A Properties of Block Attention

A.1 Block Attention on a Soft-label

Theorem 1. *There exist two probability distributions, $p(i = s_c)$ and $p(i = e_c)$, that makes $p(w_i \in \mathcal{C})$ equal to $p_{soft}(w_i \in \mathcal{C})$, which is defined as follows:*

$$p_{soft}(w_i \in \mathcal{C}) = \begin{cases} 1.0 & \text{if } i \in [s_a, e_a] \\ q^{|i-s_a|} & \text{if } s_w \le i < s_a \\ q^{|i-e_a|} & \text{if } e_a < i \le e_w \\ 0.0 & \text{if } i < s_w \ \text{ or } \ i > e_w \end{cases} . \tag{10}$$

Here, q is the decreasing ratio, which satisfies $q \le 1.0$. s_a and e_a are the start and end indices of an answer-span. s_a and e_a satisfy $s_a \le e_a$. s_w and e_w are the start and end indices of the segments bounded by certain window-size. s_w and e_w satisfy $s_w \le s_a$ and $e_a \le e_w$.

Proof. Based on the independent assumption between s_c and e_c in section 3.3, $p(\mathrm{w}_i \in \mathcal{C})$ becomes multiplication of two probability distributions as follows:

$$p(\mathrm{w}_i \in \mathcal{C}) = p(i \ge s_c) \times p(i \le e_c). \tag{11}$$

Then, the following two cumulative distributions, $p(i \ge s_c)$ and $p(i \le e_c)$, make $p(\mathrm{w}_i \in \mathcal{C})$ equal to $p_{\mathrm{soft}}(\mathrm{w}_i \in \mathcal{C})$:

$$p(i \ge s_c) = \begin{cases} 0.0 & \text{if } i < s_w \\ p_{\mathrm{soft}}(\mathrm{w}_i \in \mathcal{C}) & \text{if } s_w \le i < s_a \\ 1.0 & \text{if } s_a \le i \end{cases} , \tag{12}$$

$$p(i \le e_c) = \begin{cases} 1.0 & \text{if } i \le e_a \\ p_{\mathrm{soft}}(\mathrm{w}_i \in \mathcal{C}) & \text{if } e_a < i \le e_w \\ 0.0 & \text{if } e_w < i \end{cases} . \tag{13}$$

Since block attention method can predict any form of $p(i = s_c)$ and $p(i = e_c)$, any soft-label can be represented by block attention method. □

A.2 Block Attention on Multiple Spans

Block attention model can be expanded to predict multiple spans.

Theorem 2. *Any form of the following $p_{multi\text{-}span}(w_i \in \mathcal{C})$, which has m-blocks, can be represented by the multiplication of a scaling factor, k, and the probability distribution calculated by block attention model, $p(w_i \in \mathcal{C})$.*

$$p_{multi\text{-}span}(w_i \in \mathcal{C}) = \begin{cases} a & \text{if } i \in \mathcal{B}_1 \vee ... \vee i \in \mathcal{B}_m \\ \epsilon & \text{otherwise} \end{cases} . \tag{14}$$

Here, $\mathcal{B}_i$ is the set of indices of the i-th span, $\mathcal{B}_i = [s_i^b, e_i^b]$. s_i^b and e_i^b are the start and end indices of $\mathcal{B}_i$. $\mathcal{B}_i$ satisfies $s_i^b \le e_i^b$ and $e_i^b < s_{i+1}^b$ for all i.

Proof. Following two cumulative distributions and the scaling factor make $k \times p(i \ge s_c) \times p(i \le e_c)$ equal to $p_{\mathrm{soft}}(\mathrm{w}_i \in \mathcal{C})$ for all i.

$$p(i \ge s_c) = \begin{cases} (\frac{\epsilon}{a})^m & \text{if } i < s_1^b \\ (\frac{\epsilon}{a})^{m-j} & \text{if } s_j^b \le i < s_{j+1}^b;\, j \in [1, m) \\ 1.0 & \text{if } s_m^b \le i \end{cases} \tag{15}$$

$$p(i \le e_c) = \begin{cases} 1.0 & \text{if } i \le e_1^b \\ (\frac{\epsilon}{a})^j & \text{if } e_j^b < i \le e_{j+1}^b;\, j \in [1, m) \\ (\frac{\epsilon}{a})^m & \text{if } i > e_m^b \end{cases} \tag{16}$$

$$k = \epsilon \Big(\frac{a}{\epsilon}\Big)^m \tag{17}$$

Since block attention model can predict any form of $p(i = s_c)$ and $p(i = e_c)$, $p_{\text{multi-span}}(w_i \in \mathcal{C})$ can be represented by the multiplication of a scaling factor and the probability distribution calculated by block attention model. □

B Semantic Similarity Between Context Words and Questions

Soft-labeling method assumes that words near an answer-span are likely to be included in the context of a given question. We provide the basis of this assumption with the question-word similarity experiment. The question-word similarity is calculated with the cosine similarity between word vectors and question vectors. We use word2vec vectors and calculate the question vectors by averaging word vectors in the questions. Figure 7 shows that words adjacent to the answer-spans have the most similar

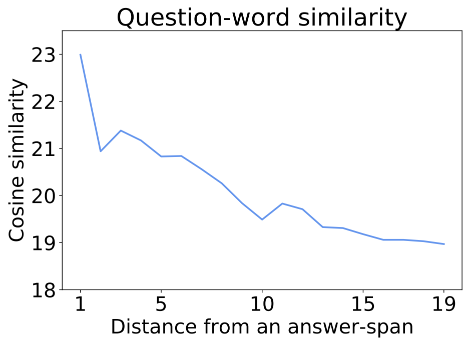

Figure 7: The semantic similarity between a given question and words in a passage. The x-axis represents the distance between a word and an answer-span. The y-axis represents the cosine similarity between the question and the word on 100 scale. Words near an answer-span are likely to have a similar meaning to a given question.

WS	Span-F1	Span-EM	F1	EM	AVG
1	77.06	64.52	80.02	68.04	72.41
2	75.95	63.35	79.80	67.84	71.73
3	76.99	64.41	80.05	68.38	72.45
4	76.38	63.96	80.09	68.44	72.21
5	77.01	64.33	80.02	68.04	72.35
7	76.37	64.19	79.81	68.11	72.12
21	76.65	64.14	79.96	68.06	72.20

meaning to given questions. Also, the similarity decreases as the distance between the words and the answer-spans increases. From the results, we verify the assumption.

C Details about Hyperparameter Settings

We vary window-size, and λ to find the optimal hyperparameters of BLANC.

C.1 Analysis on Window-size

Table 5 shows the performance of BLANC trained on NaturalQuestions with window-size $= [1, 2, 3, 4, 5, 7, 21]$. AVG represents the average of the four performances. BLANC shows the best AVG performance at WS $= 3$, and we set window-size to 3 for NaturalQuestions and NewsQA experiments.

λ	Span-F1	Span-EM
0.2	88.42 ± 0.17	76.26 ± 0.31
0.8	88.30 ± 0.16	75.71 ± 0.30

Table 6: The performance of BLANC on SQuAD1.1 with two different λ settings.

C.2 Varying λ on SQuAD1.1

Table 6 shows the performance of BLANC with two different λ settings on SQuAD1.1. The results show that BLANC performs better at $\lambda = 0.2$ than $\lambda = 0.8$ (the optimal value for NaturalQuestions) on SQuAD1.1. We set λ to 0.2 in SQuAD1.1 experiments.

What do Models Learn from Question Answering Datasets?

Abstract

While models have reached superhuman performance on popular question answering (QA) datasets such as SQuAD, they have yet to outperform humans on the task of question answering itself. In this paper, we investigate if models are learning reading comprehension from QA datasets by evaluating BERT-based models across five datasets. We evaluate models on their generalizability to out-of-domain examples, responses to missing or incorrect data, and ability to handle question variations. We find that no single dataset is robust to all of our experiments and identify shortcomings in both datasets and evaluation methods. Following our analysis, we make recommendations for building future QA datasets that better evaluate the task of question answering through reading comprehension. We also release code to convert QA datasets to a shared format for easier experimentation at `https://github.com/amazon-research/qa-dataset-converter`.

1 Introduction

Question answering (QA) through reading comprehension has seen considerable progress in recent years. This progress is in large part due to the release of large language models like BERT (Devlin et al., 2019) and new datasets that have introduced impossible questions (Rajpurkar et al., 2018), bigger scales (Kwiatkowski et al., 2019), and context (Choi et al., 2018; Reddy et al., 2019) to question answering. At the time of writing this paper, models have outperformed human baselines on the widely-used SQuAD 1.1 and SQuAD 2.0 datasets, and more challenging datasets such as QuAC have models less than 7 F1 points away. Despite these increases in F1 scores, we are still far from saying question answering is a solved problem.

Concerns have been raised over how challenging QA datasets are. Previous work has found that simple heuristics can give good performance on SQuAD 1.1 (Weissenborn et al., 2017), and successful SQuAD models lack robustness by giving inconsistent answers (Ribeiro et al., 2019) or being vulnerable to adversarial attacks (Jia and Liang, 2017; Wallace et al., 2019). If state-of-the-art models are excelling at test sets but not solving the underlying task of reading comprehension, then our test sets are flawed. We need to better understand what models learn from QA datasets. In this work, we ask three questions: (1) Does performance on individual QA datasets generalize to new datasets? (2) Do models need to learn reading comprehension for QA datasets?, and (3) Can QA models handle variations in questions?

To answer these questions, we evaluate BERT models trained on five QA datasets using simple generalization and robustness probes. We find that (1) Model performance does not generalize well outside of heuristics like question-context overlaps, (2) Removing or corrupting dataset examples does not always harm model performance, showing that models can rely on simpler methods than reading comprehension to answer questions, and (3) No dataset fully prepares models to handle question variations like filler words or negation. These findings suggest that while QA models can learn heuristics around question-context overlaps and named entities, they do not need to learn reading comprehension to perform well on QA datasets. Based on these findings, we make recommendations on how to better create and evaluate QA datasets.

2 Related Work

Our work is inspired by recent trends in NLP to evaluate generalizability and probe what models learn from datasets. In terms of generalizability, prior work has been done by Yogatama et al. (2019) who evaluated a SQuAD 1.1 model across

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2429–2438,
November 16–20, 2020.

four datasets and Talmor and Berant (2019), who comprehensively evaluated ten QA datasets. The MRQA 2019 shared task (Fisch et al., 2019) evaluated transferability across multiple datasets, and Khashabi et al. (2020) proposed a method to train one model on 17 different QA datasets. In our work, we focus on question answering through reading comprehension and extend the work on generalizability by including impossible questions in all our datasets and analyzing the effects of question-context overlap on generalizability.

There is also growing interest in probing what models learn from datasets (McCoy et al., 2019; Geirhos et al., 2020; Richardson and Sabharwal, 2020; Si et al., 2020). Previous work in question answering has found that state-of-the-art models can get good performance on incomplete input (Agrawal et al., 2016; Sugawara et al., 2018; Niven and Kao, 2019), under-rely on important words, (Mudrakarta et al., 2018), and over-rely on simple heuristics (Weissenborn et al., 2017; Ko et al., 2020). Experiments on SQuAD in particular have shown that SQuAD models are vulnerable to adversarial attacks (Jia and Liang, 2017; Wallace et al., 2019) and not robust to paraphrases (Ribeiro et al., 2018; Gan and Ng, 2019).

Our work continues exploring what models learn by comprehensively testing multiple QA datasets against a variety of simple but informative probes. We take inspiration from previous studies, and we make novel contributions by using BERT, a state-of-the-art model, and running several experiments against five different QA datasets to investigate the progress made in reading comprehension.

3 Datasets

	Train	Dev
SQuAD	130,319	11,873
TriviaQA	110,647	14,229
NQ	110,857	3,368
QuAC	83,568	7,354
NewsQA	101,707	5,666

Table 1: Train and dev set sizes of the datasets used in our experiments

	Question	Context	Answer
SQuAD	10	120	3
TriviaQA	15	746	2
NQ	9	96	4
QuAC	7	395	14
NewsQA	8	709	4

Table 2: Comparison of the average number of words in questions, contexts, and answers in each dataset

We compare five datasets in our experiments: SQuAD 2.0, TriviaQA, Natural Questions, QuAC, and NewsQA. All our datasets treat question answering as a reading comprehension task where the question is about a document and the answer is either an extracted span of text or labeled unanswerable. To consistently compare and experiment across models, we convert all datasets into a SQuAD 2.0 JSON format.[1] Since most datasets have a hidden test set, we evaluate models on the dev set and consequently refer to the dev sets as test sets in this paper. The train and dev sets sizes are shown in Table 1

Below we describe each dataset and any modifications we made to run our experiments:

SQuAD 2.0 (Rajpurkar et al., 2018) consists of 150K question-answer pairs on Wikipedia articles. To create SQuAD 1.1, crowd workers wrote questions about a Wikipedia paragraph and highlighted the answer (Rajpurkar et al., 2016). SQuAD 2.0 includes an additional 50K plausible but unanswerable questions written by crowd workers.

TriviaQA (Joshi et al., 2017) includes 95K question-answer pairs from trivia websites. The questions were written by trivia enthusiasts and the evidence documents were retrieved by the authors retrospectively. We use the variant of TriviaQA where the documents are Wikipedia articles.

Natural Questions (NQ) (Kwiatkowski et al., 2019) contains 300K questions from Google search logs. For each question, a crowd worker found a long and short answer on a Wikipedia page. We use the subset of NQ with a long answer and frame the task as finding the short answer in the long answer. We only include examples with answers in the paragraph text (as opposed to a table or list).

QuAC (Choi et al., 2018) contains 100K questions. To create QuAC, one crowd worker asked questions about a Wikipedia article to a second crowd worker, who answered by selecting a text span. To standardize training, we do not model contextual information, but we include QuAC to

---

		Evaluated on				
		SQuAD	TriviaQA	NQ	QuAC	NewsQA
Fine-tuned on	SQuAD	**75.6**	46.7	48.7	20.2	41.1
	TriviaQA	49.8	**58.7**	42.1	20.4	10.5
	NQ	53.5	46.3	**73.5**	21.6	24.7
	QuAC	39.4	33.1	33.8	**33.3**	13.8
	NewsQA	52.1	38.4	41.7	20.4	**60.1**

Table 3: F1 scores of each fine-tuned model evaluated on each test set

see how models trained without context handle context-dependent questions.

NewsQA (Trischler et al., 2017) contains 100K questions on 10K CNN articles. One set of crowd workers wrote questions based on a headline and summary, and a second set of workers found the answer in the article. We reintroduce unanswerable questions that were excluded in the original paper.

There are notable differences among our datasets in terms of genre and how they were built. In Table 2, we see a large variation in the average number of words in questions, contexts, and answers. Despite these differences, all our datasets are reading comprehension tasks. We believe a good reading comprehension model should handle question answering well regardless of dataset differences, and so we compare across all five datasets.

4 Model

Hyperparameter	Value
Batch Size	24
Learning Rate	3e-5
Epochs	2
Max Seq Length	384
Doc Stride	128

Table 4: Hyperparameter values for fine-tuning BERT based on Devlin et al. (2019)

All models are initialized from a pre-trained BERT-Base uncased model[2] with 110M parameters. For each dataset, we fine-tune on the training set using Devlin et al. (2019)'s default hyperparameters shown in Table 4. We evaluate on the dev set with the SQuAD 2.0 evaluation script (Rajpurkar et al., 2018). We run our experiments on a single Nvidia Tesla v100 16GB GPU.

In Table 5, we provide a comparison between our models and previously published BERT results. Differences occur when we make modifications to match SQuAD. We simplified NQ by removing the long answer identification task and framed the short answer task in a SQuAD format, so we see higher results than the NQ BERT baseline. For QuAC, we ignored all context-related fields and treated each example as an independent question, so we see lower results than models built on the full dataset. For NewsQA, we introduced impossible questions, resulting in lower performance. We accept these drops in performance since we are interested in comparing changes to a baseline rather than achieving state-of-the-art results.

