}}(\mathbf{E}_z) \end{aligned} \tag{9}$$

In order to reduce the number of parameters further, we experiment with factored state embeddings. We factor the state embeddings into a composition of smaller steate embeddings ($\mathbf{E}'_z \in \mathbb{R}^{\lvert\mathcal{Z}\rvert \times h/2}$) as well as block embeddings ($\mathbf{E}_m \in \mathbb{R}^{\lvert\mathcal{Z}\rvert \times h/2}$), which are shared across all states within the same emission block, i.e. all $z \in \mathcal{Z}_x$ share a block embedding. To compose these embeddings, we introduce new residual networks $f_j, j \in \{o, i, e\}$ similar to the above, yielding

$$\begin{aligned} \mathbf{H}_{\text{out}} &= f_{\text{out}}(f_o([\mathbf{E}_m, \mathbf{E}'_z])) \\ \mathbf{H}_{\text{in}} &= f_{\text{in}}(f_i([\mathbf{E}_m, \mathbf{E}'_z])) \\ \mathbf{H}_{\text{emit}} &= f_{\text{emit}}(f_e([\mathbf{E}_m, \mathbf{E}'_z])) \end{aligned} \tag{10}$$

We ablate the factored state embeddings in Sec. A.5.

A.4 Emission Constraint Ablation

Table 3 shows the results from emission constraint ablations. With a VL-HMM that has $\lvert\mathcal{Z}\rvert = 2^{14}$ states, the model is insensitive to the number of blocks M explorable given computational constraints. However, with fewer states $\lvert\mathcal{Z}\rvert = 2^{10}$ we are able to explore a lower number of blocks. With $M = 4$ blocks, the block-sparse HMM matches an unconstrained HMM with the same number of states. When $M = 8$, the block-sparse model underperforms, implying there may be room for improvement with the larger HMMs that use $M > 8$ blocks.

We additionally compare the blocks induced by Brown clustering with a uniform constraint that samples subsets of states of size n independently and uniformly from $\mathcal{Z}$. This does not admit a partitioning, which makes it difficult to apply state dropout. We therefore zero out half of the columns of the transition matrix randomly before normalization. In the bottom of Table 3, we find that models with uniform constraints are consistently outperformed by models with Brown cluster constraints as measured by validation perplexity. The models with uniform constraints also have poor validation performance despite better training performance, a symptom of overfitting.

These ablations demonstrate that the constraints based on Brown clusters used in this work may not be optimal, motivating future work that learns sparsity structure.

A.5 Factored State Representation Ablation

We examine the effect of factoring state representations into block embeddings and independent state embeddings. The results of the factored state ablation are in Figure 4. We find that the performance of independent state embeddings with is similar to a model with factored embeddings, but performs slightly worse in perplexity.

In Table 4 we see that although the factored state embeddings reduce the total number of parameters, the computation time and perplexity both get worse.

A.6 Computational Considerations

We reproduce the technique ablation table in Table 4 for reference. As we remove neural components, the number of parameters increases but the time of the forward pass decreases. This is because generating parameters from a neural network takes strictly more time than having those parameters available.

When block embeddings are removed and the full state representations are directly parameterized,

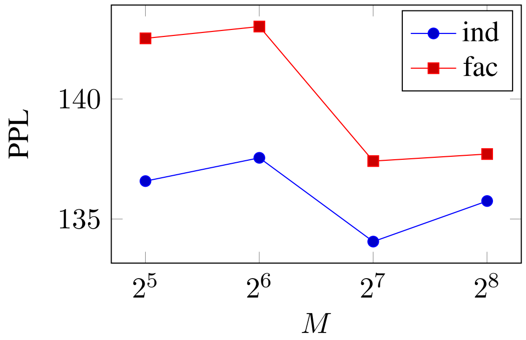

Figure 4: Perplexity on PTB by number of blocks M ($\lambda = 0.5$ and $|\mathcal{Z}| = 2^{14}$). The independent embeddings (ind) represent state embeddings by directly parameterizing $\mathbf{E}_z$, while the factored embeddings (fac) compose a smaller state embeddings matrix with block embeddings.

Model	Param	Train	Val	Time
VL-HMM (2^{14})	7.2M	115	134	40
- neural param	423M	119	169	14
- dropout	7.2M	88	157	100
+ block emb	5.6M	122	136	48

Table 4: Ablations on PTB ($\lambda = 0.5$ and $M = 128$). Param is the number of parameters, while train and val give the corresponding perplexities. Time is ms per eval batch (Run on RTX 2080).

the model is faster due to not needing to recompute the full state representations. This contrast is even more pronounced when removing neural components altogether and using a scalar parameterization, with an almost 3x speedup. This is because the distributional parameters do not need to be regenerated by a neural network if they are parameterized directly.

Coding Textual Inputs Boosts the Accuracy of Neural Networks

Abstract

Natural Language Processing (NLP) tasks are usually performed word by word on textual inputs. We can use arbitrary symbols to represent the linguistic meaning of a word and use these symbols as inputs. As "alternatives" to a text representation, we introduce Soundex, MetaPhone, NYSIIS, logogram to NLP, and develop fixed-output-length coding and its extension using Huffman coding. Each of those codings combines different character/digital sequences and constructs a new vocabulary based on codewords. We find that the integration of those codewords with text provides more reliable inputs to Neural-Network-based NLP systems through redundancy than text-alone inputs. Experiments demonstrate that our approach outperforms the state-of-the-art models on the application of machine translation, language modeling, and part-of-speech tagging. The source code is available at https://github.com/abdulrafae/coding_nmt.

1 Introduction

We introduce novel coding schemes on the inputs of Neural-Network-based Natural Language Processing (NN-NLP) that significantly boost the accuracy in three applications. The inputs of NN-NLP rely on observable forms of mental representations of linguistic expressions, and allow alternative designs. For example, both logographic kanji and syllabic kana represent Japanese words, and emoticons and emojis can express sentiments. These showcase that alternative human language representation than text is possible and highlight a common belief of most linguists: the relationship between the mental representations and their phonological forms is highly arbitrary, even though a non-arbitrary (de Saussure, 1916) mapping exists for some special cases, e.g., the bouba/kiki effect.

In our work, we ask – *Are there alternative forms* of mental representation in addition to text as we see in Japanese and Internet language *to help language understanding in NN-NLP?*

To answer this question, we blend concepts from linguistic phonetics, grammatology, and the statistics of Zipf law to find alternative language representations to text. More precisely, we code a textual word either naturally or artificially by exploring different facets of human languages, from phonetic and logogram codings to new coding constructions generalizable to all languages. Natural codings inspire the finding of artificial codings, which in turn helps us understand and explain natural codings.

All of our codings reinforce NLP inputs by reconstructing the character/symbol sequence of a word in various ways with a new alphabet. These variants and their "decomposition" are expressive because they contain insightful information about linguistic patterns in units smaller than words and even smaller than characters. For example, in the logogram Wubi (that lists in a coded form the strokes caligraphing a Chinese character), "众" (crowd) is coded as "www", which is made of three "人" (person, "w"), and "从" (follow, "ww") is a composition of two "人". A representation containing such granular details potentially reveals the semantic structure and linguistic meanings inside a word, thus enriching text and allowing a redundancy that ensures more reliable NLP inputs.

Now that we have put our previous question in context let us give an overview of how we incorporate coding schemes into an NLP framework in Figure 1. For an input sentence, we apply an alternative coding scheme word by word, then use Byte-Pair-Encoding (BPE) to recombine these symbols (to shorten the input lengths), and finally perform embeddings (EMD). In contrast to word em-

November 16–20, 2020.

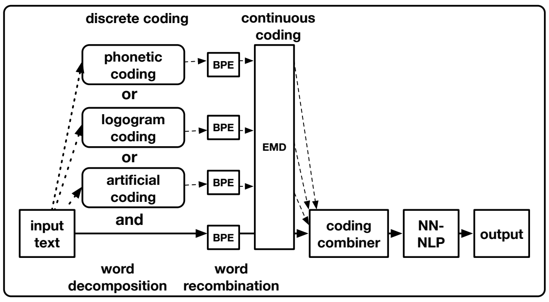

Figure 1: Workflow on how to apply discrete coding in NN-NLP by decomposing (phonetic, logogram, fix-output-length, or Huffman coding) and recombining (BPE) words.

beddings that map words to real number vectors, our coding range is discrete. The coded sentence and its original textual input are then combined in three ways: concatenation, linear-interpolation at the encoder level, and multi-source encoding with or without Bi-LSTM, attention, and multi-head attention. The combined input is fed into NN-NLP models as a black-box to decode outputs. Our approach is language-, task-, and system-independent and does not use any additional information besides our algorithms.

We conduct experiments on three NLP applications and five languages, including (1) Machine Translation (MT) on English-German, German-English, English-French, French-English, and Chinese-English; (2) Language Modeling (LM) on English; and (3) Part-of-Speech (POS) Tagging on English. Our approach significantly and consistently improves over state-of-the-art neural models: Transformer, ConvS2S, XLM, and Bi-LSTM with attention mechanisms.

In summary, our contribution mainly lies in the three consecutive folds:

1. *Phonetic, logogram, and artificial codings.* We introduce a variety of language representations by coding words through various schemes of Soundex, NYSIIS, Metaphone, Pinyin, Wubi, fixed-output-length, and Huffman codings, and propose different ways to incorporate them in NLP models. (§2)
2. *Synergistic coding.* We introduce effective ways of combining the textual inputs and their codewords with the state-of-the-art neural network architectures: concatenation, linear-interpolated encoder, and multi-source encoding with or without Bi-LSTM, attention, and multi-head attention. (§3)
3. *NLP Applications.* Our method is generalizable to different languages and can be applied to any NN-NLP system. Experiments demonstrate that our methods improve over the state-of-the-art models (Transformer, XLM, and ConvS2S) on various tasks in applications including machine translation, language modeling, and part-of-speech tagging. (§4)

2 Coding Words

We view each coding as a function γ that maps a textual word from $x \in \mathbb{V}$, a natural language vocabulary, into a codeword $\gamma(x) \in \mathcal{V}$, a codeword vocabulary:

$$\gamma : \mathbb{V} \rightarrow \mathcal{V} \tag{1}$$

For simplicity of exposition we will consider $\mathcal{V}$ to be the image of $\mathbb{V}$ under γ. Each codeword $\gamma(x)$ is a non-empty σ-string over the alphabet Σ of this coding: $\gamma(x) = \sigma_1, \sigma_2, \sigma_3 \cdots \sigma_L$ with code length L. Σ^+ is an infinite set of all possible non-empty strings over Σ, and $\mathcal{V} \subseteq \Sigma^+$.

As an example (albeit one which is practically not useful) consider the mapping of four English words to three binary codewords: $\mathbb{V} = \{\text{“to”}, \text{“be”}, \text{“or”}, \text{“not”}\}$, $\Sigma = \{0, 1\}$, $\Sigma^+ = \{0, 1, 00, 01, 10, 11, \cdots\}$, $\mathcal{V} = \{00, 01, 11\}$, $L = 2$, $\gamma(\text{“to”}) = 00, \gamma(\text{“be”}) = 01, \gamma(\text{“or”}) = 11, \gamma(\text{“not”}) = 01$, $|\mathbb{V}| = 4$, and $|\mathcal{V}| = 3$.

To instantiate this function, we start by introducing several existing linguistically-motivated coding schemes (and later on we will extend this to new coding schemes we develop): the phonetic and logogram coding as surjective functions, where in particular $|\mathbb{V}| \geq |\mathcal{V}|$; and the fixed-output-length and Huffman coding as bijections, where $|\mathbb{V}| = |\mathcal{V}|$. In traditional coding theory, a compression code has to be injective in order to be uniquely decodable. In our work, we only care about the task-specific prediction and not in decoding the original message. Therefore, we relax the injective restriction on the codings to deviate a little from the standard typical coding theory applications for technical convenience.

Throughout this paper, we choose to name the function γ as “coding” (although sometimes it is also called “encoding”) to distinguish from the encoder in the NN-NLP models. An overview of our coding schemes is illustrated in Figure 2.

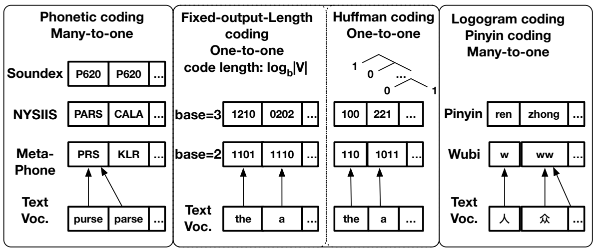

Figure 2: Examples on different coding schemes. In contrast to Pinyin only applies to Chinese, the logogram coding Wubi and its variant apply to Japanese Kanji and Chinese. Furthermore, phonetic codings, including MetaPhone, Soundex, and NYSIIS, cover most western languages. Finally, the artificial codings, i.e., the fixed-output-length and Huffman coding, can be applied to any language. Phonetic and logogram codings are many-to-one mappings, while fixed-output-length and Huffman coding are one-to-one mappings.

2.1 Phonetic Coding

We introduce three phonetic codings: Soundex, NYSIIS, MetaPhone (and Pinyin just for comparison). A phonetic algorithm (coding) is an algorithm to index words by their pronunciation and produce the corresponding phonetic-phonological representations so that expressions, or sentences can be pronounced by the speaker. The phonetic form takes surface structure as its inputs and outputs an audible, pronounced sentence. Below are the detail of each phonetic coding listed:

Soundex is a widely known phonetic algorithm for indexing names by sound and avoids misspelling and alternative spelling problems. It maps homophones to the same representation despite minor differences in spelling (Russel, 1918). Continental European family names share the 26 letters (A to Z) in English.

NYSIIS (the New York State Identification and Intelligence System Phonetic Code) is a phonetic algorithm devised in 1970 (Rajkovic and Jankovic, 2007). It takes special care to handle phonemes that occur in European and Hispanic surnames by adding rules to Soundex.

Metaphone is another algorithm (Philips, 1990) that improves on earlier systems such as Soundex and NYSIIS. The Metaphone algorithm is significantly more complicated than previous ones because it includes special rules for handling spelling inconsistencies and for looking at combinations of consonants in addition to some vowels.

Hanyu Pinyin (or Pinyin for short) is the official romanization system for Standard Chinese in mainland China. Pinyin, which means "spelled sound", was originally developed to teach Mandarin. One Pinyin corresponds to multiple Chinese characters. One Chinese word is usually composed of one or more Chinese characters.

2.2 Logogram Coding

A logogram or logograph is a written character that represents a word or phrase. We introduce to use Wubi for Chinese characters.

Wubi Wubizixing (or Wubi for short) is a Chinese character input method primarily used to input Chinese text with a keyboard efficiently. It decomposes a character based on its structure rather than its pronunciation. It is named after the rule that every character can be written with at most 4 keystrokes including -, |, 丿, hook, and 丶 with various combinations.

2.3 Zipf Law-Motivated Artificial Coding

Zipf (1935) made a key observation of human lexical systems: more frequent words tend to be shorter. This feature enables speakers to minimize articulatory effort by shortening the averaged word length in use. Modern work confirms Zipf's original observation with new refinements in illustrating key factors revealed by word frequency. In this work, we introduce artificial coding by diversifying word length to two extremes: (1) optimizing the *averaged* length to make it the shortest and (2) fixing the length of every word to make them equal. The method of fixing the output codeword lengths without optimization brings more diversity to the standard textual representations.

Fixed-Output-Length Coding Given a vocabulary $\mathbb{V}$ of size $|\mathbb{V}|$ in any language, we convert each word in the vocabulary into a codeword, which is a sequence of symbols. All unique symbols make up the alphabet. The alphabet size is the base b, a parameter controlling the code length. Each word is mapped to a sequence of L symbols, where $L = \lceil \log_b^{|\mathbb{V}|} \rceil$. If $b = 2$ an example of a codeword is "01011", whereas for $b = 3$ another example is "0201".

The mapping (conversion) from a word in the textual form into a codeword follows Algorithm 1. Firstly, we generate all possible codewords of length L. The new codeword alphabet Σ can be a

Algorithm 1 Fixed-Output-Length Coding

Input: A word sequence
Parameter: base b
Output: A code sequence

```
$L = \lceil \log_b^{|\mathbb{V}|} \rceil$ where $|\mathbb{V}|$ is the vocabulary size of the input word sequences, $L$ is the code length, and $b$ is the parameter of the alphabet size.
Generate all possible $L$-long code.
Shuffle the vocabulary words and assign one-to-one mapping between each word and the code.
for word in vocabulary do
    Output its mapped code
end for
return
```

subset of the Latin alphabets (if $b \leq 26$) or that of decimal numbers (if $b \leq 10$), for instance. Then, we uniform randomly assign each word x in the vocabulary V to a unique codeword $\gamma(x)$ with length L. This assignment is a one-to-one random mapping. A random function is completely irrelevant to noisy inputs.[1] Each word (in the text form) in a sentence will be replaced by its codeword. The coding of a word never changes regardless of the number of times it occurs in the NLP system.

Huffman Coding We consider Huffman coding (Huffman, 1952), a length-wise optimal prefix code with variable lengths, by applying Huffman coding on the fixed-output-length coding of the text input with its parameter base b. The fixed-output-length coding is random and should be incompressible with significant probability. Therefore, the Huffman coding does not significantly improve the fixed-output-length coding with respect to the machine translation accuracy, because it saves (at best) an additive constant. Algorithm 2 shows the conversion of Huffman codes.

Algorithm 2 Huffman Coding

Input: A word sequence
Parameter: base b
Output: A code sequence

```
Create huffman tree on the word sequence having $b$ children at each level
Shuffle the vocabulary words and assign one-to-one mapping between each word and the code.
for word in vocabulary do
    Output its mapped code
end for
return
```

3 Coding Combination

Below, we will discuss how to incorporate various types of codings in NLP tasks. Firstly, we code each word independently. Then, the word embedding (Mikolov et al., 2013) is trained on code- and word-based sentences separately. After that, we treat this new form of sentence representation and its written text form as two source inputs to the encoder and feed their combination into a baseline NN-NLP system. Thus, our coding is realized as a portable module that provides inputs to any NN architecture. We introduce three different combination methods to implement the interface of our coding module to various NN architectures.

We implement the combination of the text and the code forms in three ways: (1) concatenation (see Figure 3a); (2) linear interpolation (see Figure 3b), where the dark color boxes have the operation of "+"; (3) multi-source encoding on Bi-LSTM (see Figure 3b), as well as on Transformer (see Figure 3c). It is worth noting that there is no additional data or information needed except for our coding algorithms themselves.

3.1 Concatenation

Applying a coding function in Equation 1 on each word $x_1, x_2, x_3, \cdots, x_i, \cdots, x_{I'}$ in an input sentence one-by-one generates a sequence of codewords $\gamma(x_1), \gamma(x_2), \gamma(x_3), \cdots, \gamma(x_i), \cdots, \gamma(x_{I'})$ in the same length I'. Note that we use the term "word" loosely here, which can mean a word or a subword, or even a character.

The first combination method is concatenating two input sources. We apply the Byte-Pair-Encoding (Sennrich et al., 2015) (BPE) and

---

[1] A random mapping does not mean that every time we see a word we output a random value. It means that the mapping as a whole is chosen at random. Here is an example on their difference: if we want to assign a random bit string of length 2 to the word "hello" then in an article, the first time we see "hello" we may output 01 the second time 11 and so on. However, if instead of assigning i.i.d. random values we choose a random mapping γ, then the first time we evaluate "hello" with γ("hello")= 01, we will get a uniformly random value 01, but in every subsequent time in the article we evaluate the same word "hello" and get the same 01 value (the mapping γ is random, and is sampled at random but only once throughout its lifetime).

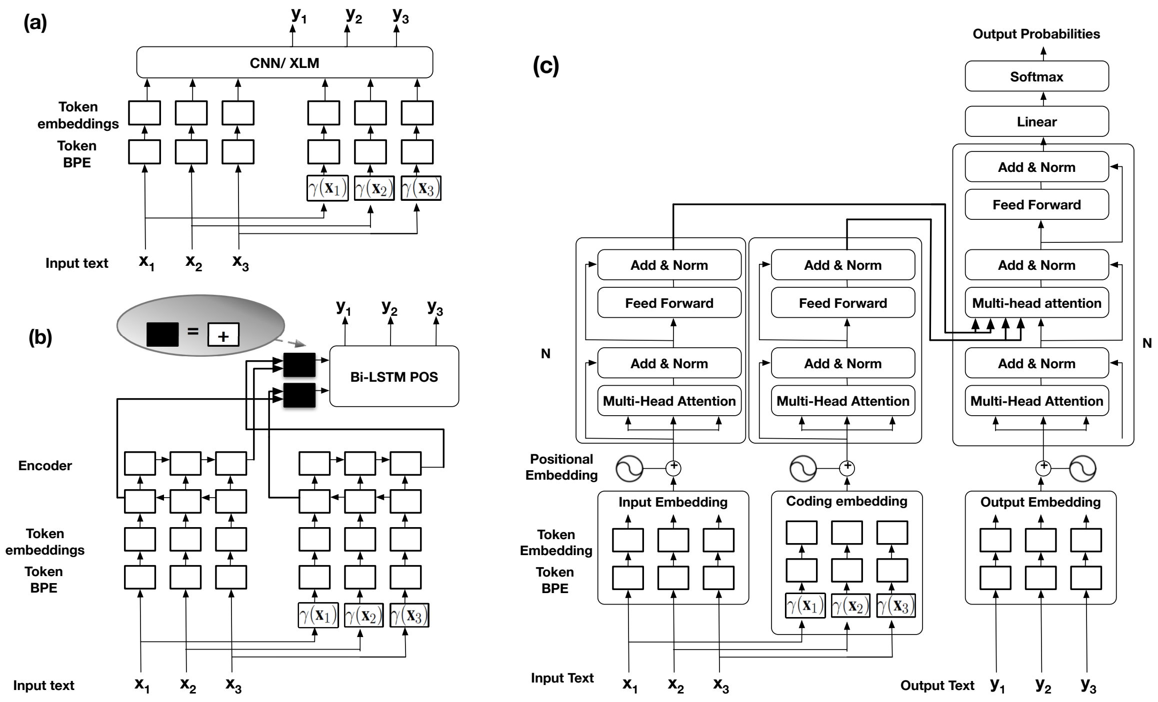

Figure 3: Combination methods for different NN architectures: (a) concatenation for ConvS2S and XLM; (b) linear interpolation and multi-source encoding for Bi-LSTM with attention; (c) multi-source encoding for Transformer.

word embeddings implemented by Řehůřek and Sojka (2010) on each word $\epsilon(x)$ and its codeword $\epsilon_\gamma(\gamma(x))$. We separately train word embedding on code- and textual sentences. Thus, $\epsilon_\gamma(\cdot)$ and $\epsilon(\cdot)$ are different functions. As shown in Figure 3a, the input to the NLP system is the embedded words of a sentence, $\tilde{\epsilon}(x_1), \tilde{\epsilon}(x_2), \tilde{\epsilon}(x_3), \cdots, \tilde{\epsilon}(x_i), \cdots, \tilde{\epsilon}(x_I)$, where $\tilde{\epsilon}(x_i)$ is the concatenation of the embedded word $\epsilon(x_i)$ and its codeword $\epsilon_\gamma(\gamma(x_i))$:

$$\tilde{\epsilon}(x_i) = [\epsilon(x_i); \epsilon_\gamma(\gamma(x_i))] \tag{2}$$

3.2 Linear Combination

The concatenation method merges two input sources and train one encoder for both. However, it may be beneficial to have textual and codeword embeddings and encoders trained separately, because they have different vocabularies. Then, those two encoders are combined linearly, a widely applied model combination technique. The input to the linear combiner is the encoded sentence, represented by a sequence of hidden states $\tilde{h^1}(\epsilon(x_I)), \cdots, \tilde{h^j}(\epsilon(x_I)), \cdots, \tilde{h^J}(\epsilon(x_I))$ of the last position I in each of the encoder layer $j \in [1, 2, \cdots, J]$. J is the number of nodes at each decoder layer. Recall that each hidden state is a real vector $\mathbb{R}^d$, and that is why we can use the vector space operations such as addition on it. For convenience, we denote the last hidden state of the j-th encoder layer that we take as the input to the decoder, $\tilde{h^j}(\epsilon(x_I))$, by $\tilde{h}^j_I$, the last hidden state of the j-th encoder layer of the original textual sentence $h^j(\epsilon(x_I))$ by h^j_I, and the last hidden state of the j-th encoder layer of the code-based sentence $h^j(\epsilon_\gamma(\gamma(x_I)))$ by $h_\gamma{}^j_I$. The combined encoder hidden state $\tilde{h^j}$ is a linear interpolation of the hidden states of the textural input and its codeword input:

$$\tilde{h^j} = (1-\alpha)h^j_I + \alpha h_\gamma{}^j_I \tag{3}$$

As shown in Figure (3b), the combined last hidden state in each layer is fed into the baseline decoder. The black blocks contains only the operator of $+$, as shown in the gray ellipse. α is the encoder weight of the coded sentence, and here, $\alpha = 0.5$.

3.3 Multi-Source Encoding.

In the linear combination method, the weight α is shared among all states in one encoder. To allow different weights for each state, we implement variations of multi-source encoding by Zoph and Knight (2016) for the POS tagging model (Joshi, 2018) (see Figure 3b). The combined hidden state $\tilde{h^j}$ in a layer j is a non-linear transformation of the concatenation of word-based and code-based hidden states of the last position I in layer j multiplied by the weight W_c

$$\tilde{h}^j = \tanh(W_c[h_I^j; h_{\gamma I}^j]). \quad (4)$$

Bi-LSTM In Bi-LSTM decoder, the cell state c of an encoder is a concatenation of the forward and backward cell states. The combined cell state $\tilde{c}$ is the sum of the word-based c and code-based c_γ encoder's cell states

$$\tilde{c} = c + c\gamma. \quad (5)$$

Single-head Attention The attention model looks at both word-based and code-based encoders simultaneously. A context vector from each source encoder c_t and $c_{\gamma t}$ is created instead of the just c_t in the single-source attention model. Hidden states from the top decoder layer looks back at previous hidden states $\tilde{h_{t-1}}$ and the context vectors of the encoders:

$$\tilde{h_t} = \tanh(W_c[\tilde{h_{t-1}}; c_t; c_{\gamma t}]) \quad (6)$$

Multi-head Attention Multi-head attention allows the model to jointly attend to information from different representation subspaces at different positions. We apply the Fairseq (Ott et al., 2019) implementation of Multilingual Translation in Transformer (Vaswani et al., 2017) treating text and codewords as two language inputs. The multilingual transformer trains on two encoders in turn iteratively. For example, in the first epoch it trains the textual encoder then trains the codeword encoder; in the second epoch, it trains again the textual then the codeword encoder, and so on.

4 NLP Applications

4.1 Combination Methods

NMT We improve over two state-of-the-art Neural Machine Translation (NMT) baselines: the Convolutional Sequence to Sequence Learning (ConvS2S) by Gehring et al. (2017) and the Transformer by Vaswani et al. (2017). On ConvS2S, we concatenate (+) the input sentence with its coded sentence using the method in § 3.1 illustrated in Figure 3a. On the Transformer baseline, we combine the input sentence with the encoded sentence using "multi-head attention" as described in § 3.3 and illustrated in Figure 3c.

LM For Neural Language Modeling, we treat the text sentence as one language and the coded sentence as another language and combine them with the cross-lingual Language model (XLM; Lample and Conneau, 2019) using the toolkit introduced in Ott et al. (2019). The combination method is in § 3.1 and Figure 3a.

POS tagging We implement linear combination illustrated in Figure 3b (with the gray area) and non-linear multi-encoders that are described in Equations (4) to (6) and Figure 3b (without the gray area). The input to the multi-encoder is the text and coded sentences, and its output is directly fed into the POS tagger. For the linear combined encoder, we element-wise linearly interpolate the text encoding vector and the code coding vector, each trained separately. For example, the subscript "0.5" indicates an interpolation with equal weights.

4.2 Application 1: Machine Translation

Tasks and Languages. We verify our approaches on three MT tasks (datasets): WMT'14 (WMT, 2014), WMT'18 (WMT, 2018), and IWSLT'17 (IWSLT, 2017)). We carry out experiments for different translation directions: English to French (EN-FR), French to English (FR-EN), English to German (EN-DE), German to English (DE-EN), and Chinese to English (ZH-EN).

Table 2: Vocabulary size [K] of WMT'14 News (EN-DE) and WMT'18 Bio (EN-FR) before and after applying BPE with different codings.

WMT'14 and WMT'18 We conduct experiments on WMT'14 News English-German dataset, which contains around *4.6 million* sentences before pre-processing. We also conduct experiments

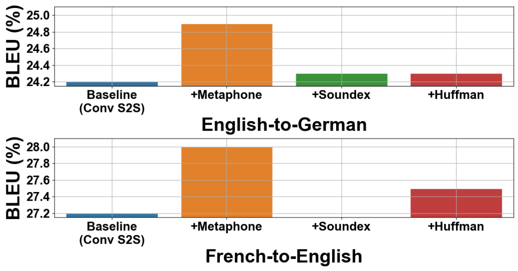

Figure 4: Translation results in BLEU[%] on WMT'14 News and WMT'18 Bio task. BPE operations: $32k$. Baseline is (Gehring et al., 2017) on words. In this paper, we denote baselines for all experiments on all tasks with their names, referring to standard textual word inputs. Systems by adding the codeword inputs on baselines are denoted as "+..".

on English-French dataset forn WMT'18 Biomedical Task that contains around *2.8 million* sentences. Table 1 shows vocabulary statistics on the source/target of the training data before and after applying codings. We use Moses tokenizer and restrict 250 characters per sentence and 1.5 length ratio between source and target sentences as a filter in pre-processing. The Byte-pair encoding model is jointly trained on the source textual word inputs, codeword inputs, and target outputs for French and German systems, and separately trained on the source and target for Chinese systems. We applied concatenation for ConvS2S baselines and multi-source encoding for transformer baselines in all tasks, respectively. For ConvS2S we set the embedding dimension as 512, the learning rate as 0.25, the gradient clipping as 0.1, the dropout ratio as 0.2, and the optimizer as NAG. For transformer, we set the embedding dimension as 512, the learning rate as 0.0005, the minimum learning rate as 10^{-9}, the warmup learning rate as 10^{-7}, the optimizer batas as 0.9 and 0.98 for adam optimizer, the dropout ratio as 0.3, the weight decay as 0.0001, the shared decoders and shared decoder embedding as true. The training is terminated until the validation loss does not decrease for five consecutive epochs. We compute the BLEU score using *sacrebleu*.

As shown in Figure 4, on WMT'18 we achieve an improvement of +0.7 BLEU points for English-German and +0.8 BLEU points for French-English, respectively. Some phonetic coding may be more suitable for certain languages than others. Metaphone works best for English because it handles spelling variations and inconsistencies. According to its orthography, the German spelling is largely phonetic (unlike English spelling), thus adding phonetics does not help much in DE-EN NMT.

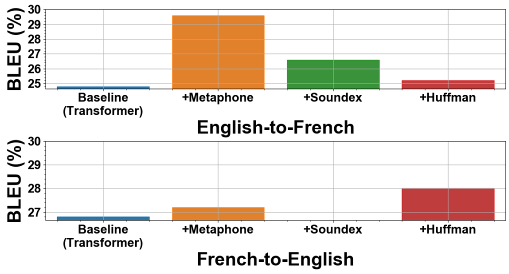

Figure 5: Translation results in BLEU[%] on small task IWSLT'17. FR-EN & EN-FR. BPE: $16k$. Baseline is (Vaswani et al., 2017) on words. Dev: test2013-2015; Test: test2017.

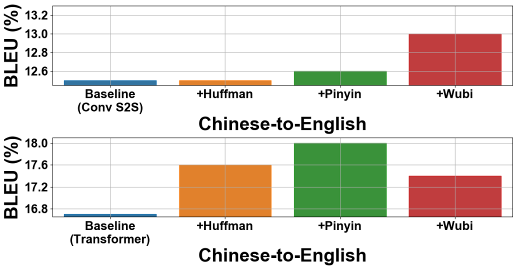

Figure 6: Translation results in BLEU[%] on small task IWSLT'17. ZH-EN. BPE: $16k$. Baselines are (Gehring et al., 2017; Vaswani et al., 2017) on words. Dev: test2010-2015; Test: test2017.

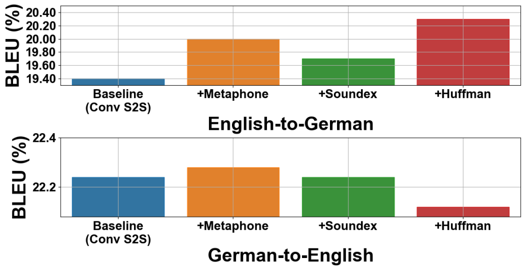

Figure 7: Translation results in BLEU[%] on small task IWSLT'17. DE-EN, EN-DE. BPE: $16k$. Baselines are (Gehring et al., 2017) on words. Dev: test2010-2015; Test: test2017.

IWSLT In IWSLT'17 task, we achieved +5.2 BLEU point on EN-FR and +1.9 BLEU point on FR-EN. We also add Pinyin for Chinese-English translation on IWSLT'17 (IWSLT, 2017) as a supplementary experiment. Adding Wubi also enhances the baseline performance. On the Transformer baseline, we use the codewords as the input source test set during decoding. Note that all experiments are conducted on the real datasets, without using/verifying on any artificial noise anywhere.

Model Complexity. We tune the dropout parameters for conducting the following experiments: *Words* and *W+Metaphone* on IWSLT'17 EN-FR. The drop out value is set by default to 0.2, and the beam-size to 12. Figure 8 shows how translation accuracy changes by varying the dropout value. The highest BLEU score is at a dropout of 0.2 for the baseline and 0.2 and 0.3 in our approach. A higher optimal value of dropout means fewer nodes in the Neural Networks are needed to opt NMT quality. This implies that adding auxiliary inputs will reduce the model complexity.

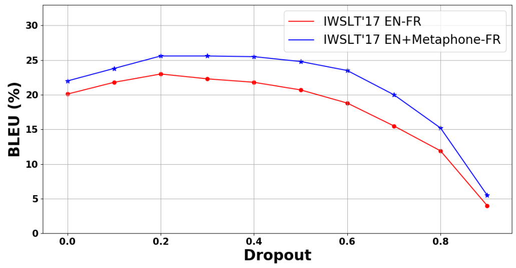

Figure 8: Dropout optimum. x-axis: the dropout value.

Model parameter size. Table 3 shows the change of the parameter size when applying our approaches. Our parameters include weights and biases of neural network models. The parameter size reduces when we concatenate the original inputs with our codewords because the vocabulary size reduces (although the BPE operations stay the same as the baseline). The parameter size increases when we use the multi-source encoding because we added more encoder for the codeword input.

Table 3: Number of model parameters [M] on WMT'14 News, WMT'18 Bio, and IWSLT'17 tasks. Baselines are ConvS2S and Transformer on word input. Systems by adding the codeword inputs on baselines are denoted as "+..".

Training Speed. Table 5 shows the system training time (with BPE $32k$ operations). The total time (in minutes) is listed in the first column, and the number of epochs is in the second. Combining codewords reduces the model complexity. Therefore, the training becomes more efficient and needs a smaller number of epochs to converge. The total training time of our approaches is comparable to that of baselines, sometimes even less.

4.3 Application 2: Language Modeling (LM)

Task and result. We train and evaluate the English part of EN-FR IWSLT'17 dataset and also on English part of EN-DE WMT'14 News dataset. We use 256 embedding dimensions, six layers, and eight heads for efficiency. We set dropouts to 0.1, the learning rate to 0.0001, and BPE operations to $32k$. We used Adam optimizer with betas of 0.9 0.999. As shown in Table 7, adding Metaphone significantly reduces PPL of the baseline system, i.e., 20.1% relatively. "+NYSIIS_WA" indicates the system with NYSIIS but adding word alignments between English and its coded form; see Table 7.