Dataset	Reference	Ours
SQuAD	76.3 (Liu et al., 2019)	75.6
TriviaQA	56.3 (Yang et al., 2019)	58.7
NQ	52.7 (Alberti et al., 2019)	73.5
QuAC	54.4 (Qu et al., 2019)	33.3
NewsQA	66.8 (Takahashi et al., 2019)	60.1

Table 5: Comparison to previously reported F1 scores. Differences occur when we make modifications to match SQuAD.

5 Experiments

In this section, we discuss the experiments run to evaluate what models learn from QA datasets. All results are reported as F1 scores since they are correlated with Exact Match scores and are more forgiving to sometimes arbitrary cutoffs of answers (for example, we prefer to give some credit to a model for selecting "Charles III" even if the answer was "King Charles III").

---

[2] `https://github.com/google-research/bert#pre-trained-models`

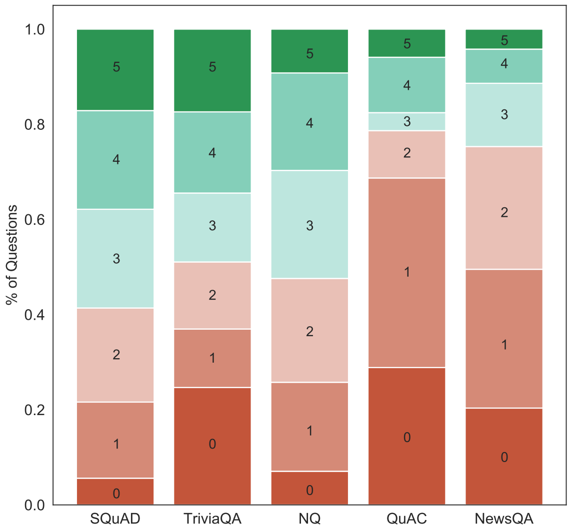

Figure 1: A bar graph of how many questions in each dataset are answered by 0, 1, 2, 3, 4, or 5 models

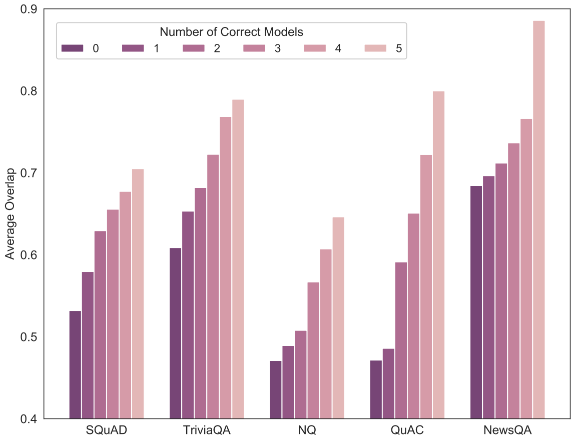

Figure 2: More models correctly answer answerable questions if they have higher question-context overlap.

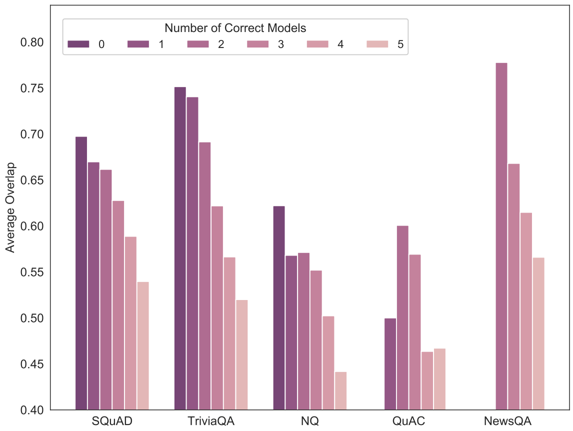

Figure 3: More models correctly answer impossible questions if they have lower question-context overlap. NewsQA has four bars since all impossible NewsQA questions were correctly answered by at least 1 model.

5.1 Does performance on individual QA datasets generalize to new datasets?

For our first experiment, we evaluate the generalizability of models to out-of-domain examples. While most work in QA has focused on evaluating against a single test set, generalizability is an important feature. If we cannot get good, generalizable performance on research datasets, we will struggle to expand to the variety of questions an open-domain QA system can face. Several papers have focused on generalizability by evaluating transferability across datasets (Talmor and Berant, 2019; Yatskar, 2019), generalizability to out-of-domain data (Fisch et al., 2019), and building cross-dataset evaluation methods (Dua et al., 2019).

We test generalizability by fine-tuning models on each dataset and evaluating against all five test sets. The results are reported as F1 scores in Table 3. The rows show a single model's performance across all five datasets, and the columns show the performance of all the models on a single test set. The model-on-self baseline is indicated in bold.

All models take a drop in performance when evaluated on an out-of-domain test set. This shows that performance on an individual dataset does not generalize across datasets, confirming results found on different mixes of datasets (Talmor and Berant, 2019; Yogatama et al., 2019). However there is variation in how the models perform. For example, models score up to 53.5 F1 points on SQuAD without seeing SQuAD examples, while models do not score above 21.6 F1 points on QuAC without QuAC examples. This suggests that some test sets are easier than others.

To quantify this, we calculate what proportion of each test set can be correctly answered by how many models. This data is represented as a bar graph in Figure 1. Each bar represents one dataset, and the segments show how much of the test set is answered correctly by 0 to 5 of the models.

We consider questions easier if more models correctly answer them. The figure shows that QuAC and NewsQA are more challenging test sets and contain a higher proportion of questions that are answered by 0 or 1 model. In contrast, more than half of SQuAD and NQ and almost half of TriviaQA can be answered correctly by 3 or more models.

While difficult questions pose a challenge for QA models, too many easy questions inflate our understanding of a model's performance. What

	Experiment	Question	Answer Text	Answer Start
1	Original	Who was the Norse leader	Rollo	308
2	Random Label	Who was the Norse leader	succeeding	721
3	Shuffled Context	Who was the Norse leader	Rollo	480
4	Incomplete (first half)	Who was	Rollo	308
5	Incomplete (first word)	Who	Rollo	308
6	Incomplete (no words)		Rollo	308
7	Filler word	Who really was the Norse leader	Rollo	308
8	Negation	Who wasn't the Norse leader	Rollo	308

Table 6: Examples of how question-answer pairs are modified in each experiment

makes a question easy? We identified a trend between question difficulty and the overlap between the question and the context. We measured overlap as the number of words that appeared in both the question and the context divided by the number of words in the question. For answerable questions, Figure 2 shows that more models return correct answers when there is higher overlap, while Figure 3 shows that fewer models correctly identify impossible questions when there is higher overlap. This suggests that models learn to use question-context overlap to identify answers. Models may even over-rely on this strategy and return answers to impossible questions when no answer exists.

Overall, the results show that our models do not generalize well to different datasets. The models do seem to exploit question-context overlap, even on questions that are out-of-domain. Reducing the number of high overlap questions in a dataset could create more challenging datasets in the future and better evaluate generalization and test more complex strategies for question answering.

5.2 Do models need to learn reading comprehension for QA datasets?

State-of-the-art models get good performance on QA datasets, but does good performance mean good reading comprehension? Or are models able to take shortcuts to arrive at the same answers? We explore this by performing three dataset ablation experiments with random labels, shuffled contexts, and incomplete questions. If models can answer test set questions with incorrect or missing information, then the models are likely not learning the task of reading comprehension. The three experiments and their results are discussed in the next sections.

		% of Random Labels		
Dataset	Baseline	10%	50%	90%
SQuAD	78.5	77.1	73.9	32.1
TriviaQA	46.8	36.6	10.9	0.0
NQ	70.6	68.1	60.5	19.4
QuAC	20.3	16.4	1.8	0.3
NewsQA	56.3	50.8	30.2	2.0

Table 7: F1 scores of answered questions decrease as models are fine-tuned on increasingly noisy data.

5.2.1 Random Labels

A robust model should withstand some amount of noise at training time to offset annotation error. However if a model can perform well with a high level of noise, we should be wary of what the model has learned. In our first dataset ablation experiment, we evaluated how various amounts of noise at training time affected model performance.

To introduce noise to the training sets, we randomly selected 10%, 50%, or 90% of the training examples that were answerable and updated the answer to a random string from the same context and of the same length as the original answer. We ensured that the random answer contained no overlaps with the original answer. For simplicity, we did not alter impossible examples. An example of a random label is in the second row of Table 6.

We fine-tuned new models on increasingly noisy training sets and evaluated them on the original test sets. The results are in Table 7 in terms of F1 scores and reported only for answerable questions. On training sets with 10% random labels, all models see an F1 score drop. SQuAD, NQ, and NewsQA achieve over 90% of their baseline score, showing robustness to a reasonable level of noise. TriviaQA and QuAC take larger F1 hits (achieving only 78% and 81% of their baselines), suggesting that they are less robust to this noise.

As the amount of noise increases, most F1 scores drop to nearly 0. SQuAD and NQ, however, are suspiciously robust even when 90% of their training examples are random. SQuAD achieves 41% of its baseline and NQ achieves 27% of its baseline with training sets that are 90% noise. We find it unlikely that randomly selected strings provide a signal, so this suggests that some examples in each test set are answerable trivially and without learning reading comprehension.

5.2.2 Shuffled Context

Dataset	Baseline	Shuffled Context
SQuAD	75.6	70.5
TriviaQA	58.7	38.7
NQ	73.5	64.5
QuAC	33.3	32.4
NewsQA	60.1	48.2

Table 8: F1 scores decrease, but not dramatically, on test sets with shuffled context sentences.

The task of reading comprehension aims to measure how well a model understands a given passage. If a model is able to answer questions without understanding the logic or structure of a passage, we can get high scores on a test set but be no closer to learning reading comprehension. In our second experiment, we investigate how much of model performance can be accounted for without understanding the full passage.

For each context paragraph in the test set, we split the context by sentence, randomly shuffled the sentences, and rejoined the sentences into a new paragraph. The original answer text remained the same, but the answer start token was updated by locating the correct answer text in the shuffled context. An example is in the third row of Table 6.

We used our models fine-tuned on the original training sets and evaluated on the shuffled context test sets. The results are in Table 8. TriviaQA sees the largest drop in performance, achieving only 66% of its baseline, followed by NewsQA with 80% of its baseline. SQuAD and QuAC, on the other hand, get over 93% of their original baselines even with randomly shuffled contexts. TriviaQA and NewsQA have longer contexts, with an average of over 700 words, and so shuffling longer contexts seems more detrimental. While these results show that models do not rely on naive approaches, like position, they do show that for many questions, models do not need to understand a paragraph's structure to correctly predict the answer.

5.2.3 Incomplete Input

Dataset	Baseline	First Half	First Word	No Words
SQuAD	75.6	36.4	22.8	49.5
TriviaQA	58.7	45.8	31.8	30.4
NQ	73.5	61.4	50.3	32.7
QuAC	33.3	25.2	22.4	20.2
NewsQA	60.1	43.6	26.3	13.4

Table 9: F1 scores decrease with incomplete input, but models can return correct answers with no question.

QA dataset creators and their crowd workers spend considerable effort hand-crafting questions that are meant to challenge a model's ability to understand language. But are models using the questions? In previous work, Agrawal et al. (2016) found that a Visual Question Answering (VQA) model could get good performance with just half the original question, while Sugawara et al. (2018) saw drops in BiDAF model performance on QA datasets with increasingly incomplete questions. We expand on these previous works by using BERT, including impossible questions, and introducing NER baselines for comparison.

We created three variants of each test set containing only the first half, first word, or no words from each question. The answer expectations were not changed. Examples are in the fourth, fifth, and sixth rows of Table 6.

We evaluated models fine-tuned on the original training set on the incomplete test sets. The results are in Table 9. F1 scores mostly decrease on test sets with incomplete input, but models can return correct answers without being given the question. SQuAD achieves 65% of its baseline given no question, an increase from the First Word test set primarily because of higher success on impossible questions. NQ achieves up to 68% of its baseline F1 score given the first word and up to 44% given no question. These results show that not all examples require full or any question understanding to make correct predictions. We also see higher F1 scores compared to Sugawara et al. (2018) when using the first word. In TriviaQA, Sugawara et al. (2018) saw their F1 score drop by 75% (from 49.3 to 12.5) while we see a drop of 46% (from 58.7 to 31.8), which could suggest that our BERT models have overfit more than BiDAF models.

How can models answer without the full question? We investigated our results further by creating two naive named entity recognition (NER) baselines using spaCy[3] to see if models can rely on entity types. For our First Word NER baseline, we used the first word of the question to choose an entity as the answer. If a question started with "who", we returned the first person entity in the context, for "when", the first date, for "where", the first location, and for "what", the first organization, event, or work of art. The results are in the First Word NER column of Table 10. With the exception of NewsQA, we are able to achieve over 40% of baseline performance with this NER system.

Dataset	Baseline	First Word NER	Person NER
SQuAD	75.6	30.0	26.7
TriviaQA	58.7	25.2	8.9
NQ	73.5	35.9	24.1
QuAC	33.3	17.2	6.0
NewsQA	60.1	11.3	8.8

Table 10: NER baselines on QA datasets

Our Person NER baseline returns the first person entity found in each context. The results are shown in Table 10. Both NQ and SQuAD achieve 33-35% of their baseline by only extracting the first person entity. TriviaQA sees a much larger drop when using only person entities, suggesting there is more entity type variety in the TriviaQA test set. These results show that some questions can be answered by extracting entity types and without needing most or all of the question text.

5.3 Can QA models handle variations in questions?

The previous section found that models can perform well on test sets even as seemingly important features are stripped from datasets. This section considers the opposite problem: Can models remain robust as features are added to datasets? To analyze this, we run two experiments where we add filler words and negation to test set questions.

5.3.1 Filler Words

Dataset	Baseline	Filler Words
SQuAD	75.6	69.5
TriviaQA	58.7	56.5
NQ	73.5	67.6
QuAC	33.3	31.2
NewsQA	60.1	54.8

Table 11: F1 scores slightly decrease on test sets where a filler word is added to the question.

If a QA model understands a question, it should handle semantically equivalent questions equally well. While previous works have shown poor model performance on paraphrased questions (Ribeiro et al., 2018; Gan and Ng, 2019), we take an even simpler approach by adding filler words that do not affect the rest of the question. For each question in the test set, we randomly added one of three filler words (*really*, *definitely*, or *actually*) before the main verb, as identified by spaCy. An example is shown in the seventh row of Table 6.

Table 11 shows the results of models fine-tuned on their original training sets and evaluated on the filler word test sets. All models drop between 2 to 5 F1 points. Although these drops may seem small, they do show that even a naive approach can hurt performance. It is no surprise that more sophisticated paraphrases of questions cause models to fail. The SQuAD model in particular had better performance when 50% of the training set was randomly labeled (73.9) than when filler words were added to the test set (69.5), suggesting that our models have become robust to less consequential features.

5.3.2 Negation

Negation is an important grammatical construction for QA systems to understand. Giving the same answer to a question and its negative (Who invented the telescope? vs. Who didn't invent the telescope?) can frustrate or mislead users. In previous work, Kassner and Schütze (2019) studied negation by manually negating 305 SQuAD 1.1 questions and found that a BERT model largely ignored negation. We expand on this work by using the full SQuAD 2.0 dataset and comparing performance across five datasets.

---

[3] `https://spacy.io`

Dataset	Baseline	Negation
SQuAD	75.6	2.0
TriviaQA	58.7	42.0
NQ	73.5	68.9
QuAC	33.3	16.1
NewsQA	60.1	52.3

Table 12: With the exception of SQuAD, models continue to return the original answer when given a negated question.

For each dataset, we negated every question in the test set by mapping common verbs (i.e. *is*, *did*, *has*) to their contracted negative form (i.e. *isn't*, *didn't*, *hasn't*) or by inserting *never* before the main verb, as identified by spaCy. We keep the original answers in the test set since we want to evaluate how often the original answer is returned for the negative question. In this case, a lower F1 score means better performance. An example is in the last row of Table 6.

We used the models fine-tuned on their original training sets and evaluated them on the negated test sets. The results are in Table 12 and show how often each model continued to return the original answer given a negative question. We see that SQuAD outperforms all the other models by giving the original answer to a negative question less than 3% of the time. Other models return the original answer to the negative question between 48% and 94% of the time, suggesting that the negation is largely ignored.

Dataset	*n't*	*never*
SQuAD	0.85	0.89
TriviaQA	0.31	0.48
NQ	0.37	0.34
QuAC	0.17	0.17
NewsQA	0.14	0.06

Table 13: The percentage of questions in the training set containing *n't* or *never* that are impossible

Does the SQuAD model understand negation, or is this a sign of bias? Table 13 shows how often a question containing *n't* or *never* was impossible in the training set. SQuAD has a high bias, with 85% of questions containing *n't* and 89% of questions containing *never* being impossible. This difference could be a result of SQuAD annotators having a bias to include *n't* or *never* more often in impossible questions than answerable questions, while impossible questions in other datasets were more organically collected. This suggests that SQuAD's performance is due to an annotation artifact. These results find that no dataset adequately prepares a model to understand negation.

6 Conclusions

In this work, we probed five QA datasets with six tasks and found that our models did not learn to generalize well, remained suspiciously robust to incorrect or missing data, and failed to handle variations in questions. These findings show that models learn simple heuristics around question-context overlap or entity types and pick up on underlying patterns in the datasets that allow them to remain robust to corrupt examples but not to valid variations. The shortcomings in datasets and evaluation methods make it difficult to judge if models are learning reading comprehension. Based on our work, we make the following recommendations to researchers who create or evaluate QA datasets:

- **Test for generalizability**: Models are more valuable to real-world applications if they generalize. New QA model should report performance across multiple relevant datasets.
- **Challenge the models**: Evaluating on too many easy questions can inflate our judgement of what a model has learned. Discard questions that can be solved trivially by high overlap or extracting the first named entity.
- **Be wary of cheating**: Good performance does not mean good understanding. Probe datasets by adding noise, shuffling contexts, or providing incomplete input to ensure models aren't taking shortcuts.
- **Include variations**: Models should be prepared to handle a variety of questions. Include variations such as filler words or negation to existing questions to evaluate how well models have understood a question.
- **Standardize dataset formats**: When creating new datasets, consider following a standardized format, such as SQuAD, to make cross-dataset evaluations simpler.

Abstract

Document interpretation and dialog understanding are the two major challenges for conversational machine reading. In this work, we propose Discern, a discourse-aware entailment reasoning network to strengthen the connection and enhance the understanding for both document and dialog. Specifically, we split the document into clause-like elementary discourse units (EDU) using a pre-trained discourse segmentation model, and we train our model in a weakly-supervised manner to predict whether each EDU is entailed by the user feedback in a conversation. Based on the learned EDU and entailment representations, we either reply to the user our final decision "yes/no/irrelevant" of the initial question, or generate a follow-up question to inquiry more information. Our experiments on the ShARC benchmark (blind, held-out test set) show that Discern achieves state-of-the-art results of 78.3% macro-averaged accuracy on decision making and 64.0 BLEU1 on follow-up question generation. Code and models are released at `https://github.com/Yifan-Gao/Discern`.

Rule Text: 7(a) loans are the most basic and most used type loan of the Small Business Administration's (SBA) business loan programs. It's name comes from section 7(a) of the Small Business Act, which authorizes the agency to provide business loans to **American small businesses**. The loan program is designed to assist **for-profit businesses** that are **not able to get other financing from other resources**.

User Scenario: I am a 34 year old man from the United States who owns their own business. We are an American small business.
User Question: Is the 7(a) loan program for me?
Follow-up $\mathbf{Q}_1$: Are you a for-profit business?
Follow-up $\mathbf{A}_1$: Yes.
Follow-up $\mathbf{Q}_2$: Are you able to get financing from other resources?
Follow-up $\mathbf{A}_2$: No.
Final Answer: Yes. (You can apply the loan.)

Figure 1: An example dialog from the ShARC (Saeidi et al., 2018) dataset. The machine answers the user question by reading the rule text, interpreting the user scenario, and keeping asking follow-up questions to clarify the user's background until it concludes a final answer. Requirements in the rule text are bold.

1 Introduction

Conversational Machine Reading (CMR) is challenging because the rule text may not contain the literal answer, but provide a procedure to derive it through interactions (Saeidi et al., 2018). In this case, the machine needs to read the rule text, interpret the user scenario, clarify the unknown user's background by asking questions, and derive the final answer. Taking Figure 1 as an example, to answer the user whether he is suitable for the loan program, the machine needs to interpret the rule text to know what are the requirements, understand he meets "American small business" from the user scenario, ask follow-up clarification questions about "for-profit business" and "not get financing from other resources", and finally it concludes the answer "Yes" to the user's initial question.

Existing approaches (Zhong and Zettlemoyer, 2019; Sharma et al., 2019; Gao et al., 2020) decompose this problem into two sub-tasks. Given the rule text, user question, user scenario, and dialog history (if any), the first sub-task is to make a decision among "Yes", "No", "Inquire" and "Irrelevant". The "Yes/No" directly answers the user question and "Irrelevant" means the user question is unanswerable by the rule text. If the user-provided information (user scenario, previous dialogs) are not enough to determine his fulfillment or eligibility, an "Inquire" decision is made and the second sub-task is activated. The second sub-task is to capture the underspecified condition from the rule text and generate a follow-up question to clarify it. Zhong and Zettlemoyer (2019) adopt BERT (De-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2439–2449,
November 16–20, 2020.

vlin et al., 2019) to reason out the decision, and propose an entailment-driven extracting and editing framework to extract a span from the rule text and edit it into the follow-up question. The current state-of-the-art model EMT (Gao et al., 2020) uses a Recurrent Entity Network (Henaff et al., 2017) with explicit memory to track the fulfillment of rules at each dialog turn for decision making and question generation.

In this problem, document interpretation requires identification of conditions and determination of logical structures because rules can appear in the format of bullet points, in-line conditions, conjunctions, disjunctions, etc. Hence, correctly interpreting rules is the first step towards decision making. Another challenge is dialog understanding. The model needs to evaluate the user's fulfillment over the conditions, and jointly consider the fulfillment states and the logical structure of rules for decision making. For example, disjunctions and conjunctions of conditions have completely different requirements over the user's fulfillment states. However, existing methods have not considered condition-level understanding and reasoning.

In this work, we propose DISCERN: **Disc**ourse-Aware **E**ntailment **R**easoning **N**etwork . To better understand the logical structure of a rule text and to extract conditions from it, we first segment the rule text into clause-like elementary discourse units (EDUs) using a pre-trained discourse segmentation model (Li et al., 2018). Each EDU is treated as a condition of the rule text, and our model estimates its entailment confidence scores over three states: ENTAILMENT, CONTRADICTION or NEUTRAL by reading the user scenario description and existing dialog. Then we map the scores to an entailment vector for each condition, and reason out the decision based on the entailment vectors and the logical structure of rules. Compared to previous methods that do little entailment reasoning (Zhong and Zettlemoyer, 2019) or use it as multi-task learning (Gao et al., 2020), DISCERN is the first method to explicitly build the dependency between entailment states and decisions at each dialog turn.

DISCERN achieves new state-of-the-art results on the blind, held out test set of ShARC (Saeidi et al., 2018). In particular, DISCERN outperforms the previous best model EMT (Gao et al., 2020) by 3.8% in micro-averaged decision accuracy and 3.5% in macro-averaged decision accuracy. Specifically, DISCERN performs well on simple in-line conditions and conjunctions of rules while still needing improvements on understanding disjunctions. Finally, we conduct comprehensive analyses to unveil the limitation of DISCERN and current challenges for the ShARC benchmark. We find one of the biggest bottlenecks is the user scenario interpretation, in which various types of reasoning are required.

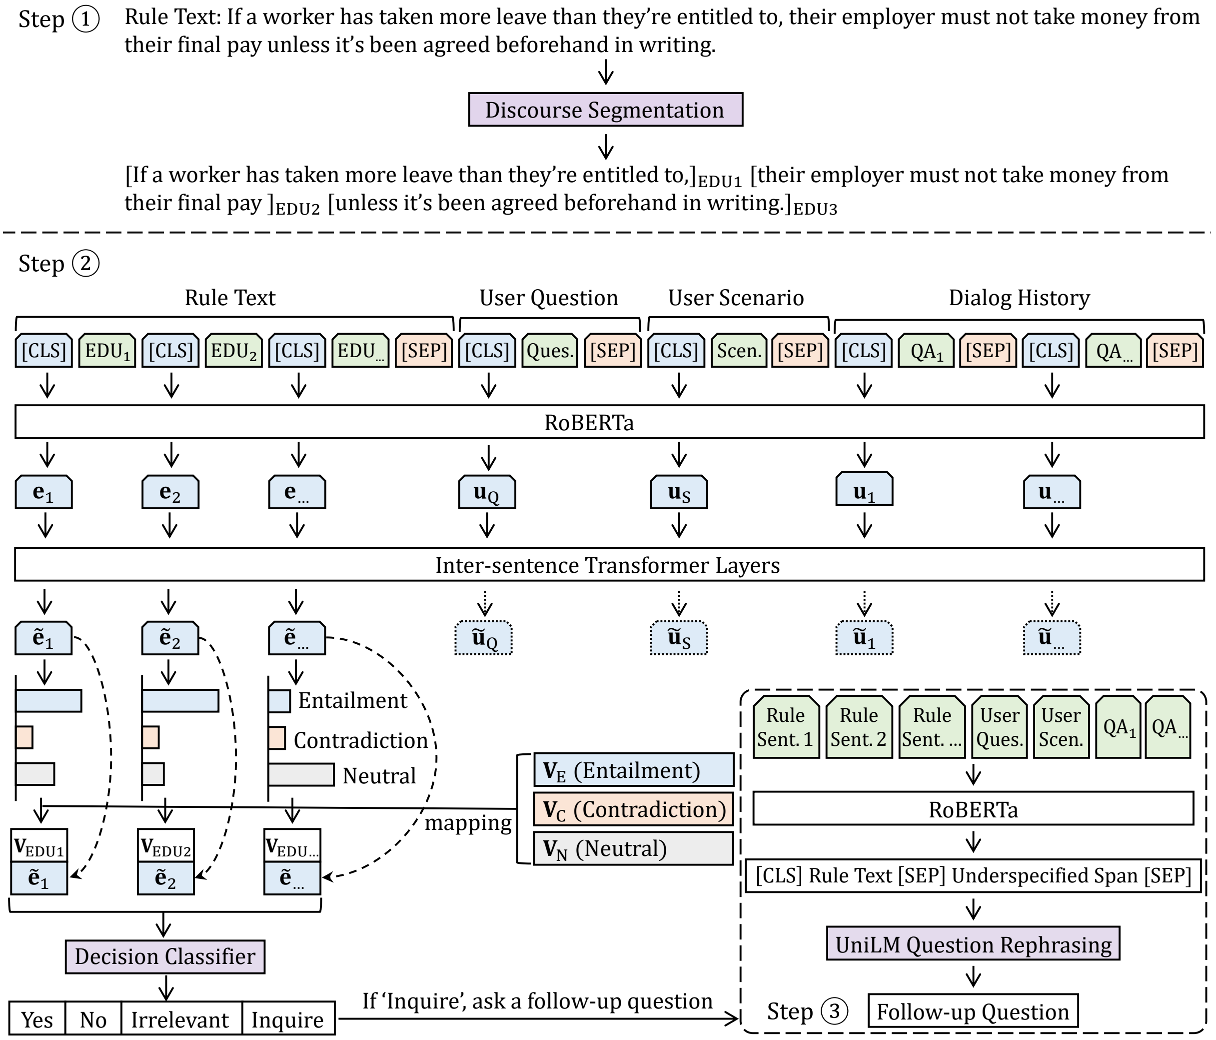
2 DISCERN Model

DISCERN answers the user question through a three-step process shown in Figure 2:

1. First, DISCERN segments the rule text into individual conditions using discourse segmentation.
2. Taking the user-provided information including the user question, user scenario and dialog history as inputs, DISCERN predicts the entailment state and maps it to an entailment vector for each segmented condition. Then it reasons out the decision by considering the logical structure of the rule text and the fulfillment of each condition.
3. Finally, if the decision is "Inquire", DISCERN generates a follow-up question to clarify the underspecified condition in the rule text.

2.1 Rule Segmentation

The goal of rule segmentation is to understand the logical structure of the rule text and parse it into individual conditions for the ease of entailment reasoning. Ideally, each segmented unit should contain at most *one* condition. Otherwise, it will be ambiguous to determine the entailment state for that unit. Determining conditions is easy when they appear as bullet points, but in most cases (65% samples in the ShARC dataset), one rule sentence may contain several in-line conditions as exemplified in Figure 2. To extract these in-line conditions, we find discourse segmentation in discourse parsing to be useful. In the Rhetorical Structure Theory or RST (Mann and Thompson, 1988) of discourse parsing, texts are first split into a sequence of clause-like units called elementary discourse units (EDUs). We utilize an off-the-shelf discourse segmenter (Li et al., 2018) to break the rule text into a sequence of EDUs. The segmenter uses a pointer network and achieves 92.2% F-score with Glove vectors and 95.55% F-score with ELMo embeddings on the standard RST benchmark testset,



Step ① Rule Text: If a worker has taken more leave than they're entitled to, their employer must not take money from their final pay unless it's been agreed beforehand in writing.

[If a worker has taken more leave than they're entitled to,]$_{\text{EDU1}}$ [their employer must not take money from their final pay]$_{\text{EDU2}}$ [unless it's been agreed beforehand in writing.]$_{\text{EDU3}}$

Figure 2: The overall diagram of our proposed DISCERN. DISCERN first segments the rule text into several elementary discourse units (EDUs) as conditions (Section 2.1). Then, taking the segmented conditions, user question, user scenario, and dialog history as inputs, DISCERN reasons out the decision among "Yes", "No", "Irrelevant" and "Inquire" (Section 2.2). If the decision is "Inquire", the question generation model asks a follow-up question (Section 2.3). *(Best viewed in color)*

which is close to human agreement of 98.3% F-score (Joty et al., 2015; Lin et al., 2019b). As exemplified in Figure 2 Step ①, the rule sentence is broken into three EDUs, in which two conditions ("If a worker has taken more leave than they're entitled to", "unless it's been agreed beforehand in writing") and the outcome ("their employer must not take money from their final pay") are split out precisely. For rule texts which contain bullet points, we directly treat these bullet points as conditions.

2.2 Decision Making via Entailment Reasoning

Encoding. As shown in Figure 2 Step ②, inputs to DISCERN include the segmented conditions (EDUs) in the rule text, user question, user scenario, and follow-up question-answer pairs in dialog history, each of which is a sequence of tokens. In order to get the sentence-level representations for all individual sequences, we insert an external `[CLS]` symbol at the start of each sequence, and add a `[SEP]` symbol at the end of every type of inputs. Then, DISCERN concatenates all sequences together, and uses RoBERTa (Liu et al., 2019) to encode the concatenated sequence. The encoded `[CLS]` token represents the sequence that follows it. In this way, we extract sentence-level representations of conditions (EDUs) as $\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_N$, and also the representations of the user question $\mathbf{u}_Q$, user scenario $\mathbf{u}_S$, and M turns of dialog history $\mathbf{u}_1, ..., \mathbf{u}_M$. All these vectorized representations are of d dimensions (768 for RoBERTa-base).