4.4 Application 3: POS Tagging

Task and result We evaluate our approach in POS Tagging on Brown Corpus (Francis and Kucera, 1979). Brown corpus is a well-known

5 Related Work

Previous important work investigated the role of auxiliary information to NLP tasks, such as polysemous word embedding structures by Arora et al. (2016), factored models by García-Martínez et al. (2016), and feature compilation by Sennrich and Haddow (2016). We emphasize that we do not use any additional information besides our algorithms.

Hayes (1996); Johnson et al. (2015) applied explicit phonological rules or constraints to tasks such as word segmentation. In neural networks, we can implicitly learn from phonetic data and leave the networks to discover hidden phonetic features through end-to-end training opt specific NLP tasks, instead of applying hand-coded constraints.

Closely related, but independent to our work, is the character-based MT, such as the work of Ling et al. (2015) and Chung et al. (2016), among many others. We go beyond text level representations and look for novel representations for decompositions, sometimes even smaller than characters.

Different from the inspiring work that uses Pinyin (Du and Way, 2017), skip-ngram (Bojanowski et al., 2017), and Huffman on source/target (Chitnis and DeNero, 2015), our study aims to improve NN-NLP including NMT overall rather than only eliminating unknown words, introducing six new codings into NLP in addition to Pinyin and text. Importantly, our artificial codings apply on all languages. Moreover, we achieve experimental improvements overall. Liu et al. (2018) added Pinyin embedding to robustify NMT against homophone noises. They described that it was unknown why Pinyin also improved predictions on the clean test. This is a very interesting work, and we explain this phenomenon through our theory that *the multi-channel coding offers an ensemble of the code words and the text, making the communication more reliable*.

6 Conclusion

In this paper, we conduct a comprehensive study on how to code textual inputs from multiple linguistically-motivated perspectives and how to integrate alternative language representations into NN-NLP systems. We propose to use Soundex, NYSIIS, MetaPhone, logogram, fixed-output-length, and Huffman codings into NLP and describe how to combine them in state-of-the-art NN architectures, such as Transformer, ConvS2S, Bi-LSTM with attentions. Our paradigm is general for any language and adaptable to various models. We conduct extensive experiments on five languages over six tasks. Our approach appears to be very useful and achieves up to 20.77%, 20%, and 15.79% relative improvements on state-of-the-art models of MT, LM, and POS, respectively.

Learning from Task Descriptions

Abstract

Typically, machine learning systems solve new tasks by training on thousands of examples. In contrast, humans can solve new tasks by reading some instructions, with perhaps an example or two. To take a step toward closing this gap, we introduce a framework for developing NLP systems that solve new tasks after reading their descriptions, synthesizing prior work in this area. We instantiate this framework with a new English language dataset, ZEST, structured for task-oriented evaluation on unseen tasks. Formulating task descriptions as questions, we ensure each is general enough to apply to many possible inputs, thus comprehensively evaluating a model's ability to solve each task. Moreover, the dataset's structure tests specific types of systematic generalization. We find that the state-of-the-art T5 model achieves a score of 12% on ZEST, leaving a significant challenge for NLP researchers.[1]

1 Introduction

The dominant paradigm in supervised NLP today is learning from examples, where machine learning algorithms are trained using a large set of task-specific input-output pairs. In contrast, humans learn to perform the same task by reading a description, after which they are able to perform the task in a zero-shot manner—indeed, this is how crowd-sourced NLP datasets are constructed. In this paper, we argue that learning from task descriptions in this way is a necessary attribute of a general purpose NLP system, and we propose it as a new paradigm to train and test NLP systems.

Recent work in NLP has shown significant progress in learning tasks from examples. Large pretrained language models have dramatically improved performance on standard benchmarks (Peters et al., 2018; Devlin et al., 2019; Raffel et al., 2019) and have shown promising results in zero shot prediction by leveraging their language understanding capabilities (Levy et al., 2017; Zhou et al., 2018; Yin et al., 2019).

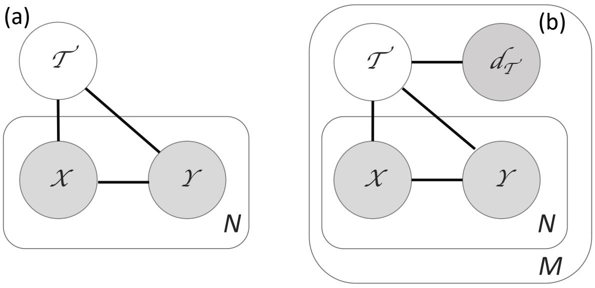

Figure 1: Comparison of (a) supervised learning from examples with observed input X, output Y, corresponding to an unobserved task τ (b) our proposed method of learning from task descriptions where systems can make inferences about unseen tasks τ given a natural language description d_τ.

Despite this progress, there are many serious issues that come with learning from examples. There is an almost infinite number of tasks that a person might wish to solve with a general-purpose NLP system. Learning to solve these tasks by reading a description instead of observing a collection of examples would solve the problem of having to create training sets for each language task. Such a system would also be more accessible to practitioners and domain experts in other fields, who could describe their tasks and solve them, opening up new avenues of research where it is expensive or infeasible to gather training data.

Additionally, we find that current supervised learning techniques partly achieve their success due to memorizing uninteresting aspects of the training distribution (Gururangan et al., 2018; Geva et al., 2019; Gardner et al., 2020). Teaching a system to learn a task from the description alone would alleviate these biases, as new training data would not be needed to learn a novel task.

[1] Data, evaluation code, baseline models, and leaderboard at `https://allenai.org/data/zest`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1361–1375,
November 16–20, 2020.

In this paper, we synthesize prior approaches to zero-shot learning in NLP and provide a formal framework for thinking about the zero-shot prediction problem. We show that previous zero-shot approaches are limited in both scope of application and rigour of evaluation. For example, while prior work has used zero-shot prediction for text classification, entity typing, and relation extraction, we push this to the more complex task of slot filling.

We instantiate our formalism in an English language dataset, ZEST (**ZE**ro **S**hot learning from **T**ask descriptions), that is formatted similarly to reading comprehension datasets, in that we formulate task descriptions as questions and pair them with paragraphs of text. We choose this format as it provides a natural way to crowdsource data. This zero-shot dataset differs from typical reading comprehension datasets, however, in that each task description is paired with twenty different passages, and we evaluate a model's ability to solve the task, not just give the correct answer for a single (question, passage) pair. That is, given a question, a model produces some decision function f, and it is this function which we comprehensively evaluate on many different inputs. We also carefully select axes on which to evaluate the generalization of a model to different kinds of task descriptions, changing task descriptions in specific ways to systematically push the field towards more interesting and complex task descriptions.

We evaluate models based on recent state-of-the-art sequence to sequence architectures, which seem most suited to the task of zero shot prediction in this setting. We find that our best model based on T5 (Raffel et al., 2019) achieves a score of only 12% on this data, leaving a significant gap to our human performance estimate of 42%. Zero shot learning from complex task descriptions remains a significant challenge for current NLP systems.

2 Learning from task descriptions

This section describes our framework for enabling zero-shot generalization to unseen tasks, and relates it to prior work.

2.1 Learning from examples

Consider the supervised learning setting[2] where the goal is to learn a function $y = f_\theta(x)$, with trainable parameters θ, for a particular task. We define the task τ as:

- a definition for the sets of allowable inputs $x \in \mathcal{X}$, outputs $y \in \mathcal{Y}$, and,
- a probability distribution $p_\tau(x, y)$.

In text classification, for example, $\mathcal{X}$ is natural language text and $\mathcal{Y}$ is a categorical label from one of C classes. In the single task setting, the function f is learned by collecting a dataset of labeled examples $\mathcal{D} = \{(x_1, y_1), \dots (x_N, y_N)\}$ sampled from $p_\tau(x, y)$ (see Fig. 1a). We call this "learning from examples". Crucially, once $\mathcal{D}$ is constructed, the underlying task definition is discarded, assumed to be captured in the labeled (x_i, y_i) pairs.

There are many ways to sample from $p_\tau(x, y)$ to create a dataset. One approach, in cases such as language modeling where p_τ is defined by a set of rules, just applies the rules to raw text. Another popular approach uses human annotation. In this case, the most common strategy factorizes $p_\tau(x, y) = p_\tau(y|x)p_\tau(x)$, samples from $p_\tau(x)$ via some method (e.g. collecting text from the domain of interest), and uses a natural language task description, d_τ, to describe $p_\tau(y|x)$. The description is shown to human annotators who use it to compute $\arg\max_{y \in \mathcal{Y}} p(y|x_0)$ for a given x_0.

2.2 Learning from task descriptions

The largest downside to learning from examples is that every new task requires collecting a new dataset to learn a new function $f_\theta(x)$ for the task. This approach also discards the task definition after the labeled dataset is constructed, despite the fact that the task definition carries all of the information necessary for a human to solve the task. Moreover, it holds the task constant at test time (except in certain limited cases, see Sec. 2.4).

Our proposed framework, which we call "learning from task descriptions", removes these restrictions. First, instead of discarding the task definition, we provide a natural language description of it to the model, in addition to the input x. Second, by providing the model with the task description, we expect it to generalize to *unseen tasks* at test time in a zero-shot way.

These modifications shift the learning problem from fitting a probability distribution in the learning from examples approach, to understanding the semantics of a task description in order to apply it

---

[2] This setting also includes popular self-supervised objectives such as autoregressive or masked language modeling.

to a given input in the learning from task descriptions approach. Successfully building a model to perform in this manner would open up a wide range of NLP applications whereby one could simply construct an NLP system by describing the desired output in natural language.

Our proposed framework is illustrated in Fig. 1b. In contrast to learning from examples, we assume the task description d_τ is observed for M different tasks, and that each of these tasks has some number N of observed (x_i, y_i) pairs.

2.3 Task competence

In order to test whether a system can adequately perform an unseen task, we propose a new evaluation metric as follows. Traditional evaluation metrics in supervised learning are averages over instance-level metrics, that is, they perform independent computation on individual (x, y) pairs and aggregate them across a dataset to produce a summary score. As we are interested in assessing whether a model can competently perform a task from its description, we instead first evaluate whether a model can perform each individual task using the entire *set* of (x, y) pairs for a given task, and then report averages over all tasks.

Formally, a dataset with M tasks can be viewed as the concatenation of M different N_j sized datasets, $\mathcal{D}_j = \{(x_1, y_1), \ldots (x_{N_j}, y_{N_j})\}$, one for each task. We assume each task has an associated metric $\mu_j(\mathcal{D}_j, f_\theta) \in \mathbb{R}$, which is used to compute the model performance for task τ_j on $\mathcal{D}_j$ for the model represented by f_θ. For simplicity, we assume each metric is such that larger values indicate better performance[3]. Then, for a given level of competence c_j for task τ_j, we say that the model can perform the task if $\mu_j \geq c_j$. The final model competence metric is the average individual task competence over the dataset, $c = \frac{1}{M}\sum_j \mathbb{1}(\mu_j \geq c_j)$, where $\mathbb{1}$ is the indicator function. In the special case where c_j has the same threshold T for all j, we write "C@T" to represent the competence at T.

As a concrete example of this metric, consider the simple case where all M tasks are binary classification (so that unseen classes correspond to unseen tasks). If we adopt accuracy as the metric for all tasks, and set c_j to 90% for all j then a C@90 of 72% indicates that the model is able to successfully classify unseen inputs x into a set of unseen classes $\mathcal{Y}$ with at least 90% accuracy, for 72% of the unseen tasks τ.

2.4 Discussion

Prior researchers have recognized the limitations of learning from examples, and have worked to address some of them. Our proposed framework builds upon and generalizes much of this work.

Zero-shot learning (Chang et al., 2008; Socher et al., 2013; Norouzi et al., 2013) asks systems to generalize to unseen classes at test time. In this approach, the task is the same at both train and test time—models are only asked to generalize to new classes. In terms of the graphical model in Fig. 1, prior work attaches a natural language description to some new y_i at test time. In contrast, our approach asks models to generalize to entire unseen *tasks*, attaching the natural language description to the task variable τ. Zero-shot learning has been widely adopted including for classification (Dauphin et al., 2013), entity typing (Ma et al., 2016; Zhou et al., 2018) and relation extraction (Levy et al., 2017; Shi and Lin, 2019).

More closely related to our approach are the zero-shot experiments in Radford et al. (2019); Brown et al. (2020) that provide a generative language model with a prompt (that could be viewed as a type of task description) and asks for a completion. This is similar to the observation in Petroni et al. (2019) that it is possible to extract knowledge graph relationships from large language models with an appropriate prompt. ZEST provides a benchmark dataset for systematically measuring how well models can generalize to many tasks in the zero-shot setting.

Multitask learning (Caruana, 1997; Collobert and Weston, 2008) seeks to learn a single model that can solve multiple tasks simultaneously, similar to our framework that seeks to learn a model that can solve many tasks. However, in multitask learning each task is learned from examples, and the model is not able to generalize to unseen tasks. This is also the case for newer control code type approaches (Raffel et al., 2019; Keskar et al., 2019) to multitask learning, where the task is encoded as short string, often containing no information other than a largely meaningless identifier.

There are also connections between our proposed framework and tasks such as natural language inference (NLI) or reading comprehension (RC), where two natural language inputs (a

---

[3] This can be achieved by rescaling if necessary.

premise and a hypothesis for NLI, and a question and passage for RC) are used to predict some output. In our case, we have two observed variables, x and d_τ, which influence the prediction of the output y (Fig. 1). Indeed, the baseline model that we discuss in Section 5 takes a similar approach to NLI and RC and jointly models the two textual inputs. This correspondence has been used in prior work, where Yin et al. (2019) used a model pretrained on MNLI (Williams et al., 2018) to perform zero-shot text classification. A key difference, however, is that hypotheses in NLI and questions in RC are typically only paired with single inputs. In fact, they typically only make sense for a single input, and thus it is hard to characterize these narrow questions as "task descriptions".

Lastly, the problem of learning from task descriptions is fundamentally one of translating a natural language description into some executable function that can operate on arbitrary inputs. This problem has been well-studied for narrow domains in the semantic parsing literature (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011; Andreas et al., 2013), though the input is typically a single static database, not arbitrary natural language text. Attempts to generalize semantic parsing to more open domains are still nascent (Chen et al., 2020; Gupta et al., 2020).

3 Instantiating the Framework

Section 2 showed a framework for training and testing a general purpose system that could perform unseen NLP tasks. An ideal system in this framework would be able to read the descriptions of the tasks in the GLUE suite (Wang et al., 2019) and perform well with no additional training. However, this goal is far beyond the current capabilities of today's models. In order to make progress, we must break down the problem into manageable steps. In this section we outline the scope that we envision for a reasonable NLP-focused dataset that can push forward the current state of learning from task descriptions, without being so challenging as to be out of reach. Sec. 4 describes the data collection process for ZEST, our new English benchmark built following this scope.

To define the scope, we begin by considering the types of applications a model that could successfully learn from task descriptions might enable. The largest bottleneck in building NLP applications today is collecting labeled data. Our framework would eliminate this step, making it possible to build ad hoc NLP applications to easily filter, categorize, or extract structured information from corpora. For example, when planning a camping trip, one might want to know "What are the names of all the campgrounds and their locations?" that are listed in a collection of documents, which specifies an ad hoc request to return all examples of the `located_at` relationship between the `campground` and `location` entity types. Accordingly, it's important to include examples of the basic task building blocks of such a system: classification, typed entity extraction, and relation extraction in a benchmark dataset. In doing so, it would unify the prior work in zero-shot NLP (Sec. 2.4) that has focused on just a single task, and require a single model to be able to handle any of these tasks at test time, instead of separate models for each task.

More concretely, as each task τ defines a set of allowable outputs $y \in \mathcal{Y}$, we can mix multiple output sets $\mathcal{Y}$ in a single dataset as long as the output set is specified in the task description. ZEST includes the most common output sets: discrete classes, lists of (optionally) typed spans from the input, and relationships between spans. Examples of each are shown in Table 1, where it is clear from the task description which output $\mathcal{Y}$ is expected. In addition, we also include the `NA` output (Rajpurkar et al., 2018), signifying that it is not possible to solve the task given the input x. For example, if the task asks a model to extract campground names but the input is an unrelated news article, the output is `NA`. Being able to correctly identify unsolvable tasks is important in a practical setting where it is not reasonable to expect every possible task to be solvable with every possible input.

To move beyond aggregating existing approaches into a single dataset, recall that in our framework observing the task description d_τ in addition to the input x allows us to test a model's generalization relative to four variables: x, y, τ, and d_τ (Fig. 1). Motivated by this observation, we propose an approach that systematically varies the task descriptions and inputs while controlling for other sources of variability in order to test whether a system can generalize in multiple ways. To implement this idea, we begin by collecting a set of task descriptions, d_τ, inputs x, and associated outputs, y. This *base* group of instances already allows us to test performance of unseen tasks on un-

Generalization	Question	Input Passage (shortened)	Answer
Base	Can I hike to a waterfall at this national park?	... Yet here at Whiskeytown NRA, we encourage you to chase waterfalls - go visit them! Whiskeytown has four major waterfalls ...	Yes
Paraphrase	Is there a waterfall to hike to at this national park?	(same as above)	Yes
Semantic Flips	Can I hike to a canyon at this national park?	... descending 1,300 feet (396 m) past a large alcove, the trail meanders in a wide canyon ...	Yes
Composition	What time of year is best to see the popular waterfalls in this national park?	... Two viewing platforms provide the best view of Great Falls. This overlook is the last place that the Falls can be viewed ...	NA
Output Structure	What waterfall hikes are there in this national park and are they wheelchair accessible?	... Bridalveil Fall is often the first waterfall you'll see when entering ... Although paved, this is trail is not wheelchair accessible due to its grade.	[{"waterfall hike":"Bridalveil Fall", "wheelchair accessible": "No"}]

Table 1: Example instances from ZEST. The composition question is combined with "What are the popular tourist spots in this national park?" We chose to format the relation extraction questions as JSON, see Section 5.2 for details.

seen input. We further augment it with four types of controlled generalization: paraphrase, semantic flips, composition, and output structure. Examples of each type of generalization are given in Table 1.

Paraphrase We can test generalization to changes in the task description d_τ while keeping the task τ fixed by paraphrasing the description. By also fixing x, we can use these paraphrases to test whether a model consistently predicts the correct output given the same input and underlying task. As we collect applicable inputs x for a task using a retrieval mechanism given the task description (Section 4), this also adds some lexical distance between the input and the description, to avoid simple lexical shortcuts to solving the task (Gardner et al., 2019).

Semantic flips Closely contrasting examples have long provided an effective means of evaluation in NLP (Levesque et al., 2012; Sennrich, 2017), forcing a model to understand how small changes in inputs correspond to large changes in expected outputs. We take inspiration from this idea to include task description semantic flips, where a given task is modified in a minimal way (e.g. by changing a single word) to semantically change the meaning of the task. As the description is largely unchanged (including the output set $\mathcal{Y}$), this tests whether systems can distinguish between descriptions that are minimally changed.

Composition To further test whether systems can understand a task description, we can compose base tasks into new tasks with operators such as "and" and "or". By examining the performance difference between the base group of tasks and the compositionally generated group of tasks we can estimate the extent to which a system can compose tasks in a novel way.

Output structure We can also test whether models can generalize to unseen structured outputs $y_1 \in \mathcal{Y}$ where y_1 is not seen in the training set. Among the many ways to accomplish this, we chose a method that asks models to produce output equivalent to slot filling or n-ary relationship extraction in the zero-shot setting. In this case, task descriptions correspond to a specification of an output structure that includes typed entity and relationship extraction where the entity types and relationships have not been seen in training.

4 Collecting ZEST

To illustrate our novel way of evaluating and framing the "learning from task descriptions" problem, we provide an empirical demonstration of where current systems fail by collecting a challenge dataset. We hope this will serve as a starting point for making progress towards this goal of learning from descriptions. In this section we describe our annotation efforts, which consist of our design for the dataset, as well as three crowdsourcing steps: collecting tasks (in question form), gathering relevant documents, and annotating answers for the (task, document) pairs.

4.1 Dataset Design

Our dataset consists of base task descriptions which are varied along the four areas of generalization found in Section 3, allowing us to systematically control for generalization across the different base tasks. We collect annotations for approximately 20 different input documents for each task so that we can calculate the competency metric.

The framework described in Section 2.4 applies to any task description, thus, it is agnostic to the specific format. In deciding how to format the task descriptions in ZEST we chose to use a question format for the tasks, as crowdsourcing annotations for questions is well established, and a QA format may potentially allow transfer from existing question answering datasets. We note however, that a declarative task description such as "return a list of hikes in the national park described in the document" fundamentally asks for the same information as the question "what are the hikes in this national park?" As a result, we will use the terms *task description* and *question* interchangeably when discussing our creation of ZEST.

4.2 Task Generation

As each question should apply to numerous documents, we used Mechanical Turk[4] to crowdsource common questions that someone might ask about three different domains: U.S. presidents, dog breeds, and U.S. national parks. We use multiple domains to include diversity in our tasks, choosing domains that have a multitude of entities to which a single question could be applied. Workers were asked to generate questions that could apply to any entity in that domain and we manually removed questions that contained duplicate meanings to maintain a rich semantic space. This left us with approximately 100 base task descriptions for each domain. These tasks were generated before gathering input documents, alleviating biases from having workers who had already seen the input passages.

Statistic	**Train**	**Dev**	**Test**
(task, passage) pairs	10,766	2,280	11,980
Avg. passage words	121	122	122
Number of tasks	538	114	599
Avg. task len [words]	12.3	12.2	11.8
`NA` percent	0.62	0.67	0.62
Classification Percent	0.46	0.49	0.44

Table 2: Summary Statistics for ZEST. Note that `NA` is the most frequent answer.

We split these tasks into 50% test, 40% train, and 10% development. We then employed other workers to alter them along one of the four areas of generalization. For the paraphrase generation, we asked workers to paraphrase the text so that it retained its original meaning but had a different wording. For the semantic flip questions we asked the workers to keep as much of the task description the same as possible, but to make a slight change that would alter the meaning of the task. Composition tasks were created by randomly sampling three tasks from within each dataset split to combine, letting the worker choose two out of the three. Tasks for the output structure were created by expanding the base tasks to include multiple structured sub-tasks, using a custom built UI that automatically compiled workers' responses into JSON format.

Each task description created for a particular area of generalization followed its base task to the corresponding dataset split. Hence the test set contains its own unique base questions as well the derived questions for each area of generalization.

---

[4] We initially opened our crowdsourcing pipeline to the U.S. population on Mechanical Turk that had above a 99% acceptance rate with over 5000 completed HITs, but reduced this pool to only include workers who performed well on initial HITs.

4.3 Passage Retrieval

In order to gather a unique set of passages that pertain to a given question, we used Bing and Google Custom Search engines, focusing the results on a narrow subset of webpages. For U.S. Presidents, our queries were limited to results from Wikipedia pages (for all 45 presidents) as well as information contained on Whitehouse.gov, containing biographies and accomplishments for each President and First Lady. Similarly, we limited our queries of dog breeds to all 524 pages of Dog Breeds on Wikipedia. The U.S. National Park passages were retrieved from sub-pages of the National Parks website. On each of these domains, we ensured that no single entity garnered more than 5% of the total input documents. Details on how we used these search engines to gather the passages can be found in Appendix A and in our code.

4.4 Document Annotations

We paired the gathered task descriptions with their respective passages and employed our expert workers from Mechanical Turk to annotate the answers. We had three workers annotate each (task, document) pair. For the tasks that could be answered with a yes or no response, final answers were chosen by taking the majority answer. For tasks that involved extracting information from the passage, we used the answer that was the subset of the other answers, preferring shorter responses over longer responses. 25,026 (task, input, answer) triples, with a total of 1251 task descriptions split across the three domains. These tasks were distributed as 45% extraction, 45% classification and 10% mixed (due to the output structure tasks). More summary statistics can be found in Table 2. Our annotation costs were approximately 9,000 USD.

5 Establishing a Baseline

This section describes our baseline model results.

5.1 Evaluation

Due to class imbalance, we adopt F1 as the metric when computing the task competency (Sec. 2.3). However, to account for partial overlap between model and gold answers, we modify the precision P and recall R as follows. Each task τ has a number of instances (x_i, y_i). For each instance, we compute a partial overlap score s_i that includes an output-type aware[5] best alignment between the model and gold answers and scores individual elements with a word overlap based method. This is similar to common practice in QA evaluation, extended to handle ZEST's output types. Then, with `NA` as the negative class, we compute $P = \sum_i s_i/m^+$, $R = \sum_i s_i/g^+$ where m^+ and g^+ are the total model predicted positive (not-`NA`) and gold positive instances.

We take each task's F1 score and evaluate the competency metric for each task, reporting these scores in our final results. Additionally, when tasks are closely related we use a more stringent *consistency* metric (Gardner et al., 2020) that computes whether a model is competent in both tasks at the same time. For paraphrases and semantic flips, our C@T metrics only count a model as competent for a task if it is competent for both the base task description and the changed task description. This helps to avoid giving the model credit for artificially simple decision boundaries that only accidentally solve the task.

5.2 Modeling

For baselines, we adopt two recent state-of-the-art models, T5 (Raffel et al., 2019) and BART (Lewis et al., 2020), both because of their positions on top of popular NLP leaderboards and their text-to-text nature. Beyond training on ZEST alone, we also trained T5 using multitask learning (MTL) with a combination of other QA datasets to test transfer to ZEST: BoolQ (Clark et al., 2019), MultiRC (Khashabi et al., 2018), ReCoRD (Zhang et al., 2018), and SQuAD (Rajpurkar et al., 2016).

Data Preprocessing To prepare each task's instances for the model, we prepended "zeroshot question: " to the task description and "zeroshot context: " to the document, then joined these two parts together with whitespace. For output structure generalization, we formatted the answers as JSON to enable more complex zero-shot relation extraction tasks. Thus, the models output answers as both text and JSON, in a seq-to-seq fashion, depending on the question type. When the question calls for JSON, we deserialize and evaluate it, counting deserialization failures as errors. See Appendix B for more on data preprocessing.

Training & Hyper-parameters For T5 11B, our best baseline, training used input and output

---

[5] ZEST includes strings, sets of strings, lists of dicts, and three discrete classes (Yes/No/NA) as valid output types.

	Dev			Test		
	Mean	C@75	C@90	**Mean**	C@75	C@90
BART-large ZEST only	40	13	8	38	11	4
T5-11B ZEST only	56	32	12	55	28	11
T5-11B ZEST w/MTL	56	35	14	56	28	12
Human Estimate				74	61	42

Table 3: Overall performance of baseline models showing the mean F1 and competency at 75% and 90%. Our best model, a T5 model with multi-task learning from other QA datasets (Section 5.2), is only able to perform 12% of unseen tasks at 90% F1, compared to a human estimate of 42% of tasks at 90% competency.

	Dev			Test		
Generalization Type	**Mean**	C@75	C@90	**Mean**	C@75	C@90
Base	71	48	16	63	43	22
Paraphrase	64	36	12	56	32	16
Composition	66	44	22	65	41	15
Semantic Flips	54	27	9	47	18	5
Output Structure	33	20	10	47	10	3
Overall w/MTL	56	35	14	56	28	12

Table 4: Detailed T5-11B results for ZEST with multi-task learning using other QA datasets (Section 5.2).

Input	**Mean**	C@75	C@90
Full data	56	32	12
Question only	12	10	7
Context only	1	1	1

Table 5: T5-11B ablation results on the development set using the full dataset, question only and context only. Only the overall results are shown. The context only model predicted `NA` for each instance.

sequence lengths of 512, a batch size of 32, and grid searched four different learning rates (5e-4, 1e-3, 2e-3, and 4e-3). See Appendix C for BART and other T5 details.

5.3 Results

We present our overall results on ZEST, an ablation using T5 to probe for annotation artifacts (Gururangan et al., 2018), and an error analysis breaking down common mistakes.

Baseline Performance Table 3 shows the performance of the baselines on ZEST, as well as an estimate of human performance.[6] We report mean F1 across all *instances* in the data, ignoring their grouping into tasks, as well as our proposed C@T metric, for $T \in \{75, 90\}$. The best T5-11B model has mean performance of 56% on the development set, while the BART model has lower scores. Moreover, when we evaluate *task competence*, we see these models only rarely successfully solve the whole task well. For C@90, the T5 model's overall score is only 12% on the test set. Multitasking ZEST with other QA datasets only slightly improved results. Table 4 shows a detailed breakdown of performance across generalization type for the T5 model with multi-tasking. Detailed results for BART are in the Appendix. Model performance decreases as the generalization difficulty increases from the Base level to Output Structure. Consistently recovering models from task descriptions alone remains a significant challenge.

Annotation Artifacts & Ablations Table 5 shows ablations on the dev set using T5, illustrating that both the question and context are needed for the model to perform well, as one would expect. We see that in the context only ablation, the model predicted `NA` (majority class) for all instances, showing that there were not any systematic biases in the passages alone that the model could exploit. The context only F1 is non-zero due the fact that one task had all NA answers, which is

---

[6] Computed by having an author label answers to 55 tasks from the test set.

Error	Question	Input Passage (shortened)	Predicted	Correct
Recall (30%)	Did this president get a graduate degree?	... at Harvard University, where he earned an M.A. in economics ...	N/A	Yes
Precision (37%)	Are the volcanoes in this national park dormant?	... Dormant: A volcano that is inactive or resting, but is likely to erupt again in the near future. Extinct: A volcano that has stopped erupting ...	Yes	NA
Partial (9%)	What kind of trout can be found at this national park?	... The presence of non-native brown trout has the potential to impact brook trout and other native fish populations within several of the park's premier large streams ...	Brown trout	Brown trout,brook trout
Other (24%)	Was this dog breed accepted in the american kennel club in the last twenty years?	... The Cavalier would go on to be recognized by the American Kennel Club in 1995 ...	No	Yes

Table 6: Error distribution of the baseline model. Recall errors are when the model incorrectly predicts N/A; precision errors are when the model should have predicted N/A, but didn't; partial answers are when the model failed to predict all of the members of a list. Other common errors included failing to apply reasoning to answer a question, and predicting the wrong key names when producing JSON outputs.

counted as competent by convention.

Error Analysis In order to more clearly understand where these models fail, we examined 100 instances of model errors and categorized them. The most frequent errors were when the model failed to recognize the answer (30% of the time) or predicted something when the answer was `NA` (37%). We provide detailed examples and descriptions in Table 6. Interestingly, the model failed to output parseable JSON on only 1.5% of all structure questions in the test set and generated a JSON structure format for only 0.008% of non-structure questions, showing strong results for learning the format for outputting the complex relationships.

6 Conclusion

We introduced a framework for creating general purpose NLP systems that can solve tasks from natural language descriptions, synthesizing and extending previous work in zero-shot learning. To make progress toward this goal, we create a dataset, ZEST, that rigorously evaluates how well a model truly understands each task. The dataset is designed to test models' ability to systematically generalize across four different areas. State-of-the-art performance on ZEST is 12%, leaving much room for future improvement.

While we have been focused on zero shot learning from task descriptions, our framework also permits few-shot scenarios where a task description is given along with a handful of examples, making meta-learning approaches applicable. This is an interesting avenue for future work, for which ZEST should also be useful. To facilitate future work, we make our models, code, and data available at `https://allenai.org/data/zest`.

A Gathering Passages

We used Google and Bing search engines to gather documents for our task descriptions, creating a custom endpoint with a limited number of websites (described in Section 4.3) for each domain. Each task description was processed by removing stop words and then used as a query through the respective custom search endpoint. This allowed us to retrieve search snippets and URLs that could be used for further processing.

We used each search snippet to generate the full passage, retrieving the full text of any paragraph that was contained in the snippet, or a random amount (between 0 and 3) of sentences before and after each snippet if the full length of the passage exceeded 300 words. This ensured that we maintained crucial information from the query while mitigating potential bias from the search engine.

B Data Preprocessing

In order to facilitate training a text-to-text model on ZEST, we took each task and generated a collection of input-output text pairs. These pairs were then regarded as individual examples in the training—we did not explore approaches that keep examples grouped together by their task. To generate each input, we prepended "zeroshot question: " before the task description and "zeroshot context: " before the corresponding document. In the case of T5, we appended two newline characters to each and then joined them together, whereas BART used a single space. For each output, we simply used the target ZEST provides.

C Training Details

To facilitate reproducing our experiments, this appendix provides additional details on how we trained and ran predictions for the models. Code to reproduce the baseline results is available from `https://allenai.org/data/zest`.

C.1 T5 Details

Our baselines build off the T5 11B model (Raffel et al., 2019): a text-to-text encoder-decoder structured transformer pretrained via masked language modeling and multi-tasking. T5 11B has 11 billion parameters. Our training, evaluation, and modeling code used the original implementation released with the T5 work.[7]

Training, Evaluation, & Hyper-parameters Since T5 frames tasks as text-to-text, the model was trained via teacher forcing (Williams and Zipser, 1989). Fixed hyper-parameters include an input sequence length of 512, an output sequence length of 512, and a batch size of 32 examples (i.e., instances of tasks, not tasks themselves—see **Data Preprocessing**). The ZEST + MTL baseline equally weighted each component dataset during training, sampling them at the same rate. To tune the learning rate, for each T5 baseline we performed a grid-search over four values: 5e-4, 1e-3, 2e-3, and 4e-3. The best learning rate for each baseline was 4e-3 for context-only, 1e-3 for question-only, 1e-3 for ZEST-only (full data), and 5e-4 for ZEST + MTL. The model was trained for 25,000 updates with checkpoints taken approximately every 2,500 steps. Throughout training, we kept the 10 most recent checkpoints. All other training specifics were identical to those used in the original T5 work (Raffel et al., 2019). For early stopping, we chose the checkpoints with the highest per-instance accuracy on dev to evaluate on test.[8]

Hardware & Compute We trained the T5 models using three v3-256 TPUs on Google Cloud, using one TPU per model and running experiments in parallel. The T5 implementation we built off integrates with Mesh Tensorflow (Shazeer et al., 2018), which provides automatic data and model parallelism. For training, we set a model parallelism of 16. All T5 baselines trained the same model (T5 11B), only on different data. Training took 2 hours, 44 minutes, and 38 seconds on average with a standard deviation of 15 minutes and 28 seconds across the 16 runs. Evaluation on the validation set for the ZEST-only (full data), context-only, and question-only baselines took on average 26 minutes and 9 seconds with a standard deviation of 1 minute and 4 seconds across 12 runs, while evaluation for the ZEST + MTL baseline took on average 45 minutes and 15 seconds with a standard deviation of 1 minute and 11 seconds across 4 runs.[9]

---

[7] `https://github.com/google-research/text-to-text-transfer-transformer`

[8] Note that this metric differs from the evaluation we use for reporting results, which is more complex to compute.

[9] The multi-task baseline took longer to evaluate because we also evaluated it on the other tasks besides ZEST.

C.2 BART Details

BART (Lewis et al., 2020) is a text-to-text encoder-decoder structured transformer pretrained with a denoising autoencoding objective. We used the BART-large model with 406 million parameters as implemented in `transformers`[10]. We followed the original hyperparameters recommended by the authors for fine tuning for summarization[11] with the exception of tuning the batch size, learning rate, number of training epochs, and sequence lengths. In particular, we used a batch size of 32, maximum source/target sequence lengths of 512/64, four beams for decoding, weight decay of 0.01 and 0.1 label smoothing. Learning rate was tuned in [3e-5, 5e-5] and number of epochs in [3, 5, 10, 15, 20], with the best model on the development set having learning rate=3e-5 for 15 epochs. Training took approximately 3.5 minutes per epoch on a single RTX 8000 GPU. Detailed results for the best model are shown in Table 9.

D Evaluation Details

As described in Section 5.1, we evaluate the model in a rigorous manner in order to test how well it truly understands each task. We follow conventions established from previous work in the field (Dua et al., 2019; Dasigi et al., 2019) in evaluating typical Reading Comprehension benchmarks and expand upon them, to account for novel output structures.

Evaluating Classification Classification evaluation is straightforward, taking the modified F1 metric (defined in Section 5.1) of the `yes`, `no`, and `NA` classes.