Entailment Prediction. In order to reason out the correct decision for the user question, it is necessary to figure out the fulfillment of conditions in the rule text. We propose to formulate the fulfillment prediction of conditions into a multi-sentence entailment task. Given a sequence of conditions (premises) and a sequence of user-provided information (hypotheses), a system should output ENTAILMENT, CONTRADICTION or NEUTRAL for each condition listed in the rule text. In this context, NEUTRAL indicates that the condition has not been mentioned from the user information.

We utilize an inter-sentence transformer encoder (Vaswani et al., 2017) to predict the entailment states for all conditions simultaneously. Taking all sentence-level representations $[\mathbf{e}_1; \mathbf{e}_2; ...; \mathbf{e}_N; \mathbf{u}_Q; \mathbf{u}_S; \mathbf{u}_1; ...; \mathbf{u}_M]$ as inputs, the L-layer transformer encoder makes each condition attend to all the user-provided information to predict whether the condition is entailed or not. We also allow all conditions can attend to each other to understand the logical structure of the rule text.

Let the transformer encoder output of the i-th condition as $\tilde{\mathbf{e}}_i$, we use a linear transformation to predict its entailment state:

$$\mathbf{c}_i = \mathbf{W}_c \tilde{\mathbf{e}}_i + \mathbf{b}_c \in \mathbb{R}^3, \tag{1}$$

where $\mathbf{c}_i = [c_{\text{E},i}, c_{\text{C},i}, c_{\text{N},i}] \in \mathbb{R}^3$ contains confidence scores of three entailment states ENTAILMENT, CONTRADICTION, NEUTRAL for the i-th condition in the rule text.

Since there are no ground truth entailment labels for individual conditions, we adopt a heuristic approach similar to Gao et al. (2020) to get the noisy supervision signals. Given the rule text, we first collect all associated follow-up questions in the dataset. Each follow-up question is matched to a segmented condition (EDU) in the rule text which has the minimum edit distance. For conditions in the rule text which are mentioned by follow-up questions in the dialogue history, we label the entailment state of a condition as `Entailment` if the answer for its mentioned follow-up question is `Yes`, and label the state of this condition as `Contradiction` if the answer is `No`. The remaining conditions not covered by any follow-up question are labeled as `Neutral`. Let r indicate the correct entailment state. The entailment prediction is weakly supervised by the following cross entropy loss, normalized by total number of K conditions in a batch:

$$\mathcal{L}_{\text{entail}} = -\frac{1}{K} \sum_{i=1}^{K} \log\ \text{softmax}(\mathbf{c}_i)_r \tag{2}$$

Decision Making. After knowing the entailment state for each condition in the rule text, the remaining challenge for decision making is to perform logical reasoning over different rule types such as disjunction, conjunction, and conjunction of disjunctions. To achieve this, we first design three d-dimension entailment vectors $\mathbf{V}_\text{E}$ (Entailment), $\mathbf{V}_\text{C}$ (Contradiction), $\mathbf{V}_\text{N}$ (Neutral), and map the predicted entailment confidence scores of each condition to its vectorized entailment representation:

$$\mathbf{V}_{\text{EDU},i} = \sum_{k \in [\text{E,C,N}]} c_{k,i} \mathbf{V}_\text{k} \in \mathbb{R}^d, \tag{3}$$

These entailment vectors are randomly initialized and then learned during training. Finally, DISCERN jointly considers the logical structure of rules $\tilde{\mathbf{e}}_i$ and the entailment representations $\mathbf{V}_{\text{EDU},i}$ of conditions to make a decision:

$$\alpha_i = \mathbf{w}_\alpha^\top [\mathbf{V}_{\text{EDU},i}; \tilde{\mathbf{e}}_i] + b_\alpha \in \mathbb{R}^1 \tag{4}$$

$$\tilde{\alpha}_i = \text{softmax}(\alpha)_i \in [0,1] \tag{5}$$

$$\mathbf{g} = \sum_i \tilde{\alpha}_i [\mathbf{V}_{\text{EDU},i}; \tilde{\mathbf{e}}_i] \in \mathbb{R}^{2d} \tag{6}$$

$$\mathbf{z} = \mathbf{W}_z \mathbf{g} + \mathbf{b}_z \in \mathbb{R}^4 \tag{7}$$

where $[\mathbf{V}_{\text{EDU},i}; \tilde{\mathbf{e}}_i]$ denotes the vector concatenation, α_i is the attention weight for the i-th condition that determines whether the i-th condition should be taken into consideration for the final decision. $\mathbf{z} \in \mathbb{R}^4$ contains the predicted scores for all four possible decisions "Yes", "No", "Inquire" and "Irrelevant". Let l indicate the correct decision, $\mathbf{z}$ is supervised by the following cross entropy loss:

$$\mathcal{L}_{\text{dec}} = -\log\ \text{softmax}(\mathbf{z})_l \tag{8}$$

The overall loss for the Step ② decision making is the weighted-sum of decision loss and entailment prediction loss:

$$\mathcal{L} = \mathcal{L}_{\text{dec}} + \lambda \mathcal{L}_{\text{entail}} \tag{9}$$

2.3 Follow-up Question Generation

If the predicted decision is "Inquire", the follow-up question generation model is activated, as shown in Step ③ of Figure 2. It extracts an *underspecified* span from the rule text which is uncovered from the user's feedback, and rephrases it into a well-formed question. Existing approaches put huge efforts in extracting the underspecified span, such as entailment-driven extracting and ranking (Zhong and Zettlemoyer, 2019) or coarse-to-fine reasoning (Gao et al., 2020). However, we find that such sophisticated modelings may not be necessary, and we propose a simple but effective approach here.

We split the rule text into sentences and concatenate the rule sentences and user-provided information into a sequence. Then we use RoBERTa to encode them into vectors grounded to tokens, as here we want to predict the position of a span within the rule text. Let [$\mathbf{t}_{1,1}$, ..., $\mathbf{t}_{1,s_1}$; $\mathbf{t}_{2,1}$, ..., $\mathbf{t}_{2,s_2}$; ...; $\mathbf{t}_{N,1}$, ..., $\mathbf{t}_{N,s_N}$] be the encoded vectors for tokens from N rule sentences, we follow the BERTQA approach (Devlin et al., 2019) to learn a start vector $\mathbf{w}_s \in \mathbb{R}^d$ and an end vector $\mathbf{w}_e \in \mathbb{R}^d$ to locate the start and end positions, under the restriction that the start and end positions must belong to the same rule sentence:

$$\text{Span} = \arg\max_{i,j,k}(\mathbf{w}_s^\top \mathbf{t}_{k,i} + \mathbf{w}_e^\top \mathbf{t}_{k,j}) \qquad (10)$$

where i, j denote the start and end positions of the selected span, and k is the sentence which the span belongs to. The training objective is the sum of the log-likelihoods of the correct start and end positions. To supervise the span extraction process, the noisy supervision of spans are generated by selecting the span which has the minimum edit distance with the to-be-asked question. Lastly, following Gao et al. (2020), we concatenate the rule text and span as the input sequence, and finetune UniLM (Dong et al., 2019), a pre-trained language model to rephrase it into a question.

3 Experiments

3.1 Experimental Setup

Dataset. ShARC (Saeidi et al., 2018) dataset is the current benchmark to test entailment reasoning in conversational machine reading [1]. The dataset contains 948 rule texts clawed from 10 government websites, in which 65% of them are plain text with in-line conditions while the rest 35% contain bullet-point conditions. Each rule text is associated with a dialog tree (follow-up QAs) that considers all possible fulfillment combinations of conditions. In the data annotation stage, parts of the dialogs are paraphrased into the user scenario. These parts of dialogs are marked as `evidence` which should be extracted (entailed) from the user scenario, and are not provided as inputs for evaluation. The inputs to the system are the rule text, user question, user scenario, and dialog history (if any). The output is the answer among Yes, No, Irrelevant, or a follow-up question. The train, development, and test dataset sizes are 21890, 2270, and 8276, respectively.

Evaluation Metrics. The decision making sub-task uses macro- and micro- accuracy of four classes "Yes", "No", "Irrelevant", "Inquire" as metrics. For the question generation sub-task, we evaluate models under both the official end-to-end setting (Saeidi et al., 2018) and the recently proposed oracle setting (Gao et al., 2020). In the official setting, the BLEU score (Papineni et al., 2002) is calculated only when both the ground truth decision and the predicted decision are "Inquire", which makes the score dependent on the model's "Inquire" predictions. For the oracle question generation setting, models are asked to generate a question when the ground truth decision is "Inquire".

Implementation Details. For the decision making sub-task, we finetune RoBERTa-base model (Wolf et al., 2019) with Adam (Kingma and Ba, 2015) optimizer for 5 epochs with a learning rate of 5e-5, a warm-up rate of 0.1, a batch size of 16, and a dropout rate of 0.35. The number of inter-sentence transformer layers L and the loss weight λ for entailment prediction are hyperparameters. We try 1,2,3 for L and 1.0, 2.0, 3.0, 4.0, 5.0 for λ, and find the best combination is $L = 2, \lambda = 3.0$, based on the development set results. For the question generation sub-task, we train a RoBERTa-base model to extract spans under the same training scheme above, and finetune UniLM (Dong et al., 2019) 20 epochs for question rephrasing with a batch size of 16, a learning rate of 2e-5, and a beam size 10 for decoding in the inference stage. We repeat 5 times with different random seeds for all experiments on the development set and report the average results along with their standard deviations. It takes two hours for training on a 4-core server with an Nvidia GeForce GTX Titan X GPU.

3.2 Results

Decision Making Sub-task. The decision making results in macro- and micro- accuracy on the blind, held out test set of ShARC are shown in Table 1. DISCERN outperforms the previous best

EMT (Gao et al., 2020)	69.4	74.8	60.9	46.0
EMT+entailment (Gao et al., 2020)	69.1	74.6	63.9	**49.5**
DISCERN (our single model)	**73.2**	**78.3**	**64.0**	49.1

Table 1: Performance on the blind, held-out test set of ShARC end-to-end task.

Models	Yes	No	Inq.	Irr.
BERTQA	61.2	61.0	62.6	96.4
E^3	65.9	70.6	60.5	96.4
UrcaNet	63.3	68.4	58.9	95.7
EMT	70.5	73.2	70.8	98.6
DISCERN	**71.9**	**75.8**	**73.3**	**99.3**

Table 2: Class-wise decision prediction accuracy among "Yes", "No", "Inquire" and "Irrelevant" on the development set of ShARC.

Models	BLEU1	BLEU4
E^3	52.79±2.87	37.31±2.35
E^3+UniLM	57.09±1.70	41.05±1.80
EMT	62.32±1.62	47.89±1.58
DISCERN (BERT)	64.13±0.43	50.73±0.72
DISCERN	**64.23**±0.84	**50.85**±0.89

Table 3: Oracle question generation performance on the development set of ShARC.

model EMT (Gao et al., 2020) by 3.8% in micro-averaged accuracy and 3.5% in macro-averaged accuracy. We further analyze the class-wise decision prediction accuracy on the development set of ShARC in Table 2, and find that DISCERN have far better predictions than all existing approaches whenever a decision on the user's fulfillment is needed ("Yes", "No", "Inquire"). It is because the predicted decisions from DISCERN are made upon the predicted entailment states while previous approaches do not build the connection between them.

Question Generation Sub-task. DISCERN outperforms existing methods under both the official end-to-end setting (Table 1) and the recently proposed oracle setting (Table 3). Because the comparison among models is only fair under the oracle question generation setting (Gao et al., 2020), we compare DISCERN with E^3 (Zhong and Zettlemoyer, 2019), E^3+UniLM (Gao et al., 2020), EMT (Gao et al., 2020), and our ablation DISCERN (BERT) in Table 3. Interestingly, we find that, in this oracle setting, our proposed simple approach is even better than previous sophisticated models such as E^3 and EMT which jointly learn question generation and decision making via multi-task learning. From our results and investigations, we believe the decision making sub-task and the follow-up question generation sub-task do not share too many commonalities so the results are not improved for each task in their multi-task training. On the other hand, our question generation model is easy to optimize because this model is separately trained from the decision making one, which means there is no need to balance the performance between these two sub-tasks. Besides, RoBERTa backbone performs comparably with its BERT counterpart.

In our detailed analyses, we find DISCERN can locate the next questionable sentence with 77.2% accuracy, which means DISCERN utilizes the user scenario and dialog history well to locate the next underspecified condition. We try to add entailment prediction supervision to help DISCERN to locate the unfulfilled condition but it does not help. We also try to simplify our approach by directly fine-tuning UniLM to learn the mapping between concatenated input sequences and the follow-up clarification questions. However, the poor result (around 40 for BLEU1) suggests this direction still remains further investigations.

3.3 Ablation Study

Table 4 shows an ablation study of DISCERN for the decision making sub-task on the development set of ShARC, and we have the following observations:

Models	Micro Acc.	Macro Acc.
DISCERN	74.97±0.27	79.55±0.35
DISCERN (BERT)	73.07±0.21	77.77±0.24
DISCERN (w/o EDU)	73.34±0.22	78.25±0.57
DISCERN (w/o Trans)	74.25±0.36	78.78±0.57
DISCERN (w/o $\tilde{\mathrm{e}}$)	73.55±0.26	78.19±0.30
DISCERN (w/o $\mathbf{V}_{\mathrm{EDU}}$)	72.95±0.23	77.53±0.19

Table 4: Ablation Study of DISCERN for decision making on the development set of ShARC.

Logical Type	# samples	Micro Acc.	Macro Acc.
Simple	569	82.78±1.48	86.91±1.31
Disjunction	726	69.97±1.85	75.89±1.38
Conjunction	698	74.47±2.41	79.78±1.74
Other	277	73.29±2.53	77.17±1.54

Table 5: Decision prediction accuracy categorized by logical types of rules on the ShARC development set.

RoBERTa *vs.* BERT. DISCERN (BERT) replaces the RoBERTa backbone with BERT while other modules remain the same. The better performance of RoBERTa backbone matches findings from Talmor et al. (2019), which indicate that RoBERTa can capture negations and handle conjunctions of facts better than BERT.

Discourse Segmentation *vs.* Sentence Splitting. DISCERN (w/o EDU) replaces the discourse segmentation based rule parsing with simple sentence splitting, and we observe there is a 1.63% drop on the micro-accuracy. This is intuitive because we observe 65% of the rule texts in the training set contains in-line conditions. To better understand the effect of discourse segmentation, we also evaluate DISCERN and DISCERN (w/o EDU) on just that portion of examples that contains multiple EDUs. The micro-accuracy of decision making is 75.75 for DISCERN while it is 70.98 for DISCERN (w/o EDU). The significant gap shows that discourse segmentation is extremely helpful.

Are Inter-sentence Transformer Layers Necessary? We investigate the necessity of inter-sentence transformer layers because RoBERTa-base already has 12 transformer layers, in which the sentence-level `[CLS]` representations can also interact with each other via multi-head self-attention. Therefore, we remove the inter-sentence transformer layers and use the RoBERTa encoded `[CLS]` representations for entailment prediction and decision making. The results show that removing the inter-sentence transformer layers (DISCERN w/o Trans) hurts the performance, which suggests that the inter-sentence self-attention is essential.

Both Condition Representations and Entailment Vectors Facilitate Decisions. We remove either the condition representations $\tilde{\mathrm{e}}_i$ or the entailment vectors $\mathbf{V}_{\mathrm{EDU}}$ in Eqn.4 & 6 for decision predictions. The results show that both sides of the information are useful for making decisions. Presumably, the condition representations account for the logical forms of rule texts and entailment vectors contain the fulfillment states for these conditions.

3.4 Analysis of Logical Structure of Rules

To see how DISCERN understands the logical structure of rules, we evaluate the decision making accuracy according to the logical types of rule texts. Here we define four logical types: "Simple", "Conjunction", "Disjunction", "Other", which are inferred from the associated dialog trees. "Simple" means there is only one requirement in the rule text while "Other" denotes the rule text have complex logical structures, for example, a conjunction of disjunctions or a disjunction of conjunctions. Table 5 shows decision prediction results categorized by different logical structures of rules. DISCERN achieves the best performance on the "Simple" logical type which only needs to determine the single condition is satisfied or not. On the other hand, DISCERN does not perform well on rules in the format of disjunctions. We conduct further analysis on this category and find that the error comes from user scenario interpretation: the user has already provided his fulfillment in the user scenario but DISCERN fails to extract it. Detailed analyses are further conducted in the following section.

3.5 How Far Has the Problem Been Solved?

In order to figure out the limitations of DISCERN, and the current challenges of ShARC CMR, we disentangle the challenges of scenario interpretation and dialog understanding in ShARC by selecting different subsets, and evaluate decision making and entailment prediction accuracy on them.

Baseline. Because the classification for unanswerable questions ("irrelevant" class) is nearly solved (99.3% in Table 2), we create the baseline subset by removing all unanswerable examples from the development set. Results for this baseline are shown in **ShARC (Answerable)** of Table 6.

Dataset	Decision Making		Entailment Prediction	
	Micro Acc.	Macro Acc.	Micro Acc.	Macro Acc.
ShARC (Answerable)	73.55±0.33	73.46±0.27	86.41±0.39	81.13±0.39
Dialog History Subset	79.29±1.62	76.37±1.95	92.41±0.38	90.12±0.68
Scenario Subset	63.50±1.58	60.18±1.72	82.76±0.46	59.40±1.04
ShARC (Evidence)	84.93±0.29	84.37±0.24	91.46±0.68	89.90±1.40

Table 6: Decision making and entailment prediction results over different subsets of the ShARC development set.

Dialog History Subset. We first want to see how DISCERN understands dialog histories (follow-up QAs) without the influence of user scenarios. Hence, we create a subset of ShARC (Answerable) in which all samples have an empty user scenario. The performance over 224 such samples is shown in "Dialog History Subset" of Table 6. Surprisingly, the results on this portion of samples are much better than the overall results, especially for the entailment prediction (92.41% micro-accuracy).

Scenario Subset. With the curiosity to see what is the bottleneck of our model, we test the model ability on scenario interpretation. Similarly, we create a "Scenario Subset" from ShARC (Answerable) in which all samples have an empty dialog history. Results in Table 6 ("Scenario Subset") show that interpreting scenarios to extract the entailment information within is exactly the current bottleneck of DISCERN. We analyze 100 error cases on this subset and find that various types of reasoning are required for scenario interpretation, including numerical reasoning (15%), temporal reasoning (12%), and implication over common sense and external knowledge (46%). Besides, DISCERN still fails to extract user's fulfillment when the scenarios paraphrase the rule texts (27%). Examples for each type of error are shown in Figure 3. Among three classes of entailment states, we find that DISCERN fails to predict ENTAILMENT or CONTRADICTION precisely – it predicts NEUTRAL in most cases for scenario interpretation, resulting in high micro-accuracy in entailment prediction but the macro-accuracy is poor. The decision accuracy is subsequently hurt by the entailment results.

ShARC (Evidence). Based on the above observation, we replace the user scenario in the ShARC (Answerable) by its `evidence` and re-evaluate the overall performance on these answerable questions. As described in Section 3.1 Dataset, the `evidence` is the part of dialogs that should be entailed from the user scenario. Table 6 shows that the model improves 11.38% in decision making micro-accuracy if no scenario interpretation is required, which validates our above observation.

4 Related Work

Entailment Reasoning in Reading Comprehension. Understanding entailments (or implications) of text is essential in dialog and question answering systems. ROPES (Lin et al., 2019a) requires reading descriptions of causes and effects and applying them to situated questions, while ShARC (Saeidi et al., 2018), the focus of DISCERN, requires to understand rules and apply them to questions asked by users in a conversational manner. Most existing methods simply use BERT to classify the answer without considering the structures of rule texts (Zhong and Zettlemoyer, 2019; Sharma et al., 2019; Lawrence et al., 2019). Gao et al. (2020) propose Explicit Memory Tracker (EMT), which firstly addresses entailment-oriented reasoning. At each dialog turn, EMT recurrently tracks whether conditions listed in the rule text have already been satisfied to make a decision.

In this paper, we also explicitly model entailment reasoning for decision making, but there are three key differences between our DISCERN and EMT: (1) we apply discourse segmentation to parse the rule text, which is extremely helpful because there are many in-line conditions in rules; (2) Our stacked inter-sentence transformer layers extract better features for entailment prediction, which could be seen as a generalization of their recurrent explicit memory tracker. (3) Different from their utilization of entailment prediction which is treated as multi-task learning for decision making, we directly build the dependency between entailment prediction states and the predicted decisions.

Discourse Applications. Discourse analysis uncovers text-level linguistic structures (e.g., topic, coherence, co-reference), which can be useful for many downstream applications, such as coherent text generation (Bosselut et al., 2018) and text sum-

Error Type	%	Example
Numerical Reasoning	15	**Relevant Rule**: Each attachment must be less than 10MB. **Scenario**: The attachment right now isn't less than 10MB, but I think I can compress so it becomes less than 10MB. **Question**: Can I upload the attachment? **Entailment State** Gold: `Entailment`; Predict: `Contradiction`
Temporal Reasoning	12	**Relevant Rule**: The Additional State Pension is an extra amount of money you could get on top of your basic State Pension if you're: … * a woman born before 6 April 1953 **Scenario**: I live with my husband. We both have worked all our lives. Both of us were born in 1950. **Question**: Can I get Additional State Pension? **Entailment State** Gold: `Entailment`; Predict: `Contradiction`
Commonsense Reasoning	46	**Relevant Rule**: Homeowners may apply for up to $200,000 to repair or replace their primary residence to its pre-disaster condition. **Scenario**: My home was flooded **Question**: Is this loan suitable for me? **Entailment State** Gold: `Entailment`; Predict: `Unknown`
Paraphrase Reasoning	27	**Relevant Rule**: The Montgomery GI Bill (MGIB) is an educational assistance program enacted by Congress to attract high quality men and women into the Armed Forces. **Scenario**: I applied and found out I can get a loan. My dad wants me to join the army, but I don't. I'd rather go to school. **Question**: Does this program meet my needs? **Entailment State** Gold: `Contradiction`; Predict: `Unknown`

Figure 3: Types of scenario interpretation errors in the development data based on 100 samples.

marization (Joty et al., 2019; Cohan et al., 2018; Xu et al., 2020). Recently, discourse information has also been introduced in neural reading comprehension. Mihaylov and Frank (2019) design a discourse-aware semantic self-attention mechanism to supervise different heads of the transformer by discourse relations and coreferring mentions. Different from their use of discourse information, we use it as a parser to segment surface-level in-line conditions for entailment reasoning.

5 Conclusion

In this paper, we present DISCERN, a system that does discourse-aware entailment reasoning for conversational machine reading. DISCERN explicitly builds the connection between entailment states of conditions and the final decisions. Results on the ShARC benchmark shows that DISCERN outperforms existing methods by a large margin. We also conduct comprehensive analyses to unveil the limitations of DISCERN and challenges for ShARC. In future, we plan to explore how to incorporate discourse parsing into the current decision making model for end-to-end learning. One possibility would be to frame them as multi-task learning with a common (shared) encoder.

Abstract

We present a scalable, low-bias, and low-cost method for building a commonsense inference dataset that combines automatic extraction from a corpus and crowdsourcing. Each problem is a multiple-choice question that asks contingency between basic events. We applied the proposed method to a Japanese corpus and acquired 104k problems. While humans can solve the resulting problems with high accuracy (88.9%), the accuracy of a high-performance transfer learning model is reasonably low (76.0%). We also confirmed through dataset analysis that the resulting dataset contains low bias. We released the datatset to facilitate language understanding research.[1]

1 Introduction

Along with the progress of deep learning, there have been many studies that consider task settings and build their datasets for training/evaluating language understanding ability by computers (Wang et al., 2019b,a).

Language understanding by computers requires two types of knowledge: knowledge of language (meaning of words, syntax, and so forth) and knowledge of our world and society beyond language.

The former problem of acquiring linguistic knowledge has been solved to a large extent by general-purpose language models, such as BERT (Devlin et al., 2019), which are pre-trained using a large corpus. It is now possible to represent the meaning of a word as a vector according to its context. Fine-tuning based on these vectors has made natural language inference, paraphrase recognition, and question answering without requiring deep inference as accurate as humans.

On the other hand, there are still many problems with acquiring knowledge beyond language. Actually it is open-ended, and we had better start with fundamental knowledge, i.e., commonsense. Still, it is not easy to focus on commonsense, guaranteeing some generality as commonsense.

There have been some approaches to guarantee such generality. SWAG (Zellers et al., 2018), for example, focuses on knowledge about daily events that can be visually perceived. This method greatly limits the range of commonsense that can be acquired. CommonsenseQA (Talmor et al., 2019) is based on the basic vocabulary that is covered by ConceptNet (Speer et al., 2017), which is one of the largest commonsense knowledge bases. This prevents the scalability, generating only 12k problems from the whole data of ConceptNet.

Another important point is that biases in building datasets must be reduced as much as possible. In the above two approaches, question or distractor sentences were created automatically or by crowdsourcing. This causes generation biases of language models or produces certain patterns (*annotation artifacts*) by crowdsourced writing (Gururangan et al., 2018).

We use a text corpus to solve these problems. We propose a method to build a commonsense inference dataset by extracting contingent pairs of basic event expressions (hereafter, **contingent basic event pairs**) from a corpus and verifying them by crowdsourcing. Basic event expressions (hereafter, **basic events**) are defined as expressions composed of high-frequency predicate-argument structures that are extracted from a corpus and aggregated by clustering according to their usages. Contingent basic event pairs are extracted by identifying contingency relations between basic events using discourse parsing.

For instance, the following contingent basic event pairs are acquired.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2450–2460,
November 16–20, 2020.

I am hungry, so
a. I drink coffee.
b. I have a meal.
c. I sweat.
d. I get sleepy.

Table 1: A sample problem. The correct choice is bolded.

(1) a. I am hungry, so I have a meal.
b. If I have a meal, I get sleepy.
c. Since I am sleepy, I drink coffee.
d. If I exercise hard, I sweat.

Based on these contingent pairs, we can generate a **commonsense inference problem** by adopting later events of other pairs as distractors, as shown in Table 1. Since the problem is based on basic events, it guarantees some generality as commonsense.

Since our method is based on automatic extraction from a corpus, it is scalable and the domain is not limited. In addition, there is no bias caused by crowdsourcing because we ask crowdworkers to just verify a sentence. Although the key idea of our proposed method is language-independent, we build a Japanese commonsense inference dataset in this study by exploiting existing resources.

The contributions of this paper are summarized as follows.

- We propose a scalable, low-bias, and low-cost method for building a commonsense inference dataset that combines automatic extraction from a corpus and crowdsourcing.
- We built a Japanese commonsense inference dataset from a web corpus of 715m sentences that consists of 104k multiple-choice questions.
- While humans can solve the resulting problems with high accuracy (88.9%), the accuracy of a high-performance transfer learning model is low (76.0%), which shows that there is a reasonable gap in commonsense inference ability. We also confirm that the resulting dataset contains low bias.

2 Related Work

Language resources for commonsense inference that have been built so far can be classified into knowledge bases and QA datasets.

Commonsense knowledge bases have been constructed by experts, crowdsourcing, and games with a purpose. Cyc (Lenat, 1995) and Open Mind Common Sense projects (Speer et al., 2017) collected various relations between entities and events. They include causal relations between events, but the number of these relations is not high. ATOMIC (Sap et al., 2019) is a knowledge base that is comprised of 877k if-then pairs of basic events. They collected these pairs using crowdsourcing based on frequent basic events extracted from several corpora. These fully manual or crowdsourcing approaches are costly and have a problem of scalability. Also, methods for incorporating such knowledge bases into an NLP model have been studied but have not been established yet.

Many QA datasets for commonsense inference have been built. They include COPA (Choice of Plausible Alternatives) (Roemmele et al., 2011), SWAG (Zellers et al., 2018), HellaSWAG (Zellers et al., 2019), and CommonsenseQA (Talmor et al., 2019). These datasets can be solved to some extent by machine comprehension models (Devlin et al., 2019) that have been rapidly improved. There have been also some approaches that transfer knowledge in such a dataset to downstream tasks using multi-task learning (Liu et al., 2019). We briefly introduce these datasets below.

COPA consists of 1,000 two-choice questions that ask a causal relation between two sentences. Each question provides a premise sentence and requires to choose its cause or ending sentence from two alternatives. This dataset was manually created for the purpose of evaluation and is too small to learn commonsense by computers.

SWAG is a commonsense inference dataset consisting of 113k multiple-choice questions that ask the most appropriate verb phrase following a given context. To guarantee generality as commonsense, questions were created from video captions, and thus the domain of the dataset is limited to the physical world. For each question, two consecutive sentences were extracted from a video caption, the first sentence and the subject of the second sentence compose a context, and the rest was regarded as a correct choice. Distractors were generated from a language model. To obtain high-quality distractors, SWAG removed those that are easily discriminated by an answer model. SWAG was solved by BERT with a similar accuracy to humans. This was attributed to biases that were embedded in distractor sentences by an LSTM-based language model and detected by BERT (Zellers et al., 2019). They newly built HellaSwag using a better language model to make biases undetectable by BERT. However, the accuracy for solving HellaSwag is also approaching to human performance (Liu et al., 2020). The bias problem has not been solved yet.

CommonsenseQA is a commonsense inference dataset consisting of 12k multiple-choice questions based on the commonsense knowledge base, ConceptNet. A question is created by crowdsourcing based on a subgraph consisting of a source concept and three target concepts connected with the same relationship. A crowdworker creates a question sentence which includes the source concept and whose answer is only one of the target concepts. This method uses an existing resource and lacks scalability. In addition, because the load of creating question sentences is large for crowdworkers, they tend to use the same words and styles repeatedly, leading bias in question sentences.

3 A Method for Generating Commonsense Inference Problems

A commonsense inference problem consists of a context (question) and four choices. The question asks to choose the most appropriate choice following the context, as shown in Table 1.

These problems should be based on basic events to guarantee generality as commonsense. In addition, to guarantee scalability and reduce biases, we combine automatic extraction from a corpus and verification by crowdsourcing. Our method to generate commonsense inference problems consists of the following procedure (Figure 1).

1. Acquire basic events from high-frequency predicate-argument structures.
2. Apply discourse parsing to a corpus and extract event pairs that are recognized as having a contingency relation and composed of basic events.
3. Verify whether the extracted event pairs have a contingency relation by crowdsourcing and obtain contingent basic event pairs.
4. Generate commonsense inference problems by taking a correct choice from a contingent pair and selecting distractors from other event pairs.

Case frame	CS	Case fillers
kowasu (1) (injure)	*ga* $_{1756}$ *wo* $_{70135}$ *de* $_{3941}$	I $_{83}$, person $_{65}$, ... stomach $_{25643}$, body $_{17242}$, ... stress $_{297}$, eating $_{174}$, ...
kowasu (2) (destroy)	*ga* $_{502}$ *no* $_{10147}$ *wo* $_{18274}$	person $_{42}$, Japan $_{42}$, ... place $_{873}$, room $_{851}$, ... atmosphere $_{8140}$, image $_{3774}$, ...
...		

Table 2: Examples of Japanese case frames. CS denotes case slots, where *ga*, *wo*, *de*, and *no* mean nominative, accusative, instrumental, and genitive, respectively. The number following case or a case filler represents its frequency. Examples are expressed only in English for space limitation.

We describe the details of each step in the following subsections.

3.1 Acquisition of Basic Events

Basic events are defined as expressions composed of high-frequency predicate-argument structures that are extracted from a corpus and aggregated by clustering according to their usages. As a source of basic events, we employ *case frames* (Kawahara et al., 2014) that are automatically constructed by clustering predicate-argument structures.