Evaluating Answer Spans We evaluate extracted answer spans by first aligning the gold and predicted answers (in the case of multiple extracted spans) and computing the F1 word overlap score. We take the max F1 score (with respect to the different answers given by annotators) as the final score for that prediction. This F1 word-overlap score is calculated from the code of (Dua et al., 2019). We then compute the task F1 score following Section 5.1.

Evaluating Output Structure Questions As each output structure answer could contain multiple entities (contained in dictionaries, to use JSON terminology. In Table 1 the entity would be "Bridalveil Fall"), we first align all entities in the predicted and gold answers together. We then use each (key, value) pair as a answer, matching the gold pair to the predicted pair. The score for the value comparisons is evaluated as described in the above two sub-sections, w.r.t whether the value is a classification answer or an extracted answer. We then weight the value score by the key F1 score, as the key is given in the question and is only a reference to the actual answer (e.g. a model should not receive credit for getting the key right, but should receive a penalty for getting the key wrong). Each (key, value) pair in all answers for the given task is used in calculating the final task F1 score, as described in Section 5.1.

E Baseline Results

This appendix provides the full results breakdown for T5 trained on ZEST alone, BART, and human performance. In addition, we've reproduced Table 4 in this appendix for easy comparison.

jing-amelia.li@polyu.edu.hk

Abstract

This paper studies social emotions to online discussion topics. While most prior work focus on emotions from writers, we investigate readers' responses and explore the public feelings to an online topic. A large-scale dataset is collected from Chinese microblog Sina Weibo with over 13 thousand trending topics, emotion votes in 24 fine-grained types from massive participants, and user comments to allow context understanding.[1] In experiments, we examine baseline performance to predict a topic's possible social emotions in a multi-label classification setting. The results show that a seq2seq model with user comment modeling performs the best, even surpassing human prediction. More analyses shed light on the effects of emotion types, topic description lengths, contexts from user comments, and the limited capacity of the existing models.

1 Introduction

Social media have become a popular outlet for people to voice opinions, share viewpoints, and exchange ideas. It provides us with rich resource to research public opinions of the trending topics and hear people's voice over important social events, such as the global COVID-19 crisis. However, our ever-changing physical world leads to the rapid evolution of discussion topics in online world; it is far beyond humans' capability to catch them in real time. It consequently presents a pressing need for automatic sentiment (Wang et al., 2011; Yang and Eisenstein, 2017) and emotion (Abdul-Mageed and Ungar, 2017; Aragón et al., 2019) analysis.

Nevertheless, most of the related work focus on the feelings from writers (Tang et al., 2014; Huang and Carley, 2019; Singh et al., 2019) and the existing studies concerning reader emotions mostly tackle well-written texts, such as news reports (Li et al., 2016; Zhou et al., 2018; Yang et al., 2019). Limited work has been done to characterize collective feelings from the public (henceforth **social emotions**) to an online topic described with fragmented and colloquial social media language. Where some previous efforts gather viewpoints from limited readers through user replies (Alhothali and Hoey, 2015; Li et al., 2019) or manual annotations (Buechel and Hahn, 2017; Bostan et al., 2019), we focus on social emotions reflecting aggregated feelings from large amount of people.

[H]:#张艺兴整蛊GAI#
[T]: Lay played tricks on GAI.
[E]: 😂: *lol*; 🤦: *facepalm*; 🐶: *doge (tease)*.

Figure 1: A Weibo hashtag and its resulting social emotions. H is the original hashtag in Chinese and T is its English translation. E shows the top three emojis voted by online users and their meanings (seperated by ":").

In light of these concerns, we present a novel task to infer *social emotions to online topics*. Its goal is to predict the possible emotions from the majority of readers given a few words description of a trending social media topic. The task will benefit various applications, such as topic analysis (Wang et al., 2011) and event detection (Yang et al., 2019). It would help people understand and foresee how the general public thinks of an event even before it becomes a trending topic on social media. More importantly, it is to induce a society's collective emotions to a discussion topic, which is helpful to gain machines' affective analysis ability for more appropriate response behaviors and will potentially advance human-computer interactions (Strapparava and Mihalcea, 2007).

To better illustrate our task, Figure 1 displays a topic trended on a popular Chinese microblog

November 16–20, 2020.

Sina Weibo (henceforth **Weibo**). Here *hashtags* (phrases between two "#"s) are considered as user-annotated discussion topics following the common practice (Wang et al., 2011, 2019). Also shown are the top three reader emotions voted by the online users.[2] As can be seen, the social media style writing — short and informal — makes it challenging to capture what feelings a topic is likely to evoke. The example concerns the story of two celebrities (Lay and GAI) in a variety show, where one needs to make sense of "整蛊" (an internet slang means "play tricks on") and access some background to get why most voters leaned on hilarious emotions.

As the pilot study for online topics' social emotions, *we also present the very first dataset for this task, which contains large-scale popular topics, their corresponding social emotions, and user comments for context understanding.* We first gather over 13 thousand Weibo topics (in hashtag forms) associated with fine-grained emotion types represented as 24 emoji labels and contributed by more than 3 thousand online users on average. Compared with the related resource from news websites, our dataset prepared via social media crowd sourcing exhibits larger scale, more annotators, and finer-grained emotion types. Moreover, we collect abundant user comments for each topic, which enables context modeling to access public thoughts. It will later benefit future work to examine how social emotions are shaped in online discussions.

Extensive experiments are carried out on our dataset. We first discuss how the baselines and popular multi-label classification models work to predict the top three reader emotions. The results show that seq2seq-based models obtain the best overall results and user comments can further boost the performance via providing richer contexts. We also find that machines exhibit a superiority on our task compared with humans and point out the possible bias from individuals to sense public emotions. Afterwards, model performances are quantified over varying emotions and hashtag length, where user comments consistently result in the performance gain. Finally, we probe into our output to analyze how user comments help and the limitation of the existing models.

2 Related Work

Our work is related with emoji studies, which mostly focus on how writers will tag emojis to represent the emotions reflected in the texts, e.g., posts, tweets, news (Abdul-Mageed and Ungar, 2017; Barbieri et al., 2018; Demszky et al., 2020). Different from them, we concern readers' collective responses to an online topic, which has never been studied before. We are also inspired by topic-oriented sentiment analysis (Wang et al., 2011) concerning writer's sentiment polarity in positive and negative. Compared with them, we investigate fine-grained public emotions from readers, which is ignored in the existing research and extensively studied here.

As for the analysis of readers' emotions (a.k.a., affective analysis) (Strapparava and Mihalcea, 2007; Tang and Chen, 2012), some of them collected emotion signals (or emojis) from user replies (Alhothali and Hoey, 2015; Li et al., 2019) or manual annotation (Buechel and Hahn, 2017; Bostan et al., 2019). Responsive emotions are collected from limited readers and hence cannot reflect social emotions from the public. Other studies adopt emotion votes on news websites to gather public feelings on news (Li et al., 2016; Zhou et al., 2018; Yang et al., 2019). However, news reports usually exhibit more formal style than online topics in social media language. None of the above work examine public emotions to online discussion topics, which is the gap filled in this study.

3 Data Collection and Analysis

Data Collection. Our dataset is built based on a Weibo emotion vote, where it provides users to vote for an emoji from a total of 24 emojis in the form of a questionnaire to represent their feelings to a trending hashtag.

Here comes the steps to collect the data. First, we tracked the trending hashtags following the everyday Weibo topic summary list [3] from Apr to May 2020. For topics trended before that, we resort to a webpage listing the historical hot topics since Nov 2019.[4] Then, we searched and parsed their emotion vote webpage via querying the hashtag in HTTP requests[5] with the `selenium` package.

---

[2] The information comes from a vote on Weibo. It encourages online users to select an emoji from a total of 24 to describe their responsive emotions to a trending hashtag. More details will be discussed later in Section 3.

[3] `https://s.weibo.com/top/summary`

[4] `https://github.com/Writeup001/weibo_Hot_Search`

[5] `https://m.s.weibo.com/hot/attitude?query=xxx`, where xxx refers to a hashtag name.

Next, the crawled pages were parsed and analyzed using `lxml` package to gather the topics' emotion voting results. At last, hashtags with less than 100 voters were removed to filter out biased results.

As Weibo only keeps emotions gaining the top three votes, we will hence focus on the top three emotions in the following discussions. These emotions were selected by over 83% voters on average and can still reflect feelings from the majority.

Furthermore, to access the contexts of hashtags, we collected some user comments involved in a hashtag's discussion. Concretely, we first visited the hashtag page[6] through HTTP requests and obtained the popular Weibo messages that carry the hashtag. Then from the HTML codes, we extracted the IDs of the top four messages. Their comments were later gathered from the messages' comment pages[7] using an open source toolkit.[8]

Dataset	Size	Len	Voters	Emos
Zhou et al. (2018)	5,586	702.4	157	6
Bostan et al. (2019)	5,000	11.3	331	8
Our dataset	13,766	5.4	3,250	24

Table 1: Statistics: our data vs. prior resource. Size and emos are the # of instances and emotion types. Len and voters are the average # of words (after Chinese word segmentation) and the involved voters per instance.

Data Analysis. The statistics of our dataset in comparison with the related resources are shown in Table 1. Both Zhou et al. (2018) and Bostan et al. (2019) present social emotions over news: the former contains Chinese news articles while the latter English news headlines. Our data contains more instances, each with less words, more voters (for annotations), and emotions with finer-grained types. In addition, our dataset presents 408.7 user comments on average for each instance (hashtag), whose average length is 12 Chinese words.

In our dataset, most of the topics are hot events in real life. For example, a few topics collected in the late 2019 concern the social unrest in Hong Kong, while many topics trended in 2020 are about the COVID-19 outbreak. We characterize the topics by keywords and find that 15% topics contain the word "新冠" (COVID-19) while the number rises to 32% if more relevant keywords are included, such as "医生" (doctor), "口罩" (face mask), and "武汉" (Wuhan). We also examine the relations of the keywords in topics and the responsive emojis voted by users. It is seen that hashtags with "新冠" (COVID-19) are most likely to result in 😭 (*cry*) while users tend to choose 🐱 (*tease*) to respond to hashtags containing "特朗普" (Trump).

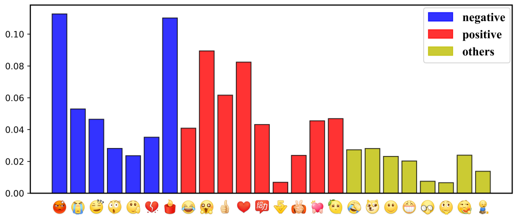

Figure 2: User preferences over varying emotions. X-axis: 24 emotions in emojis; y-axis: proportions of voters who selected the emotion. Emotions are grouped into positive, negative, and others by our interpretations and shown in blue, red, and yellow bars.

To further analyze the 24 fine-grained emotions, Figure 2 shows how the voter number distribute over varying emotions. This implies the diverse preferences of user voters to pick up varying emotion labels and the challenging label imbalance issue of our task. We also observe that positive and negative emotions are approximately equally distributed, both used more often than emotions in "others" group, probably due to their complicated and vague meanings.

4 Experiments and Discussions

4.1 Experimental Setup

Data Preprocessing and Model Setup. We employed an open-source toolkit `pkuseg` for Chinese word segmentation.[9] For experimental setup, we follow a multi-label classification setting to predict the top three emotions and split the dataset into 85% for training, 5% for validation, and 10% for test. All the non-neural models have hyperparameters tuned on the validation set via grid search and employ features from the pre-trained publicized Chinese embeddings (Li et al., 2018). Neural models are set up following the original papers.

Comparison Models. We first consider two weak baselines, one yields random prediction (henceforth RANDOM) and the other ranks the emotions by frequency (henceforth FREQ). Then,

---

[6] `https://s.weibo.com/weibo?q=xxx`, where xxx refers to a hashtag name.

[7] `https://weibo.cn/comment/hot/MID?&page=PID`, where MID refers the message ID and PID can be changed to turn pages and crawl more comments.

[8] `https://github.com/keyucui/weibo_topic_analyze`

[9] `https://github.com/lancopku/PKUSeg-python`

four non-neural baselines are selected: binary relevance (Boutell et al., 2004) (BR), classifier chain (Read et al., 2011) (CC), multi-label KNN (Zhang and Zhou, 2007) (ML-KNN), and label powerset (Tsoumakas and Katakis, 2007) (LP).

In addition, a popular neural sequence generation model is involved, which is based on seq2seq with a weighted decoder to generate label sequence (henceforth SGM) (Yang et al., 2018). To further exploit contexts from user comments, we consider an extension of SGM that is able to leverage user comments. Our intuition is that readers may voice opinions there with words possibly reflect public emotions. To that end, we first use TextRank (Mihalcea and Tarau, 2004) to extract the 50 keywords from comments. Then we concatenate keywords with the hashtag, feed them both into SGM, and name the new model as SGM+UC.

Evaluation Metrics. Here, we adopt three popular metrics from multi-label classification (Qin et al., 2019): label-F1 (average F1 over labels), instance-F1 (average F1 over instances), and hamming loss measured on the predicted and ground-truth label sequences (Koyejo et al., 2015).

4.2 Experimental Results

Table 2 shows the main comparison results, where we draw the following observations. First, SGM generally perform better than the non-neural baselines. Its gain on label-F1 is whereas small (even outperformed by LP) indicating its incapability to well handle label imbalance compared with non-neural models. Second, external features from user comment results in the better results from SGM+UC than SGM. We further examine words in hashtags and find only 11.6% on average appear in the sentiment lexicon built based on NTUSD (Ku and Chen, 2007) and HowNet (Yan et al., 2008). It shows that most words in hashtags are not explicit sentiment indicators, rendering the challenge to tackle our task. If additionally considering comments, the number will benefit 49% relative increase (to 17.3%), because readers' viewpoints exhibited there may narrow the gap between topic description and social emotions.

In addition, we investigate whether an individual's feelings are always consistent with the public's. Here 96 test hashtags were sampled and two native Chinese speakers were invited to select the first three emotions occurred to them. The results are also displayed in Table 2 (bottom) together with the performance of SGM and SGM+UC on the same test samples. We find model performance is better than human results, suggesting the possible bias of individual thoughts from public viewpoints. Then, we asked the same annotators to review the hashtags and their emotions from votes, where they thought 75% and 76% voted emotions make sense to them. It means that most social emotions can still be understood by individuals though they may sometimes disagree with the majority.

	L-F1	I-F1	HL
Weak Baselines			
Random	0.100	0.125	0.219
Freq	0.064	0.343	0.164
Non-neural Models			
BR	0.254	0.336	0.300
CC	0.227	0.304	0.234
ML-KNN	0.245	0.366	0.158
LP	0.279	0.423	0.144
Neural Models			
SGM	0.260	0.450	0.137
SGM+UC	**0.308**	**0.532**	**0.117**
Human vs. Machine			
Human 1	0.244	0.330	0.168
Human 2	0.192	0.267	0.183
SGM	0.249	0.392	0.152
SGM+UC	**0.289**	**0.465**	**0.133**

Table 2: Comparison results of multi-label classification models to predict the top three emotions. L-F1 (label-F1) and ins-F1 (instance-F1): the higher the better; HL (Hamming Loss): the lower the better.

Another point leading to the disagreement is the prominence of Janus emojis (with two opposite meanings) in social media; for instance, 🙂, originally positive has turned out to mean "I don't care".

Results over Varying Emotions. We then examine how models perform to predict varying emotions and Table 3 shows the results of SGM and SGM+UC.[10] It is first observed that models exhibit diverse F1 over varying emotions, which indicates the difficulty levels vary to understand different emotions. We also notice that user comments boost precision, recall, and F1 for most emotions, which again indicates the usefulness of comments to indicate various social emotions.

Results over Varying Topic Length. Next, we explore how hashtag length affects model prediction and show the results from the neural models and LP over varying hashtag length in Figure 3(a). SGM may heavily rely on training data scale and exhibits a performance drop for long hashtags (with

---

[10] We only consider emotions appearing in the top three of at least 100 test hashtags to avoid bias.

Emotion	Precision	Recall	F1

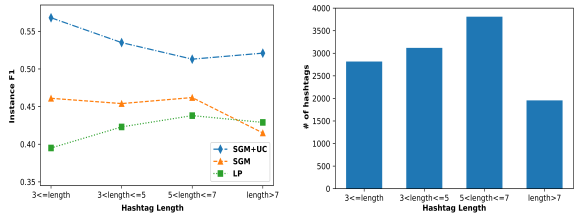
over 7 words). Because such hashtags have less instances available for training (as shown in Figure 3(b)). Nevertheless, SGM+UC consistently perform better, suggesting that the context from user comments can helpfully alleviate data sparsity.



(a) Length vs. Instance F1 (b) Length vs. Hashtag Count

Figure 3: Instance F1 (left y-axis) in prediction and training hashtag number (right y-axis) over hashtag length (Chinese word count shown in x-axis).

4.3 Further Discussions

Case Study. As discussed above, it is sometimes difficult to induce readers' responses from a short and informal hashtag, such as the example in Figure 1. Recall that 整蛊 (*play tricks on*) is essential to predict emotions, while as an uncommon slang, its semantics may not be easy to capture in the limited context. However, keywords in comments, such as 可爱 (*cute*), 搞笑 (*funny*), 调皮 (*naughty*), etc., will contribute to signal the amusements from readers. Without them, SGM only produces common emotions: 😱 (*wow*), 😅 (*shocked*), and ❤ (*love*).

Error Analysis. Here we probe into the model outputs and analyze the errors occur. One major error type comes from the heavy reliance on trending words. For example, most models predict negative feelings when observing 新冠肺炎 (*COVID-19*), even for hashtags raising good points and touching stories. The other is the incapability to correctly predict some uncommon emotions, such as 😳 (*not easy*). Future work should concern how to handle imbalanced labels in fine-grained social emotions.

5 Conclusion

We have investigated social emotions to online discussion topics. A large-scale Chinese Weibo dataset is built containing trending hashtags, emotion votes, and user comments (for context modeling). In experiments, we have shown that the prediction of social emotions is challenging and the modeling of user comments may usefully bridge topic descriptions and public emotions.

Abstract

Existing approaches for named entity recognition suffer from data sparsity problems when conducted on short and informal texts, especially user-generated social media content. Semantic augmentation is a potential way to alleviate this problem. Given that rich semantic information is implicitly preserved in pre-trained word embeddings, they are potential ideal resources for semantic augmentation. In this paper, we propose a neural-based approach to NER for social media texts where both local (from running text) and augmented semantics are taken into account. In particular, we obtain the augmented semantic information from a large-scale corpus, and propose an attentive semantic augmentation module and a gate module to encode and aggregate such information, respectively. Extensive experiments are performed on three benchmark datasets collected from English and Chinese social media platforms, where the results demonstrate the superiority of our approach to previous studies across all three datasets.[1]

1 Introduction

The increasing popularity of microblogs results in a large amount of user-generated data, in which texts are usually short and informal. How to effectively understand these texts remains a challenging task since the insights are hidden in unstructured forms of social media posts. Thus, named entity recognition (NER) is a critical step for detecting proper entities in texts and providing support for downstream natural language processing (NLP) tasks (Pang et al., 2019; Martins et al., 2019).

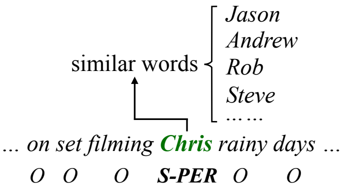

Figure 1: An example shows that an NE tagged with "*PER*" (Person) is suggested by its similar words.

However, NER in social media remains a challenging task because (i) it suffers from the data sparsity problem since entities usually represent a small part of proper names, which makes the task hard to be generalized; (ii) social media texts do not follow strict syntactic rules (Ritter et al., 2011). To tackle these challenges, previous studies tired to leverage domain information (e.g., existing gazetteer and embeddings trained on large social media text) and external features (e.g., part-of-speech tags) to help with social media NER (Peng and Dredze, 2015; Aguilar et al., 2017). However, these approaches rely on extra efforts to obtain such extra information and suffer from noise in the resulted information. For example, training embeddings for social media domain could bring a lot unusual expressions to the vocabulary. Inspired by studies using semantic augmentation (especially from lexical semantics) to improve model performance on many NLP tasks (Song and Xia, 2013; Song et al., 2018a; Kumar et al., 2019; Amjad et al., 2020), it is also a potential promising solution to solving social media NER. Figure 1 shows a typical case. "*Chris*", supposedly tagged with "*Person*" in this example sentence, is tagged as other labels in most cases. Therefore, in the predicting process, it is difficult to label "*Chris*" correctly. A sound solution is to augment the semantic space of "*Chris*" through its similar words, such as "*Jason*" and "*Mike*", which can be obtained by existing pre-trained word embeddings from the general domain.

In this paper, we propose an effective approach to NER for social media texts with semantic augmentation. In doing so, we augment the semantic

space for each token from pre-trained word embedding models, such as GloVe (Pennington et al., 2014) and Tencent Embedding (Song et al., 2018b), and encode semantic information through an attentive semantic augmentation module. Then we apply a gate module to weigh the contribution of the augmentation module and context encoding module in the NER process. To further improve NER performance, we also attempt multiple types of pre-trained word embeddings for feature extraction, which has been demonstrated to be effective in previous studies (Akbik et al., 2018; Jie and Lu, 2019; Kasai et al., 2019; Kim et al., 2019; Yan et al., 2019). To evaluate our approach, we conduct experiments on three benchmark datasets, where the results show that our model outperforms the state-of-the-arts with clear advantage across all datasets.

2 The Proposed Model

The task of social media NER is conventionally regarded as sequence labeling task, where an input sequence $\mathcal{X} = x_1, x_2, \cdots, x_n$ with n tokens is annotated with its corresponding NE labels $\widehat{\mathcal{Y}} = \widehat{y}_1, \widehat{y}_2, \cdots, \widehat{y}_n$ in the same length. Following this paradigm, we propose a neural model with semantic augmentation for the social media NER. Figure 2 shows the architecture of our model, where the backbone model and the semantic augmentation module are illustrated in white and yellow backgrounds, respectively. For each token in the input sentence, we firstly extract the most similar words of the token according to their pre-trained embeddings. Then, the augmentation module use an attention mechanism to weight the semantic information carried by the extracted words. Afterwards, the weighted semantic information is leveraged to enhance the backbone model through a gate module.

In the following text, we firstly introduce the encoding procedure for augmenting semantic information. Then, we present the gate module to incorporate augmented information into the backbone model. Finally, we elaborate the tagging procedure for NER with the aforementioned enhancement.

2.1 Attentive Semantic Augmentation

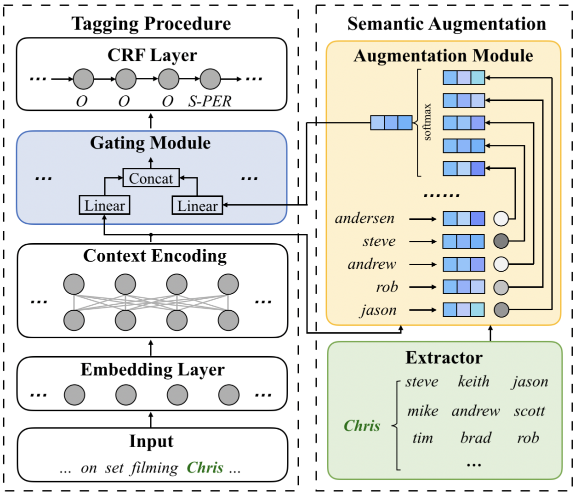

Figure 2: The overall architecture of our proposed model with semantic augmentation. An example sentence and its output NE labels are given, where the augmented semantic information for the word "*Chris*" are also illustrated with the processing through the augmentation module and the gate module.

The high quality of text representation is the key to obtain good model performance for many NLP tasks (Song et al., 2017; Sileo et al., 2019). However, obtaining such text representation is not easy in the social media domain because of data sparsity problem. Motivated by this fact, we propose semantic augmentation mechanism for social media NER by enhancing the representation of each token in the input sentence with the most similar words in their semantic space, which can be measured by pre-trained embeddings.

In doing so, for each token $x_i \in \mathcal{X}$, we use pre-trained word embeddings (e.g., GloVe for English and Tencent Embedding for Chinese) to extract the top m words that are most similar to x_i based on cosine similarities and denote them as

$$C_i = \{c_{i,1}, c_{i,2}, \cdots, c_{i,j}, \cdots, c_{i,m}\} \qquad (1)$$

Afterwards, we use another embedding matrix to map all extracted words $c_{i,j}$ to their corresponding embeddings $\mathbf{e}_{i,j}$. Since not all $c_{i,j} \in C_i$ are helpful for predicting the NE label of x_i in the given context, it is important to distinguish the contributions of different words to the NER task in that context. Consider that the attention and weight based approaches are demonstrated to be effective choices to selectively leverage extra information in many tasks (Kumar et al., 2018; Margatina et al., 2019; Tian et al., 2020a,d,b,c), we propose an attentive semantic augmentation module (denoted as AU) to weight the words according to their contributions to the task in different contexts. Specifically, for each token x_i, the augmentation module assigns a weight to each word $c_{i,j} \in C_i$ by

$$p_{i,j} = \frac{exp(\mathbf{h}_i \cdot \mathbf{e}_{i,j})}{\sum_{j=i}^{m} exp(\mathbf{h}_i \cdot \mathbf{e}_{i,j})}, \qquad (2)$$

where $\mathbf{h}_i$ is the hidden vector for x_i obtained from the context encoder with its dimension matching that of the embedding (i.e., $\mathbf{e}_{i,j}$) of $c_{i,j}$. Then, we apply the weight $p_{i,j}$ to the word $c_{i,j}$ to compute the final augmented semantic representation by

$$\mathbf{v}_i = \sum_{j=1}^{m} p_{i,j} \mathbf{e}_{i,j}, \tag{3}$$

where $\mathbf{v}_i$ is the derived output of AU, and contains the weighted semantic information. Therefore, the augmentation module ensures that the augmented semantic information are weighted based on their contributions and important semantic information is distinguished accordingly.

2.2 The Gate Module

We observe that the contribution of the obtained augmented semantic information to the NER task could vary in different contexts and a gate module (denoted by GA) is naturally desired to weight such information in the varying contexts. Therefore, to improve the capability of NER with the semantic information, we propose a gate module to aggregate such information to the backbone NER model. Particularly, we use a $reset$ gate to control the information flow by

$$\mathbf{g} = \sigma(\mathbf{W}_1 \cdot \mathbf{h}_i + \mathbf{W}_2 \cdot \mathbf{v}_i + \mathbf{b}_g), \tag{4}$$

where $\mathbf{W}_1$ and $\mathbf{W}_2$ are trainable matrices and $\mathbf{b}_g$ the corresponding bias term. Afterwards, we use

$$\mathbf{u}_i = [\mathbf{g} \circ \mathbf{h}_i] \oplus [(\mathbf{1} - \mathbf{g}) \circ \mathbf{v}_i] \tag{5}$$

to balance the information from context encoder and the augmentation module, where $\mathbf{u}_i$ is the derived output of the gate module; $\circ$ represents the element-wise multiplication operation and $\mathbf{1}$ is a 1-vector with its all elements equal to 1.

2.3 Tagging Procedure

To provide $\mathbf{h}_i$ to the augmentation module, we adopt a context encoding module (denoted as CE) proposed by Yan et al. (2019). Compared with vanilla Transformers, this encoder additionally models the direction and distance information of the input, which has been demonstrated to be useful for the NER task. Therefore, the encoding procedure of the input text can be denoted as

$$\mathbf{H} = CE(\mathbf{E}), \tag{6}$$

where $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_n]$ and $\mathbf{E} = [\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_n]$ are lists of hidden vectors and embeddings of $\mathcal{X}$, respectively. In addition, since pretrained word embeddings contain substantial context information from large-scale corpus, and different types of them may contain diverse information, a straightforward way of incorporating them is to concatenate their embedding vectors by

$$\mathbf{e}_i = \mathbf{e}_i^1 \oplus \mathbf{e}_i^2 \oplus \ldots \oplus \mathbf{e}_i^T, \tag{7}$$

where $\mathbf{e}_i$ is the final word embedding for x_i and T the set of all embedding types. Afterwards, a trainable matrix $\mathbf{W}_u$ is used to map $\mathbf{u}_i$ obtained from the gate module to the output space by $\mathbf{o}_i = \mathbf{W}_u \cdot \mathbf{u}_i$. Finally, a conditional random field (CRF) decoder is applied to predict the labels $\widehat{y_i} \in L$ (where L is the set with all NE labels) in the output sequence $\widehat{\mathcal{Y}}$ by

$$\widehat{y_i} = \arg\max_{y_i \in L} \frac{exp(\mathbf{W}_c \cdot \mathbf{o}_i + \mathbf{b}_c)}{\sum_{y_{i-1}y_i} exp(\mathbf{W}_c \cdot \mathbf{o}_i + \mathbf{b}_c)}, \tag{8}$$

where $\mathbf{W}_c$ and $\mathbf{b}_c$ are the trainable parameters to model the transition for y_{i-1} to y_i.

3 Experiments

3.1 Settings

In our experiments, we use three social media benchmark datasets, including WNUT16 (W16) (Strauss et al., 2016), WNUT17 (W17) (Derczynski et al., 2017), and Weibo (WB) (Peng and Dredze, 2015), where W16 and W17 are English datasets constructed from Twitter, and WB is built from Chinese social media platform (Sina Weibo). For all three datasets, we use their original splits and report the statistics of them in Table 1 (e.g., the number of sentences (#Sent.), entities (#Ent.), and the percentage of unseen entities (%Uns.) with respect to the entities appearing in the training set).

For model implementation, we follow Lample et al. (2016) to use the BIOES tag schema to represent the NE labels of tokens in the input sentence. For the text input, we try two types of embeddings

"DS" and "AU" represent the direct summation and attentive augmentation module, respectively. Y and N denote the use and non-use of corresponding modules.

for each language.[2] Specifically, for English, we use ELMo (Peters et al., 2018) and BERT-cased large (Devlin et al., 2019); for Chinese, we use Tencent Embedding (Song et al., 2018b), and ZEN (Diao et al., 2019).[3] In the context encoding module, we use a two-layer transformer-based encoder proposed by Yan et al. (2019) with 128 hidden units and 12 heads. To extract similar words carrying augmented semantic information, we use the pre-trained word embeddings from GloVe for English and those embedding from Tencent Embeddings for Chinese to extract the most similar 10 words (i.e., $m = 10$) [4]. In the augmentation module, we randomly initialize the embeddings of the extracted words (i.e., $\mathbf{e}_{i,j}$ for $c_{i,j}$) to represent the semantic information carried by those words.[5]

During the training process, we fix all pre-trained embeddings in the embedding layer and use Adam (Kingma and Ba, 2015) to optimize negative log-likelihood loss function with the learning rate set to $\eta = 0.0001$, $\beta_1 = 0.9$ and $\beta_2 = 0.99$. We train 50 epochs for each method with the batch size set to 32 and tune the hyper-parameters on the development set[6]. The model that achieves the best performance on the development set is evaluated on the test set with the $F1$ scores obtained from the official conlleval toolkits[7].

3.2 Overall Results

To explore the effect of the proposed attentive semantic augmentation module (AU) and the gate module (GA), we run different settings of our model with and without the modules. In addition, we also try baselines that use direct summation (DS) to leverage the semantic information carried by the similar words, where the embeddings of the words are directly summed without weighting through attentions. The experimental results ($F1$) of the baselines and our approach on the development and test sets of all datasets are reported in Table 2(a) and (b), respectively.

There are some observations from the results on the development and test sets. First, compared to the baseline without semantic augmentation (ID=1), models using direct summation (DS, ID=2) to incorporate different semantic information undermines NER performance on two of three datasets, namely, W17 and WB; on the contrary, the models using the proposed attentive semantic augmentation module (AU, ID=4) consistently outperform the baselines (ID=1 and ID=2) on all datasets. It indicates that AU could distinguish the contributions of different semantic information carried by different words in the given context and leverage them accordingly to improve NER performance. Second, comparing the results of models with and without the gate module (GA) (i.e. ID=3 vs. ID=2 and ID=5 vs. ID=4), we find that the models with gate module achieves superior performance to the others without it. This observation suggests that the importance of the information from the context encoder and AU varies, and the proposed gate module is effective in adjusting the weights according to their contributions.

Moreover, we compare our model under the best setting with previous models on all three datasets in Table 3, where our model outperforms others on all datasets. We believe that the new state-of-the-

---

[2] We report the results of using each individual type of embeddings in Appendix A.

[3] We obtain the pre-trained BERT model from `https://github.com/google-research/bert`, Tencent Embeddings from `https://ai.tencent.com/ailab/nlp/embedding.html`, and ZEN from `https://github.com/sinovation/ZEN`. Note that we use ZEN because it achieves better performance than BERT on different Chinese NLP tasks. For reference, we report the results of using BERT in Appendix B.

[4] The results of using other embeddings as sources to extract similar words are reported in the Appendix C.

[5] We also try other ways (e.g., GloVe for English and Tencent Embedding for Chinese) to initialize the word embeddings, but do not find significant differences.

[6] We report the details of hyperparameter settings of different models in the Appendix D.

[7] The script to evaluate all models in the experiments is obtained from `https://www.clips.uantwerpen.be/conll2000/chunking/conlleval.txt`.

Table 3: Comparison of $F1$ scores of our best performing model (the full model with augmentation module and gate module) with that reported in previous studies on all English and Chinese social media datasets.

art performance is established. The reason could be that compared to previous studies, our model is effective to alleviate the data sparsity problem in social media NER with the augmentation module to encode augmented semantic information. Besides, the gate module can distinguish the importance of information from the context encoder and AU according to their contribution to NER.

4 Analysis

4.1 Performance on Unseen Named Entities

Since this work focuses on addressing the data sparsity problem in social media NER, where the unseen NEs are one of the important factors that hurts model performance. To analyze whether our approach with attentive semantic augmentation (AU) and the gate module (GA) can address this problem, we report the recall of our approach (i.e., "+AU+GA") to recognize the unseen NEs on the test set of all datasets in Table 4. For reference, we also report the recall of the baseline without AU and GA, as well as our runs of previous studies (marked by "*"). It is clearly observed that our approach outperforms the baseline and previous studies on unseen NEs on all datasets, which shows that it can appropriately leverage semantic information carried by similar words and thus alleviate the data sparsity problem.

Model	W16	W17	WB
# of Unseen NEs	2778	912	189
*Devlin et al. (2019)	49.02	46.73	45.98
*Yan et al. (2019)	48.97	46.89	45.71
Baseline	49.04	46.72	45.79
Ours (+AU +GA)	**51.27**	**49.45**	**48.81**

Table 4: The recall of our models with and without the attentive semantic augmentation (AU) and the gate module (GA) on unseen named entities (whose numbers are also reported at the first row) on all three datasets. The results of our runs of previous models (marked with "*") are also reported for references.

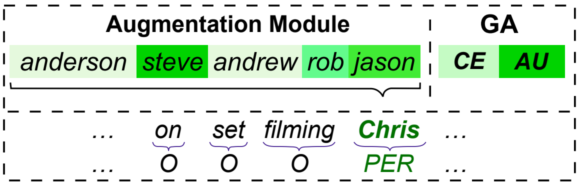

Figure 3: An example of helping recognize the NE "*Chris*" by augmented semantic information (darker color refers to greater value). "CE" and "AU" represent the context encoder and attentive augmentation module, respectively.

4.2 Case Study

To demonstrate how the augmented semantic information improves NER with the attentive augmentation module and the gate module, we show the extracted augmented information for the word "*Chris*" and visualize the weights for each augmented term in Figure 3, where deeper color refers to higher weight. In this case, the words "*steve*" and "*jason*" have higher weights in AU. The explanation could be that in all cases, these two words are a kind of "*Person*". Thus, higher attention to these terms helps our model to identify the correct NE label. On the contrary, the term "*anderson*" and "*andrew*" never occur in the dataset, and therefore provide no helpful effect in this case and eventually end with the lower weights in AU. In addition, a model can also mislabel "*Chris*" as "*Music-Artist*", because "*Chris*" belongs to that NE type in most cases and there is a word "*filming*" in its context. However, our model with the gate module can distinguish that the information from semantic augmentation is more important and thus make correct prediction.