In the case frame data, each predicate has multiple case frames distinguished according to their usages. Each case frame consists of multiple case slots, and each case slot contains possible case fillers. Table 2 shows some examples of Japanese case frames.

In this study, we extract high-frequency predicate-argument structures from case frames as basic events. First, from the case frame data, the top α predicates in active voice are obtained. For each predicate, frequent case frames, case slots, and case fillers are selected until the cumulative sum of frequencies reaches $\beta\%$, $\gamma\%$, and $\delta\%$, respectively. For example, case frames are selected until covering $\beta\%$ of the frequency of a target predicate. These thresholds are empirically set according to a target language.

Table 3 shows some examples of basic events acquired from Japanese case frames. The parameters for Japanese basic events are described in Section 4.

3.2 Automatic Extraction of Contingent Basic Event Pairs

We apply dependency and discourse parsing to a text corpus and extract event pairs connected with both dependency and contingency relations.

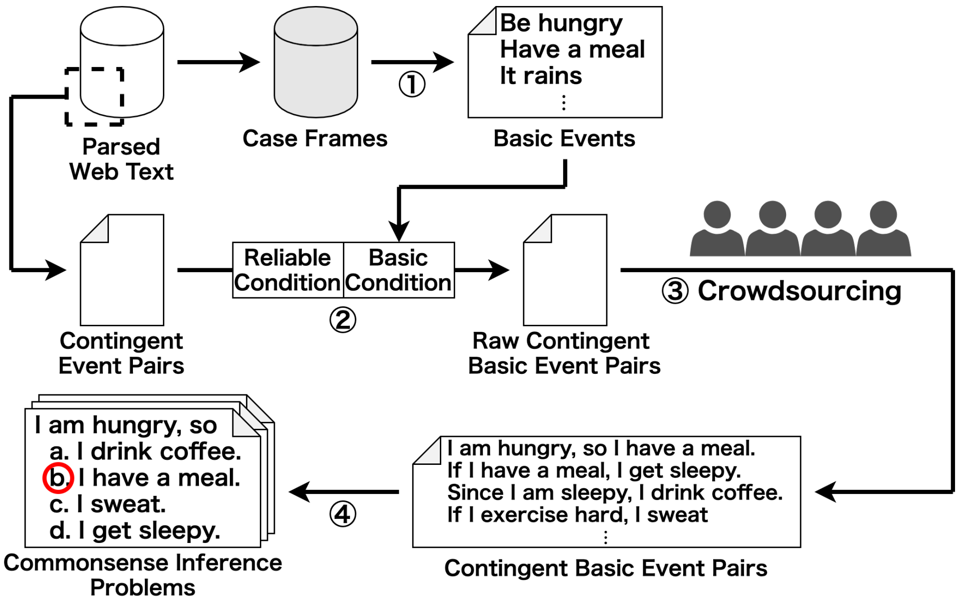

Figure 1: The overview of our proposed method.

Case frame	CS	Case fillers
kowasu (1) (injure)	*wo*	stomach, body
kowasu (2) (destroy)	*no* *wo*	place, room, ... atmosphere, image
torikaeru (replace)	*wo*	door, glass, ...
hatudou (activate)	*ga*	effect

Table 3: Examples of Japanese basic events.

The contingency relation between events should be expressed by an explicit discourse marker and be a causal or conditional relation, corresponding to "CONTINGENCY:Cause" or "CONTINGENCY:Condition" in the Penn Discourse Treebank (Prasad et al., 2008).

To select highly reliable parts from analysis results and to extract only general event pairs as commonsense, we keep event pairs satisfying the following conditions. Here, we call the first event that represents a cause or reason **former event** and the second event **latter event**.

Reliable The former and latter events are unambiguously connected.

In the case that only two clauses exist in a sentence, there is no ambiguity. In the case that more than two clauses exist in a sentence, we extract a reliable part based on language-dependent criteria.

Basic Both the former and latter events are composed of a basic event.

This condition can be applied in a straightforward way, but we need to take care of the case that an argument in the latter event is pronominalized or omitted. If the latter event does not have an explicit argument, we recover it with any of the arguments in the former event and examine whether the recovered latter event is composed of a basic event.

For example, consider the event pair "the glass breaks on impact → I replace it". In this case, we generate recovered latter events "I replace the glass" and "I replace impact" by substituting an argument in the former event for "it". Then, we examine whether either of them is composed of a basic event and extract this event pair because "replace glass" is a basic event as shown in Table 3.

Finally, the following post-processes are performed so that crowdworkers in the next step can accurately judge event pairs.

- To exclude event pairs that are less eventful or contain web-specific functional expressions, the frequency of basic events included in the obtained event pairs is counted, and event pairs that contain one of high-frequency basic events are excluded. For example, "問題がない (have no problem)" and "情報が満載 (have much information)" are detected as high-frequency meaningless events in Japanese.

- Event pairs that contain demonstratives or unknown words are excluded.

3.3 Verification of Contingent Basic Event Pairs through Crowdsourcing

We select contingent basic event pairs from the extracted basic event pairs using crowdsourcing. We ask crowdworkers to select one of the following two alternatives for each event pair.

1. A is a cause or reason of B.

2. Other relation or no relation.

Here, "A" denotes the former event, and "B" denotes the latter event.

We ask multiple workers to evaluate each event pair and adopt the evaluation that half or more of the workers agree. We finally obtain event pairs whose aggregated evaluation is "A is a cause or reason of B" as contingent basic event pairs.

3.4 Generation of Commonsense Inference Problems

We generate commonsense inference problems from the obtained contingent basic event pairs. We regard the former event as a context (question) and the latter event as a correct choice. Distractors are automatically selected from the latter events of other event pairs.

In general, highly similar distractors to the correct choice are not distinguishable even by humans. Meanwhile, dissimilar distractors can be easily distinguished by machines. We select moderately similar distractors under the following conditions.

Choice-Similarity The similarity between the correct choice and a candidate latter event is in a range, $\mathrm{RANGE}_{\mathrm{choice}}$.

This similarity is calculated using the cosine similarity between vectors of (latter) events. This vector is defined as an average vector of content words contained in an event.

Context-Similarity The similarity between the context and the former event of a candidate latter event is in a range, $\mathrm{RANGE}_{\mathrm{context}}$.

This similarity is calculated in the same way as the condition **Choice-Similarity**.

To improve the appearance of problems, we select latter events whose ratio of the number of words against the correct choice is in a range, $\mathrm{RANGE}_{\mathrm{length}}$.[2]

If more than three distractors are obtained, we randomly select three out of them. If less than three distractors are obtained, we do not generate a problem from the contingent basic event pair.

4 Building a Japanese Commonsense Inference Dataset

We built a Japanese commonsense inference dataset using the method described in Section 3.

Acquisition of basic events

We extracted Japanese basic events from the Kyoto University case frames[3], which had been constructed from 10 billion web sentences. We set the thresholds α, β, γ, and δ to 5,000, 75, 50, and 50, respectively. As a result, we obtained 28,642 basic events. Examples of the obtained basic events are shown in Table 3.

Automatic extraction of contingent basic event pairs

We automatically extracted contingent basic event pairs from a Japanese web corpus consisting of approximately 715 million sentences. We used the Japanese parser, KNP[4] to extract event pairs from the corpus. KNP does dependency parsing and also labels explicit discourse relations between clauses (events). As a result, approximately 85 million contingent basic event pairs were extracted.

Next, to extract highly reliable basic event pairs, the **Reliable** and **Basic** conditions were applied. For the **Reliable** condition, if there are more than two clauses in a sentence, we extract only the last two clauses because in Japanese the dependency goes from left to right.

Finally, we performed the post-processes to extract 164,910 contingent basic event pairs. The detailed statistics are listed in Table 4.

To investigate the effectiveness of the **Basic** condition, we randomly selected 100 event pairs from "+Reliable" and "+Reliable+Basic" in Table 4, and manually evaluated them. For convenience, we name each set of the selected event pairs "R" and

---

[2] As a result of our preliminary experiment, we found that this condition did not affect the model performance. Hence, we do not investigate this condition.

[3] `https://www.gsk.or.jp/catalog/gsk2018-b`

[4] `http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP`

Item	Number
sentences	714,605,164
contingent event pairs	85,357,299
+Reliable	51,904,745
+Reliable+Basic	517,321
+post-processing	164,910

Table 4: Detailed statistics about extraction of event pairs. For example, the number of “+Reliable” shows the number of contingent event pairs that satisfy the **Reliable** condition.

“RB”, respectively. As a result of the manual evaluation, 47 event pairs in “R” and 76 event pairs in “RB” were judged as understandable with commonsense. Here is an example in “R” that would be excluded by the **Basic** condition: “サイクロンを発動すると→破壊できる (activate the cyclone→we can destroy)”. “Activate the cyclone” is not a basic event as shown in Table 3, which is a domain-specific expression especially used in fiction. By the **Basic** condition, we can remove such non-general event pairs. Thus, we can see that the **Basic** condition is effective in acquiring general knowledge at the level of commonsense.

Verification of contingent basic event pairs through crowdsourcing

Next, we selected contingent basic event pairs from the extracted event pairs using crowdsourcing. We used the crowdsourcing service, Yahoo! Crowdsourcing[5]. A crowdworker was presented with 17 questions (event pairs) per task, each of which asked to choose one from the two alternatives. Two of the 17 event pairs were check questions with a hidden ground truth, and the answers of crowdworkers who mistakenly judged these event pairs were excluded. Each event pair was verified by four crowdworkers, and we selected the event pairs two or more of whose evaluations are “A is a cause or reason of B”.

As a result of crowdsourcing, 104,266 contingent basic event pairs were selected from 164,910 pairs, which means that approximately one-third of pairs were removed. This ratio roughly corresponds to the result of the above investigation on the effectiveness of the **Basic** condition. The total cost of crowdsourcing was 484,000 JPY (4,495 USD), and the cost per problem was 4.7 JPY (4.5 cents).

Train	Development	Test
83,127	10,228	10,291

Table 5: Statistics of the dataset.

Generation of commonsense inference problems

Finally, we generated commonsense inference problems from the acquired contingent basic event pairs. The similarity range, $\mathrm{RANGE}_{\mathrm{choice}}$, in the condition **Choice-Similarity** was set to the range of 0.4 to 0.6, and the similarity range, $\mathrm{RANGE}_{\mathrm{context}}$, in the condition **Context-Similarity** was set to the range of 0.5 to 0.7. We set $\mathrm{RANGE}_{\mathrm{context}}$ slightly higher than $\mathrm{RANGE}_{\mathrm{choice}}$ because **Context-Similarity** controls the similarity to the correct choice more indirectly than **Choice-Similarity**. To calculate the similarity between events, we used word vectors that were induced from 200 million sentences of the Japanese web corpus using word2vec[6]. The length range, $\mathrm{RANGE}_{\mathrm{length}}$, was set to the range of 0.5 to 2.0.

As a result, 103,907 problems were generated from the 104,266 contingent basic event pairs. Table 7 shows examples of the obtained problems with BERT’s predictions (described in Section 5.1). On this default setting, the mean and median numbers of the eligible candidates before finally selecting three were 3,459 and 1,355, respectively.

To create a standard split of the obtained problems, we split the problems into train/development/test sets with the ratio 8:1:1. We performed the split in the way that both the train set and the development/test set do not contain the problems generated from the identical “seed”. The term “seed” refers to a pair of basic events that compose former and latter events in a contingent basic event pair. For example, the seed of the top left example in Table 7 is a pair of “装置が故障 (a device breaks)” and “装置を交換 (replace a device)”. In addition, we removed some problems in the development/test sets so that there are no duplicate pairs of a context and a distractor between the train set and the development/test sets. The statistics of the resulting dataset are listed in Table 5.

Investigation of human accuracy

To investigate the accuracy of human answers, we randomly sampled 1,500 problems and collected answers from five crowdworkers for each problem.

---

[5] `https://crowdsourcing.yahoo.co.jp/`

[6] `https://code.google.com/archive/p/word2vec/`

We prepared three sets of 500 problems and did crowdsourcing on different dates to be solved by different sets of crowdworkers. As a result, the average accuracy of individual crowdworkers was 83.8% and that of the answers aggregated by majority voting was 88.9%.

5 Experiments

We conducted experiments to investigate the performance of a transfer learning model on the constructed commonsense inference dataset.

5.1 Model

We used BERT (Devlin et al., 2019) as a transfer learning model for our experiments. BERT achieved high performance on various benchmark tasks including natural language inference and question answering. For pre-training, the model solves a masked language modeling task and a next sentence prediction task simultaneously to obtain context-aware word representations. To apply this model to each downstream task, a layer is added on top of the output, and all the parameters are fine-tuned on the task.

In our experiments, we input pairs of a context and a choice separated by special tokens following the previous work (Talmor et al., 2019). For example, the context “お腹 が 空いた ので (I am hungry, so)” and the choice “ご飯 を 食べる (I have a meal)” would become “[CLS] お腹 ... [SEP] ご飯 ... [SEP]”. The hidden representation of each [CLS] token is converted to a score through a linear layer, and the choice with the highest value is selected as an answer.

We define the objective function as follows.

$$L = -\frac{1}{N}\sum_{k=1}^{N}\log\frac{\exp(\mathbf{w}^T\mathbf{c}_{kj})}{\sum_{i=1}^{4}\exp(\mathbf{w}^T\mathbf{c}_{ki})} \qquad (1)$$

where N is a batch size, $\mathbf{w}$ is the parameters in a linear layer, j is the index of a correct choice among $1 \cdots 4$, and $\mathbf{c}_{ki}$ is the hidden representation of each [CLS] token.

We adopted $\text{BERT}_{\text{LARGE}}$ as a BERT model. We used the Japanese pre-trained $\text{BERT}_{\text{LARGE}}$ WWM model[7], which performed pre-training using 18 million sentences of Japanese Wikipedia with whole word masking. We fine-tuned the pre-trained model for 3 epochs. We used the following hyper-parameters: a batch size of 8[8], a learning rate of 2e-5, and maximum sequence length of 128.

Model		Accuracy
Chance		0.250
$\text{BERT}_{\text{LARGE}}$		0.760
Human	1 worker	0.838
	5 workers	0.889

Table 6: Performance of $\text{BERT}_{\text{LARGE}}$ and humans.

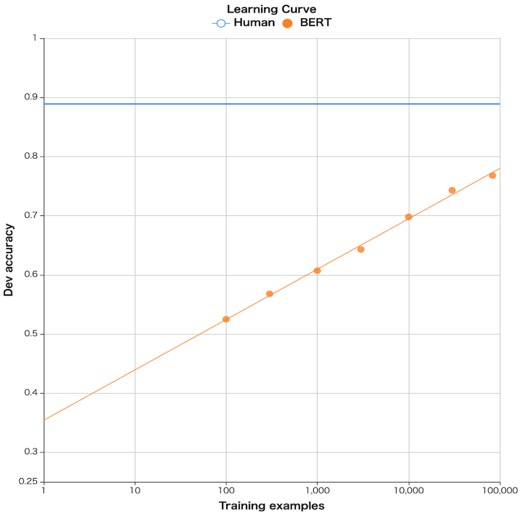

Figure 2: Learning curve of the BERT model on the development set.

5.2 Experimental Results

We evaluated the model performance with accuracy. The $\text{BERT}_{\text{LARGE}}$ model achieved an accuracy of 0.760, as shown in Table 6. We can see that there is a reasonable gap between the BERT model and the human performance.

Figure 2 shows the learning curve of the BERT model on the development set. We can expect by extrapolation that approximately 1.9 million training examples are required to achieve human performance, which is not practical. It is meaningful to develop better models to solve this dataset toward the human accuracy.

5.3 Analysis

We briefly analyze the results of the BERT model. Table 7 shows some examples that the BERT model answered correctly and incorrectly. As can be seen from the top left example, lexical overlap between a context and a choice is a clue to solve the problem. There are some noticeable examples that the BERT model answered incorrectly as a result of overemphasizing this.

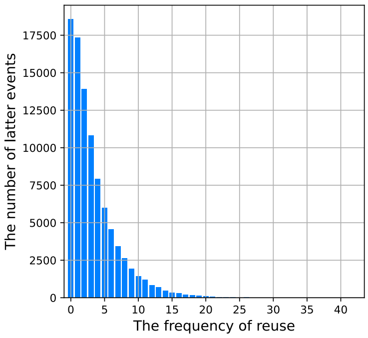

Figure 3: Counts of how many times each latter event is used as a distractor.

6 Investigation of the Dataset

6.1 Investigation of Biases

Several studies have reported that, due to unintended biases in a dataset, many problems can be solved by just observing a part of question sentences (Gururangan et al., 2018; Zellers et al., 2019). To investigate the existence of bias in our dataset, we measured model performance when we input only the choices by omitting their context during fine-tuning and inference phases. In this investigation, we used the same model and hyperparameters as described in Section 5.1.

As a result, the BERT$_{\mathrm{LARGE}}$ model achieved an accuracy of 41.2%. Compared with the result in Section 5.2, the performance is significantly low, which indicates that the constructed dataset contains low bias. To investigate the result that the performance without the context (41.2%) is a bit higher than the chance rate (25%), we counted how many times each latter event is used as a distractor. Figure 3 shows the result of counting. We speculate that some latter events are frequently reused and thus can be easily judged as incorrect by the BERT model. We will tackle this problem in the future to further lower the bias.

6.2 Investigation of the Conditions on Selecting Distractors

We investigated how the conditions on selecting distractors affect the quality of the dataset. Specifically, we built datasets by removing the upper or lower bounds of each similarity range, RANGE$_{\mathrm{choice}}$ and RANGE$_{\mathrm{context}}$, and evaluated model and human performances on each dataset. We evaluated model performance on each development set using the same model settings as described in Section 5.1. We calculated human performance in the same way as described in Section 4.

Table 8 shows the result of this investigation. This result indicated the effectiveness of the upper and lower bounds. Specifically, by removing the upper bound, some problems contained distractors that were highly similar to the correct choice, and thus both the model and humans could not solve

RANGE		BERT$_{\text{LARGE}}$	Human
choice	context		
(0.4, 0.6)	(0.5, 0.7)	0.768	0.889 (0.838)
(0.4, 1.0)	(0.5, 0.7)	0.727	0.822 (0.788)
(0.4, 0.6)	(0.5, 1.0)	0.730	0.818 (0.777)
(-1.0, 0.6)	(0.5, 0.7)	0.767	0.887 (0.839)
(0.4, 0.6)	(-1.0, 0.7)	0.846	0.928 (0.888)

Table 8: Results of investigation of the conditions on selecting distractors. The numbers in parentheses at the rightmost column represent average accuracies of individual crowdworkers.

them. By removing the lower bound, the relatedness between a context and distractors decreased, and thus the generated problems became easy to solve especially for the model. Accordingly, it is important to select moderately similar distractors.

7 Conclusion

In this paper, we proposed a scalable, low-bias, and low-cost method for building a commonsense inference dataset that combines automatic extraction from a corpus and crowdsourcing. Each problem is a multiple-choice question that asks contingency between basic events. We applied the proposed method to a Japanese web corpus and acquired 103,907 problems. While the human accuracy was high (88.9%), the BERT$_{\text{LARGE}}$ accuracy was reasonably low (76.0%). We also confirmed that the dataset contained low bias, and thus it can be used as a good benchmark for language understanding research.

In the future, we will make a model learn commonsense with the obtained dataset and consider applying it to semantic tasks, such as anaphora resolution and discourse parsing.

For commonsense acquisition from text, there is a problem that every commonsense is not written in text because of reporting bias (Gordon and Van Durme, 2013). To acquire a wider range of commonsense, it is possible to combine our method with other methods based on physical world resources, such as video captions used in SWAG.

Abstract

Deepfake detection, the task of automatically discriminating machine-generated text, is increasingly critical with recent advances in natural language generative models. Existing approaches to deepfake detection typically represent documents with coarse-grained representations. However, they struggle to capture factual structures of documents, which is a discriminative factor between machine-generated and human-written text according to our statistical analysis. To address this, we propose a graph-based model that utilizes the factual structure of a document for deepfake detection of text. Our approach represents the factual structure of a given document as an entity graph, which is further utilized to learn sentence representations with a graph neural network. Sentence representations are then composed to a document representation for making predictions, where consistent relations between neighboring sentences are sequentially modeled. Results of experiments on two public deepfake datasets show that our approach significantly improves strong base models built with RoBERTa. Model analysis further indicates that our model can distinguish the difference in the factual structure between machine-generated text and human-written text.

1 Introduction

Nowadays, unprecedented amounts of online misinformation (e.g., fake news and rumors) spread through the internet, which may misinform people's opinions of essential social events (Faris et al., 2017; Thorne et al., 2018; Goodrich et al., 2019; Kryściński et al., 2019). Recent advances in neural generative models, such as GPT-2 (Radford et al., 2019), make the situation even severer as their ability to generate fluent and coherent text may enable adversaries to produce fake news. In this work, we study deepfake detection of text, to automatically discriminate machine-generated text from human-written text.

Neural Fake News

Zarif: No nuclear enrichment prohibition by Iran

April 15, 2019

··· The law currently imposes a 100 million euro ($113 million) fine on Iran in case of a violation, but under the new bill, if Saudis violate the arms embargo, Tehran will be handed a 2 billion euros fine. ···

Figure 1: An example of machine-generated fake news. We can observe that the factual structure of entities extracted by named entity recognition is inconsistent.

Previous works on deepfake detection of text are dominated by neural document classification models (Bakhtin et al., 2019; Zellers et al., 2019; Wang et al., 2019; Vijayaraghavan et al., 2020). They typically tackle the problem with coarse-grained document-level evidence such as dense vectors learned by neural encoder and traditional features (e.g., TF-IDF, word counts). However, these coarse-grained models struggle to capture the fine-grained factual structure of the text. We define the factual structure as a graph containing entities mentioned in the text and the semantically relevant relations among them. As shown in the motivating example in Figure 1, even though machine-generated text seems coherent, its factual structure is inconsistent. Our statistical analysis further reveals the difference in the factual structure between human-written and machine-generated text (detailed in Section 3). Thus, modeling factual structures is essential for detecting machine-generated text.

Based on the aforementioned analysis, we propose **FAST**, a graph-based reasoning approach uti-

November 16–20, 2020.

lizing **FA**ctual **S**tructure of **T**ext for deepfake detection. With a given document, we represent its factual structure as a graph, where nodes are automatically extracted by named entity recognition. Node representations are calculated not only with the internal factual structure of a document via a graph convolution network, but also with external knowledge from entity representations pre-trained on Wikipedia. These node representations are fed to produce sentence representations which, together with the coherence of continuous sentences, are further used to compose a document representation for making the final prediction.

We conduct experiments on a news-style dataset and a webtext-style dataset, with negative instances generated by GROVER (Zellers et al., 2019) and GPT-2 (Radford et al., 2019) respectively. Experiments show that our method significantly outperforms strong transformer-based baselines on both datasets. Model analysis further indicates that our model can distinguish the difference in the factual structure between machine-generated text and human-written text. The contributions are summarized as follows:

- We propose a graph-based approach, which models the fine-grained factual structure of a document for deepfake detection of text.
- We statistically show that machine-generated text differs from human-written text in terms of the factual structures, and injecting factual structures boosts detection accuracy.
- Results of experiments on news-style and webtext-style datasets verify that our approach achieves improved accuracy compared to strong transformer-based pre-trained models.

2 Task Definition

We study the task of deepfake detection of text in this paper. This task discriminates machine-generated text from human-written text, which can be viewed as a binary classification problem. We conduct our experiments on two datasets with different styles: a news-style dataset with fake text generated by GROVER (Zellers et al., 2019) and a large-scale webtext-style dataset with fake text generated by GPT-2 (Radford et al., 2019). The news-style dataset consists of 25,000 labeled documents, and the webtext-style dataset consists of 520,000 labeled documents. With a given document, systems are required to perform reasoning about the content of the document and assess whether it is "human-written" or "machine-generated".

3 Factual Consistency Verification

In this part, we conduct a statistical analysis to reveal the difference in the factual structure between human-written and machine-generated text. Specifically, we study the difference in factual structures from a consistency perspective and analyze entity-level and sentence-level consistency.

Through data observation, we find that human-written text tends to repeatedly mention the same entity in continuous sentences, while machine-written continuous sentences are more likely to mention irrelevant entities. Therefore, we define **entity consistency count (ECC)** of a document as the number of entities that are repeatedly mentioned in the next w sentences, where w is the sentence window size. **Sentence consistency count (SCC)** of a document is defined as the number of sentences that mention the same entities with the next w sentences. For instance, if entities mentioned in three continuous sentences are "*A and B; A; B*" and $w = 2$, then $ECC = 2$ because two entities A and B are repeatedly mentioned in the next 2 sentences. $SCC = 1$ because only the first sentence has entities mentioned in the next 2 sentences. We use all 5,000 pairs of human-written and machine-generated documents from the news-style dataset and each pair of documents share the same metadata (e.g., title) for statistical analysis. We plot the kernel density distribution of these two types of consistency count with sentence window size $w = \{1, 2\}$.

As shown in Figure 2, human-written documents are more likely to have higher entity-level and sentence-level consistency count. This analysis indicates that human-written and machine-generated text are different in the factual structure, thus modeling consistency of factual structures is essential in discriminating them.

4 Methodology

In this section, we present our graph-based reasoning approach, which considers factual structures of documents, which is used to guide the reasoning process for the final prediction.

Figure 3 gives a high-level overview of our approach. With a document given as the input, our system begins by calculating the contextual word representations by RoBERTa (§ 4.1). Then, we

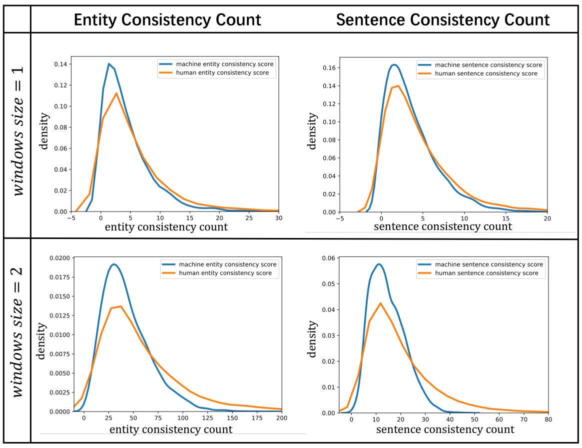

Figure 2: Statistical analysis about entity-level and sentence-level consistency. Orange curve and blue curve indicate kernel density estimation curve for human-written document and machine-generated document respectively. X-axis indicates the value of consistency count and y-axis indicates probability density.

build a graph for capturing the internal factual structure of the whole document (§ 4.2). With the constructed graph, we initialize node representations utilizing internal and external factual knowledge and propagate and aggregate information by a graph neural network to learn graph-enhanced sentence representations (§ 4.3). Then, to model the consistent relations of continuous sentences and compose a document representation for making the final prediction, we employ a sequential model with help of coherence scores from a pre-trained next sentence prediction (NSP) model (§ 4.4).

4.1 Word Representation

In this part, we present how to calculate contextual word representations by a transformer-based model. In pratice, we employ RoBERTa (Liu et al., 2019).

Taking a document d as the input, we employ RoBERTa to learn contextual semantic representations for words [1]. RoBERTa encoder $\mathcal{B}$ maps document $\boldsymbol{x}$ with length $|\boldsymbol{x}|$ into a sequence of following hidden vectors.

$$\boldsymbol{h}(\boldsymbol{x}) = [\boldsymbol{h}(\boldsymbol{x})_1, \boldsymbol{h}(\boldsymbol{x})_2, \cdots, \boldsymbol{h}(\boldsymbol{x})_{|\boldsymbol{x}|}] \quad (1)$$

where each $\boldsymbol{h}(\boldsymbol{x})_i$ indicates the contextual representation of word i

4.2 Graph Construction

In this part, we present how to construct a graph to reveal the internal factual structure of a document. In practice, we observe that selecting entities, the core participants of events, as arguments to construct the graph leads to less noise to the representation of the factual structure. Therefore, we employ a named entity recognition (NER) model to parse entities mentioned in each sentence. Specifically, taking a document as the input, we construct a graph in the following steps.

- We parse each sentence to a set of entities with an off-the-shelf NER toolkit built by AllenNLP [2], which is an implementation of Peters et al. (2017). Each entity is regarded as a node in the graph.
- We establish links between inner-sentence and inter-sentence entity node pairs to capture the structural relevance. We add inner-sentence edges to entity pairs in the same sentence for they are naturally relevant to each other. Moreover, we add inter-sentence edges to literally similar inter-sentence entity pairs for they are likely to be the same entity.

After this process, the graph reveals the fine-grained factual structure of a document.

4.3 Graph Neural Network

In this part, we introduce how to initialize node representations and exploit factual structure utilizing multi-layer graph convolution network (GCN) to propagate and aggregate information and finally produce sentence representations.

4.3.1 Node Representation Initialization

We initialize node representations with contextual word representations learnt by RoBERTa and external entity representations pre-trained on Wikipedia.

Contextual Representation Since each entity node is naturally a span of words mentioned in the document, we calculate the contextual representation of each node by the contextual words representations $\boldsymbol{h}(\boldsymbol{x})$. Supposing an entity e consists of n words, then the contextual representation $\varepsilon_{\mathcal{B}}$ is calculated with the following formula:

$$\varepsilon_{\mathcal{B}} = ReLU(\boldsymbol{W}_{\mathcal{B}} \frac{1}{n} \sum_{i=0}^{n} \boldsymbol{h}(\boldsymbol{x})_{e^i}) \quad (2)$$

where $\boldsymbol{W}_{\mathcal{B}}$ is a weight metric, e^i is the absolute position in the document of the i^{th} word in the span of entity e, and $ReLU$ is an activation function.

---

[1] In practice, "words" may indicate tokens or token-pieces, we use "words" for a better illustration here.

[2] `https://demo.allennlp.org/named-entity-recognition`

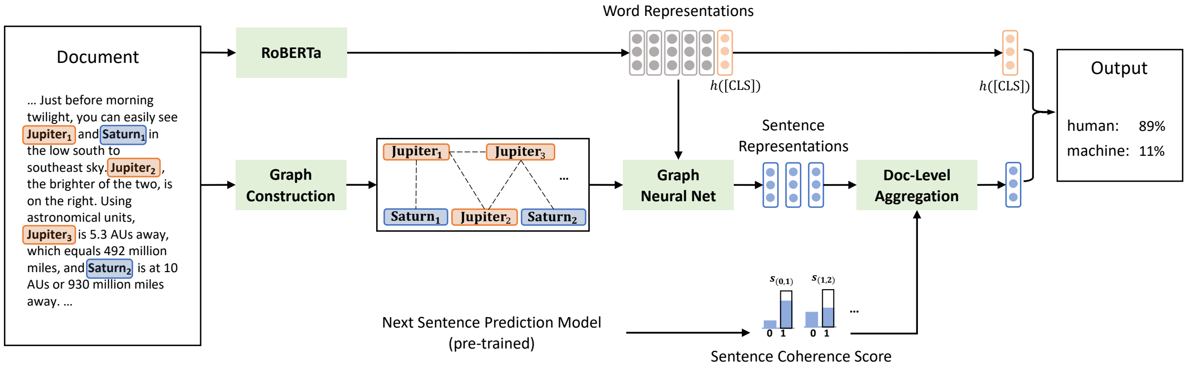

Figure 3: An overview of our approach. Taking a document as the input, we first calculate contextual word representations via RoBERTa (§ 4.1) and represent the factual structure as a graph (§ 4.2). After that, we employ graph neural network to learn sentence representations (§ 4.3). Then, sentence representations are composed to a document representation considering coherence of continuous sentences before making the final prediction (§ 4.4).