5 Conclusion

In this paper, we proposed a neural-based approach to enhance social media NER with semantic augmentation to alleviate data sparsity problem. Particularly, an attentive semantic augmentation module is suggested to encode semantic information and a gate module is applied to aggregate such information to tagging process. Experiments conducted on three benchmark datasets in English and Chinese show that our model outperforms previous studies and achieves the new state-of-the-art result.

Appendix A: Effect of Using Different Embeddings

Model	Emb.	W16	W17	WB
Baseline	ELMo	52.16	47.31	-
+AU+GA		54.31	48.76	-
Baseline	BERT	52.09	48.33	-
+AU+GA		**54.16**	**49.57**	-
Baseline	Tencent	-	-	60.54
+AU+GA		-	-	63.12
Baseline	ZEN	-	-	66.09
+AU+GA		-	-	**68.96**

Table 5: Experimental results ($F1$ scores) of our approach with semantic augmentation (AU) and gate module (GA) on all datasets, where only one type of embeddings is used in the embedding layer to represent the input sentence. The results of their corresponding baseline without AU and GA are also reported.

In our main experiments, we use two types of embeddings for each language: ELMo (Peters et al., 2018) and BERT-cased large (Devlin et al., 2019) for English, and Tencent Embedding (Song et al., 2018b) and ZEN (Diao et al., 2019) for Chinese. In Table 5, we report the results ($F1$ scores) of our model with the best setting (i.e. the full model with semantic augmentation (AU) and gate module (GA)) as well as the baselines without AU and GA, where either one of the two types of embedding is used to represent the input sentence. From the results, it is found that our model with AU and GA can consistently outperforms the baseline models with different settings of embeddings.

Appendix B: Comparison Between BERT and ZEN on WB

Embeddings	WB
BERT + Tencent	69.56
ZEN + Tencent	**69.80**

Table 6: Experimental results ($F1$ scores) of our model with AU and GA on the WB dataset, where BERT or ZEN is used as one of the two types of embeddings (the other one is Tencent Embedding) to represent the input sentence for the embedding layer.

In our main experiments, we use ZEN (Diao et al., 2019) instead of BERT (Devlin et al., 2019) as the embedding to represent the input for Chinese. The reason is that ZEN achieves better performance compared with BERT, which is confirmed by Table 6 with its results ($F1$ scores) showing the performance of our approach with the best settings (i.e. two types of embeddings with AU and GA.) on

WB dataset. Either BERT or ZEN is used as one of the two types of embeddings (the other type of embedding is Tencent Embedding).

Appendix C: Effect of Using Different Embeddings to Extract Similar Words

Model	**Source**	**W16**	**W17**	**WB**
Baseline		49.56	49.11	66.02
Ours (+AU+GA)	Word2vec	54.94	50.22	-
	GloVe	**55.01**	**50.36**	-
	Giga	-	-	69.68
	Tencent	-	-	**69.80**

Table 7: Experimental results ($F1$ scores) of our best performing models (i.e., the ones with AU and GA) using different types of pre-trained embeddings as the source to extract similar words. The results of baseline (the one without AU and GA) are also reported.

In addition to use embeddings for input sentence representation, we also try different embedding sources (i.e. pre-trained word embeddings) to extract similar words for each token in the input sentence. For English, we use Word2vec (Mikolov et al., 2013) and Glove (Manning et al., 2014); for Chinese, we use Giga (Zhang and Yang, 2018) and Tencent Embedding (Song et al., 2018b).[8] The experimental results of our model with the best setting (i.e., the one with AU and GA) using different sources are reported in Table 7. The result of the baseline model without AU and GA is also reported for reference. The results show that our approach can consistently outperforms the baseline with different sources to find similar words, which demonstrates the robustness of our approach.

Appendix D: Hyper-parameter Settings

	Values	**Best**
Dropout rate	0, 0.1, 0.2, 0.3	0.2
Learning rate	e^{-5}, e^{-4}, e^{-3}	e^{-4}
Batch size	8, 16, 32	32
Number of layers	1, 2, 4	2
Number of head	4, 8, 12	12
Hidden units	64, 128, 256	128
# of similar of words (m)	5, 10, 20	10

Table 8: All values of different hyper-parameters as well as the best one used in our experiments.

We report all values of the hyper-parameters tried for our models in Table 8, where we try different combinations of them and find the best hyper-parameter configurations (which is also reported in Table 8) on the development set of each dataset.

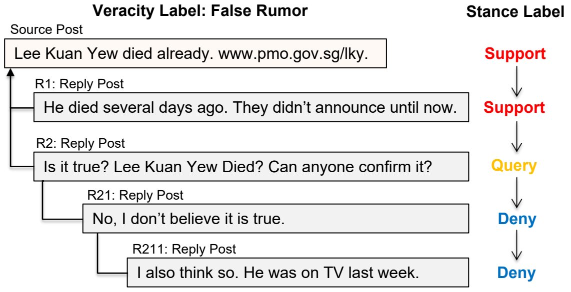
Abstract

The prevalent use of social media enables rapid spread of rumors on a massive scale, which leads to the emerging need of automatic rumor verification (RV). A number of previous studies focus on leveraging stance classification to enhance RV with multi-task learning (MTL) methods. However, most of these methods failed to employ pre-trained contextualized embeddings such as BERT, and did not exploit inter-task dependencies by using predicted stance labels to improve the RV task. Therefore, in this paper, to extend BERT to obtain thread representations, we first propose a Hierarchical Transformer[1], which divides each long thread into shorter subthreads, and employs BERT to separately represent each subthread, followed by a global Transformer layer to encode all the subthreads. We further propose a Coupled Transformer Module to capture the inter-task interactions and a Post-Level Attention layer to use the predicted stance labels for RV, respectively. Experiments on two benchmark datasets show the superiority of our Coupled Hierarchical Transformer model over existing MTL approaches.

1 Background

Recent years have witnessed a profound revolution in social media, as many individuals gradually turn to different social platforms to share the latest news and voice personal opinions. Meanwhile, the flourish of social media also enables rapid dissemination of unverified information (i.e., rumors) on a massive scale, which may cause serious harm to our society (e.g., impacting presidential election decisions (Allcott and Gentzkow, 2017)). Since manually checking a sheer quantity of rumors on social media is naturally labor-intensive and time-consuming, it is crucial to develop an automatic rumor verification approach to mitigate their harmful effect.



Lee Kuan Yew died already. www.pmo.gov.sg/lky.

He died several days ago. They didn't announce until now.

Is it true? Lee Kuan Yew Died? Can anyone confirm it?

No, I don't believe it is true.

I also think so. He was on TV last week.

Figure 1: An example conversation thread with both rumor veracity label and stance labels. Each post has a stance label towards the claim in the source post, and the source claim was later identified as *false rumor*.

Rumor verification is typically defined as a task of determining whether the source claim in a conversation thread is *false rumor*, *true rumor*, or *unverified rumor* (Zubiaga et al., 2018a). In the literature, much work has been done for rumor verification (Liu et al., 2015; Ma et al., 2016; Ruchansky et al., 2017; Chen et al., 2018; Kochkina and Liakata, 2020). Among them, one appealing line of work focuses on exploiting stance signals to enhance rumor verification (Zubiaga et al., 2016), since it is observed that people's stances in reply posts usually provide important clues to rumor verification (e.g., in Fig. 1, if the source claim is denied or queried by most replies, it is highly probable that the source claim contains misinformation and is *false rumor*).

This line of work has attracted increasing attention in recent years. A number of multi-task learning (MTL) methods have been proposed to jointly perform stance classification (SC) and rumor verification (RV) over conversation threads, including Sequential LSTM-based methods (Li et al., 2019), Tree LSTM-based methods (Kumar and Carley,

---

[1] Note that the concept of hierarchy in this paper is different from that in Yang et al. (2016), as we use hierarchy to refer to a neural structure that first models the local interactions among posts within each subthread, followed by modeling the global interactions among all the posts in the whole thread.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1392–1401,
November 16–20, 2020.

2019), and Graph Convolutional Network-based methods (Wei et al., 2019). These MTL approaches are mainly constructed upon the MTL2 framework proposed in Kochkina et al. (2018), which aims to first learn shared representations with shared layers in the low level, followed by learning task-specific representations with separate stance-specific layers and rumor-specific layers in the high level.

Although these MTL approaches have shown the usefulness of stance signals to rumor verification, they still suffer from the following shortcomings: (1) The first obstacle lies in their single-task models for SC or RV, whose randomly initialized text encoders such as LSTM tend to overfit existing small annotated corpora. With the recent trend of pre-training, many pre-trained text encoders such as BERT have been shown to overcome the overfitting problem and achieve significant improvements in many NLP tasks (Devlin et al., 2019). However, unlike previous sentence-level tasks, our SC and RV tasks require the language understanding over conversation threads in social media. Since BERT is unable to process arbitrarily long sequences due to its maximum length constraint in the pre-training stage, it remains an open question how to extend BERT to our SC and RV tasks. (2) Another important limitation of previous studies lies in their multi-task learning framework. First, the MTL2 framework used in existing methods fails to explicitly model the inter-task interactions between the stance-specific and rumor-specific layers. Second, although it has been observed that people's stances in reply posts are crucial to rumor verification, the stance distributions predicted from stance-specific layers have not been utilized for rumor veracity prediction in the MTL2 framework.

To address the above two shortcomings, we explore the potential of BERT for stance-aware rumor verification, and propose a new multi-task learning model based on Transformer (Vaswani et al., 2017), named Coupled Hierarchical Transformer. Our main contributions can be summarized as follows:

- To extend BERT as our single-task model for SC and RV, we propose a Hierarchical Transformer architecture. Specifically, we first flatten all the posts in a conversation thread into a long sequence, and then decompose them evenly into multiple subthreads, each within the length constraint of BERT. Next, each subthread is encoded with BERT to capture the local interactions between posts within the subthread, and then a Transformer layer is stacked on top of all the subthreads to capture the global interactions between posts in the whole conversation thread.
- To tackle the limitations of the MTL2 framework, we first design a Coupled Transformer Module to capture the inter-task interactions between the stance-specific and the rumor-specific layers. Moreover, to utilize the stance distributions predicted for each post, we propose to concatenate them with its associated post representations, followed by a post-level attention mechanism to automatically learn the importance of each post for the final rumor verification task.

Evaluations on two benchmark datasets demonstrate the following: First, compared with existing single-task models, our Hierarchical Transformer brings consistent performance gains on Macro-F_1 for both SC and RV tasks. Second, our Coupled Hierarchical Transformer outperforms the state-of-the-art multi-task learning approach by 9.2% and 6.3% on Macro-F_1 for the two benchmarks, respectively.

2 Related Work

Stance Classification: Although stance classification has been well studied in different contexts such as online forums (Hasan and Ng, 2013; Lukasik et al., 2016; Ferreira and Vlachos, 2016; Mohammad et al., 2016), a recent trend is to study stance classification towards rumors in different social media platforms (Mendoza et al., 2010; Qazvinian et al., 2011). These studies can be roughly categorized into two groups. One line of work aims to design different features to capture the sequential property of conversation threads (Zubiaga et al., 2016; Aker et al., 2017; Pamungkas et al., 2018; Zubiaga et al., 2018b; Giasemidis et al., 2018). Another line of work attempts to apply recent deep learning models to automatically capture effective stance features (Kochkina et al., 2017; Veyseh et al., 2017). Our work extends the latter line of work by proposing a hierarchical Transformer based on the recent pre-trained BERT for this task. Moreover, we notice that our BERT-based hierarchical Transformer is similar to the model proposed in (Pappagari et al., 2019), but we want to point out that our model design in the input and output layers is specific to stance classification, which is different from their work.

Rumor Verification: Due to the negative impact of various rumors spreading on social media, rumor verification has attracted increasing attention in recent years. Existing approaches to single-task rumor verification generally belong to two groups. The first line of work focuses on either employing a myriad of hand-crafted features (Qazvinian et al., 2011; Yang et al., 2012; Kwon et al., 2013; Ma et al., 2015) including post contents, user profiles, information credibility features (Castillo et al., 2011), and propagation patterns, or resorting to various kinds of kernels to model the event propagation structure (Wu et al., 2015; Ma et al., 2017). The second line of work applies variants of several neural network models to automatically capture important features among all the propagated posts (Ma et al., 2016; Ruchansky et al., 2017; Chen et al., 2018). Different from these studies, the goal in this paper is to leverage stance classification to improve rumor verification with a multi-task learning architecture.

Stance-Aware Rumor Verification: The recent advance in rumor verification is to exploit stance information to enhance rumor verification with different multi-task learning approaches. Specifically, Ma et al. (2018a) and Kochkina et al. (2018) respectively proposed two multi-task learning architectures to jointly optimize stance classification and rumor verification based on two different variants of RNN, i.e., GRU and LSTM. More recently, Kumar and Carley (2019) proposed another multi-task LSTM model based on tree structures for stance-aware rumor verification. Our work bears the same intuition to these previous studies, and aims to explore the potential of the pre-trained BERT to this multi-task learning task.

3 Methodology

In this section, we first formulate the task of stance classification (SC) and rumor verification (RV). We then describe our single-task model for SC and RV, followed by introducing our multi-task learning framework for stance-aware rumor verification.

3.1 Task Formulation

Given a Twitter corpus, let us first use $\mathbb{D} = \{C_1, C_2, \ldots, C_{|\mathbb{D}|}\}$ to denote a set of conversation threads in the corpus. Each thread C_i is then assumed to consist of a post with the source claim S^0 and a sequence of reply posts sorted in chronological order, denoted by R^1, R^2, ... , R^N.

For the SC task, given an input thread C_i, we assume that each post (including a source post and reply posts) in the thread is annotated with a stance label towards the source claim, namely *support*, *deny*, *query*, and *comment*. Formally, let $\mathbf{s} = (s^0$, s^1, ..., $s^N)$ denote the sequence of stance labels, and the goal of SC is to learn a sequence classification function g: $S^0, R^1, \ldots, R^N \rightarrow s^0, s^1, \ldots, s^N$.

For the RV task, we assume that each input thread C_i is associated with a rumor label y_i, which belongs to one of the three classes, namely *false rumor*, *true rumor*, and *unverified rumor*. The goal of RV is to learn a classification function f: $C_i \rightarrow y_i$.

3.2 Hierarchical Transformer for Stance Classification and Rumor Verification

In this subsection, we present our proposed Hierarchical Transformer, which is a single-task learning framework encompassing the tasks of SC and RV. Fig. 2 illustrates the overview of our model, which mainly consists of four modules, including input thread transformation, local context encoding, global context encoding, and output layers.

Motivation: Although BERT has been widely adopted in various NLP tasks (Devlin et al., 2019), its application to our SC and RV tasks is not trivial. First, most previous studies employed BERT to obtain token-level representations for sentence or paragraph understanding, while our SC and RV tasks primarily require sentence-level representations for conversation thread understanding. Second, due to the maximum length constraint during the pre-training stage, BERT cannot be directly applied to encode arbitrarily long sequences, e.g., conversation threads in our tasks. Although truncating the input sequences is a feasible solution, it will inevitably ignore many posts that might be crucial for rumor verification.

Our main idea to address the limitations above is to divide the long sequence of a thread into shorter sequences, each within the length constraint of BERT, and to use a hierarchical model to capture the global interactions at the top layer.

Input Thread Transformation: First, to obtain post-level representations, we insert two special tokens, i.e., [CLS] and [SEP], to the beginning and the end of each post, where the [CLS] token is intended to represent the semantic meaning of the post following it. We then sort the transformed posts in each thread C_i in chronological order, followed by flattening them into a long sequence. Second, to eliminate the maximum length constraint,

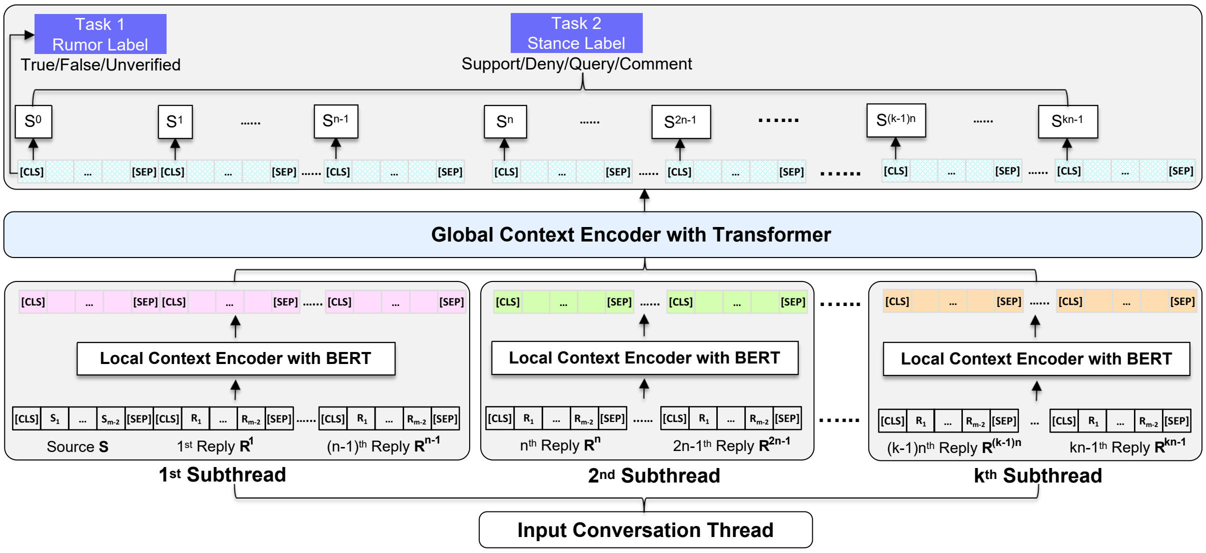


Figure 2: Our Single-Task Model (Hierarchical Transformer) for Stance Classification and Rumor Verification.

we propose to decompose the flattened sequence into multiple subthreads, so that each subthread has the same number of posts, and the sequence length of each subthread satisfies the length constraint.

Formally, let $C_i = (S^0, R^1, \ldots, R^N)$ denote the flattened thread, where S^0 is the source post, and R^j refers to the j-th reply post. As shown in the bottom of Fig. 2, we assume that C_i is decomposed into k subthreads, each subthread consists of n consecutive posts, and each post consists of m tokens[2]. For the j-th post in the thread C_i, let us use $\mathbf{P}_j = (\mathbf{x}^j_{\text{CLS}}, \mathbf{x}^j_1, \ldots, \mathbf{x}^j_{m-2}, \mathbf{x}^j_{\text{SEP}})$ to denote its input representations, where each token $\mathbf{x}$ is represented by summing up its word embeddings, segment embeddings and position embeddings. For the l-th subthread in C_i, we use $\mathbf{B}_l = (\mathbf{P}_{l0}, \mathbf{P}_{l1}, \ldots, \mathbf{P}_{l(n-1)})$ to refer to it.

Local Context Encoding (LCE): Next, we employ the pre-trained BERT to separately process the k subthreads to capture the local interactions between adjacent posts within each subthread:

$$\mathbf{h}_l = \text{BERT}(\mathbf{B}_l), \quad l = 1, 2, \ldots, k \tag{1}$$

where $\mathbf{h}_l \in \mathbb{R}^{nm \times d}$ is the hidden representation generated for the l-th subthread.

Global Context Encoding (GCE): To further capture the global interactions between all the posts in the whole conversation thread, we propose to first concatenate the hidden representations of each subthread: $\mathbf{h} = \mathbf{h}_1 \oplus \mathbf{h}_2 \oplus \ldots \oplus \mathbf{h}_k$. We then feed $\mathbf{h}$ to a standard Transformer layer as follows:

$$\widetilde{\mathbf{h}} = \text{LN}(\mathbf{h} + \text{MH-ATT}(\mathbf{h})), \tag{2}$$

$$\mathbf{H} = \text{LN}(\widetilde{\mathbf{h}} + \text{FFN}(\widetilde{\mathbf{h}})), \tag{3}$$

where MH-ATT and FFN respectively refer to the multi-head self-attention and the feed forward network (Vaswani et al., 2017), and LN refers to layer normalization (Ba et al., 2016).

Output Layers: Based on the global hidden representation $\mathbf{H}$, we further stack the output layers to make predictions for SC and RV, respectively. Specifically, for the SC task, we treat the hidden state of the j-th [CLS] token as the representation for the j-th post, followed by adding a softmax layer to classify its stance towards the source claim:

$$p(s^j \mid \mathbf{H}^j_{\text{CLS}}) = \text{softmax}(\mathbf{W}_s^\top \mathbf{H}^j_{\text{CLS}} + \mathbf{b}_s), \tag{4}$$

where $\mathbf{W}_s \in \mathbb{R}^{d \times 4}$ and $\mathbf{b}_s \in \mathbb{R}^4$ are learnable parameters. Moreover, for the RV task, we add a softmax layer over the last hidden state of the first [CLS] token for rumor veracity prediction:

$$p(y \mid \mathbf{H}^0_{\text{CLS}}) = \text{softmax}(\mathbf{W}_r^\top \mathbf{H}^0_{\text{CLS}} + \mathbf{b}_r), \tag{5}$$

where $\mathbf{W}_r \in \mathbb{R}^{d \times 3}$ and $\mathbf{b}_r \in \mathbb{R}^3$ are weight and bias parameters.

3.3 Coupled Hierarchical Transformer for Stance-Aware Rumor Verification

Based on the above single-task model (i.e., Hierarchical Transformer), we describe our proposed multi-task learning (MTL) framework for stance-aware rumor verification in this subsection.

Baseline MTL Framework: To exploit the stance signals for rumor verification, a widely used MTL

---

[2] Note that for parallel computing, each post is padded or truncated to have the same number of tokens, i.e., m, and each subthread is padded to have the same number of posts, i.e., n.

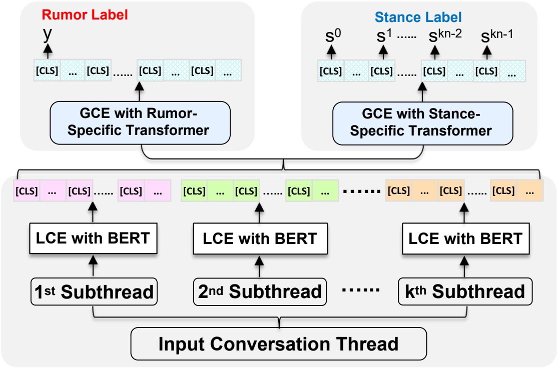

Figure 3: Baseline Multi-Task Learning Framework (MTL2) for Stance-Aware Rumor Verification.

framework is the MTL2 model proposed in Kochkina et al. (2018), which assumes that the SC and RV tasks share the low-level neural layers but the high-level layers are specific to each task. As illustrated in Fig. 3, to adapt our Hierarchical Transformer to this MTL2 framework, we propose to share the input and LCE modules between SC and RV, followed by employing separate GCE and output modules for these two tasks, respectively.

Motivation: However, as mentioned before, this baseline MTL framework has two major limitations. First, it fails to consider the inter-task interaction. Since the GCE module in SC is supervised to capture salient stance-specific features such as *no doubt*, *agree* and *fake news*, these features can be leveraged to guide the GCE module in RV to capture those important rumor-specific features closely related to stance features. Moreover, since both stance-specific and rumor-specific features are intuitively crucial to RV, it is necessary to effectively integrate them. Second, it ignores the sequential stance labels predicted from the output module in SC. Actually, the predicted stance distributions for each post can capture the temporal evolution of public stances towards the source claim, which may reflect indicative clues for veracity prediction.

Coupled Transformer Module: To model inter-task interactions, we devise a Coupled Transformer Module with two coupled components in Fig. 4: a stance-specific Transformer and a cross-task Transformer.

Concretely, we first employ a standard Transformer layer (i.e., Eqn (2) and Eqn (3)) to obtain stance-specific representations $\mathbf{P}$ in the right channel. Next, to learn the inter-task interactions in the left channel, we design a multi-head stance-aware attention mechanism (MH-SATT) by treating $\mathbf{P}$ as queries, and $\mathbf{h}$ as keys and values, which essentially leverages stance-specific features in $\mathbf{P}$ to

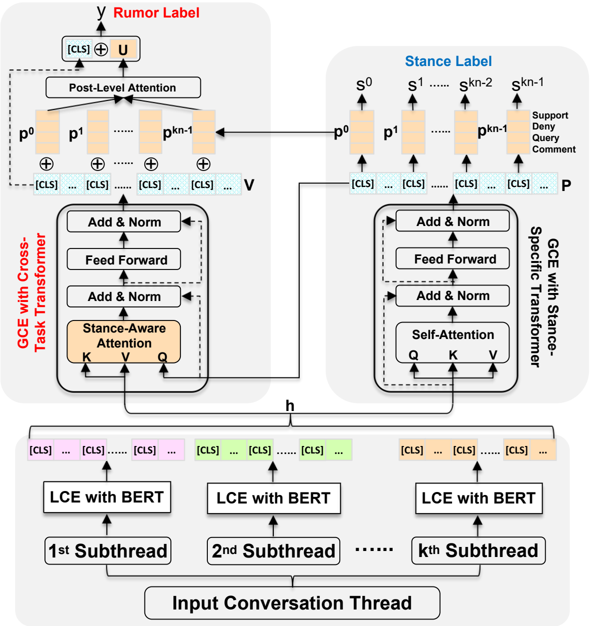

Figure 4: Our Multi-Task Learning Framework (Coupled Hierarchical Transformer) for Stance-Aware Rumor Verification.

guide our model to pay more attention to stance-aware rumor-specific features. Specifically, the i-th head of MH-SATT is defined as follows:

$$\mathrm{SATT}_i(\mathbf{P},\mathbf{h}) = \mathrm{softmax}\Big(\frac{[\mathbf{W_q P}]^\top[\mathbf{W_k h}]}{\sqrt{d/z}}\Big)[\mathbf{W_v h}]^\top, \quad (6)$$

where $\{\mathbf{W_q}, \mathbf{W_k}, \mathbf{W_v}\} \in \mathbb{R}^{d/z \times d}$ are parameters, and z is the number of heads.

Moreover, to integrate stance-specific and rumor-specific features, we propose to add a layer norm together with a residual connection as follows:

$$\widetilde{\mathbf{V}} = \mathrm{LN}(\mathbf{P} + \text{MH-SATT}(\mathbf{P},\mathbf{h})). \quad (7)$$

Finally, we add a feed-forward network and a layer normalization to get the rumor-stance hybrid representations $\mathbf{V}$:

$$\mathbf{V} = \mathrm{LN}(\widetilde{\mathbf{V}} + \mathrm{FFN}(\widetilde{\mathbf{V}})). \quad (8)$$

Post-Level Attention with Stance Labels: To address the second limitation, we propose to concatenate each post's stance distribution and its corresponding hidden representation, followed by a post-level attention layer to automatically learn the importance of each post.

Specifically, as shown in Fig. 4, we first use Eqn (4) to predict the stance distribution of the j-th post in the right channel, denoted by $\mathbf{p}^j$. We then treat the hybrid representation of the j-th [CLS] token (i.e., $\mathbf{V}^j_{\mathrm{CLS}}$) as the representation of the j-th post, and concatenate it with $\mathbf{p}^j$, followed by feeding them to a post-level attention layer to obtain the stance label-aware thread representation $\mathbf{U}$:

			Stance Labels				**Rumor Veracity Labels**		
Dataset	#Threads	#Tweets	*#Support*	*#Deny*	*#Query*	*#Comment*	*#True*	*#False*	*#Unverified*
SemEval-17	325	5,568	1,004	415	464	3,685	145	74	106
PHEME	2,402	105,354			-		1,067	638	697

Table 1: Basic statistics of the SemEval-2017 dataset and the PHEME dataset.

$$u_j = \mathbf{v}^\top \tanh\Big(\mathbf{W}_h(\mathbf{V}^j_{\text{CLS}} \oplus \mathbf{p}_j)\Big), \tag{9}$$

$$\alpha_j = \frac{\exp(u_j)}{\sum_{l=1}^{N} \exp(u_l)}, \tag{10}$$

$$\mathbf{U} = \sum_{j=1}^{N} \alpha_j (\mathbf{V}^j_{\text{CLS}} \oplus \mathbf{p}_j). \tag{11}$$

Output Layers: Finally, since $\mathbf{V}^0_{\text{CLS}}$ and $\mathbf{U}$ can be considered as the token-level thread representation and the post-level thread representation respectively, we propose to concatenate them to predict the veracity label of the source claim:

$$p(y \mid \mathbf{V}^0_{\text{CLS}}, \mathbf{U}) = \text{softmax}\Big(\mathbf{W}^\top(\mathbf{V}^0_{\text{CLS}} \oplus \mathbf{U}) + \mathbf{b}\Big), \tag{12}$$

where $\mathbf{W} \in \mathbb{R}^{(2d+4)\times 3}$ and $\mathbf{b} \in \mathbb{R}^3$ are weight and bias terms.

Model Training: To optimize all the parameters in our Coupled Hierarchical Transformer, we adopt the alternating optimization strategy to minimize the following objective function, which is a combination of the cross-entropy loss of the two tasks:

$$\begin{aligned} \mathcal{J} = -\Big(&\frac{1}{M}\sum_{i=1}^{M} \log p(y_i \mid \mathbf{V}^0_{\text{CLS}}, \mathbf{U}) \\ &+ \frac{1}{M'}\sum_{k=1}^{M'}\sum_{j=1}^{N} \log p(s^j \mid \mathbf{P}^j_{\text{CLS}})\Big), \end{aligned} \tag{13}$$

where M and M' refer to the number of samples for the tasks of RV and SC, respectively.

4 Experiments

In this section, we first evaluate our single-task model on both stance classification (SC) and rumor verification (RV), followed by evaluating our multi-task learning model on RV. Finally, we perform further analysis to provide deeper insights into our proposed multi-task learning model.

4.1 Experiment Setting

Dataset: To demonstrate the effectiveness of our proposed approaches, we carry out experiments on two benchmark datasets, i.e., **SemEval-2017** and **PHEME**. Table 1 shows the basic statistics of the two datasets.

Specifically, **SemEval-2017** is a widely used dataset from SemEval-2017 Challenge Task 8, which contains 325 Twitter conversation threads discussing rumors (Derczynski et al., 2017). The dataset has been split into training, development, and test sets, where the former two sets are related to eight events and the test set covers two additional events. Since each thread is annotated with a rumor veracity label and each post in the thread is annotated with its stance towards the source claim, this dataset is used for evaluating both SC and RV tasks in this work.

PHEME is a well known dataset for RV, which contains 2402 Twitter conversation threads discussing nine events. For fair comparison with existing approaches, we perform cross-validation experiments based on leave-one-event-out settings: for each fold, all the threads related to one event are used for testing, and all the threads related to the other eight events are used for training. Following previous studies (Kochkina et al., 2018; Wei et al., 2019), **PHEME** is only used for evaluating the performance of RV.

Since the class distribution of the two datasets are imbalanced, we employ Macro-F_1 as the main evaluation metric and accuracy as the secondary evaluation metric for both tasks.

Parameter Settings: Our models are based on the pre-trained uncased *BERT*$_{base}$ model (Devlin et al., 2019), where the number of BERT layers is 12 and the number of attention heads is z = 12. Moreover, for both Hierarchical Transformer and Coupled Hierarchical Transformer, we set the learning rate as 5e-5, and the dropout rate as 0.1. Due to memory limitation, for each conversation thread, the number of subthreads is set to k = 6, and the maximum input length of each subthread is set as 512. For each subthread, the number of posts is set to n = 17, and the number of tokens in each post is fixed to m = 30. Moreover, the batch size is respectively set as 4 and 2 for Hierarchical Transformer and Coupled Hierarchical Transformer, respectively. We implement all the models based on PyTorch with a *24GB NVIDIA TITAN RTX* GPU.

	Single Stance Type Evaluation				Overall Evaluation

Table 3: Results of rumor veracity prediction. Single-Task indicates that stance labels are not used during the training stage. † indicates that our Coupled Hieararchical Transformer model is significantly better than the best compared system with p-value $<$ 0.05 based on McNemar's significance test.

4.2 Main Results

4.2.1 Evaluation on Single-Task Models

In this subsection, we compare our proposed Hierarchical Transformer with existing single-task models for SC and RV, respectively.

Stance Classification (SC): We first consider the following competitive approaches that focus on SC only: (1) *SVM* is a baseline method that feeds conversation-based and affective-based features to linear SVM (Pamungkas et al., 2018); (2) *BranchLSTM* is an LSTM-based architecture designed by Kochkina et al. (2018), which focuses on modeling the sequential branches in each thread; (3) *Temporal ATT* is an attention-based model proposed by Veyseh et al. (2017), which treats each post's adjacent posts in a conversation timeline as its local context, followed by employing attention mechanism over the local context to learn the importance of each adjacent post; (4) *Conversational GCN* is the state-of-the-art approach recently proposed by Wei et al. (2019), which leverages graph convolutional network to model the relations between posts in each thread.

We report the SC results in Table 2. First, it is clear to observe that our Hierarchical Transformer model performs much better than all the compared systems on Macro-F_1. Second, compared with previous approaches, our model shows its strong capability of detecting posts belonging to the *support* and *deny* stances. This is crucial for veracity prediction, because the *support* and *deny* stances usually provide important clues to identify the *true* and *false* rumors respectively (see Fig. 5). All these observations demonstrate the general effectiveness of our Hierarchical Transformer model.

Rumor Verification (RV): We then consider several competitive systems that focus on RV only: (1) *RvNN* is a recursive neural network model based on top-down tree structure, which is proposed by Ma et al. (2018b); (2) *Hierarchical GCN-RNN* is a variant of *Conversational GCN* for veracity prediction; (3) *PLAN* is the state-of-the-art approach recently proposed by Khoo et al. (2020), which uses a randomly initialized Transformer to encode each conversation thread.

We report the RV results of compared systems on **SemEval-2017** and **PHEME** in the top part of Table 3. First, compared with earlier methods for RV, we observe that our Hierarchical Transformer model gains significant improvements, outperforming *Hierarchical GCN-RNN* by 5.2 and 5.5 absolute percentage points on Macro-F_1 for the two datasets, respectively. Second, even compared with the recent state-of-the-art model *PLAN*, our model

Methods (TFM: Transformer)	Macro-F_1	Accuracy
Hierarchical TFM	**0.372**	**0.441**
- Truncating Input & Removing Global TFM	0.354	0.409
Coupled Hierarchical TFM	**0.396**	**0.466**
- Removing Post-Level Attention	0.385	0.430
- Replacing Cross-Task TFM with TFM	0.390	0.456

Table 4: Ablation study on the PHEME dataset.

can still bring moderate performance gains on the two datasets. Since *PLAN* is based on randomly initialized Transformer whereas our model is based on pre-trained Transformer (i.e., BERT), this shows the usefulness of employing pre-trained models for RV, which agrees with our first motivation.

4.2.2 Evaluation on Multi-Task Models

In this subsection, we evaluate the effectiveness of our Coupled Hierarchical Transformer model, and consider several multi-task learning frameworks for stance-aware rumor verification: (1) *BranchLSTM+NileTMRG* is a pipeline approach, which first trains a *BranchLSTM* model for SC, followed by a SVM classifier for RV (Kochkina et al., 2018); (2) *MTL2* is the MTL framework proposed in (Kochkina et al., 2018), which shares a single LSTM channel but uses two separate output layers for SC and RV, respectively; (3) *Hierarchical PSV* is a hierarchical model proposed by (Wei et al., 2019), which first learns content and stance features via *Conversational-GCN*, followed by exploiting temporal evolution for RV via *Stance-Aware RNN*; (4) *MTL2-Hierarchical Transformer* is our adapted MTL2 model which is introduced in Section 3.3.

In the bottom part of Table 3, we can first find that all the multi-task learning models achieve better performance than their corresponding single-task baselines across the two datasets, which verifies the usefulness of stance signals for RV. Second, among all the multi-task learning approaches, it is clear to observe that our Coupled Hierarchical Transformer model consistently achieves the best results on both **SemEval-2017** and **PHEME**, which outperforms the second best method by 2.3 and 2.1 absolute percentage points on Macro-F_1 for the two datasets, respectively. These observations show the superiority of our proposed model over previous multi-task learning methods for stance-aware rumor verification.

4.3 Ablation Study

To examine the impact of each key component in our single-task and multi-task approaches, we further perform ablation study in this subsection.

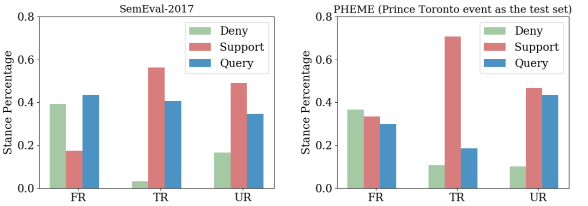

Figure 5: Correlation between predicted stance classes (y-axis) and predicted rumor labels (x-axis) from our Coupled Hierarchical Transformer on test sets of our two datasets.

As shown in Table 4, for our proposed Hierarchical Transformer, we can see that if we directly apply BERT to our RV task (i.e., truncating the input thread and removing the global Transformer layer), the performance will drop significantly. This is in line with our first motivation, and also demonstrates the effectiveness of our proposed model.

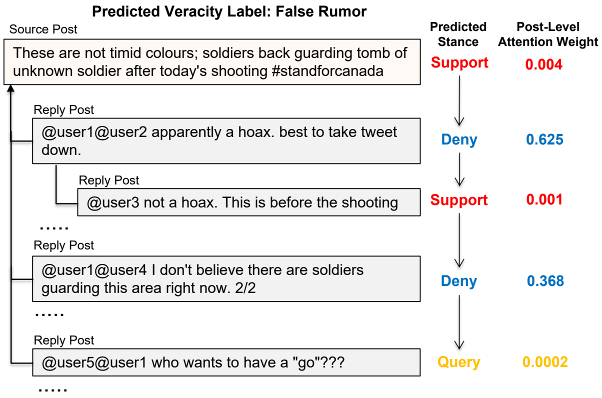
Moreover, for our multi-task learning framework (i.e., Coupled Hierarchical Transformer), the post-level attention layer shows its indispensable role because of the significant performance drop after removal. Meanwhile, replacing our cross-task Transformer with the standard Transformer will lead to moderate performance drop in both datasets, which also suggests its importance to our full model.

4.4 Correlation Between Predicted Stance Labels and Veracity Labels

To better understand the usefulness of stance signals to veracity prediction in our Coupled Hierarchical Transformer, we first analyze the correlation between predicted stance classes and predicted veracity labels on our two datasets. Since the *comment* stance is not crucial for rumor verification, we focus on the other three stance classes, i.e., *deny*, *query*, and *support*.

As shown in Fig. 5, we can clearly see that *true rumor* is more closely associated with the *support* stance, whereas *false rumor* is generally dominated by the other two stances *deny* and *query*. This suggests that our multi-task learning model has implicitly learnt that the stance signal can provide important clues to rumor verification.

Case Study: To provide deeper insights into our Coupled Hierarchical Transformer, we carefully choose one representative sample from our test set, and show the stance and veracity prediction results as well as the attention weights of each post learnt in the post-level attention layer. Due to space limitation, we only show five posts with the top-5 attention weights in the thread.



These are not timid colours; soldiers back guarding tomb of unknown soldier after today's shooting #standforcanada

@user1@user2 apparently a hoax. best to take tweet down.

@user3 not a hoax. This is before the shooting

@user1@user4 I don't believe there are soldiers guarding this area right now. 2/2

@user5@user1 who wants to have a "go"???

Figure 6: Stance classes and rumor labels predicted by Coupled Hierarchical Transformer on a test sample in PHEME dataset.

In Fig. 6, we can see that although the source claim is supported by some replies, our model learns to pay much higher attention weights to the two posts with *deny* stance while primarily ignoring the other posts, which may help our model correctly predict its veracity label as *false rumor*.

5 Conclusion

In this paper, we first examined the limitations of existing approaches to stance classification (SC) and rumor verification (RV). To tackle these limitations, we first proposed a single-task model (i.e., Hierarchical Transformer) for SC and RV, followed by designing a multi-task learning framework with a Coupled Transformer module to capture inter-task interactions and a Post-Level Attention Layer to use stance distributions for the RV task. Experiments on two benchmarks show the effectiveness of our single-task and multi-task learning methods.

Abstract

Attribution of natural disasters/collective misfortune is a widely-studied political science problem. However, such studies typically rely on surveys, expert opinions, or external signals such as voting outcomes. In this paper, we explore the viability of using unstructured, noisy social media data to complement traditional surveys through automatically extracting attribution factors. We present a novel prediction task of *attribution tie detection* of identifying the factors (e.g., poor city planning, exploding population etc.) held responsible for the crisis in a social media document. We focus on the 2019 Chennai water crisis that rapidly escalated into a discussion topic with global importance following alarming water-crisis statistics. On a challenging data set constructed from YouTube comments (72,098 comments posted by 43,859 users on 623 videos relevant to the crisis), we present a neural baseline to identify attribution ties that achieves a reasonable performance (accuracy: 87.34% on attribution detection and 81.37% on attribution resolution). We release the first annotated data set of 2,500 comments in this important domain[1].

1 Introduction

Water crisis is one of the pressing current environmental challenges. More than a billion people do not have access to clean drinking water, and every year nearly two million children die from water borne diseases (Watkins, 2006). One-third of the world's most extensive groundwater systems are under severe stress (Richey et al., 2015). The forecasts look even more grim; nearly two-thirds of the world population could be water stressed by 2025 (Seckler et al., 1999). While the crisis has reached an alarming level far and wide, India is listed as one of the major at-risk countries (Rost et al., 2008). In June 2019, the longstanding Chennai water crisis (WashingtonPost, 2019) escalated into an international talking point, revealing alarming statistics of the water crisis in India looming in near future. In this context, we define a new task of inferring *attribution ties* through large scale analysis of relevant social media discussions. Our main contributions in this paper are the following.

Social: Apportioning attribution for a collective crisis or misfortune still remains a challenge in social science, despite the presence of a large body of political science literature on retrospective voting (see, e.g., Ferejohn 1986; Peffley 1984) or psychological literature on attribution (see, e.g., Shaver 2012). Prior social science literature (Griffin et al., 2008) primarily relies on traditional surveys for attribution analysis. Unlike traditional surveys, social media analyses are vastly cheaper, have faster turnaround time, can be conducted at different spatiotemporal granularities and aggregate a larger number of opinions than traditional surveys can usually afford. For instance, the most-recent PEW survey (Pew) focused on India was conducted in 2018 on only 2,521 users. In contrast, our data set consists of comments from 43,859 users.

Data set on crisis attribution: To the best of our knowledge, we present the first large scale social media analysis of the Chennai water crisis via a substantial corpus of 72,098 YouTube comments posted by 43,859 users on 623 relevant videos. Our choice of YouTube is informed by

November 16–20, 2020.

(1) its global reach; (2) its popularity in the Indian subcontinent (HindustanTimes, 2019); and (3) prior literature of analyzing globally important events (Palakodety et al., 2020a,c; Cinelli et al., 2020). We not only analyze and present the nuances of social media conversation in Indian subcontinental English, but we also release the first annotated data set on this important domain.

NLP task and model: Our main machine learning contributions are a new task of detecting *attribution ties* from unstructured web data and baselines that automatically detect them. Table 1 lists a few example comments from our data set. We argue that the task of attribution ties detection is a challenging NLP task that requires subtle understanding of language constructs. Consider the following example: '*stop have* ***9 kids family***'. In this comment, a growing population is attributed as the possible cause of the water crisis. While there is no surface level text match with the term *'population'*, humans can still infer it from the semantic equivalence of *population'* and *'9 kids family'*. As there can be many equivalent ways of expressing attributions, a semantic understanding of the language is necessary for the task. Moreover, although necessary, establishing semantic equivalence is not sufficient for attribution detection. Consider another example: '*can't feed* ***9 kids family***'. In this example, we again see that the same phrase *'9 kids family'* is present, yet the comment is not attributing to *'population'* for the water crisis. Hence, to correctly detect an attribution tie, we also need to understand the context in which an attribution factor is mentioned. Finally, scarcity of labelled data and the informal nature of conversation in social media pose additional challenges. We present a spectrum of model architectures with increasing sophistication that encode these topical and contextual information to detect attribution ties from a user comment. We use pre-trained language model (LM) to leverage transfer learning and overcome the challenge of paucity of labelled data. Furthermore, we demonstrate that fine-tuned, pre-trained LMs on Indian social media data have the ability to generalize and tackle the quirks of English written by non-native speakers. We find that applying such models improves the performance on the attribution detection task, even though the underlying LM was tuned on a data set that primarily focused on a topic (2019 Indian General Election) (Palakodety et al., 2020b) different from ours.

Attribution factor	Comment
Overpopulation	people need to stop having kids otherwise this lack of good water problem will spread
Climate change	coastline cities like mumbai and chennai is going to sink under water after sea rise due to global warming while we fight for water
Deforestation	plant trees dumb ass trees will hold water as well as soil you have no trees at all that is why you have not water
Contamination | Public water wastage	from the water truck they poured much of it on the ground they put dead bodies and trash in their own water
Government | Public water wastage	not only government but all the the civilian sorry equally responsible for or the water crisis i live in Delhi and it is not a single day when i have not encounter water wastage

Table 1: Examples of *attribution ties* in our data set. Multiple factors are separated by | .

2 Related Work

Water crisis has received sustained research focus in a diverse set of fields such as food policy research (Hanjra and Qureshi, 2010), earth science (Qin et al., 2007), social science (Foltz, 2002), and water research (Schindler and Donahue, 2006; Narula et al., 2011; von Medeazza, 2006), encompassing a broad range of dimensions including the socio-hydrological, ethical, cultural, and foreign policy aspects of the crisis. Our work relies on these lines of research to compile a list of possible attribution factors (see, Table 3). However, our focus is different as we seek to tackle the NLP challenges associated with analyzing attributions from noisy social media data. Our work shares similar motivations to a recently-reported work on the Flint water crisis (Oz and Bisgin, 2016) that evaluated attributions from a substantial tweet corpus. Our work is different from Oz and Bisgin (2016) for the the following reasons: first, our data set is linguistically more challenging (see Section 3.2) as a vast majority of the content creators are non-native speakers of English, second, we propose a learning problem that automates the detection of attributions while Oz and Bisgin (2016) formed different hypotheses on the nature of the attributions and then accepted or rejected those hypotheses based on randomly sampled data labelled by annotators.

Methodologically, our work is closely related with automatic extraction of blame ties (Liang et al., 2019). Similar to Liang et al. (2019), we seek to extract causal ties (Miwa and Bansal, 2016) between a crisis and different possible factors. However, unlike the present work, Liang et al. (2019) focused on a clean corpus obtained from three major US newspapers. In contrast, we embrace the challenge of detecting *attribution ties* from noisy, social media data which involves the following challenges. First, these discussions are produced in a part of the globe where vast majority of content contributors are non-native speakers of English. Second, social media discussions encompass a diverse set of expressions ranging from stating pure fact or statistics to crude disgust and subtle sarcasm, and attribution topics are often expressed in widely different ways. For example, both the comments, '*we must protect our forests* ***plant more trees***' and '*just rewind and see how many* ***trees have vanished*** *over the years to accommodate more space for buildings and malls*' deemed *deforestation* responsible for water crisis but have different ways of expressing it. In contrast, Liang et al. (2019) dealt with a set of well constructed entities that are easy to detect in a sentence due to their crisp word boundaries.

3 Data Set

3.1 YouTube Video Comments

Using the publicly available YouTube's Search API, we query YouTube with the following search queries: *Chennai water crisis*; and *India water crisis*. For each query, we construct our video set, $\mathcal{V}$, by adding 350 recommended videos. Upon removal of duplicate videos and videos without a single comment, $\mathcal{V}$ is pruned to contain 623 unique videos. For each video in $\mathcal{V}$, we extract posted comments using the publicly available YouTube Data API. Our overall comment data set, $\mathcal{D}_{all}$, consists of 72,098 comments.

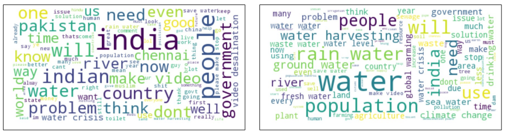
Since India is a country with vast linguistic diversity, a language identification technique is required to extract comments written in English. We use a recently-proposed language identification method (Palakodety et al., 2020a) that has been successfully used for both document and token level language identification (KhudaBukhsh et al., 2020) and other multilingual settings (Palakodety et al., 2020b) and extracted comments written in English. Our filtered set of English comments, $\mathcal{D}$, consists of 41,791 comments.

3.2 Data Set Challenges

Beyond the typical challenges posed by noisy social media texts, in our case, the vast majority of the contributors are non-native English speakers often employing a telegraphic and colloquial style. We outline some of these challenges with representative examples next. A detailed treatment of this challenge is presented in (Sarkar et al., 2020).

Topic 1 (17.6%)	Topic 2 (16.3%)	Topic 3 (9.6%)	Topic 4 (9.5%)	Topic 5 (8.2%)
water	india	change	india	muslim
save	country	climate	pakistan	indian
need	population	global	river	india
drink	people	human	china	religion
river	indian	nature	kashmir	hindu
waste	problem	animal	shit	like

Table 2: Most relevant tokens for five major topics discovered in our data set using Blei et al. (2003).



(a) $\mathcal{D}$ (b) $\mathcal{D}_{pruned}$

Figure 1: Word cloud visualizations of $\mathcal{D}$ and $\mathcal{D}_{pruned}$.

Spelling errors: We notice a considerable amount of phonetic spelling errors (e.g., '*check the* ***expedinjar*** *level in India and other countries*' originally intended to express **expenditure**).
Out of vocabulary (OOV) words: Several comments use contraction (e.g., '***plz*** *make* ***vdo*** *in rainwater harvesting*'), hence generating OOV words. Our data set has only 28.9% intersection of words with GloVe (Pennington et al., 2014) vocabulary.
Grammatical errors: Several comments suffer from grammatical disfluencies (e.g., '*this not happen everyear because of heat wave in south india this happen*') making our analysis challenging.

3.3 Topical Focus

To present a broad overview of the topics, Table 2 summarizes our topic modeling results using LDA (Blei et al., 2003). As shown in Table 2, the main topics of discussion relevant to the crisis involve call to save water (topic 1), overpopulation as a major problem (topic 2), and climate change (topic 3). A considerable fraction of overall discussion is focused on peripheral topics unrelated to the water crisis (topic 4 and topic 5). For example, the presence of topics surrounding India and Pakistan is not surprising since the Pulwama terror attack in Kashmir (Feb, 2019) and an ensuing India-Pakistan conflict was a major contemporaneous sociopolitical issue (BBC).

3.4 Data Pruning

Since the peripheral discussions unrelated to water crisis are not meaningful for our current analysis, in order to reduce annotation cost, we use an embedding-based method to first filter in comments

topographical disadvantage, weather, climate change, global warming, industrial development, petroleum industry, water intensive industries, oil sands development expansion of urban areas, conversion of lands for human usage, urban waste, corruption, mismanagement, contamination, industrial wastewater, industrial waste draining, cyanobacteria, bacteria, overpopulation, population shift, excessive demand, irresponsible irrigation, water intensive irrigation, irrigation water demand, irrigated agriculture, water intensive agriculture, inefficient irrigation, water withdrawals, irresponsible water pumping, public water wastage, excessive usage, indifference of policy makers, lack of funding , funding cuts, lack of study, loss of water bodies, depletion of ground water, permanent removal from water cycle groundwater exploitation, strain on natural resources, deforestation, nutrient loss in soil, eutrophication, drought, flood, damming, impoundment, human activity, water intensive protein rich diet, consumption by livestock, inefficient distribution system

Table 3: List of factors obtained from existing water crisis literature.

more likely to be relevant to the water crisis.

First, we consult relevant research conducted by the water research, urban planning, political science and environmental science communities, and ground our analysis through constructing a list of potential factors scientists typically identify as possible reasons for water scarcity. Our list (presented in Table 3) is based on literature (1) focusing on the global water crisis; (2) targeted analysis on a wide range of geographic regions; and (3) the specific water crisis in Chennai and broadly in India (Schindler and Donahue, 2006; Hanjra and Qureshi, 2010; Qin et al., 2007; Foltz, 2002; Marshall, 2011; Rodell et al., 2009; Narula et al., 2011; von Medeazza, 2006).

Since several factors listed in Table 3 are semantically close, we define 21 broad attribution categories listed in Table 4. We acknowledge that several other reasonable and logical partitions of these attribution categories are possible.

While the list presented in Table 3 is comprehensive covering a broad range of geographical regions, given India's multi-layered socio-political diversity, some of the attribution factors may not be present in the compiled list. In such cases, we instructed the annotators to describe the category in a simple English phrase of not more than four words. For instance, religion was a category discovered by our annotators; a small fraction of comments blamed specific religions for overpopulation and contaminating the Ganges. Similarly, (lack of) desalination facilities was identified as another factor.

Let $\mathcal{F}$ denote the set of factors presented in Table 3. Let a comment d be represented as a sequence of sentences $s_1, \ldots, s_n$. For each s_i, we compute the embedding-based cosine similarity between $\langle s_i, f \rangle$, $f \in \mathcal{F}$ (denoted as $Cosine(\langle s_i, f \rangle)$). We use 300 dimensional GloVe (Pennington et al., 2014) embeddings in this step. While calculating the embedding of a sentence, we removed stopwords and OOV words and computed a tf-idf weighted mean of the remaining words. For a given comment, attribution factor pair, $\langle d, f \rangle$, the similarity score, $sim(\langle d, f \rangle)$ is defined as $sim(\langle d, f \rangle) = \max_i\ (Cosine(\langle s_i, f \rangle))$ We removed all the $\langle d, f \rangle$ pairs for which - either $sim(\langle d, f \rangle)$ is less than 0.7 or f do not fall in the top 20 percentile of the nearest comments of any attribution factor.

Our pruned comment set, $\mathcal{D}_{pruned}$, consists of 2,282 comments (9,004 sentences). A word cloud visualization (see, Figure 1) reveals that our pruning method lends more prominence to water specific tokens than tokens unrelated to the crisis (e.g., Pakistan). We randomly sampled 1,500 comments from $\mathcal{D}_{pruned}$ (6,135 sentences), and 1,000 comments from $\mathcal{D}$ (3,284 sentences) for annotation. The percentages of comments having at least one attribution from $\mathcal{D}$ and $\mathcal{D}_{pruned}$ are 24.30% and 73.87%, respectively (i.e., embedding-based pruning yields more positives than random sampling).

Combining the samples from $\mathcal{D}$ and $\mathcal{D}_{pruned}$, we obtain our final data set of 2,500 annotated comments. Since a comment may consist of multiple sentences with different sentence attributing to different factors, our annotators labeled at the granularity of a sentence. After annotation, we obtain 1,351 comments with at least one attribution. We next merge contiguous sentences (from the same comment) with identical label into a single sentence yielding 2,385 positives and 5,837 negatives.

3.5 Characterizing the Annotated Data

Three annotators proficient in Hindi, English and Bengali conducted annotation in two separate phases. In the first phase, the annotators label if a sentence contains an attribution. A high Fleiss' κ measure of this task (0.86) indicates strong inter-rater agreement. Next, they specify the attribution factor chosen from the list presented in Table 3. For a given instance, a rater is allowed to choose multiple labels if she deems appropriate. Next, disagreements are resolved through a follow-up adjudication process. Following (Pavlick and Kwiatkowski, 2019), we surface any inherent ambiguity/disagreement between annotators in the final set of labels. Even after the adjudication process, if raters fail to resolve (say, $rater_1$ sticks to attribute a and $rater_2$ and $rater_3$ stick to attribute b), we propagate $\{a, b\}$ as the final label (accounting for 2.4% of the non-singleton labels). We find

Broad Category	Sub-categories
Agriculture	agricultural use, water intensive irrigation, inefficient irrigation, water intensive crops
Climate change	climate change, global warming, weather
Corruption	corruption, mismanagement
Damming	damming, impoundments
Deforestation	deforestation, nutrient loss in soil
Desalination	desalination
Government inaction	government inaction, indifference of policy makers, lack of proper funding
Groundwater exploitation	groundwater exploitation, strain on natural resources
Human activity	human activity, water intensive protein rich diet, consumption by livestock
Industrial development	industrial development, petroleum industry, water intensive industries, oil sands development
Lack of awareness	lack of awareness, lack of study
Lack of infrastructure	lack of infrastructure, inefficient distribution system
Lack of harvesting	lack of rainwater harvesting, lack of water preservation
Loss of water bodies	loss of water bodies, loss of water tables
Natural calamities	drought, flood
Overpopulation	overpopulation, excessive demand, population shift
Pollution	pollution, contamination, industrial waste water, industrial draining
Public water wastage	public water wastage, excessive usage
Religion	religion, Hindu caste system, Islam
Water Withdrawals	water withdrawals, irresponsible water pumping
Urbanization	urbanization, expansion of urban areas, land conversion, urban waste

Table 4: 21 broad categories of attribution factors.

that overpopulation, climate change, deforestation, public water wastage, pollution and government inaction are recurrent themes in the discussion.

4 Model Specification

4.1 Attribution Task

Given a set of YouTube comments $\mathcal{D}$ and a set of attributing factors $\mathcal{F}$ as described in Section 3, we aim to learn the underlying *attribution ties* between a comment $d \in \mathcal{D}$ and the set of attributing factors $f \in \mathcal{F}$. A simple way to model this can be posing the task as a multi-class classification over $\mathcal{F}$. We model this instead as learning a probability density function which determines for a tuple $\langle d, f \rangle$, how likely the factor f is attributed in the comment d. This allows us to learn the attribution relationship over a generic set of factors that may not be completely known *a priori*. Given a set of pairs of $\langle d, f \rangle$ labelled as positives (i.e., f is attributed in d), we aim to learn the different ways people express themselves when they attribute f in d. We define, $\mathcal{A}\colon (\mathcal{D}, \mathcal{F}) \mapsto [0, 1]$ as an attribution function that estimates the probability of the attribution relationship given $\langle d, f \rangle$ pair as input.

The task of designing the attribution function poses the following challenges. At a conceptual level, we need to model the specific topical relationship between d and f where the context of f in d is an attribution and not just a simple mention. In addition, the model needs to operate on the type of language used in social media, taking into account the challenges associated with non-native English speakers (mentioned in Section 3.2). At the implementation level, due to scarcity of labelled data, it is not possible to train an end-to-end LM that can capture all these nuances and hence we used pre-trained LMs such as `BERT` and its fine-tuned variant `BERT`$_{Indian}$ (Palakodety et al., 2020b). We address the over-fitting problem caused by low volume of labeled data by constraining the model to use a small number of trainable parameters while learning the underlying LM. As mentioned in Section 1, our proposed model aims to capture both the *topical similarity* of f in d and the *context* in which f is used in d. For every word $w_i \in d$ where $i = 1, 2, \ldots, n$ are the indices of each word in the comment, we define $\mathit{Similarity}_i^f$ as a semantic similarity measure between word w_i and attribute f. Furthermore we define, $\mathit{Context}_i^f$ as the measure that word w_i is used to express the context in which f is mentioned as the attributing factor for the crisis. To compute $\mathit{Similarity}_i^f$, we use an idea similar to attention mechanism by (Bahdanau et al., 2015). Specifically, we use cosine similarity between the representations of the attribution factor f and representations of w_i from the LM. We formulate $\mathit{Context}_i^f$ as an inversely correlated function of $\mathit{Similarity}_i^f$, where our intuition is for a positively labeled data-point, every word w_k that doesn't represent f, must capture its context in d.

4.2 Model Architecture

The model architecture is demonstrated in Figure 2. Applying the above intuition for a $\langle d, f \rangle$ pair (a comment-attribute tuple), we first obtain the contextual word embeddings $e(w_i)$ and $e(w_j)$ for words, $w_i \in d$ and $w_j \in f$ respectively, by using an LM such as `BERT`. As the attribution factors contain only a few words, we set the representation $E(f)$ for the attribution factor f as the mean embedding, $\mathit{mean}_{j \in |f|}\{e(w_j)\}$ (Eq. 1).

We then construct the probability function, $\mathit{Similarity}_i^f$ (Eq. 3), for a factor f and a word w_i, by using the cosine similarity (denoted as c_i in Eq. 2) between $E(f)$ and $e(w_i)$. The *topical similarity*, $E_{topic}(d)$ (Eq. 5) for the entire comment d is represented as a linear combination of the contextual word embeddings, $e(w_i)$ weighted by individual $\mathit{Similarity}_i^f$. Finally, we use $1 - c_i$ as a loose mea-

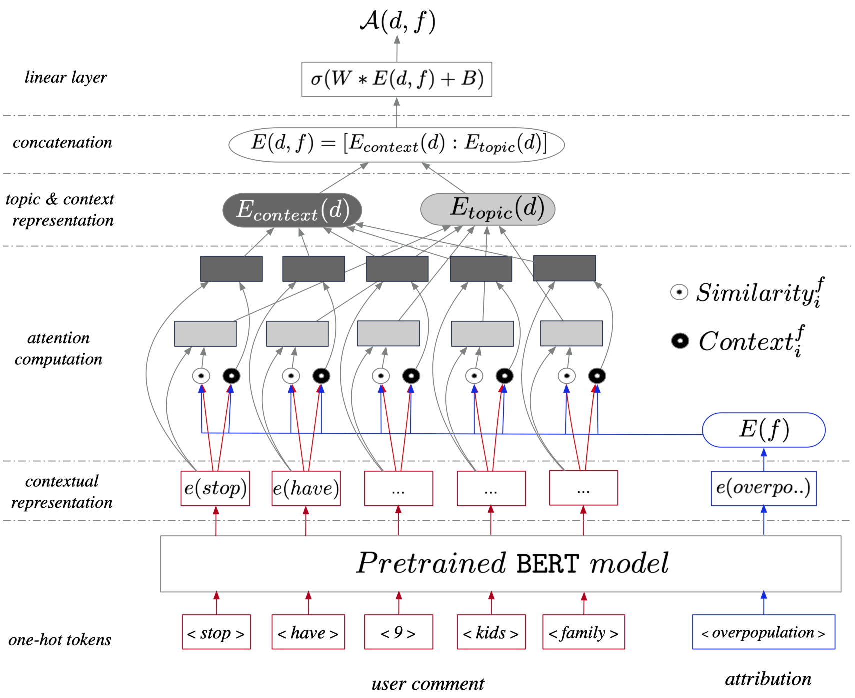


Figure 2: Model architecture

sure of inverse cosine similarity for constructing the probability function, $Context_i^f$ (see Eq. 4) and similarly generate the non-topical contextual representation $E_{context}(d)$ (Eq. 6) for the comment. Note that,

$$E(f) = mean_{j \in |f|}\{e(w_j)\} \tag{1}$$

$$c_i = Cosine(e(w_i),\ E(f)) \tag{2}$$

$$Similarity_i^f = \sigma(\alpha * c_i + \beta) \tag{3}$$

$$Context_i^f = \sigma(\alpha * (1 - c_i) + \beta) \tag{4}$$

$$E_{topic}(d) = \sum_{i \in |d|} Similarity_i^f\ *\ e(w_i) \tag{5}$$

$$E_{context}(d) = \sum_{i \in |d|} Context_i^f\ *\ e(w_i) \tag{6}$$

In Equations 3 and 4, α and β are the hyperparameters and $\sigma(.)$ is the sigmoid function to scale the cosine similarities to $[0, 1]$ range. The concatenation of the $E_{topic}(d)$ and $E_{context}(d)$ is used as the final representation of the $\langle d, f \rangle$ pair:

$$E(d, f) = [E_{topic}(d) : E_{context}(d)] \tag{7}$$

The final representation, $E(d, f)$, is passed through a linear layer with dropouts to model the attribution function $\mathcal{A}$ and is trained with Binary Cross Entropy loss (BCELoss) using binary labels. The linear layer, with learnable parameters W and B, is defined as follows,

$$\mathcal{A}(d, f) = \sigma(W * E(d, f)\ +\ B) \tag{8}$$

5 Experimental Setup

5.1 Model Training

We use an 80:10:10 split to divide the labeled data into training, validation and hold out sets, respectively. Two different pre-trained LM weights are used to bootstrap our model. We first use the basic-`BERT` ('bert-base-uncased') model by initializing our model with the pre-trained weights obtained from Huggingface's transformer API (Wolf et al., 2019). The weights for the other model `BERT`$_{Indian}$, were generated by (Palakodety et al., 2020b) where the authors fine-tuned `BERT` on a large corpus of 2 million comments posted in a 100 day period leading up to the 2019 Indian General Election. The `BERT`$_{Indian}$ weights boost the performance over `BERT` weights in our task, as it was trained on linguistic expressions typical to Indian social media. In addition to the `BERT` variants, we also experiment with few other baseline setups explained in details in Section 5.3.

We use a linear feed-forward layer to convert the language representation vectors to logits. We found adding more layers in the feed-forward network was detrimental towards training; perhaps due to less amount of available training data. For training our models, we used the Adam optimizer (Kingma and Ba, 2014) with a learning rate of $1.8\mathrm{e}{-5}$ and a batch size of 4. The hyper-parameters α and β are set to 10 and -5 respectively.

5.2 Performance Measures

We evaluate our models' performance at two different levels. Our original task is to identify if a YouTube comment is attributing to one (or more) attribution factor(s) and deeming it (them) responsible for the water crisis. Since the number of comments without any attribution is significantly higher than the number of comments with attribution, we conduct a fine-grained evaluation of our models' performance in the following way. We divide our prediction task in two sub-tasks: (1) attribution *detection* and (2) attribution *resolution*. While the detection task aims to predict the presence of attribution in a sentence, the resolution task involves correctly identifying the attributed factor. Furthermore, we measure resolution at a conservative top-1 as well as a relaxed top-3 setting to analyze the model's performance with near-similar attributes.

For the detection task, we apply a threshold to determine if the sentence has any attribution at all from a provided set of attribution factors. The threshold value is tuned on the validation set. Hence, the detection task reduces to evaluating the condition $\mathcal{A}(d, f') \geq T$, where $f' = \arg\max_{f \in \mathcal{F}} \mathcal{A}(d, f)$. For resolution, we choose the best attribution factor f' for the conservative top-1 setting. For the relaxed top-3 setting, we order the list of attribution factors $f \in \mathcal{F}$ by the corresponding score $\mathcal{A}(d, f)$ and pick the top three candidates from the list.

In presence of multiple attribution factors, we use a set membership test to assign a binary outcome. Let $\mathcal{F}_{true} \subseteq \mathcal{F}$ denote the ground truth set of attribution factors for a comment d, and our classifier predicts attribution factors $\mathcal{F}_{predicted}$ for d. The binary outcome of the prediction task is $\mathbb{I}(F_{predicted} \cap \mathcal{F}_{true} \neq \emptyset)$, where $\mathbb{I}$ is the indicator function denoting success or failure for the resolution task.

5.3 Baselines and Ablation Study

We now describe our baseline (denoted by $\mathcal{M}_{\texttt{GloVe}}$) and models. We start with a simple model and add sophisticated techniques in subsequent iterations.

- **Word embedding ($\mathcal{M}_{\texttt{GloVe}}$):** We use a GloVe (Pennington et al., 2014) embedding-based similarity measure to establish our baseline. The baseline is inspired by the observation presented in Arora et al. (2017) and emphasizes on the intuition that weighted word embeddings produce high quality sentence representations. We use an idf (inverse document frequency) weighted sum of GloVe word embeddings for all the words in a sentence to compute the sentence representation. Next, we use the same method for the attribution factors to get the attribution representation. A cosine similarity between the sentence and attribution representations is used to determine this baseline with no task-specific training.
- **Classification over `BERT` ($\mathcal{M}^{simple}_{\texttt{BERT}}$):** $\mathcal{M}^{simple}_{\texttt{BERT}}$ uses an LM based classification technique where we build a linear classifier on top of the pre-trained `BERT`. We take the mean contextual embeddings, $E(d) = mean_{i \in |d|}\{e(w_i)\}$ for the words $w_i \in d$ as the sentence representation and, $E(f) = mean_{j \in |f|}\{e(w_j)\}$ for the words $w_j \in f$ as the attribution representation. A linear layer is trained over the concatenated vector $[\ E(d) : E(f)\ ]$ to learn the attribution relationship between comment d and factor f. While training, both the new parameters from the linear layer and the underlying `BERT` parameters are learned. We notice that freezing the `BERT` parameters to train only the top linear layers yields inferior results for all the LM based setups.
- **Topical similarity model ($\mathcal{M}^{topic}_{\texttt{BERT}}$):** In this model, we only use the topic similarity to create the topical representation of d as $E_{topic}(d)$ (Eq. 5). The factor f is represented by $E(f)$ (Eq. 1). The concatenation of the two $[\ E_{topic}(d) : E(f)\ ]$ is passed to the linear layer and is jointly trained with the language model parameters.
- **Final architecture ($\mathcal{M}^{final}_{\texttt{BERT}_{Indian}}$):** This model uses both $E_{topic}(d)$ (Eq. 5) and $E_{context}(d)$ (Eq. 6) as described in Section 4. We find that the introduction of contextual representation $E_{context}(d)$ over the previous setup performs better.
- **Switching to $\texttt{BERT}_{Indian}$ ($\mathcal{M}^{final}_{\texttt{BERT}_{Indian}}$):** The architecture of this setup is identical to $\mathcal{M}^{final}_{\texttt{BERT}}$ with the sole modification being the use of $\texttt{BERT}_{Indian}$ (described in 5.1) instead of `BERT`.

6 Results

We summarize the performance of our baseline and models in Table 5. Following standard practice in evaluating performance on data sets with class im-

Model	*Metric*	*Detection*	*Resolution*	*Resolution + top 3*
$\mathcal{M}^{final}_{\texttt{BERT}_{Indian}}$	P	75.88	**70.14**	74.10

	Acc	57.62	36.77	40.85

Table 5: Performance comparison of our models and baselines. For a given task and a performance measure, the best model's performance is highlighted in bold. Precision, recall and accuracy are denoted by **P**, **R**, and **Acc**, respectively.

public water wastage	everyone forgot within 2 or 3 month later again forget to save and waste water.
lack of harvesting	last year chennai received crazy rains all that water went in drain if we had harvested it and let it replenish ground water borewells would not have run dry this year
deforestation	we cut trees to build flat malls multi stored buildings
government inaction	discorperted i know where you are coming from but do not blame the farmers i think it is more of a governmental problem but farmers should not be in the reap where you sow
contamination	stop using chemical soaps and liquids so that drainage is not harsh for environment human waste and kitchen waste need to be decomposed in each home
overpopulation | deforestation | pollution	the basic reason is population for everything cause this planet had a limit to hold people and to add more we are doing deforestation polluting our rivers air pollution and wasting water. . .

Table 6: Example instances that our classifier correctly resolved.

balance, we focus on precision, recall and F1 score as performance metrics instead of accuracy. We observe that, on the detection task, all the BERT based models perform similarly. However, on the resolution task, the F1 score substantially improves as we keep adding sophistication to our model architecture.

Since many of the attribution factors are semantically close (e.g., loss of water bodies, water withdrawal), we also consider a relaxed resolution criterion where a resolution is evaluated as correct if the models' top three predictions have an overlap with the ground truth as described in Section 5.2.

climate change | no attribution	there is no proof of climate change droughts and floods are all natural phenomenon they have happened before there were humans also
public water wastage | human activity	the best way to save water is to stop consuming animal products so much of our precious water is used for animal agriculture
government inaction | urbanization	urban people are the reason for water shortage
overpopulation | no attribution	it has nothing to do with population control
human activity | government inaction	otherwise all our development is a waste if the people are being eliminated by carcinogens created due our irresponsible administration

Table 7: Examples of misclassified instances. Misclassified attribution factor is marked with red, ground truth is marked with blue.

6.1 Error Analysis

We now focus on some of the specific examples from both the correctly classified and misclassified sentence-attribution pairs to summarize the strengths and shortcomings of our models. As shown in Table 6, $\mathcal{M}^{final}_{\texttt{BERT}_{Indian}}$ was able to correctly identify attributions in sentences even in the presence of certain degree of grammar disfluency and an absence of the exact attribution factor per se. For instance, our model correctly resolved ‘***we cut trees*** *to build flat malls multi stored buildings*’ to *deforestation* even though the specific root terms of the attribution factor is not present in the sentence. Our model is able to identify the attribution factors correctly, even when the comments are longer with complex discourse structure and grammatical errors. For example, ‘*discorperted i know where you are coming from but do not blame the farmers i think it is more of a* ***governmental problem*** *but farmers should not be in the reap where you sow*’ was correctly attributed to *government inaction*. Furthermore, when multiple attributions are present, for example in comments like - ‘*the basic reason is* ***population*** *for everything cause this planet had a limit to hold people and to add more we are doing* ***deforestation*** *polluting our rivers air pollution and wasting water. . .* ’, our model is able to correctly predict all three attributions at top three with high confidence.

We also notice few failures that can be attributed to shortcomings of BERT-like language models (Table 7). For example, our model predicts ‘*climate change*’ is an attributing factor in the comment ‘*there is* ***no proof of climate change*** *droughts and floods are all natural phenomenon they have happened before there were humans also*’ with high confidence. Our model fails to understand the negation as well as the context; perhaps due to a well-documented limitation of `BERT`'s inability in handling negation (Kassner and Schütze, 2019).

Finally, we observe cases where the model fails to attribute the labelled factor as its top prediction, but the top three predictions feature the labelled factor. For example, '*its their fault look how they waste the water they poured half of it on the ground while drinking it and other things from the water truck they poured much of it on the ground*' was attributed to *pollution* as top factor but the labelled factor *public water wastage* was scored second highest by the model.

7 Discussion

- **Unseen attribution factor**: Our model can generalize to unseen attributions factors. For instance, with a new dummy attribution factor *pandemic* and input sentence *'this flu caused the water crisis'*, our model is able to predict *pandemic* with the highest probability. This merits a deeper exploration with a holdout attribution set we aim to investigate in future.
- **Flint water crisis**: We were curious to know how our model performs in the wild on a data set of a different water crisis. To this end, we zero in on the Flint water crisis, another major water crisis happening in a completely different part of the globe with predominantly different sets of attribution factors. On a data set of 5,000 comments randomly sampled from 503 YouTube relevant to the Flint water crisis (Butler et al., 2016), our model predicts *government inaction*, *pollution* (subsumes contamination according to Table 4), and *corruption*. A human inspection of randomly sampled 200 comments aligns with out classifier's predictions. Table 8 presents a random sample of example comments detected by our classifier.

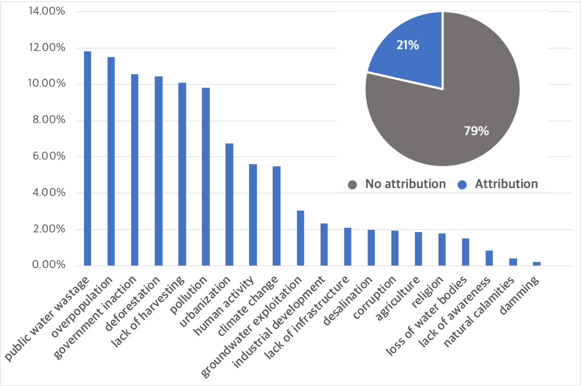

Figure 3: Distribution of number of comments detected by $\mathcal{M}^{final}_{\mathtt{BERT}_{Indian}}$ model on 40k comments.

- **The big picture**: We finally run our classifier on our initial data set of 40K English comments to obtain a bigger picture. As shown in Figure 3, we find that nearly 80% of the discussions in our corpus do not contain any attributions. This aligns with our previous annotation experiment that yielded 24.3% positives from randomly sampled comments. Among the attributed comments, we find *public water wastage*, *pollution*, and *overpopulation* are considered as primary causes for this crisis. A human inspection of randomly sampled 200 comments aligns with the classifier predictions. These insights, along with sample comments from the detected attributions, may provide a holistic view of people's opinion around the topic. In the expanding reach of social media, we thus (1) present a new approach to collect aggregated opinions on crisis attribution and complement surveys; (2) focusing on one of the most important crises of the future: water; and (3) release an annotated data set on this important domain.

government inaction	wow that is insane i feel so bad for the people of flint how has the governor kept his job so many people should be punished for this
pollution	the land is poisoned sitting around and wishing for the magical government to fix it is what children do either install water filtering stations like in arizona or move
corruption	rick snyder is a corrupt lying sociopath cutting people off from bottles of clean water is just incredibly cruel they need to vote him out of office

Table 8: Random sample of comments detected as positives from our Flint data set.

On the Reliability and Validity of Detecting Approval of Political Actors in Tweets

Abstract

Social media sites like Twitter possess the potential to complement surveys that measure political opinions and, more specifically, political actors' approval. However, new challenges related to the reliability and validity of social-media-based estimates arise. Various sentiment analysis and stance detection methods have been developed and used in previous research to measure users' political opinions based on their content on social media. In this work, we attempt to gauge the efficacy of untargeted sentiment, targeted sentiment, and stance detection methods in labeling various political actors' approval by benchmarking them across several datasets. We also contrast the performance of these pretrained methods that can be used in an off-the-shelf (OTS) manner against a set of models trained on minimal custom data. We find that OTS methods have low generalizability on unseen and familiar targets, while low-resource custom models are more robust. Our work sheds light on the strengths and limitations of existing methods proposed for understanding politicians' approval from tweets.

1 Introduction

Measuring public opinion accurately and without systematic errors is as vital for a functioning democracy as it is for scholars to understand society. Survey methodologists have developed techniques over several decades to precisely quantify public opinion. The American Association for Public Opinion Research (AAPOR) stated in their recent task force report that public opinion research is entering a new era, where digital traces would play an important role (Murphy et al., 2014). Increasingly, since the first steps were made by O'Connor et al. 2010, numerous studies have assessed the efficacy of such traces, especially social media, in measuring public opinion as a complement to polls. The run for social media approaches is not surprising, as they promise a continuous public opinion estimate based on millions of data points.

Tweet	Untargeted Sentiment	Targeted Sentiment	Stance	Approval
Trump is the only candidate I fully support	positive	positive	favor	approval
What makes me angry is the lying media brazenly attacking President Trump.	negative	positive	favor	approval
Jeb Bush is the only sane candidate in the republican lineup	positive	none	against	disapproval

Table 1: Different types of NLP measurements that can be used to understand a tweet's **approval of a predefined target** (here, Donald Trump): Untargeted/overall sentiment (UTS), targeted sentiment (TS) and stance (ST). UTS can easily fail to measure approval of the target if several potential targets are mentioned or the actual target is not explicitly present. TS cannot measure indirect opinions where the target is not mentioned, whereas ST methods are designed for this task as well.

Social-media-based metrics require new approaches, which bring forth new challenges (Olteanu et al., 2016). Sen et al. 2019 describe two primary sources of errors: *representation errors*, due to how results are inferred for the target population and *measurement errors*, due to how the target construct is measured. Researchers have made substantial advances in understanding and adjusting for representation errors (Pasek et al., 2019; Barberá, 2016). Yet, there is still a gap in knowledge about whether the lack of effectiveness of social media-based estimates is *also* due to measurement errors, i.e., the operationalization of the target construct – approval. While previous research has used external data such as polling results to (in)validate the efficacy of automated *aggregate* approval measures from social media, the *fine-grained (mis)measurement of approval on a post level* has yet to be studied.

The building blocks for measuring approval with

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1413–1426,
November 16–20, 2020.

social media are usually the textual utterances by users.[1] Related work predominantly focuses on the largest publicly available social media platform, Twitter, and employs methods ranging from sentiment lexicons (O'Connor et al., 2010; Pasek et al., 2019) to machine learning approaches (Marchetti-Bowick and Chambers, 2012; Barberá, 2016) for analyzing approval in individual tweets. Several natural language processing (NLP) approaches have been proposed to, or can be amended to, measure approval. They can be segmented into three broad classes: untargeted sentiment detection, targeted sentiment detection, and stance detection (see Table 1).[2]

Untargeted sentiment is a popular choice for measuring approval (Pasek et al., 2019; O'Connor et al., 2010; Pasek et al., 2018), possibly due to the availability of several methods that can be used without much overhead in an off-the-shelf (OTS) manner. Yet, cognitive scientists contend that attitudes such as approval are tied to an object of approval (Bergman, 1998), and untargeted sentiment, in comparison to targeted sentiment and stance, might not be the best proxy for it (c.f Table 1). Indeed, as it is the most sophisticated family of methods and aligned with what we term "approval", **stance detection** by design typically outperforms sentiment detection methods within shared tasks (e.g., SemEval) aiming to measure targets' approval. While stance may indeed be a more robust theoretical proxy, a potential obstacle towards using stance detection, instead of untargeted sentiment analysis, is the lack of OTS methods available. Even for methods that do exist, the developers intentionally or unintentionally tune their methods towards benchmark datasets (e.g., by exploiting the fact that a dataset is collected based on particular hashtags). It is thus likely that complex methods are tuned to linguistic markers of benchmark datasets and only perform well on those or similar datasets (Linzen, 2020). In this light, it is unclear if such methods can be used "tout court" on novel datasets and targets.

Therefore, we investigate the following use case: Measuring how respondents or users feel towards a certain topic or entity (which we call *target*), such as the president (O'Connor et al., 2010; Pasek et al., 2019) or presidential candidates (Barberá, 2016), where the outcome is captured on a continuum between approval and disapproval or some equivalent, e.g., favor, neutral, against. While different terms like "viewpoint", "support" or "stance" can be ascribed to this measurement, we will henceforth call it "*approval*"; this mirrors the long-standing measurement tradition in survey research to ask for the approval of political actors and issues, usually also indicated on a scale with synonymous extremes.[3] We investigate the design choices to be made by a researcher to increase reliability and validity of the measurement. [4]

Our Contributions. To investigate how well automated methods capture approval on a fine-grained tweet level, we systematically compare the validity and reliability of (i) "off-the-shelf" (OTS) usage of methods that require minimal effort to (re)use, and (ii) customized low-resource methods, leveraging popular supervised text classification models,[5] trained on varying, small-scale quantities of in-domain data, to simulate a scenario where individual datasets are labeled with realistically expendable effort (Adams-Cohen, 2020; Hughes et al., 2020). Across five different datasets, spanning seven targets, we benchmark the performance of twelve methods: eight OTS methods that have been used in the past for assessing approval or are exemplary for different types of NLP approaches that have been proposed for understanding concepts akin to approval, and four customized low-resource methods. We find more complex supervised OTS methods, especially targeted methods, do not generalize well to unseen targets, i.e., targets that are not present in the training data of these methods. But they also have high variation on familiar targets, where they struggle with measuring instances of indirect stance and absence of stances. Low resource custom methods outperform OTS methods for both types of targets. Our systematic analysis identifies and highlights gaps in current

---

[1] These can further be aggregated per user (Cohen and Ruths, 2013), but we focus on the much more common practice of measuring post-level opinions.

[2] Stance detection here is different from rumorstance detection (Kochkina et al., 2017) and argument stance detection (Lippi and Torroni, 2016), where the task is to infer the speaker's reaction to a potential rumor or argument, respectively.

[3] For example, Gallup's poll on presidential approval has remained virtually unchanged for decades (McAvoy, 2008).

[4] Quinn et al.: "The evaluation of any measurement is generally based on its reliability (can it be repeated?) and validity (is it right?)." In this work, by validity, we refer to external validity or generalizability, while reliability refers to repeating the same measurements under different conditions.

[5] In this work, we differentiate between *models* which are machine learning models that can learn from data, and *methods* which have already been trained and can be re-used without further training or fine-tuning.

methods for the measurement of approval and implies that **even though targeted sentiment and stance are better proxies for approval than untargeted sentiment, current targeted methods cannot be used in an OTS manner for measuring approval.** Our code is available at `https://github.com/gesiscss/political_approval`

2 Methods for Measuring Approval

In the section, we describe widely used methods that have been applied to mine public opinion on Twitter, particularly approval of political actors. Evaluating all pertinent methods and their varying implementations is beyond the scope of this work, therefore we choose popular approaches or those whose implementations are widely available.

We describe the three above-mentioned categories of approaches (summarized in Table 1) which can be used as proxy measures for approval or disapproval of targets.

2.1 Untargeted Sentiment

Untargeted sentiment refers to the *overall* sentiment of a sentence or document, regardless of targets mentioned. Prominent and easy-to-use representatives of untargeted sentiment methods are lexicons of positive and negative words. The word lists are hand-curated and are usually not adapted to each target dataset they are applied to. They are typically used to annotate words in documents and the ratio of positive to negative words in a document may function as an indicator of opinion (O'Connor et al., 2010). To arrive at a measurement of approval, the document for which overall sentiment is calculated is either assumed to be about the target *a priori* via the collection process of the corpus (O'Connor et al., 2010; Pasek et al., 2018), or is labeled as such through heuristics or named entity recognition. In this work, we compare various lexicons which have been used in past public opinion analysis literature: **MPQA** (Hu and Liu, 2004) and **LabMT** (Dodds et al., 2011) used by O'Connor et al. and Cody et al., respectively to understand approval of President Obama. **VADER** (Hutto and Gilbert, 2014), which is a lexicon combined with a heuristic-based preprocessing engine for understanding syntactic characteristics of sentences such as negation, was recently used to understand stance towards the economy (Conrad et al., 2019).

In contrast to lexicons, we also explore fully supervised methods including **SentiStrength (STS)** (Thelwall, 2017), a widely-used lexicon-based supervised method[6] and **SentiTreeBank (STB)** (Socher et al., 2013), trained on human-annotated web content such as online reviews. While both STS and STB include syntactic dependencies so they can account for negations and modifiers, they are target-independent and can therefore capture the overall sentiment of a tweet rather than sentiment towards a particular entity.

2.2 Targeted Sentiment

The task of Targeted Sentiment Analysis (TS) is, given a sentence, to infer the sentiment of the author towards a predefined topic or entity.[7] **TD-LSTM** (Tang et al., 2016) is a Recurrent Neural Network based approach that also takes into account syntactic dependencies, trained and tested on a Twitter dataset with tweets towards various entities and topics like Bill Gates, Lady Gaga, and Donald Trump, annotated by crowdworkers (Dong et al., 2014). TD-LSTM achieved state-of-the-art performance (69% Macro F1) on the aforementioned Twitter targeted sentiment dataset. To translate targeted sentiment to stance or approval, a function is commonly defined that transforms negative sentiment scores to disapproval or "against" and positive sentiment to approval or "for", with a residual category of "neutral" for mid-range or inconclusive scores.

2.3 Stance

Stance detection refers to a set of loosely connected tasks in NLP such as argumentation mining and rumor verification.[8] In this work, we focus on the specific case of stance detection, closely related to TS, which is the task of inferring whether a document is written in favor or against the given target. Stance detection and TS differ in that the author may take an *indirect* stance without explicitly mentioning the target. While various stance detection methods exist, we focus on two prominent example methods that have been developed specifically for detecting stance on Twitter. Mohammad et al. introduce a strong Linear SVM-based method (**SVM-SD**) trained on a stance-annotated tweet corpus with

---

[6] Sentistrength, for example, has been used to assess the sentiment of tweets mention German politicians: https://data.gesis.org/tweetskb/

[7] The task is closely related to, but distinct from, Aspect-Based Sentiment Analysis. More specifically, TS is described as Targeted Non-aspect-based Sentiment Analysis (TN-ABSA) where "the object of the analysis is simply the target entity." (Pei et al., 2019).

[8] See (Küçük and Can, 2020) for a comprehensive survey on various types of stance detection tasks.

Table 2: Overview of the tweet-level methods used to understand approval. The first eight are **off-the-shelf**, i.e., not trained on any novel data while the bottom four are **custom**, i.e., trained on minimal in-domain data. We categorise methods based on their training procedure (supervised or unsupervised), the type of proxy they measure, untargeted sentiment (UTS), targeted sentiment (TS) or stance (ST), and describe their output. Since the custom methods are trained on data annotated for stance, we also consider them to be of that type. We also include the source of implementation of off-the-shelf methods when available.

character and word n-grams that outperformed all submissions in the SemEval 2016 Stance Detection shared task A (Mohammad et al., 2016).

Secondly, for their **Distant Supervised Stance Detection (DSSD)** method, Augenstein et al. train an LSTM on tweets where stance towards various entities or topics is labeled (cf. the SemEval 2016 Stance Detection shared task A dataset (Mohammad et al., 2017)). However, the final goal of this method is to label stance in tweets towards Donald Trump, which was not included as a potential target in the training data (shared task B). To improve prediction performance for an unknown entity (Trump in this case), the authors leverage a large collection of tweets containing keywords relevant to Trump, weakly labeled based on the presence of certain keywords or hashtags such as 'MAGA' and '#yourefired', in conjunction with a bidirectional LSTM.[9] We include this method since it achieved high performance (average of 59% macro F1 on favor and against classes) on the shared task.

3 Use case scenarios

We now describe the two scenarios we explore as realistic options faced by a CSS researcher aiming to measure approval towards political actors on Twitter with their own dataset and/or targets.

3.1 "Off-the-shelf" usage

As our first scenario, we assume that a researcher does not have the resources to label their novel data and/or retrain their own model on this data and targets they are working with. A low-threshold solution is (i) the usage of dictionary-based methods or (ii) the use of existing supervised methods pretrained on a different corpus and potentially different targets.

As dictionaries are not trained by design, we employ them with only minor adaptions to their preprocessing pipelines. Due to the lack of a standardized processing pipeline for LabMT and MPQA, and to maintain consistency within the lexicons, all three of them are used in conjunction with VADER's preprocessing engine. MPQA and LabMT which yield ratio of positive and negative scores are converted to three classes reliant on a value greater (favor), lesser (against) or equal (none) to zero. Following past literature (Hutto and Gilbert, 2014), we use -0.1 and 0.1 as the threshold for converting VADER scores to positive (favor) and negative (against), respectively. STS and STB are used with their pretrained models. We re-implement TD-LSTM using the code made available by the authors (c.f Table 2 and Appendix C). TD-LSTM and STS provide scores of positive, negative and none which can be mapped to the aforementioned stance classes. For STB, we collapse the five-class output to three-class, by combining very negative (very positive) and negative (positive). Like TD-LSTM, we re-implement DSSD, and replicate SVM-SD based on Mohammad et al. 2017.

---

[9] Generating weak labels may require domain knowledge and is not equally plausible for all targets, especially for novel targets.

Target	Dataset	against		favor		none		Total
		direct	indirect	direct	indirect	direct	indirect	
Trump	CONS	156	62	53	20	9	3	303
	MTSD	620	0	989	0	454	0	2063
	PRES	387	1	144	0	96	0	628
	SEB	165	134	146	2	6	254	707

Erdoğan	PRES	378	1	81	0	141	0	601
Putin	PRES	416	0	103	0	99	0	618

Table 3: **Datasets.** The datasets used for evaluating all methods, related to different political actors and approval (stance) distribution. We use a held-out sample of this data, stratified on stance, to train low-resource custom methods on minimal data (195 tweets from each target) and use the rest for testing the OTS and custom methods.

3.2 Customized Training

For this scenario, we assume that limited resources are available to label the dataset to be analyzed towards the desired target, and that commonly available NLP models, particularly those that have been used for text classification, can be employed to train custom methods accordingly. Training data for novel targets can be expensive to generate, so we train models on a held-out minimal proportion of the test datasets (Table 3) to obtain target-specific stance methods, similar to Mohammad et al. (2017), but on a fraction of the data; 195 datapoints from each target.[10] We decide on this threshold based on the least amount of labeled data required to outperform the best performing OTS method, as further explained in Appendix A.

We consider a small number of concrete manual labels of tweets as the most realistic scenario. We do not consider using weak labels "low effort", since (i) they have to be carefully selected for each target, e.g., by a domain expert and be sufficiently tailored to the target, such as a politician-specific hashtag, and (ii) a large amount of labels would be required for retraining a method such as DSSD, which is not feasible for each dataset used in our evaluation, nor in practice in many cases.

For the custom models, we also remove stopwords (except 'not') and use unigram features to train four different types of models that are popular for text classification tasks: Logistic Regression (LR), Multinomial Naive Bayes (MNB), a Support Vector Machine (SVM) and finetuned BERT (Devlin et al., 2019). For LR, MNB and SVM, we perform five-fold cross-validation and grid search to tune hyperparameters. For BERT, 10% of the dataset is used as a validation set (c.f Appendix C for hyperparameter configurations). Our objective is not to build a state-of-the-art classifier with optimal performance, but to understand how methods utilizing minimal training data compare against OTS methods.

3.3 Baselines

To emulate an "absolute minimal effort" scenario we set up three baselines. The first is a **random baseline**, a classifier that randomly assigns a stance label (either favor, against or none) to each tweet. The second and third baseline are based on a classifier that labels every instance with the majority label for the dataset (independent of targets) (**majority-dataset**) or target (**majority-target**).

4 Experiments

Previous research established the validity of social media measures through correlations with external data sources like polls and surveys (O'Connor et al., 2010; Pasek et al., 2018; Barberá, 2016). We argue that this entangles different types of errors, such as the lack of demographic match between polls and social media users and the effect of the platform's affordances on textual expressions. By focusing on a controlled dataset of human-annotated approval at a tweet level, we can rule out confounding factors to a higher degree. Furthermore, as we see in Table 1, stance is a better proxy for approval than targeted and untargeted sentiment. Therefore, we compare the performance of the previously described methods over five different datasets that form the gold standard of stance ($\sim$ approval). Using datasets spanning different targets as well as different time periods helps us gauge the generalizability and robustness of methods. In this section, we describe our experimental setup and datasets used for evaluation and custom training.

4.1 Experimental Setup

Evaluation parameters. We use **Macro-F1** (which weights all classes equally) across all three classes to analyze performance. To assess cross-dataset and cross-target performance, we compute the mean, standard deviation and the upper (high) and lower (low) bounds of 95% confidence interval. To account for possible variance, all methods are evaluated based on average performance on the

---

[10] Since, different targets have varying amount of data, 195 tweets constitutes 5.5% of the Trump data and 12%-46% of the other targets.

evaluation datasets (Table 3) over 5 runs.

4.2 Datasets

We evaluate OTS and custom methods on the following datasets. While some of these datasets have common targets, for example, Trump is present in four of them, they are all collected in different periods of time, with different keywords (c.f Appendix B). All datasets have stance labels of 'favor', 'against', and 'none' towards the targets.

SemEval A and B. The SemEval-2016 task 6 dataset (Mohammad et al., 2017) contains topic-tweet pairs, on controversial subjects. Since our analysis is restricted to political actors, we use the portion of the task A test dataset with stance towards Hillary Clinton (**SEA**) and the task B dataset with stance towards Donald Trump (**SEB**).

Constance (CONS). Joseph et al. (2017) released a dataset containing stance towards Trump and Clinton. The authors use this dataset to understand how different annotation contexts affect crowdworkers' performance in labeling tweets for stance. The authors annotate tweets based on various contextual information such as the profile details of the tweet author.

MTSD. Sobhani et al. (2017) released a dataset where each tweet has stance towards more than one target (multi-target stance detection). The authors collected data about four presidential candidates of the US 2016 elections using related hashtags, selecting three target pairs: Donald Trump and Hillary Clinton, Donald Trump and Ted Cruz, Hillary Clinton and Bernie Sanders. We only include those tweets where one of the targets is either Trump or Clinton.[11]

Presidents (PRES). van den Berg et al. (2019) collect a dataset of tweets mentioning presidents of six G20 countries by various naming forms, which are annotated for stance. The authors investigate the role of naming variation in stance towards presidents. To do so, the authors collect tweets three query types: last-name, #first-name and first-name + (last-name/country). They then leverage crowdworkers for annotating the stance in these tweets.

4.3 Experimental Design

We run the following two experiments to assess validity and reliability respectively.

Experiment 1. We evaluate performance of methods across all targets. This allows us to assess the external validity of various OTS methods by measuring how well they generalize to unfamiliar targets (OTS scenario) compared to custom methods that have seen a minimal portion of the data related to such targets (custom training scenario).

Experiment 2A. We evaluate the performance of methods for the target Donald Trump, a target familiar to some OTS methods like TD-LSTM and DSSD, across multiple datasets (CONS, MTSD, PRES and SEB). This allow us to assess the reliability of methods in measuring the same construct ('approval of Trump'), across multiple settings which span over different time periods and employ different data collection strategies.

Experiment 2B. The advantage of stance over TS is indirect stances.[12] Therefore, we also investigate how well various methods perform on indirect stance. Here, direct stance refers to when the target is mentioned by name. For example, tweets with indirect stances towards Trump mention neither his firstname, lastname nor his Twitter handle (@realdonaldtrump). They may refer to him indirectly, say, via epithets ('@potus') or his association to other subjects or entities (example 3 in Table 1).

5 Results

We now describe our findings from the the experiments described in the previous subsection. We compare the performance of methods across different targets in Table 4 and across datasets that have been collected in different ways but include one target (Trump) in Table 5. Finally, we investigate the performance on indirect and absence of stance.

5.1 External Validity: Performance across Targets

To compare the external validity (which refers to the generalizability) of various methods we present their performance across different targets in Table 4. First, the low performance of baselines demonstrate that inferring stance is a hard task. Sentiment lexicons (VADER, LabMT, MPQA) perform surprisingly well and outperform more complex OTS methods. This indicates that targeted OTS methods do not work well for unfamiliar targets which they have not seen during the learning phase. Therefore, it is not advisable to use such methods for novel targets. **Our results indicate that targeted OTS methods, like DSSD and TD-LSTM, should not**

---

[11] For our purpose, we only use the stance towards either of these two as our final stance label.

[12] These include references to the target "through pronouns, epithets, honorifics, and relationships."(Mohammad et al., 2017)

Method	**Targets**							**Mean F1**	**Std**	**95% CI**

Table 4: **Overview of the performance (Macro F1) of different methods across all targets.** UTS = Untargeted Sentiment, TS = Targeted Sentiment, ST = Stance. Cross-target performance for supervised off-the-shelf methods are poor with high variability. Unsurprisingly, lexicons have more stable performance, but surprisingly, outperform targeted methods. The LR custom method, trained on minimal data, performs best. The results indicate that targeted off-the-shelf methods, like DSSD and TD-LSTM, are not 'general-purpose' since their performance is as good as or even worse than untargeted lexicons like VADER and MPQA for targets that are new to them.

be considered 'general-purpose', and that their performance is as good or even worse than untargeted lexicons like VADER, LabMT and MPQA for new and unseen targets such as Macron and Putin.[13] The LR custom method performs best for all targets except Macron (where the best method is VADER), while BERT performs poorly, possibly due to insufficient training data, indicating that a simple, high-bias classifier performs better than complex methods, OTS and custom alike, if the amount of available training data is low.

5.2 Reliability: Performance across Datasets for Donald Trump

Since it is not surprising that targeted methods have low generalisation to unseen targets, we now evaluate them on a familiar target: Trump (Table 5). DSSD was trained on weak Trump labels, while the training data for TD-LSTM also contained tweets with sentiment towards Trump. When comparing the performance of different methods across different datasets with approval towards Trump, we find that targeted methods perform far better than they had for unseen targets but still show a wide range of variation. DSSD for example, which achieves strong results on SEB, drops in performance across all other datasets. The inconsistency and reduced performance of supervised methods could be due to difference in label distribution in train and test sets (dataset drift), and the fact that scientists often finetune their methods for a specific tasks which may lower the generalizability. In this case, the heuristics used to generate weakly labeled data to train DSSD may not hold in different time periods. One can finetune these methods for each dataset separately, but this is not always feasible due to the lack of computational skills and/or availability of data; either weakly labeled data or larger quantities of 'strongly' labeled data required for training deep learning models. Our results also indicate that even if weak labels are generated for a specific target, they might not help the method trained on them to generalize beyond the dataset from which weak labels were generated.

MTSD is the most difficult dataset to classify for most methods, possibly due to the presence of multiple entities and different stances towards them. TD-LSTM outperforms stance detection methods on all non-SEB datasets but performs poorly on SEB. As seen for other targets, the LR custom method surpasses OTS methods in mean F1, while BERT performs poorly. **Our results indicate that**

---

[13] To rule out issues due to model architecture, we also finetune BERT models on weak labels used to train DSSD. This model slightly outperforms DSSD but still has worse performance than VADER and the LR custom method.

low resource methods might be more advantageous than OTS method, when the sample that needs to be analyzed may have different characteristics (say, time period or keywords used for tweet selection) to the OTS methods' training data, even if the target entity is the same.

Method	**Trump Datasets**				**Mean F1**	**Std**	**95% CI**	
	CONS	**MTSD**	**PRES**	**SEB**			**high**	**low**
majority-target	27.86	15.39	25.44	19.90	22.15	4.85	31.66	12.63
majority-dataset	27.86	21.65	25.44	19.90	23.71	3.12	29.83	17.59
SVM-SD (ST)	26.40	15.54	29.24	28.96	25.03	5.59	36.00	14.07
STB (UTS)	29.98	18.18	30.96	28.20	26.83	5.09	36.81	16.86
random	25.93	32.85	30.01	32.15	30.24	2.70	35.52	24.95

STS (UTS)	32.50	30.58	32.09	27.88	30.76	1.81	34.31	27.21
BERT (custom)	31.25	40.66	30.39	22.22	31.13	6.53	43.93	18.32
LabMT (UTS)	29.26	31.37	36.12	35.86	33.15	2.94	38.91	27.40
TD-LSTM (TS)	32.44	30.98	39.87	38.84	35.53	3.87	43.13	27.94
VADER (UTS)	29.52	35.65	**40.11**	37.96	35.81	3.96	43.57	28.05
SVM (custom)	32.05	41.88	31.93	41.05	36.73	4.75	46.04	27.42
MNB (custom)	**34.25**	38.84	34.71	39.57	36.84	2.38	41.51	32.17
DSSD (ST)	31.76	29.72	34.17	**60.59**	39.06	12.53	63.61	14.50
LR (custom)	31.66	**43.88**	33.85	47.30	**39.17**	6.58	52.07	26.28

Table 5: **Overview of the performance of methods measuring support of Donald Trump** Targeted supervised methods like TD-LSTM and DSSD outperform sentiment lexicons, with a few exceptions such as VADER (comparable performance). DSSD performs notably worse on datasets other than SEB and shows high standard deviation. Custom LR methods outperform off-the-shelf methods, even for familiar targets.

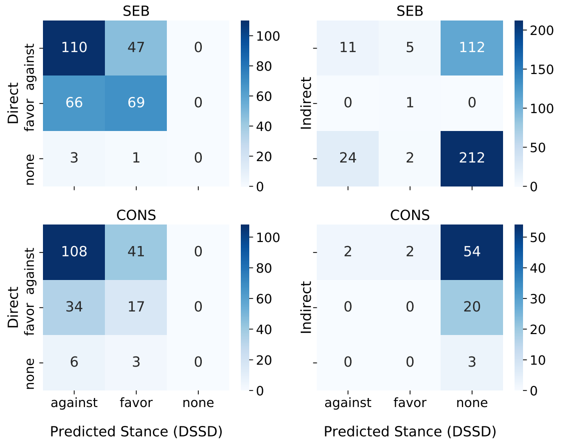

Figure 1: Confusion matrices of DSSD on SEB and CONS disaggregated by directness of stance. DSSD labels most of the indirect cases in SEB as 'none' and has difficulties assessing indirect stance in CONS.

5.3 Error Analysis

We analyze why current OTS methods fail by taking a closer look at their performance on two dimensions: directness and presence of stance. As a case study, we focus on DSSD and compare its performance on SEB (F1 score of 60.6%), to other datasets, where performance is relatively lower.

Tweet	**Dataset**	**Stance Type**	**True Stance**	**Predicted Stance**
After today SCOTUS has passed more legislation than congress. #tcot #semST	SEB	indirect	none	none
mr. t uses the #scientology method-never defend, always attack. #debatenight	CONS	indirect	against	none
I want a debate b/t Donald Trump and Hilary Clinton but it's their spouses on stage instead	MTSD	direct	none	favor

Table 6: **Examples of misclassifications by DSSD in different Trump datasets.** In SEB, most instances of 'none' do not mention Trump (example 1), while in the others like MTSD, these are tweets which mention him but do not express a clear favorable or unfavorable stance, which DSSD misclassifies as 'favor' or 'against' (example 3). On the other hand, it also misclassifies favorable or unfavorable tweets which indirectly mention Trump as 'none' (example 2).

Direct vs Indirect Stance. Recall that the advantage of stance detection over targeted sentiment detection is that in the former, *indirect* stance, where the target is not explicitly mentioned, can also be measured. Therefore, we compare the performance of DSSD for both direct and indirect stances in SEB and CONS in Figure 1.[14] We find that DSSD is better at measuring direct stances, especially those against the target, than indirect ones (c.f example 3 in Table 6) which corroborates previous findings of indirect stance being harder to automatically detect (Mohammad et al., 2017). Lower performance of automated methods for indirect stance, the advantage of stance detection over targeted sentiment analysis, implies a need for novel approaches.

No Stance. Figure 2 shows that DSSD misclassifies most and some portion of 'none' in non-SEB datasets, and SEB, respectively. This could be due to qualitative differences between the 'none' class in different datasets. From Table 3, we see that almost all tweets with no stance in SEB are of type indirect stance (example 1 in Table 6). [15] PRES and MTSD do not have instances of indirect stance and therefore tweets with no stance in them, directly mention Trump (example 2). DSSD misclassifying instances of no stance in PRES and MTSD, indicates that it does not recognize neutral mentions of targets as 'none'. The confusion be-

---

[14] MTSD and PRES, do not contain indirect stance.

[15] While example 1 seems unrelated to Trump, we argue that it still constitutes an indirect mention with no stance since all tweets in SEB contained stance-indicative or stance-neutral hashtags related to the target which were replaced with #semST during annotation by crowdworkets (Mohammad et al., 2016).

tween tweets which do not mention the target at all (tweets with indirect favorable or unfavorable stances) and tweets that mention the target but do not express a stance towards them (neutral tweets) could be due to the nature of weak labels used to train the method. **Our results indicate that the interplay of presence of stance, neutrality and directness needs to be investigated further.**

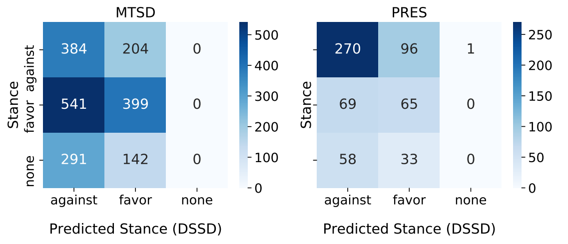

Figure 2: Confusion matrices of DSSD on MTSD and PRES. DSSD has high false negatives for ‘none’.

6 Discussion

One of the goals of language technology, including NLP methods, is the ability to (re-)use them. Keeping in mind this vision, we investigate how an important construct in CSS, political approval, can be operationalized using existing NLP techniques, either through off-the-shelf sentiment and stance detection methods or through custom domain-specific methods. By comparing the performance of twelve methods over five datasets with approval towards seven targets, we find that targeted OTS methods do not perform well across targets or datasets that span over different time periods and have been collected using different collection strategies. Concretely, (i) targeted OTS methods do not generalize beyond the targets they were trained on. They are as good as or even worse than general-purpose lexicons in this case; (ii) even for familiar targets, targeted methods, especially stance detection, have high fluctuations and perform worse than sentiment lexicons for certain datasets; (iii) Finally, stance methods do not have a clear advantage over targeted sentiment in understanding approval due to the latter’s low performance on indirect stance.

While researchers interested in measuring approval should use targeted constructs like stance or targeted sentiment instead of overall sentiment to avoid conceptual confusion, current targeted methods need to be improved before they can be used in an off-the-shelf manner. Since OTS targeted methods do not perform well for unknown targets, authors of papers on stance detection and target-dependent sentiment analysis should clarify if their method works only for certain targets (target-specific) or can be used to measure stance towards any unseen target (general-purpose), i.e., clarify the borders of their method’s applicability. The high performance of sentiment lexicons, especially for unseen targets (Table 4), implies that these resources can be used with ML techniques for general-purpose stance detection. The poor performance of DSSD on other Trump datasets implies that, compared to sentiment analysis methods, stance methods are more susceptible to changes in topic and time. Future SemEval challenges should consider this when constructing test datasets and mention the hashtags and keywords they use for data collection. In our error analysis, we show that current stance detection methods, which are slated as being capable of measuring indirect opinions expressed via ”pronouns, epithets, honorifics and relationships,” perform poorly on indirect stance. This suggests that future research should explore approaches like coreference resolution (for pronouns), word sense disambiguation (for epithets), and background knowledge (relationships to other entities). Finally, to help practitioners and CSS researchers interested in measuring the approval of novel and familiar targets beyond a data collection setting familiar to an OTS method, we find that minimal in-domain models are preferable.

Limitations. This work does not capture all methods that have been proposed for assessing political approval but focuses on those that have been popular in the past or are exemplary for different types of methods (untargeted sentiment, targeted sentiment, and stance). Second, we only consider approval towards named entities, which we find is already a difficult task, especially for indirect stances. In the future, we hope to explore abstract topics like ‘immigration’ where differentiating between direct and indirect stance is non-trivial and ensemble models that combine the strengths of multiple methods.

Acknowledgement. We thank all the authors of datasets and methods used in this study for making their contribution available for reuse. We thank Mattia Samory, Katrin Weller, Juhi Kulshrestha and the anonymous reviewers for their constructive feedback and insightful discussions.

Appendix for “On the Reliability and Validity of Detecting Approval of Political Actors in Tweets”

This appendix provides more details on the training data used for the custom methods (Appendix A), the evaluation datasets (Appendix B), and the training of different supervised methods including description of hyperparameters and how they were set (Appendix C).

A Training Data for Low-resource Custom Methods

We experiment with varying number of datapoints for training the low-resource custom methods and compare their performance against the OTS methods. The change in performance with increasing training data for Trump is in shown in Figure 3. We choose the least amount of data, 195 tweets, required to outperform the best OTS method, in this case, DSSD. With more training data, performance of customized methods improve but we attempt to show the least cost a researcher would incur for labeling additional data in their novel dataset for better performance than OTS methods. Custom methods for other targets also behave in a similar manner (c.f Figure 4), with certain targets like Putin outperforming the best OTS method, STB in this case, with fewer than 195 labeled tweets. Therefore, instead of having different training sizes for different targets, we use the same amount and find that the LR custom methods outperform OTS methods for all targets except Macron. The proportion of training data used for each target is mentioned in Table 9

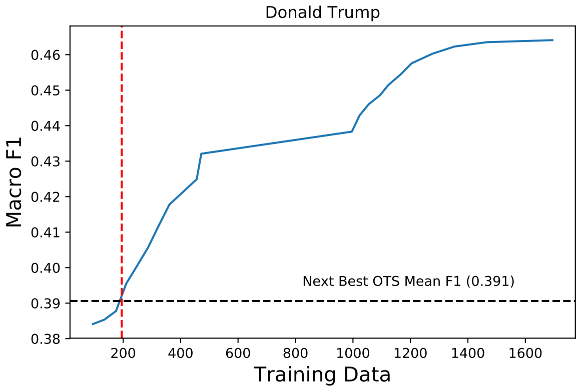

Figure 3: Relationship between increasing training data and performance (Mean Macro F1) for the target Donald Trump. We find that 195 datapoints are needed to train a custom model (LR in this case), that can outperform the best performing OTS method, DSSD.

B Evaluation Datasets

We briefly describe the datasets used for evaluation in Section 4.2. We provide more details on the specific datasets as well as how we rehydrated some of them (MTSD and PRES) based on tweet IDs released by the dataset authors (c.f Table 7). We also include the specific keywords and hashtags used to collect tweets and the period of data collection when available. The keywords used to collect the SEB data is not mentioned, and neither is the exact time period of data collection for SEB, SEA and MTSD therefore, based on the nature of the tweets, we estimate to be during the US 2016 elections.

C Training Supervised Methods

OTS Methods. The ML OTS methods we re-implement are SVM-SD, TD-LSTM, and DSSD. The training data used to re-implement these methods are described in Table 11. Since these methods are used in an off-the-shelf manner, we do not finetune them on a separate in-domain dev set. Nonetheless, the hyperparameters of TD-LSTM and DSSD are set according to the finetuning done on their original development set, while SVM-SD is finetuned through five-fold cross validation and grid search. The hyperparameters for these methods are listed in Table 10.

Dataset	Target	Stance			Methods Trained
		Against	Favor	None	
SemEval A (Train fold)	Atheism	304	92	117	SVM-SD DSSD
	Climate Change	15	212	168	
	Feminist Movement	328	210	126	
	Hillary Clinton	361	112	166	
	Legalization of Abortion	334	105	164	
Weak Labels Augenstein et al.	Donald Trump	5074	4645	8912	DSSD
Targeted Sentiment Dong et al.	miscellaneous	1411	1411	2826	TD-LSTM

Table 11: **Off-the-Shelf Methods’ Training Datasets.** Training Datasets used for training various OTS supervised methods related to different named entity targets and their stance distribution. Note that the Hillary Clinton data is from the SEA training set and does not overlap with the test data in Table 3.

In-domain Methods. We train 4 types of in-domain models: Logistic Regression, Multinomial Naive Bayes, SVM and finetuned BERT. Since a researcher would train a model based on the novel target she wants to analyze, we train separate models for each target, leading to 28 different models (seven targets and 4 model types) over 5 runs. Abstract

Machine reading comprehension (MRC) has achieved significant progress on the open domain in recent years, mainly due to large-scale pre-trained language models. However, it performs much worse in specific domains such as the medical field due to the lack of extensive training data and professional structural knowledge neglect. As an effort, we first collect a large scale medical multi-choice question dataset (more than 21k instances) for the National Licensed Pharmacist Examination in China. It is a challenging medical examination with a passing rate of less than 14.2% in 2018. Then we propose a novel reading comprehension model `KMQA`, which can fully exploit the structural medical knowledge (i.e., medical knowledge graph) and the reference medical plain text (i.e., text snippets retrieved from reference books). The experimental results indicate that the `KMQA` outperforms existing competitive models with a large margin and passes the exam with 61.8% accuracy rate on the test set.

1 Introduction

Question: 患者，女，27岁，确诊**慢性乙型肝炎**3年，近日化验结果：HBV-DNA 2×10^5 copies/mL, ALT 122 U/L。拟予以**抗病毒治疗**，首选的药物是哪个？ A female patient, aged 27 years old, has been diagnosed with ***chronic hepatitis B*** for 3 years. Recent results show: HBV-DNA 2×10^5 copies/mL, ALT 122 U/L. The initial diagnosis is to take ***antiviral treatment*** for her. Which is the preferred one among the following drugs?
Options: **A**. 阿糖腺苷 Ara adenosine. **B**. 恩替卡韦 Entecavir. ✓ **C**. 泛昔洛韦 Famciclovir. **D**. 利巴韦林 Ribavirin. **E**. 膦甲酸钠 Sodium foscarnet.
Option B retrieved text snippets: 临床用于抗乙型肝炎病毒的药物有拉米夫定, 阿德福韦, 干扰素-α, 利巴韦林, 恩替卡韦等... Drugs used clinically against hepatitis B virus include lamivudine, adefovir, interferon-α, ribavirin, entecavir, ...
Option B knowledge facts: (恩替卡韦, 适应症, 慢性乙型肝炎) (entecavir, indication, chronic hepatitis B) (恩替卡韦, 二级分类, 抗病毒药) (entecavir, second class, antiviral drugs)

Table 1: An example from our multiple-choice QA task in a medical exam (✓: correct answer option).

With the advent of large scale datasets such as SQuAD (Rajpurkar et al., 2016, 2018), RACE (Lai et al., 2017), and Natural Questions (Kwiatkowski et al., 2019; Lee et al., 2019) on the open domain, machine reading comprehension (MRC) has become a hot topic in the natural language processing field. In the past few years, the MRC has obtained substantial progress, and many recent models have surpassed the human performance on several datasets. The superiority of these models is mainly attributed to two significant aspects: 1) the powerful representations ability of large pre-trained language models (PLMs), which can cover or remember most of the language variations *implicitly*. For example, among the top 10 works on SQuAD 2.0, nine models are based on ALBERT (Lan et al., 2020).[1] 2) the most popular MRC datasets belong to the open domain, which are built from news, fiction, and Wikipedia text, etc. The answers to most questions can be derived from the given plain text directly.

Compared to the open domain MRC, medical MRC is more challenging, while owning the great potential of benefiting clinical decision support. There still lacks the popular benchmark medical MRC dataset. Some recent works are trying to construct medical MRC dataset such as PubMedQA (Jin et al., 2019), emrQA (Pampari et al., 2018) and HEAD-QA (Vilares and Gómez-Rodríguez, 2019), etc. However, either these data sets are noisy (e.g., due to semi-automatically or heuristic rules generated), or the annotated data

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1427–1438,
November 16–20, 2020. ©2020 Association for Computational Linguistics

scale is too small (Yoon et al., 2019; Yue et al., 2020). Instead, we constructs a large scale medical MRC dataset by collecting 21.7k multiple-choice problems with human-annotated answers for the National Licensed Pharmacist Examination in China. This entrance exam is a challenging task for humans, which is used to assess human candidates' professional medical knowledge and skills. According to the statistics data, the examinee's pass rate in 2018 is less than 14.2%. [2] The text of the reference books is used as the plain text for the questions. One example is illustrated in Table 1.

Though several pre-trained language models have been introduced for domain-specific MRC, BERT based models are not as consistently dominant as they are in open field MRC tasks (Zhong et al., 2020; Yue et al., 2020). Another challenge is that medical questions are often more difficult; no labeled paragraph contains the answer to a given question. Searching for multiple relevant snippets from possibly large-scale text such as the whole reference books is usually required. In many cases, the answer can not be found explicitly from the relevant snippets, and the medical background knowledge is needed to derive the correct answers from the relevant snippets. Therefore, unlike open domain, just using the powerful pre-trained language model and plain text cannot obtain the high performance for medical MRC. For example, in Table 1, the relevant snippets (the 3rd row) can only induce that *Ribavirin* and *Entecavir* are the possible answers for the given question (the 1st row). If the triples from medical knowledge graph (*entecavir*, *indication*, *chronic hepatitis B*) is used, we can quickly obtain the correct answer as *Entecavir*.

Here, we propose a novel medical MRC model `KMQA`, which exploits the reference medical text and external medical knowledge. Firstly, `KMQA` models the representations of interaction between question, option, and retrieved snippets from reference books with the co-attention mechanism. Secondly, the novel proposed knowledge acquisition algorithm is performed on the medical knowledge graph to obtain the triples strongly related to questions and options. Finally, the fused representations of knowledge and question are injected into the prediction layer to determine the answer. Besides, `KMQA` acquires factual knowledge via learning from an intermediate relation classification task and enhances entity representation by constructing a sub-graph using question-to-options paths. Experiments show that our unified framework yields substantial improvements in this task. Further ablation study and case studies demonstrate the effectiveness of the injected knowledge. We also provide an online homepage at `http://112.74.48.115:8157`.

2 Related Work

Medical Question Answering The medical domain poses a challenge to existing approaches since the questions may be more challenging to answer. BioASQ (Tsatsaronis et al., 2012, 2015) is one of the most significant community efforts made for advancing biomedical question answering (QA) systems. SeaReader (Zhang et al., 2018) is proposed to answer questions in clinical medicine using documents extracted from publications in the medical domain. Yue et al. (2020) conduct a thorough analysis of the emrQA dataset (Pampari et al., 2018) and explore the ability of QA systems to utilize clinical domain knowledge and to generalize to unseen questions. Jin et al. (2019) introduce PubMedQA where questions are derived based on article titles and can be answered with its respective abstracts. Recently, pre-trained models have been introduced to medical domain (Lee et al., 2020; Beltagy et al., 2019; Huang et al., 2019a). They are trained on unannotated biomedical texts such as PubMed abstracts and have been proven useful in biomedical question answering. In this paper, we focus on multiple choice problems in medical exams that are more difficult and diverse, which allows us to directly explore the capabilities of QA models to encode domain knowledge.

Knowledge Enhanced Methods KagNet (Lin et al., 2019) represents external knowledge as a graph, and then uses graph convolution and LSTM for inference. Ma et al. (2019) adopt the BERT-based option comparison network (OCN) for answer prediction, and propose an attention mechanism to perform knowledge integration using relevant triples. Lv et al. (2020) propose a GNN-based inference model on conceptual network relationships and heterogeneous graphs of Wikipedia sentences. BERT-MK (He et al., 2019) integrates fact triples in the KG, while REALM (Guu et al., 2020) augments language model pre-training algorithms with a learned textual knowledge retriever. Unlike previous works, we incorporate external knowledge

---

[2] `http://www.cqlp.org/info/link.aspx?id=3599&page=1`

implicitly and explicitly. Built upon pre-trained models, our work combines the strengths of both text and medical knowledge representations.

3 Method

The medical MRC task in this paper is a multiple-choice problem with five answer candidates. It can be formalized as follows: given the question Q and answer candidates $\{O_i\}$, the goal is to select the most plausible correct answer $\hat{O}$ from the candidates. `KMQA` utilizes textual evidence spans and incorporates **K**nowledge graphs facts for **M**edical multi-choice **Q**uestion **A**nswering. As shown in Figure 1, it consists of several modules: (a) the multi-level co-attention reader that computes context-aware representations for the question, options and retrieved snippets, and enables rich interactions among their representations. (b) the knowledge acquisition which extracts knowledge facts from KG given the question and options. (c) the injection layer that further incorporates knowledge facts into the reader, and (d) a prediction layer that outputs the final answer. And also, we utilize the relational structures of question-to-options paths to further augment the performance of `KMQA`.

3.1 Multi-level Co-attention Reader

Given an instance, text retrieval system is firstly used to select evidence spans for each question-answer pair. We take the concatenation of question and candidate answer as input, and keep `top-N` relevant passages. These passages are combined as new evidence spans. Here, we use BM25-based search indexer (Robertson and Zaragoza, 2009) and medical books as text source.

Multi-level co-attention reader is used to represent the evidence spans E, the question Q and the option O. We formulate the input evidence spans as $E \in \mathbb{R}^m$, the question as $Q \in \mathbb{R}^n$ and a candidate answer as $O \in \mathbb{R}^l$, where m, n and l is the max length of the evidence spans, question and candidate answer respectively. Similar to (Devlin et al., 2019), given the input E, Q and O, we apply the WordPiece tokenizer and concatenate all tokens as a new sequence (`[CLS]`,E,`[SEP]`,Q,#,O,`[SEP]`), where "`[CLS]`" is a special token used for classification and "`[SEP]`" is a delimiter. Each token is initialized with a vector by summing the corresponding token, segment and position embedding, and then encoded into a hidden state by the BERT based pre-trained language model.

Generally, the PLMs are pre-trained on the large scale open domain plain text, which lacks the knowledge of the medical domain. There are some recent works show that to further pre-train PLMs on the intermediate tasks can significantly improve the performance of target task (Wang et al., 2019; Clark et al., 2019; Pruksachatkun et al., 2020). Following this observation, we incorporate knowledge from the Chinese Medical Knowledge Graph (CMeKG) (Byambasuren et al., 2019)[3] by intermediate-task training. The CMeKG is a Chinese knowledge graph in medical domain developed by human-in-the-loop approaches based on large-scale medical text data using natural language processing and text mining technology. Currently, it contains 11,076 diseases, 18,471 drugs, 14,794 symptoms, 3,546 structured knowledge descriptions of diagnostic and therapeutic technologies, and 1,566,494 examples of medical concept links, along with attributes describing medical knowledge. The triple in CMeKG consists of four parts: head entity, tail entity and relation along with an attribute description. To acquire factual knowledge, we adopt the relation classification task to further pre-train PLMs on this dataset. This task requires a model to classify the relational labels of a given entity pair based on context. Specifically, we select a subset from CMeKG with 163 distinctive relations and include only the triples in which the relation related to drugs and disease types in the exam. Then, we discard all the relations with fewer than 5,000 entity pairs and retain 40 relations and 1,179,780 facts. After that, we concatenate two entities and insert "`[SEP]`" between the two as input, and then apply a linear layer to "`[CLS]`" vector of the last hidden feature of PLM to perform relation classification. Next, we discard the classification layer and initialize the corresponding part of the PLM with other parameters, denoted as $\mathcal{B}$. Finally, we employ $\mathcal{B}$ to get encoding representation $\mathbf{H}_{cls} \in \mathbb{R}^h$, $\mathbf{H}_E \in \mathbb{R}^{m \times h}$, $\mathbf{H}_Q \in \mathbb{R}^{n \times h}$, $\mathbf{H}_O \in \mathbb{R}^{l \times h}$, $\mathbf{H}_{QE} \in \mathbb{R}^{(n+m) \times h}$ respectively, where h is the hidden size.

To strengthen the information fusion from the question to the evidence spans as well as from the evidence spans to the question, we adopt a multi-level co-attention mechanism, which has been shown effective in previous models (Xiong

```

et al., 2017; Seo et al., 2017; Huang et al., 2019b). Taking the candidate answer representation O as input, we compute three types of attention weights to capture its correlation to the question, the evidence, and both the evidence and question, and get question-attentive, evidence-attentive, and question and evidence-attentive representations:

$$\tilde{\mathbf{H}}_O = \mathbf{H}_O \mathbf{W}_t + \boldsymbol{b}_t, \tag{1}$$

$$\mathbf{A}_O^Q = \mathrm{Softmax}(\tilde{\mathbf{H}}_O \mathbf{H}_Q^\top)\mathbf{H}_Q \in \mathbb{R}^{l \times h}, \tag{2}$$

$$\mathbf{A}_O^E = \mathrm{Softmax}(\tilde{\mathbf{H}}_O \mathbf{H}_E^\top)\mathbf{H}_E \in \mathbb{R}^{l \times h}, \tag{3}$$

$$\mathbf{A}_O^{QE} = \mathrm{Softmax}(\tilde{\mathbf{H}}_O \mathbf{H}_{QE}^\top)\mathbf{H}_{QE} \in \mathbb{R}^{l \times h}, \tag{4}$$

where $\mathbf{W}_t$ and $\boldsymbol{b}_t$ are learnable parameters. Next we fuse these representations as follows:

$$\mathbf{T}_O = \mathrm{LSTM}([\mathbf{A}_O^Q; \mathbf{A}_O^E; \mathbf{A}_O^{QE}]) \in \mathbb{R}^{l \times h}, \tag{5}$$

where $[;]$ denotes concatenation operation. Finally, we apply column-wise max and mean pooling on $\mathbf{T}_O$ and concatenate it with $\mathbf{H}_{cls}$. It obtains the new option representation $\tilde{\mathbf{T}}_O \in \mathbb{R}^{3h}$.

3.2 Knowledge Acquisition

In this section, we describe the method to extract knowledge facts from knowledge graph in details. Once the knowledge is determined, we can choose the appropriate integration mechanism for further knowledge injection, such as attention mechanism (Sun et al., 2018; Yang et al., 2019; Ma et al., 2019), pre-training tasks (He et al., 2019) and multi-task training (Xia et al., 2019).

Given a question Q and a candidate answer O, we first identify the entity and its type in the text by entity linking. The identified entity exactly matches the concept in KG. We also perform soft matching of part-of-speech rules and filter out stop words, and obtain key entities for Q according to category description, such as "*western medicine*", "*symptoms*", "*Chinese herbal medicine*" as $\mathcal{E}_Q$. After that, we retrieve all triples $\mathcal{S}_O$ whose head or tail contains the entities of O as knowledge facts for this option. For these knowledge facts, we first convert head-relation-tail tokens into regular words by template function g in order to generate a pseudo-sentence. For example, "(*chronic hepatitis B*, *Site of disease*, *Liver*)" is converted to "*The site of disease of chronic hepatitis B is liver*". Then we can get re-rank option facts for each question-answer pair with the method shown in Algorithm 1, which uses the word mover's distance (Kusner et al., 2015) as similarity function empirically. The reason we apply it is to be able to find higher-quality knowledge facts that are more relevant to current option and input them into the model. The embedding function $\mathcal{F}$ here is the mean pooling of sentence word vectors. The word embedding uses 200-dimension pre-trained embedding for Chinese words and phrases (Song et al., 2018). Although not perfect, the triple text found by Algorithm 1 does provide some useful information that can help the model find the correct answer.

3.3 Knowledge Injection and Answer Prediction

We first concatenate the returned option fact text as F, and then use the $\mathcal{B}$ to generate an embedding of this pseudo-sentence:

$$\mathbf{H}_F = \mathcal{B}(F). \tag{6}$$

Let $\mathbf{H}_F \in \mathbb{R}^{s\times h}$ be the concatenation of the final hidden states, where s is max length, and we then adopt the attention mechanism to model the interaction between $\mathbf{H}_F$ and the PLMs encoding output of question $\mathbf{H}_Q$:

$$\boldsymbol{\mathcal{M}}_{FQ} = (\mathbf{W}_{fq} \circ \mathbf{H}_F)\mathbf{H}_Q^\top, \tag{7}$$

$$\mathbf{A}_Q^F = \text{Softmax}(\boldsymbol{\mathcal{M}}_{FQ})\mathbf{H}_Q, \tag{8}$$

$$\mathbf{A}_F^Q = \text{Softmax}(\boldsymbol{\mathcal{M}}_{FQ})\text{Softmax}(\boldsymbol{\mathcal{M}}_{FQ}^\top)\mathbf{H}_F, \tag{9}$$

$$\mathbf{H}_{\boldsymbol{FQ}} = [\mathbf{H}_F; \mathbf{A}_Q^F; \mathbf{H}_F \circ \mathbf{A}_Q^F; \mathbf{H}_F \circ \mathbf{A}_F^Q], \tag{10}$$

$$\mathbf{T}_F = \text{Tanh}(\mathbf{H}_{\boldsymbol{FQ}}\mathbf{W}_{proj}), \tag{11}$$

where element-wise multiplication is denoted by $\circ$. Specifically, $\mathbf{H}_F$ is linear transformed using $\mathbf{W}_{fq} \in \mathbb{R}^{s\times h}$. Then, the similarty matrix $\boldsymbol{\mathcal{M}}_{FQ} \in \mathbb{R}^{s\times n}$ is computed using standard attention. Then we use $\boldsymbol{\mathcal{M}}_{FQ}$ to compute question-to-knowledge attention $\mathbf{A}_Q^F \in \mathbb{R}^{s\times h}$ and knowledge-to-question attention $\mathbf{A}_F^Q \in \mathbb{R}^{s\times h}$. Finally, the question-aware knowledge textual representation $\mathbf{T}_F \in \mathbb{R}^{s\times h}$ is computed, where $\mathbf{W}_{proj} \in \mathbb{R}^{4h\times h}$. Finally, max pooling and mean pooling are applied on the $\mathbf{T}_F$ to generate final knowledge representation $\tilde{\mathbf{T}}_F \in \mathbb{R}^{2h}$. In the output layer, we combine textual representation $\tilde{\mathbf{T}}_O$ with the knowledge representation $\tilde{\mathbf{T}}_F$. For each candidate answer O_i, we compute the loss as follows:

$$\mathbf{T}_C = [\tilde{\mathbf{T}}_O; \tilde{\mathbf{T}}_F], \tag{12}$$

$$Score(O_i|E,Q,F) = \frac{\exp(\mathbf{W}_{out}^\top \mathbf{T}_C^i)}{\sum_{j=1}^{5} \exp(\mathbf{W}_{out}^\top \mathbf{T}_C^j))}, \tag{13}$$

where $\mathbf{W}_{out} \in \mathbb{R}^{1\times 5h}$. We add a simple feed-forward classifier as the output layer which takes the contextualized representation $\mathbf{T}_C$ as input and outputs the answer score $Score(O_i|E,Q,F)$. Finally, the candidate with the highest score is chosen as the answer. The final loss function is obtained as follows:

$$\mathcal{L} = -\frac{1}{C}\sum_i \log(Score(\hat{O}_i|E,Q,F)) + \lambda||\theta||_2, \tag{14}$$

where C is the number of training examples, and $\hat{O}_i$ is the ground truth for the i-th example, θ denotes all trainable parameters.

3.4 Augmenting with Path Information

For concepts in question and options (remove entities that are not diseases, drugs, and symptoms), we combine them in pairs and retrieve all paths between them within 3 hops to form a sub-graph about the option. For example, (*chronic hepatitis B* → *related diseases* → *cirrhosis* → *medical treatment* → *entecavir*) is a path for (*chronic hepatitis B*, *entecavir*).

Then, we apply L layer graph convolutional networks (Kipf and Welling, 2017) to update the representation of the nodes, which is similar to (Lin et al., 2019; Yang et al., 2019). Here, we set L equals 2. The vector $\boldsymbol{h}_i^{(0)} \in \mathbb{R}^h$ for concept c_i in the sub-graph g is initialized by the average embedding vector of tokens similar to §3.2. Then, we update them at $(l+1)$-th layer using the following equation:

$$\boldsymbol{h}_i^{(l+1)} = \sigma(\mathbf{W}_{gcn}\boldsymbol{h}_i^{(l)} + \sum_{j\in\mathcal{N}_i} \frac{1}{|\mathcal{N}_i|}\mathbf{W}_{gcn}\boldsymbol{h}_j^{(l)}), \tag{15}$$

where $\mathcal{N}_i$ is the neighboring nodes, σ is ReLU activation function, $\mathbf{W}_{gcn}$ is the weight vector. After that, we update i-th tokens representation $\boldsymbol{t}_i \in \mathbf{T}_O$ with the corresponding entity vector via a sigmoid gate to the new token representation $\boldsymbol{t}_i'$:

$$g_i = \text{Sigmoid}\left(\mathbf{W}_s\left[\boldsymbol{t}_i; \boldsymbol{h}_i^L\right]\right), \tag{16}$$

$$\boldsymbol{t}_i' = g_i \circ \boldsymbol{t}_i + (1-g_i) \circ \boldsymbol{h}_i^L. \tag{17}$$

4 Dataset

We use the National Licensed Pharmacist Examination in China [4] as the source of questions. The exam is a comprehensive evaluation of the professional skills of candidates. Medical practitioners have to pass the examination to obtain the qualification for licensed pharmacist in China. Passing the

---

[4] `http://english.nmpa.gov.cn/2019-07/19/c_389177.htm`

exam requires getting a minimum of 60% of the total score. The pharmacy comprehensive knowledge and skills part of the exam consists of 600 multiple-choice problems over four categories. To test the generalizability of MRC models, we use the examples of this part in the previous five years (2015-2019) as the test set, and exclude questions of multiple-answer type. In addition to that, we also collected over 24,000 problems from the Internet and exercise books. After removing duplicates and incomplete questions (e.g. no answer), we randomly divide it into training, development sets according to a certain ratio, and remove the problems similar to the test set according to the condition that the edit distance is less than 0.1. The detailed statistics of the final problem set, named as NLPEC, are shown in Table 2.

	Train	**Dev**	**Test**
# Questions	18,703	2,500	550
Avg. words of questions	16.72	17.15	42.82
Avg. words of candidate options	3.48	3.38	3.62
Avg. words of retrieval evidences	84.17	81.75	86.09
Avg. sentences of each evidence	3.82	3.79	4.02
Candidate options per problem		5	

Table 2: Statistics of our NLPEC dataset.

We use the official exam guide book of the National Licensed Pharmacist Examination as text source (NMPA, 2018). It has 20 chapters, including pharmaceutical practice and medication, self-medication for common diseases, and medication for organ system diseases. The book covers most of the necessary contents of the examination. In order to ensure the quality of retrieval, we first convert it into structured electronic versions through OCR tools, and then manually proofread and divide all the texts into paragraphs. Meanwhile, we also extract passages from other literature and add it to the text source, including the pharmacological effects and clinical evaluation of various drugs, explanations of drug monitoring and descriptions of essential medicines.

5 Experiment

5.1 Experiment Settings

We use the Google-released BERT-base model as the PLM (Devlin et al., 2019). We also compare the performance of `KMQA`, which uses the pre-trained RoBERTa large model (Liu et al., 2019). The pre-trained weights that we adopt are the version of whole word masking in Chinese text (Cui et al., 2019). Our model is also orthogonal to the choice of the pre-trained language model. We use AdamW optimizer (Loshchilov and Hutter, 2019) with a batch size of 32 for model training. The initial learning rate, the maximum sequence length, the learning rate warmup proportion, the gradient accumulation steps, the training epoch, the hidden size h, λ, the number of evidence spans N, and the hyperparameter K are set to 3×10^{-5}, 512, 0.1, 8, 10, 768, 1×10^{-6}, 1, and 3 respectively. The learning parameters are selected based on the best performance on the development set. Our model takes approximately 22 hours to train with 4 NVIDIA Tesla V100. In order to reduce memory usage, in our implementation, we concatenate the knowledge text and the retrieved evidence spans, and then obtain separate encoding representations. For other models, the dimension of word embeddings is 200, the hidden size is 256, and the optimizer is Adam optimizer (Kingma and Ba, 2015). We also pretrained word embeddings on a large-scale Chinese medical text.

Model	**Accuracy (%)**	
	Dev	**Test**
IR baseline	36.4	34.1
Random guess	21.3	22.8
Co-Matching (Wang et al., 2018)	56.1	45.8
BiDAF (Seo et al., 2017)	52.7	43.6
SeaReader (Zhang et al., 2018)	58.2	48.4
Multi-Matching (Tang et al., 2019)	58.4	48.7
BERT-base (Devlin et al., 2019)	64.2	52.2
ERNIE (Sun et al., 2019)	64.7	53.4
RoBERTa-wwm-ext-large (Cui et al., 2019)	70.8	57.9
KMQA (BERT-base)	67.9	57.1
KMQA (RoBERTa-wwm-ext-large)	**71.1**	**61.8**

Table 3: Performance comparison on the test set. Additional details about baselines can be found in the Appendix.

5.2 Main Results

The comparison between our method and previous works on the multi-choice question answering task over our dataset is shown in Table 3. IR baseline refers to the selection of answers using the ranking of the score of the retrieval system, and random guess refers to the selection of answers according to a random distribution. The third to fifth lines show the results of the previous state-of-the-art models. These models all employ the co-matching model and perform better than those two baselines. They use attention mechanisms to capture the correlation between retrieved evidence, questions, and candidate answers, and tend to choose the answer that is closest to the semantics of the evidence. Pre-trained language models with fine-tuning achieve more than 18% improvement over baselines. By fusion of knowledge source and text over BERT-base, the performance is further improved, which demonstrates our assumption that incorporating knowledge from the structure source can further enhance the option contextual understanding of BERT-base. Furthermore, our single model of `KMQA-RoBERTa` large, which employs RoBERTa large model pre-trained with whole word mask achieves better performance on both development set and test set and also outperforms RoBERTa large. This result also slightly surpasses the human passing score. These results demonstrate the effectiveness of our method.

Types	**Number**	**Accuracy**
Statement Best Choice	200	64.0
Best Compatible Choice	257	58.4
Case Summary Best Choice	90	66.7
Conceptual Knowledge	279	61.3
Situational Analysis	42	64.3
Logical Reasoning	226	62.0
Positive Questions	433	61.9
Negative Questions	114	61.4

Table 4: Performance of our model on different question category.

In the exam, the questions are divided into three types, namely, type A (statement best choice), type B (best compatible choice), and type C (case summary best choice). The evaluation results are listed in Table 4. We observe that the best compatible choice type accounts for the highest proportion of the questions, and the model performance is lower than the other two. According to the different methods required for answering questions, we further divide them into three types: conceptual knowledge, situational analysis, and logical reasoning. For the problem of conceptual knowledge, they account for a lot and are usually related to specific concept knowledge. It means that we also need to improve our retrieval module. According to the needs of the problem to be deduced in a positive or negative direction, we divide the problem into two categories: positive questions and negative questions. We find that their performance is similar, but the positive part accounts for a more significant proportion.

5.3 Ablation Study

To study the effect of each `KMQA` component, we also conduct ablation experiments. The results are shown in Table 5. From the experimental results, if there is no external information but only questions and options, the model is only 2.5% higher than the retrieval baseline. After adding the information retrieved by the text retrieval model and knowledge graph, the model is improved by 26.3% and 6.4% respectively, which shows the effectiveness of external information. Further, we find that pre-training on relation classification can also improve the performance of our downstream QA tasks. When the path information from the question to the option is further added, the model has 0.8% improved accuracy. If we only use retrieved snippets from reference books with the co-attention mechanism, the model has more performance drops. We also change the hyper-parameter K, and results show that the setting $K = 3$ performs best. Due to the max length of BERT model, a larger K will not bring more improvements.

Model	**Accuracy (Dev)**
Ours (BERT-base)	67.9
w/o relation classification	66.4
w/o extracted facts	65.2
w/o path information	67.1
w/o text source	45.3
w/o knowledge source	64.6
only option	38.9
K = 1 (RoBERTa)	70.2
K = 2 (RoBERTa)	70.6
K = 3 (RoBERTa)	71.1

Table 5: Ablation study in development set.

5.4 Case Study

As shown in Table 6, we choose an example to visualize joint reasoning using KG and retrieval text. In Example 1 of Table 6, we find that limited by the process of retrieval, some of the descriptions of the indications of the option are not completely relevant to the question stem, and the paragraphs contain descriptions of the chemical composition of this drug, which is noisy for answering the question. In contrast, our model is able to answer this question using both KG and textual evidence, alleviating the noise problem to some extent. Since many of the questions in our dataset are about diseases and drugs that require descriptions of their underlying meanings, using the medical KG may be the most convenient for our research.

Type	Examples
Positive Example	**Question**: 患者，男，38岁，因腹部受寒致胃痉挛性疼痛，应选用的药物是？ The patient, male, 38 years old, suffers from **stomach spasmodic pain** caused by **abdominal cold**. Which of the following drugs should be chosen? **Options:** ✓ (A). 山莨菪碱 Anisodamine. × (B). 布洛芬 Ibuprofen. × (C). 麦角胺咖啡因 Ergotamine caffeinee. × (D). 卡马西平 Carbamazepine. × (E). 吗啡 Morphine. **Evidence spans:** 对腹痛较重者或反复呕吐性腹泻者腹痛剧烈时可服山莨菪碱片，一次5mg，一日3次或痛时服用... 山莨若碱与莨菪碱在结构上的区别是，结构中醇部分为6-(S)-羟基莨菪醇（亦称山莨菪醇），与托品醇相比，在6位多了一个β-取向的羟基，这使得山莨菪碱分子的极性增强，难以透过血-脑屏障，中枢作用很弱... Anisodamine tablets can be taken for severe **abdominal pain** or recurrent vomiting diarrhea when abdominal pain is severe, 5 mg once, 3 times a day or when pain occurs... The structural difference between anisodamine and scopolamine is that the alcohol part in the structure is 6-(S)-hydroxy scopolamine (also known as anisodamine), which has a β-oriented hydroxyl group at the 6-position compared with tropinol, which makes the polarity of the anisodamine molecule enhanced, it is difficult to penetrate the blood-brain barrier, and the central role is weak... **Knowledge facts: 1.** (山莨菪碱, 适应症, 疼痛) The **indication** for anisodamine is **pain**. **2.** (山莨菪碱, 适应症, 胃肠绞痛) The **indication** for anisodamine is **spasm**. **3.** (山莨菪碱, 适应症, 痉挛) The indication for anisodamine is gastrointestinal colic. **A sample path:** 胃痉挛 → 相关疾病 → 胃病 → 临床症状及体征 → 急性单纯性胃炎 → 治疗方案 → 山莨菪碱 gastric spasm → related diseases → gastropathy → clinical symptoms and signs → acute simple gastritis → treatment plan → anisodamine
Negative Example 1 (Noisy Evidence)	**Question**: 从事驾车、高空作业的患者不宜服用的药物是？ Which drugs should not be taken by patients engaged in driving and high altitude work? **Golden answer**: 氯苯那敏 Chlorpheniramine **Predicted distractor**: 伪麻黄碱 Pseudoephedrine **Evidence spans**: 组胺H2受体阻断剂雷尼替丁、西咪替丁、法莫替丁能引起幻觉、定向力障碍。因此，对驾车司机、高空作业者、精密仪器操作者慎用，或提示在服用后休息6h再从事工作。 Histamine H2 receptor blockers ranitidine, cimetidine and famotidine can cause hallucination and disorientation. Therefore, drivers, high-altitude operators, precision instrument operators should be cautious to use, or prompt to rest for 6 hours before working. **Knowledge facts**: (氯苯那敏, 注意事项, 驾驶员、机械操作人员在工作进行时不宜使用)。 The precaution of chlorpheniramine is that it should not be used by drivers and mechanical operators during work. **Evidence spans of wrong answer**: ...氨酚伪麻美芬片 II/氨麻苯美片、美扑伪麻片中还含有H1受体拮抗剂成分，可能引起头晕、嗜睡，故服药期间不宜驾车或高空作业、操纵机器... ..., paracetamol pseudoephedrine tablets II/amphetamine tablets, and melphalan pseudoephedrine tablets also contain H1 receptor antagonist components, which may cause dizziness and sleepiness. ***So, it is inappropriate to drive or operate machines at high altitude during medication administration***...
Negative Example 2 (Weak Reasoning)	**Question**: 下列中药、化学药联合应用，不存在重复用药的是？ The following Chinese medicine and chemical medicine are used together. Which option does not exist for repeated medicine? **Golden answer**: 曲克芦丁片＋维生素C片 Troxerutin Tablets + Vitamin C Tablets **Predicted distractor**: 珍菊降压片＋氢氯噻嗪片 Zhenju Antihypertensive Tablets + Hydrochlorothiazide Tablets **Evidence spans**: （2）充分询问进食情况及用药史，避免重复用药引发维生素D中毒... (2) Fully inquire about food intake and medication history to avoid vitamin D poisoning caused by repeated medication... **Knowledge facts of wrong answer**: (珍菊降压片, 注意事项, 对氢氯噻嗪、可乐定、磺胺类药物过敏者忌用) ***The precautions of Zhenju Antihypertensive Tablets are to avoid the use of hydrochlorothiazide***, clonidine and sulfonamides in allergic patients...

Table 6: Case study and error examples of the proposed `KMQA`.

In addition, we randomly select 50 errors made by our approach from the test set, and categorize them into 4 groups:

Information Missing: In 44% of the errors, the retrieved evidence and extracted knowledge cannot provide useful information to distinguish different answer candidates, which is the major error type in our model. Taking the case "*What does the abbreviation - p.c. - stand for in prescription?*" as an example, to correctly predict the answer, we need to know that "*p.c.*" is the abbreviation that means "*after meals*" (from the Latin "*post cibum*").

Noisy Evidence: In 32% of the errors, the model is misled by noisy knowledge of other wrong answers. The reason may be that the context is too long and overlaps with the problem description. For example, in Example 2 of Table 6, both the right answer and wrong prediction could be potentially selected by retrieval evidence. However, we can intuitively get the answer through mutual verification of essential information in KG and retrieved texts.

Weak Reasoning Ability: 14% of the errors are due to the weak reasoning ability of the model, such as the understanding of symbolic units in options. For example, in Example 3 of Table 6, the model needs to first understand the joint meaning of options using common sense, and then eliminate the wrong answer with counterfactual reasoning through knowledge and text.

Numerical Analysis: 10% of the errors are from mathematical calculation and analysis questions. The model cannot handle the question like "*To prepare 1000ml 70% ethanol with 95% ethanol and distilled water, what is the volume of 95% ethanol needed?*" properly since it cannot be directly entailed by the given paragraph. Instead, it requires mathematical calculation and reasoning ability of the model.

6 Conclusion

In this work, we explore how to solve multi-choice reading comprehension tasks in the medical field based on the examination problems of licensed pharmacists, and propose a novel model `KMQA`. It explicitly combines knowledge and pre-trained models into a unified framework. Moreover, `KMQA` implicitly takes advantage of factual information via learning from an intermediate task and also transfers structural knowledge to enhance entity representation. On the test set from the real world, the `KMQA` is the single model that outperforms the human pass line. In the future, we will explore how to apply our model to more domains, and enhance the interpretability of the reasoning path when the model answers questions.

A Compared Methods

BiDAF (Seo et al., 2017) is a representative network for machine comprehension. It is a multi-stage hierarchical process that represents context at different levels of granularity and uses a bidirectional attention flow mechanism to achieve a query-aware context representation without early summarization.

Co-matching (Wang et al., 2018) uses the attention mechanism to match options with the context that composed of paragraphs and the question, and output the attention value to score the options. It is used to solve the single paragraph reading comprehension task of a single answer question.

Multi-Matching (Tang et al., 2019) applies the Evidence-Answer Matching and Question-Passage-Answer Matching module to gather matching information and integrate them to get the scores of options.

SeaReader (Zhang et al., 2018) is proposed to answer questions in clinical medicine using knowledge extracted from publications in the medical domain. The model extracts information with question-centric attention, document-centric attention, and cross-document attention, and then uses a gated layer for denoising.

BERT (Devlin et al., 2019) achieves remarkable state-of-the-art performance across a wide range of related tasks, such as textual entailment, natural language inference, question answering. It first trains a language model on an unsupervised large-scale corpus, and then the pre-trained model is fine-tuned to adapt to downstream tasks.

	TRAIN	DEV	TEST
# Knowledge facts	$1,129,780$	$50,000$	$50,000$

Model	**Accuracy (TEST)**
RoBERTa-wwm-ext-large (Cui et al., 2019)	89.4
RoBERTa-wwm-ext-large (w/o fine-tuning)	50.8
BERT-base (Devlin et al., 2019)	88.8
BERT-base (w/o fine-tuning)	50.6
DPCNN (Johnson and Zhang, 2017)	82.6
TextCNN (Kim, 2014)	67.8
ESIM (Chen et al., 2017)	77.8

Table 7: Data statistics of relation classification task and accuracy results.

RoBERTa (Liu et al., 2019) is based on BERT's language masking strategy and modifies key hyperparameters in BERT, including changing the target of BERT's next sentence prediction, and training with a larger bacth size and learning rate. It has achieved improved results than BERT on different data sets.

ERNIE (Sun et al., 2019) is designed to learn language representation enhanced by knowledge masking strategies, which includes entity-level masking and phrase-level masking. It achieves state-of-the-art results on five Chinese natural language processing tasks.

B Relation Classification

We also show the dataset that used to pre-train on the relation classification task and the performance of the pre-trained models in this task. We compare several common text classification and matching models, including TextCNN (Kim, 2014), ESIM (Chen et al., 2017), DPCNN (Johnson and Zhang, 2017). For text classification, the input of the model is the concatenation of two entity words. For ESIM, the input layer is softmax multi-classification. Through learning with the relation classification task, pre-trained models achieve improved performance on the divided test set.

C Introduction to Exam

The detailed statistics of exams in recent years are listed in Table 8. The professional qualifications for licensed pharmacists are subject to a national unified outline, unified proposition, and unified organized examination system (Fang et al., 2013). The qualification exam for licensed pharmacists is held on every October. The examination takes

Years	# Applicants (k)	# Participants (k)	Exam ratio (%)	# Passing (k)	Pass ratio (%)
2018	687.5	566.6	82.41	79.9	14.10
2017	675.2	523.2	77.50	153.0	29.19
2016	884.7	728.6	82.38	151.0	20.74
2015	1121.4	937.7	83.62	235.0	25.16
2014	840.2	702.4	83.61	137.1	19.52
2013	402.3	329.8	81.99	51.8	15.72
2012	188.1	146.8	78.09	26.0	17.68
2011	145.9	109.7	75.16	14.4	13.13
2010	132.7	100.6	75.76	11.2	11.12

Table 8: Statistics of this exam in recent years.

two years as a cycle, and those who take the examination of all subjects must pass the examination of all subjects within two consecutive examination years. The professional qualification examination for licensed pharmacists is divided into two professional categories: pharmacy and traditional Chinese pharmacy. The pharmacy exam subjects are (1) pharmacy professional knowledge (first part) (2) pharmacy professional knowledge (second part) (3) pharmacy management and regulations, and (4) pharmacy comprehensive knowledge and skills. The subjects for the examination of traditional Chinese medicine are (1) professional knowledge of traditional Chinese medicine (first part) (2) professional knowledge of traditional Chinese medicine (second part) (3) pharmaceutical management and regulations, and (4) comprehensive knowledge and skills of traditional Chinese medicine.

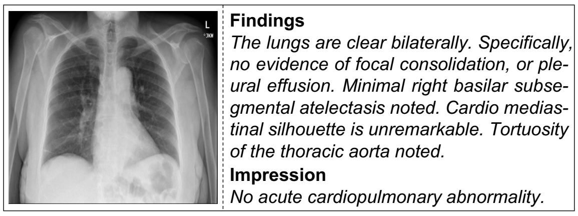
Abstract

Medical imaging is frequently used in clinical practice and trials for diagnosis and treatment. Writing imaging reports is time-consuming and can be error-prone for inexperienced radiologists. Therefore, automatically generating radiology reports is highly desired to lighten the workload of radiologists and accordingly promote clinical automation, which is an essential task to apply artificial intelligence to the medical domain. In this paper, we propose to generate radiology reports with memory-driven Transformer, where a relational memory is designed to record key information of the generation process and a memory-driven conditional layer normalization is applied to incorporating the memory into the decoder of Transformer. Experimental results on two prevailing radiology report datasets, IU X-Ray and MIMIC-CXR, show that our proposed approach outperforms previous models with respect to both language generation metrics and clinical evaluations. Particularly, this is the first work reporting the generation results on MIMIC-CXR to the best of our knowledge. Further analyses also demonstrate that our approach is able to generate long reports with necessary medical terms as well as meaningful image-text attention mappings.[1]

1 Introduction

Radiology report generation, which aims to automatically generate a free-text description for a clinical radiograph (e.g., chest X-ray), has emerged as a prominent attractive research direction in both artificial intelligence and clinical medicine. It can greatly expedite the automation of workflows and improve the quality and standardization of health care. Recently, there are many methods proposed in this area (Jing et al., 2018; Li et al., 2018; Johnson et al., 2019; Liu et al., 2019; Jing et al., 2019).



Findings
The lungs are clear bilaterally. Specifically, no evidence of focal consolidation, or pleural effusion. Minimal right basilar subsegmental atelectasis noted. Cardio mediastinal silhouette is unremarkable. Tortuosity of the thoracic aorta noted.
Impression
No acute cardiopulmonary abnormality.

Figure 1: An example chest X-ray image and its report including findings and impression.

Practically, a significant challenge of radiology report generation is that radiology reports are long narratives consisting of multiple sentences. As illustrated by Figure 1, a radiology report generally consists of a section of findings which describes medical observations, including both normal and abnormal features, as well as an impression or concluding remark summarizing the most prominent observations. Therefore, applying conventional image captioning approaches (Vinyals et al., 2015; Anderson et al., 2018) may be insufficient for radiology report generation, as such approaches are designed to briefly describe visual scenes with short sentences. The ability to provide accurate clinical descriptions for a radiograph is of the highest priority, which places a higher demand on the generation process. Nevertheless, despite the difficulties posed by these evident length and accuracy requirements, radiology reports do have their own distinctive characteristics. An important feature to note is their highly patternized nature, as illustrated by the sample report described above (Figure 1). On the basis of this patternization, many approaches have been proposed to address the challenges of radiology report generation. For example, Liu et al. (2019) found that a simple retrieval-based method could achieve a comparative performance for this task. Li et al. (2018) combined retrieval-based and generation-based methods with manually extracted

templates. Although promising results may be obtained by the retrieval-based approaches, they are still limited in the preparation of large databases, or the explicit construction of template lists to determine the patterns embedded in various reports.

In this paper, we propose to generate radiology reports via memory-driven Transformer. In detail, a relational memory (RM) is proposed to record the information from previous generation processes and a novel memory-driven conditional layer normalization (MCLN) is designed to incorporate the relational memory into Transformer (Vaswani et al., 2017). As a result, similar patterns in different medical reports can be implicitly modeled and memorized during the generation process, which thereby can facilitate the decoding of Transformer and is capable of generating long reports with informative content. Experimental results on two benchmark datasets confirm the validity and effectiveness of our approach, where Transformer with RM and MCLN achieves the state-of-the-art performance on all datasets. To summarize, the contributions of this paper are four-fold:

- We propose to generate radiology reports via a novel memory-driven Transformer model.
- We propose a relational memory to record the previous generation process and the MCLN to incorporate relational memory into layers in the decoder of Transformer.
- Extensive experiments are performed and the results show that our proposed models outperform the baselines and existing models.
- We conduct analyses to investigate the effect of our model with respect to different memory sizes and show that our model is able to generate long reports with necessary medical terms and meaningful image-text attention mappings.

2 The Proposed Method

Generating radiology reports is essentially an image-to-text generation task, for which there exist several solutions (Vinyals et al., 2015; Xu et al., 2015; Anderson et al., 2018; Cornia et al., 2019).

We follow the standard sequence-to-sequence paradigm for this task. In doing so, we treat the input from a radiology image as the source sequence $\mathbf{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_S\}, \mathbf{x}_s \in \mathbb{R}^d$, where $\mathbf{x}_s$ are patch features extracted from visual extractors and d the size of the feature vector. The corresponding report is the target sequence $Y = \{y_1, y_2, ..., y_T\}, y_t \in \mathbb{V}$, where y_t are the generated tokens, T the length of generated tokens and $\mathbb{V}$ the vocabulary of all possible tokens. An overview of our proposed model is shown in Figure 2, where the details are illustrated in following subsections.

2.1 The Model Structure

Our model can be partitioned into three major components, i.e., the visual extractor, the encoder and the decoder, where the proposed memory and the integration of the memory into Transformer are mainly performed in the decoder. The overall description of the three components and the training objective of the task is detailed below.

Visual Extractor Given a radiology image Img, its visual features $\mathbf{X}$ are extracted by pre-trained convolutional neural networks (CNN), e.g., VGG (Simonyan and Zisserman, 2015) or ResNet (He et al., 2016), and the encoded results are used as the source sequence for all subsequent modules. The process is formulated as:

$$\{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_S\} = f_v(Img) \tag{1}$$

where $f_v(\cdot)$ represents the visual extractor.

Encoder In our model, we use the standard encoder from Transformer, where the outputs are the hidden states $\mathbf{h}_i$ encoded from the input features $\mathbf{x}_i$ extracted from the visual extractor:

$$\{\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_S\} = f_e(\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_S) \tag{2}$$

where $f_e(\cdot)$ refers to the encoder.

Decoder The backbone decoder in our model is the one from Transformer, where we introduce an extra memory module to it by improving the original layer normalization with MCLN for each decoding layer as shown in Figure 2. Therefore the decoding process can be formalized as

$$y_t = f_d(\mathbf{h}_1, ..., \mathbf{h}_S, \text{MCLN}(\text{RM}(y_1, ..., y_{t-1}))) \tag{3}$$

where $f_d(\cdot)$ refers to the decoder and the details of the memory (RM) and MCLN are presented in following subsections.

Objective Given the aforementioned structure, the entire generation process can be formalized as a recursive application of the chain rule

$$p(Y|Img) = \prod_{t=1}^{T} p(y_t|y_1, ..., y_{t-1}, Img) \tag{4}$$

where $Y = \{y_1, y_2, ..., y_T\}$ is the target text sequence. The model is then trained to maximize

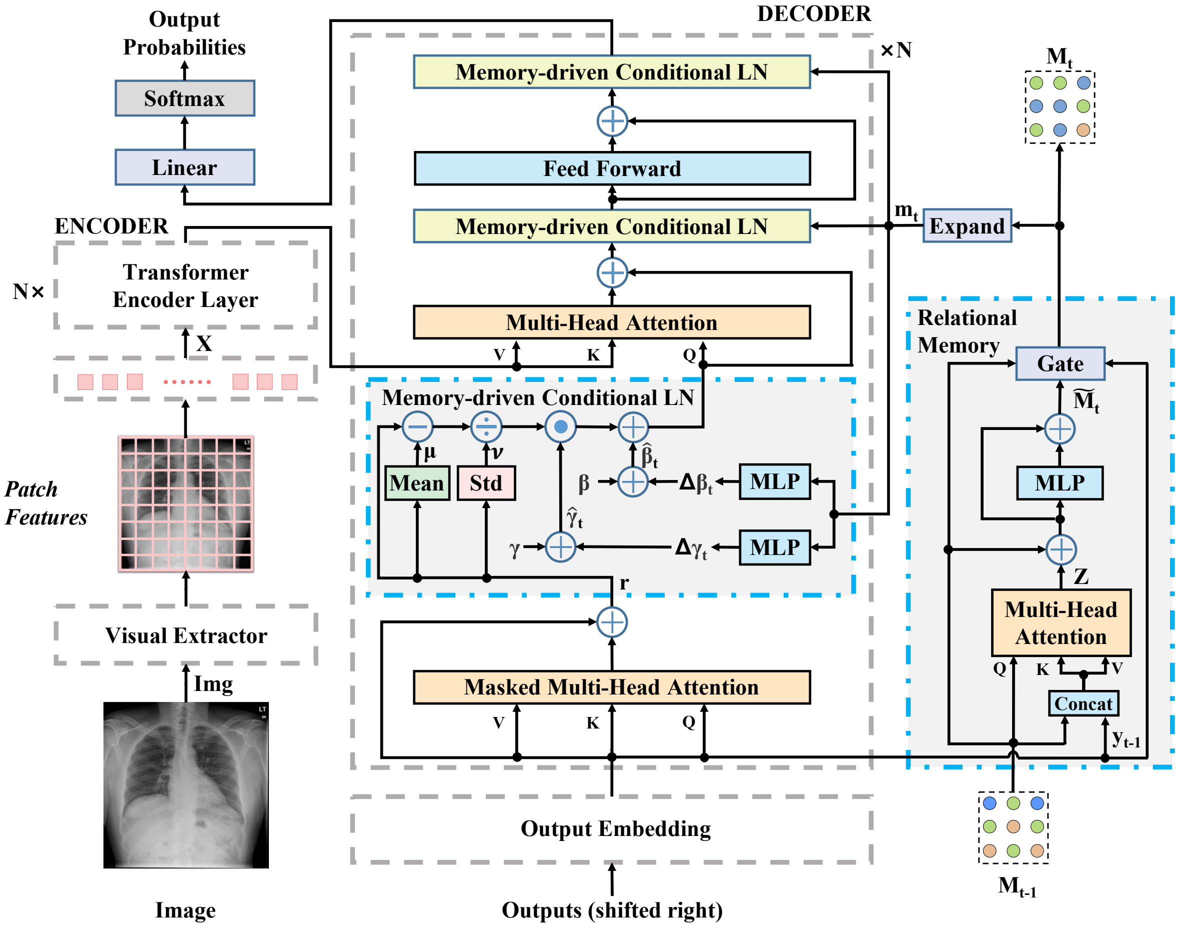

Figure 2: The overall architecture of our proposed model, where the visual extractor, encoder and decoder are shown in gray dash boxes and the details of the visual extractor and encoder are omitted. The relational memory and memory conditional layer-normalization are illustrated in grey solid boxes with blue dash lines.

$P(Y|Img)$ through the negative conditional log-likelihood of Y given the Img:

$$\theta^* = \arg\max_{\theta} \sum_{t=1}^{T} \log p(y_t|y_1, ..., y_{t-1}, Img; \theta) \tag{5}$$

where θ is the parameters of the model.

2.2 Relational Memory

For any relevant Img, they may share similar patterns in their reports and they can be used as good references for each other to help the generation process. As shown in Figure 1, patterns such as "*The lungs are clear bilaterally*" and "*no evidence of focal consolidation, or pleural effusion*" always appear in the reports of similar images and are shown simultaneously. To exploit such characteristics, we propose to use an extra component, i.e., relational memory, to enhance Transformer to learn from the patterns and facilitate computing the interactions among patterns and the generation process.

In doing so, the relational memory uses a matrix to transfer its states over generation steps, where the states record important pattern information with each row (namely, memory slot) representing some pattern information.[2] During the generation, the matrix is updated step-by-step with incorporating the output from previous steps. Then, at time step t, the matrix from the previous step, $\mathbf{M}_{t-1}$, is functionalized as the query and its concatenations with the previous output serve as the key and value to feed the multi-head attention module. Given H heads used in Transformer, there are H sets of queries, keys and values via three linear transformations, respectively. For each head, we obtain the query, key and value in the relational memory through $\mathbf{Q} = \mathbf{M}_{t-1} \cdot \mathbf{W_q}$, $\mathbf{K} = [\mathbf{M}_{t-1}; \mathbf{y}_{t-1}] \cdot \mathbf{W_k}$ and $\mathbf{V} = [\mathbf{M}_{t-1}; \mathbf{y}_{t-1}] \cdot \mathbf{W_v}$, respectively, where $\mathbf{y}_{t-1}$ is the embedding of the last output (at step $t-1$); $[\mathbf{M_{t-1}}; \mathbf{y}_{t-1}]$ is the row-wise concatenation of $\mathbf{M}_{t-1}$ and $\mathbf{y}_{t-1}$. $\mathbf{W_q}$, $\mathbf{W_k}$ and $\mathbf{W_v}$ are

---

[2] Note that the rows (memory slots) and patterns do not follow one-to-one mapping, where the entire matrix serves as a whole unit to deliver the pattern information.

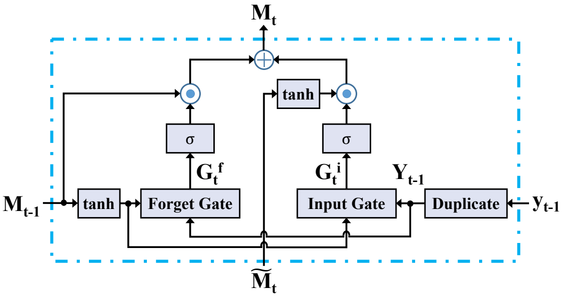

Figure 3: The illustration of the gate mechanism.

the trainable weights of linear transformation of the query, key and value, respectively. Multi-head attention is used to model $\mathbf{Q}$, $\mathbf{K}$ and $\mathbf{V}$ so as to depict relations of different patterns. As a result,

$$\mathbf{Z} = \text{softmax}(\mathbf{Q}\mathbf{K}^\top/\sqrt{d_k}) \cdot \mathbf{V} \tag{6}$$

where d_k is the dimension of $\mathbf{K}$, and $\mathbf{Z}$ the output of the multi-head attention module. Consider that the relational memory is performed in a recurrent manner along with the decoding process, it potentially suffers from gradient vanishing and exploding. We therefore introduce residual connections and a gate mechanism. The former is formulated as

$$\tilde{\mathbf{M}}_t = f_{mlp}(\mathbf{Z} + \mathbf{M}_{t-1}) + \mathbf{Z} + \mathbf{M}_{t-1} \tag{7}$$

where $f_{mlp}(\cdot)$ refers to the multi-layer perceptron (MLP). The detailed structure of the gate mechanism in the relational memory is shown in Figure 3, where the forget and input gates are applied to balance the inputs from $\mathbf{M}_{t-1}$ and $\mathbf{y}_{t-1}$, respectively. To ensure that $\mathbf{y}_{t-1}$ can be used for computation with $\mathbf{M}_{t-1}$, it is extended to a matrix $\mathbf{Y}_{t-1}$ by duplicating it to multiple rows. Therefore, the forget and input gate are formalized as

$$\mathbf{G}_t^f = \mathbf{Y}_{t-1}\mathbf{W}^f + \tanh(\mathbf{M}_{t-1}) \cdot \mathbf{U}^f \tag{8}$$

$$\mathbf{G}_t^i = \mathbf{Y}_{t-1}\mathbf{W}^i + \tanh(\mathbf{M}_{t-1}) \cdot \mathbf{U}^i \tag{9}$$

where $\mathbf{W}^f$ and $\mathbf{W}^i$ are trainable weights for $\mathbf{Y}_{t-1}$ in each gate; similarly, $\mathbf{U}^f$ and $\mathbf{U}^i$ are the trainable weights for $\mathbf{M}_{t-1}$ in each gate. The final output of the gate mechanism is formalized as

$$\mathbf{M}_t = \sigma(\mathbf{G}_t^f) \odot \mathbf{M}_{t-1} + \sigma(\mathbf{G}_t^i) \odot \tanh(\tilde{\mathbf{M}}_t) \tag{10}$$

where $\odot$ refers to the Hadamard product and σ the sigmoid function and $\mathbf{M}_t$ is the output of the entire relational memory module at step t.

2.3 Memory-driven Conditional Layer Normalization

Although memory shows its effectiveness in many NLP tasks (Sukhbaatar et al., 2015; Lample et al., 2019), it is by default applied to encoding with rather isolated designs. However, given that text generation is a dynamic process and largely affected by the output at each decoding step, memory is expected to be closely integrated to the decoder.

PATIENT #	2,770	395	790	64,586	500	293
AVG. LEN.	37.56	36.78	33.62	53.00	53.05	66.40

Table 1: The statistics of the two benchmark datasets w.r.t. their training, validation and test sets, including the numbers of images, reports and patients, and the average word-based length (AVG. LEN.) of reports.

Therefore, we propose a novel MCLN and use it to incorporate the relational memory to enhance the decoding of Transformer. Recall that in the conventional Transformer, to improve generalization, γ and β are two crucial parameters for scaling and shifting the learned representations,[3] respectively. Thus we propose to incorporate the relational memory via MCLN by feeding its output $\mathbf{M}_t$ to γ and β. Consequently, this design takes the benefit from the memory while preventing it from influencing too many parameters of Transformer so that some core information for generation is not affected.

As shown in Figure 2, in each Transformer decoding layer, we use three MCLNs, where the output of the first MCLN is functionalized as the query to be fed into the following multi-head attention module together with the hidden states from the encoder as the key and value. To feed each MCLN, at step t, the output of the relational memory $\mathbf{M}_t$ is expanded into a vector $\mathbf{m}_t$ by simply concatenating all rows from $\mathbf{M}_t$. Then, an MLP is used to predict a change $\Delta\gamma_t$ on γ_t from $\mathbf{m}_t$, and update it via

$$\Delta\gamma_t = f_{mlp}(\mathbf{m}_t) \tag{11}$$

$$\hat{\gamma}_t = \gamma + \Delta\gamma_t \tag{12}$$

Similarly, $\Delta\beta_t$ and $\hat{\beta}_t$ are performed by

$$\Delta\beta_t = f_{mlp}(\mathbf{m}_t) \tag{13}$$

$$\hat{\beta}_t = \beta + \Delta\beta_t \tag{14}$$

Afterwards, the predicted $\hat{\beta}_t$ and $\hat{\gamma}_t$ are applied to the mean and variance results of the multi-head

---

[3] In detail, γ is used to amplify the values in the learned representation and β provides a bias adjustment to them.

Table 2: The performance of all baselines and our full model on the test sets of IU X-RAY and MIMIC-CXR datasets with respect to NLG and CE metrics. BL-n denotes BLEU score using up to n-grams; MTR and RG-L denote METEOR and ROUGE-L, respectively. The average improvement over all NLG metrics compared to BASE is also presented in the "AVG. Δ" column. The performance of all models is averaged from five runs.

self-attention from the previous generated outputs:

$$f_{mcln}(\mathbf{r}) = \hat{\gamma}_t \odot \frac{\mathbf{r} - \mu}{\upsilon} + \hat{\beta}_t \qquad (15)$$

where $\mathbf{r}$ refers to the output from the previous module; μ and υ are the mean and standard deviation of $\mathbf{r}$, respectively. The result $f_{mcln}(\mathbf{r})$ from MCLN is then fed to the next module (for the 1st and 2nd MCLN) or used as the final output for generation (for the 3rd MCLN).

3 Experiment Settings

3.1 Datasets

We conduct our experiments on two datasets, which are described as follows:

- **IU X-RAY** (Demner-Fushman et al., 2016)[4]: a public radiography dataset collected by Indiana University with 7,470 chest X-ray images and 3,955 reports.
- **MIMIC-CXR** (Johnson et al., 2019)[5]: the largest radiology dataset to date that consists of 473,057 chest X-ray images and 206,563 reports from 63,478 patients.

For both datasets, we follow Li et al. (2018) to exclude the samples without reports. Then we apply their conventional splits. Specifically, IU X-RAY is partitioned into train/validation/test set by 7:1:2 of the entire dataset, and MIMIC-CXR's official split is adopted. The statistics of the datasets are shown in Table 1, with the numbers of images, reports, patients and the average length of reports.

3.2 Baseline and Evaluation Metrics

To compare with our proposed model, the following ones are used as the main baselines:

- **BASE**: this is the vanilla Transformer, with three layers, 8 heads and 512 hidden units without other extensions and modifications.
- **BASE+RM**: this is a simple alternative of our proposed model where the relational memory is directly concatenated to the output of the Transformer ahead of the softmax at each time step. This baseline aims to demonstrate the effect of using memory as an extra component instead of integration within the Transformer.

In addition, we also compare our model with those in previous studies, including conventional image captioning models, e.g., **ST** (Vinyals et al., 2015), **ATT2IN** (Rennie et al., 2017), **ADAATT** (Lu et al., 2017), **TOPDOWN** (Anderson et al., 2018), and the ones proposed for the medical domain, e.g., **COATT** (Jing et al., 2018), **HRGR** (Li et al., 2018) and **CMAS-RL** (Jing et al., 2019).

The performance of the aforementioned models is evaluated by conventional natural language generation (NLG) metrics and clinical efficacy (CE) metrics[6]. The NLG metrics[7] include BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011) and ROUGE-L (Lin, 2004). For clinical efficacy metrics, we use the CheXpert (Irvin et al., 2019)[8] to label the generated reports and compare the results with ground truths in 14 different categories related to thoracic diseases and support devices. Precision, recall and F1 are used to evaluate model performance for these metrics.

3.3 Implementation Details

We adopt the ResNet101 (He et al., 2016) pre-trained on Imagenet (Deng et al., 2009) as the visual extractor to extract patch features with the dimension of each feature set to 2,048. Note that for IU X-Ray, we use two images of a patient as input to ensure consistency with the experiment settings of previous work. The Transformer in our proposed model and all baselines are randomly initialized. For relational memory, its dimension and the number of heads in multi-head attention are set to 512 and 8, respectively, and the number of memory slots is set to 3 by default. For MCLN, we use two MLPs to obtain $\Delta\gamma$ and $\Delta\beta$ where they do not share parameters. The model is trained under cross entropy loss with ADAM optimizer (Kingma and Ba, 2015). We set the learning rate to 5e-5 and 1e-4 for the visual extractor and other parameters, respectively. We decay such rate by a factor of 0.8 per epoch for each dataset and set the beam size to 3 to balance the generation effectiveness and efficiency. Note that the aforementioned hyper-parameters are obtained by evaluating the models on the validation sets of the two datasets.

4 Results and Analyses

4.1 Effect of Relational Memory

To illustrate the effectiveness of our proposed method, we experiment with the aforementioned baselines on the two benchmark datasets. The results are reported in Table 2, with Base+RM+MCLN representing our full model (same below).

There are several observations. First, on NLG metrics, both Base+RM and Base+RM+MCLN outperform the vanilla Transformer (Base) on both datasets, which confirms the validity of incorporating memory into the decoding process in Transformer because that highly-patternized text in radiology reports are reasonably modeled to some extent. Second, our full model achieves the best performance over all baselines on different metrics, and it particularly outperforms Base+RM with significant improvement, which clearly indicates the usefulness of MCLN in incorporating memory rather than other ways of integration. Third, on NLG metrics, when comparing between the datasets, the performance gains from two memory-driven models (i.e., Base+RM and Base+RM+MCLN) over Base on IU X-Ray are larger than that of MIMIC-CXR. The reason behind might be that the IU X-Ray is relatively small and patterns among different reports in this dataset are more consistent so that our model helps more with the proposed memory. Fourthly, on the CE metrics on MIMIC-CXR, our full model shows the same trend as that for NLG metrics, where it outperforms all its baselines in terms of precision, recall and F1. This observation is important because higher NLG scores do not always result in higher clinical scores (e.g., the precision of Base+RM on CE is lower than that of Base), so

$\|\mathcal{S}\|$	PARA.	BL-1	BL-2	MTR	RG-L
1	76.6M	0.350	0.217	0.141	0.278
2	81.4M	0.355	0.215	0.141	0.278
3	86.1M	**0.360**	**0.223**	**0.144**	0.279
4	90.8M	0.354	0.217	0.142	**0.280**

Table 4: NLG scores of our full model on the MIMIC-CXR test set when different memory slots are used. PARA. denotes the number of parameters.

that the performance from CE further confirms the effectiveness of our method, whereas compared to BASE+RM, MCLN is able to leverage memory in a rather fine-grained way and thus better produce reasonable descriptions for clinical abnormalities.

4.2 Comparison with Previous Studies

We compare our full model (denoted as OURS) with existing models on the same datasets, with all results reported in Table 3 on both NLG and CE metrics. There are several observations drawn from different aspects. First, Transformer confirms its superiority to sequence-to-sequence structures in this task, which is illustrated by the comparison between our models (all baselines and our full model) and ST. Our full model also outperforms conventional image captioning models, e.g., ATT2IN, ADAATT and TOPDOWN, which are designed to generate a short piece of text for an image. This observation confirms that designing a specific model for long report generation is necessary for this task. Second, memory shows its effectiveness in this task when compared with those complicated models, e.g., HRGR uses manually extracted templates. Particularly, although on the two datasets, reinforcement learning (CMAS-RL) is proved to be the best solution with a careful design of adaptive rewards, our model achieves the same goal with a simpler method. Third, It is noticed that there are studies, e.g., HRGR, requires to utilize extra information for this task and our full model outperforms them without such requirements. This observation indicates that an appropriate end-to-end design (such as RM and MCLN) of using memory in Transformer can alleviate the need for extra resources to enhance this task.

4.3 Analysis

We analyze several aspects of our model regarding its hyper-parameters and generation results.

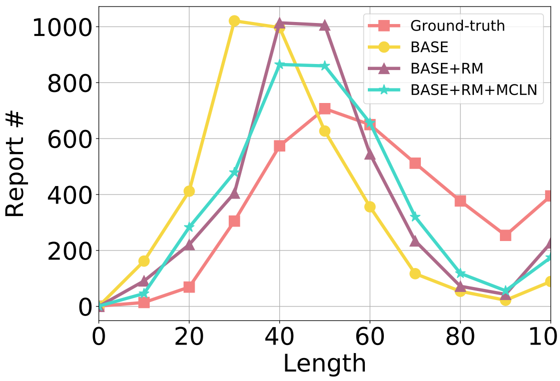

Figure 4: The length distributions of the generated reports on the MIMIC-CXR test set from BASE, BASE+RM and BASE+RM+MCLN, as well as the ground-truth.

Memory Size To show the impacts of the memory size, we train RM with different numbers of memory slots, i.e., $|\mathcal{S}| \in \{1, 2, 3, 4\}$ and the results on MIMIC-CXR are shown in Table 4. In general, since memory size controls how much information is preserved in the past generation steps, it is confirmed in the observation that enlarging memory size by the number of slots results in better overall performance, with $|\mathcal{S}| = 3$ achieving the best results. Still, we notice that the overall performance drops when $|\mathcal{S}| = 4$, which indicates that too large memory may introduce redundant and invalid information so as to negatively affect the generation process. Although enlarging memory size results in increasing parameter numbers, it is demonstrated that there are not too many parameters (comparing to the total number of parameters) introduced whenever adding one slot in the memory. This observation suggests that the proposed model is effective and efficient in learning with memory for the radiology report generation task.

Report Length In addition to NLG and CE metrics, another important criterion to evaluate generation models is the length of generated reports comparing to the ground-truth. In doing so, we categorize all reports generated on the MIMIC-CXR test set into 10 groups (within [0, 100] with interval of 10) according to their round-down lengths and draw curves for their numbers in each category for BASE, BASE+RM and BASE+RM+MCLN, as well as the ground-truth. The results are presented in Figure 4. Overall, more reports generated from BASE+RM and BASE+RM+MCLN are longer than that from BASE and their length distributions are closer to the ground-truth reports, which thus leads to better evaluation results on NLG metrics. The reason behind might be that the memory provides