Wikipedia-based Entity Representation To model external factual knowledge about entities in the knowledge base, we further represent entity e with a projected wikipedia2vec entity representation (Yamada et al., 2018), which embeds words and entities on Wikipedia pages in a common space. The Wikipedia-based entity representation ε_w is :

$$\varepsilon_w = ReLU(\boldsymbol{W}_w \boldsymbol{v}_e) \tag{3}$$

where $\boldsymbol{v}_e$ is the wikipedia2vec representation of entity e and $\boldsymbol{W}_w$ is a weight metric.

The initial representation $\boldsymbol{H}_e^{(0)} \in \boldsymbol{R}^d$ of entity node e is the concatenation of contextual representation $\varepsilon_{\mathcal{B}}$ and Wikipedia-based entity representation ε_w, with dimension d.

4.3.2 Multi-layer GCN

In order to propagate and aggregate information through multihop neighbouring nodes, we employ multi-layer Graph Convolution Network (GCN) (Kipf and Welling, 2016).

Formally, we denote the constructed graph as G and representation of all nodes as $\boldsymbol{H} \in \boldsymbol{R}^{N\times d}$, where N denote the number of nodes. Each row $\boldsymbol{H}_e \in \boldsymbol{R}^d$ in $\boldsymbol{H}$ indicates a representation of node e. We denote the adjacency matrix of graph G as $\boldsymbol{A}$ and degree matrix as $\boldsymbol{D}$. We further calculate $\widetilde{\boldsymbol{A}} = \boldsymbol{D}^{-\frac{1}{2}}\boldsymbol{A}\boldsymbol{D}^{-\frac{1}{2}}$. Then, the formula of multi-layer GCN is described as follows:

$$\boldsymbol{H}_e^{(i+1)} = \sigma(\widetilde{\boldsymbol{A}}\boldsymbol{H}_e^{(i)}\boldsymbol{W}_i) \tag{4}$$

where $\boldsymbol{H}_e^{(i)}$ denotes the representation of node e calculated by i^{th} layer of GCNs, $\boldsymbol{W}_i$ is the weight matrix of layer i. σ is an activation function. Specially, $\boldsymbol{H}_e^{(0)}$ is the initialized node representations.

Finally, through m layers of GCN, we obtain the graph-enhanced node representations based on the structure of the factual graph.

4.3.3 Sentence Representation

According to compositionality, we believe that global representation should come from partial representations. Therefore, we calculate sentence-level representations based on graph-enhanced node representations. Supposing sentence i has N_i corresponding entities, we calculate the representation $\boldsymbol{y}_i$ of sentence i as follows:

$$\boldsymbol{y}_i = \frac{1}{N_i}\sum_{j=0}^{N_i} \sigma(\boldsymbol{W_s}\boldsymbol{H}_{(i,j)} + \boldsymbol{b}_s) \tag{5}$$

where σ is an activation function, $\boldsymbol{W_s}$ is a weight matrix, $\boldsymbol{b}_s$ is a bias vector and $\boldsymbol{H}_{(i,j)}$ indicates the representation of j^{th} node in sentence i. The compositionality can also be implemented in other ways, which we leave to future work.

4.4 Aggregation to Document Representation

In this part, we present how to compose a document representation for the final prediction utilizing graph-enhanced sentence representations and coherence score calculated by a pre-trained next sentence prediction (NSP) model.

Coherence Tracking LSTM With graph-enhanced sentence representations given as the input, the factual consistency of continuous sentences is automatically modeled by a sequential model. Specifically, We employ LSTM to track the consistent relations and produce representations $\widetilde{\boldsymbol{y}_i}$ for sentence i

$$\widetilde{\boldsymbol{y}_i} = LSTM([\boldsymbol{y}_i]) \tag{6}$$

Next Sentence Prediction Model In order to further model contextual coherence of neighbouring sentence pairs as an additional information, we pre-train an NSP model to calculate the contextual coherence score for each neighbouring sentence pair. We employ RoBERTa (Liu et al., 2019) as the backbone, which receives pairs of sentences as the input and assesses whether the second sentence is a subsequent sentence of the first. Further training details are explained in Appendix A. The outputs $\boldsymbol{S}$ are described as follows.

$$\boldsymbol{S} = [S_{(0,1)}, ..., S_{(s-1,s)}] \tag{7}$$

where $s+1$ is the number of sentences in document $\boldsymbol{x}$ and each $S_{(i-1,i)}$ is the positive probability score for sentence pair $(i-1, i)$, which indicates how likely it is that sentence i is a subsequent sentence of sentence $i-1$.

Prediction with NSP Score We generate a document-level representation by composing sentence representations before making the final prediction. To achieve this, we take NSP scores as weights and calculate the weighted sum of representations of sentence pairs with the assumption that sentence pairs with higher contextual coherence score should also carry more importance in making the final prediction. The final document representation $\boldsymbol{D}$ is calculated as follows.

$$\boldsymbol{D} = \sum_{j=1}^{s} S_{(j-1,j)} * [\widetilde{\boldsymbol{y}}_{j-1}, \widetilde{\boldsymbol{y}}_j] \tag{8}$$

Finally, we make the final prediction by feeding the combination of $\boldsymbol{D}$ and the last hidden vector $\boldsymbol{h}([CLS])$ from RoBERTa through an classification layer. The goal of this operation is to maintain the complete contextual semantic meaning of the whole document because some linguistic clues are left out during graph construction.

5 Experiment

5.1 Experiment Settings

In this paper, we evaluate our system on the following two datasets:

- News-style GROVER-generated dataset provided by Zellers et al. (2019). The human-written instances are collected from RealNews, and machine-generated instances are generated by GROVER-Mega, a large state-of-the-art transformer-based generative model developed for neural fake news. We largely follow the experimental settings as described by Zellers et al. (2019) and adopt two evaluation metrics: **paired accuracy** and **unpaired accuracy**. In the paired setting, the system is given human-written news and machine-generated news with the same meta-data. The system needs to assign higher machine probability to the machine-generated news than the human-written one. In the unpaired setting, the system is provided with single news document and states whether the document is human-written or machine-generated.
- Webtext-style GPT2-generated dataset provided by OpenAI[3]. The human-written instances are collected from WebText. Machine-generated instances are generated by GPT-2 XL-1542M (Radford et al., 2019), a powerful transformer-based generative model trained on a corpus collected from popular webpages. For this dataset, we adopt binary classification accuracy as the evaluation metric.

We set nucleus sampling with $p = 0.96$ as the sampling strategy of generator for both datasets, which leads to better generated text quality (Zellers et al., 2019; Ippolito et al., 2019). The statistics of the two datasets are shown in the Table 1.

Dataset	Train	Valid	Test Set	
			Unpaired	Paired
News-style	10,000	3,000	8,000	8,000
Webtext-style	500,000	10,000	10,000	-

Table 1: Statistics of news-style and webtext-style datasets.

Furthermore, we adopt RoBERTa-Base (Liu et al., 2019) as the direct baseline for our experiments because RoBERTa achieves state-of-the-art performance on several benchmark NLP tasks. The hyper-parameters and training details of our model are described in Appendix B.

5.2 Model Comparison

Baseline Settings We compare our system with transformer-based baselines for DeepFake detection, including three powerful transformer-based pre-trained models: **BERT** (Devlin et al., 2018), **XLNet** (Yang et al., 2019) and **RoBERTa** (Liu

---

[3] `https://github.com/openai/gpt-2-output-dataset`

Size	Model	Unpaired Acc	Paired Acc
	Chance	50.0%	50.0%
355M	GROVER-Large	80.8%	89.0%
	BERT-Large	73.1%	84.1%
	GPT2	70.1%	78.8%
124M	GROVER-Base	70.1%	77.5%
	BERT-Base	67.2%	80.0%
	GPT2	66.2%	72.5%
	XLNet	77.1%	88.6%
	RoBERTa	80.7%	89.2%
	FAST	**84.9%**	**93.5%**

Table 2: Performance on the test set of news-style dataset in terms of unpaired and paired accuracy. Our model is abbreviated as FAST. Size indicates approximate model size. The performance of GROVER, BERT, and GPT2 are reported by Zellers et al. (2019)

et al., 2019), which are large bidirectional transformers achieving strong performance on multiple benchmark NLP tasks. These baselines add a simple classification layer on top of them and are fine-tuned with standard cross-entropy loss on the binary classification.

For the news-style dataset, we further compare our model with **GPT-2** (Radford et al., 2019) and **GROVER** (Zellers et al., 2019). The GROVER-based discriminator is a fine-tuned version of generator GROVER, which has three model sizes: GROVER-Base (124 million parameters), GROVER-Large (335 million parameters), and GROVER-Mega (1.5 billion parameters). Our model is not comparable with GROVER-Mega for the following reasons. Firstly, GROVER-Mega is the fake news generator, and it has a strong inductive bias (e.g., data distribution and sampling strategy) as the discriminator (Zellers et al., 2019). Secondly, GROVER-Mega has a much larger model size (1.5 billion parameters) than our model.

For the webtext-style dataset, we compare with the baselines we trained with the same hyper-parameters. We don't compare with GPT-2 because it's the generator for machine-generated text.

Results and Analysis In Table 2, we compare our model with baselines on the test set of news-style dataset with negative instances generated by GROVER-Mega. As shown in the table, our model significantly outperforms our direct baseline RoBERTa with 4.2% improvements on unpaired accuracy and 4.3% improvements on paired accuracy. Our model also significantly outperforms GROVER-Large and other strong transformer-based baselines (i.e., GPT2, BERT, XLNet).

Model	Development Acc	Test Acc
Random	50.00%	50.00%
BERT	85.32%	85.10%
XLNet	88.79%	88.56%
RoBERTa	90.46%	90.10%
FAST	**93.10%**	**93.17%**

Table 3: Performance on the development and test set of webtext-style dataset in terms of binary classification accuracy. Our model is abbreviated as FAST.

In Table 3, we compare our model with baselines on the development set and the test set of webtext-style dataset. Our model significantly outperforms strongest transformer-based baseline RoBERTa by 2.64% on the development set and 3.07% on the test set of webtext-style GPT2-generated dataset.

This observation indicates that modeling fine-grained factual structures empower our system to discriminate the difference between human-written text and machine-generated text.

5.3 Ablation Study

Moreover, we also conduct ablation studies to evaluate the impact of each component by conducting experiments about direct baseline RoBERTa-Base and four variants of our full model.

- **RoBERTa-Base** is our direct baseline without considering any structural information.
- **FAST (GCN)** calculate a global document representation by averaging node representations after representation learning by GCN.
- **FAST (GCN w/o wiki)** The node representations eliminate entity representations from wikipedia2vec and the rest are the same as FAST (GCN).
- **FAST (GCN + LSTM)** takes the final hidden state from coherence tracking LSTM (§ 4.4) as the final document-level representation.
- **FAST (GCN + LSTM + NSP)** is the full model introduced in this paper.

As shown in Figure 4, adding GCN improve performance on the development the set of news-style dataset and webtext-style dataset. This verifies that incorporating fine-grained structural information is beneficial for detecting generated text. Eliminating wikipedia-based entity representation from FAST (GCN) drops performance, which indicates

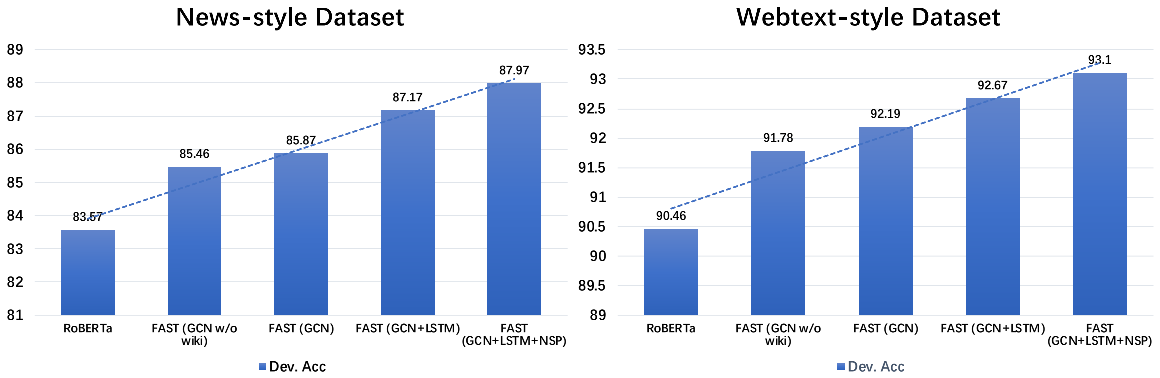

Figure 4: Ablation studies on the the development set of the two datasets in terms of binary classification accuracy.

that incorporating external knowledge is also beneficial. Moreover, incorporating coherence tracking LSTM brings further improvement on two datasets, which indicates that modeling consistency of factual structure of continuous sentences is better than simply using global structural information of the document, like the setting in FAST (GCN). Lastly, results also show that incorporating semantic coherence score of pre-trained NSP model is beneficial for discriminating generated text.

5.4 Case Study

As shown in Figure 5, we conduct a case study by giving an example. This example shows human-written news and machine-generated news with the same metadata (i.e., title). The veracity of both documents are correctly predicted by our model. With the given document, our system constructs a factual graph and makes the correct predictions by reasoning over the constructed graph. We can observe that although the continuous sentences in the machine-generated news look coherent, their factual structure is not consistent as they describe events about irrelevant entities. Instead, the human-written news has a more consistent factual structure. However, without utilizing factual structure information, RoBERTa fails to discriminate between these two articles. This observation reflects that our model can distinguish the difference in the factual consistency of machine-generated text and human-written text.

5.5 Error Analysis

To explore further directions for future studies, we randomly select 200 instances and manually summarize representative error types.

The **primary** type of errors is those caused by failing to extract core entities of sentences. The quality of a constructed graph is somehow limited by the performance of the NER model. This limitation leaves further exploratory space for extraction of internal factual structure. The **second** type of errors is caused by the weakness in the mathematical calculation of the model. For instance, a document describes that *"a smaller $5 million one-off was seized in 2016 and the National Bank of Antigua and Barbuda reclaimed $30 million stolen in the 2015 heist last year. $100 million, it was a massive amount. But now we are talking of $50 million, this is extremely conservative... "*. Humans can easily observe that the mentioned numbers are highly inconsistent in the generated text. A machine struggles to discern that. This error type calls for the development of a machine's mathematical calculation abilities. The **third** error type is caused by failing to model commonsense knowledge. For example, a famous generated document mentioned *"In a shocking finding, scientist discovered a herd of unicorns living in a remote, previously unexplored valley, in the Andes Mountains. ... These four-horned, silver-white unicorns were previously unknown to science."*. Although the text looks coherent, it is still problematic in terms of commonsense knowledge that "unicorn has only one horn". This leaves space for further research on exploring commonsense knowledge in deepfake detection.

6 Related Work

Recently, fake news detection has attracted growing interest due to the unprecedented amount of fake contents propagating through the internet (Vosoughi et al., 2018). Spreading of fake news arises public concerns (Cooke, 2018) as it may influence essential public events like politic elections (Allcott and Gentzkow, 2017). Online reviews can also be generated by machines, and

can even be as fluent as human-written text (Adelani et al., 2020). This situation becomes even more serious when recent development of large pre-trained language models (Radford et al., 2019; Zellers et al., 2019) are capable of generating coherent, fluent and human-like text. Two influential works are GPT-2 (Radford et al., 2019) and GROVER (Zellers et al., 2019), The former is an open-sourced, large-scale unsupervised language model learned on web texts, while the latter is particularly learned for news. In this work, we study the problem of discriminating machine-generated and human-written text, and evaluate on datasets produced by both GPT-2 and GROVER.

Advances in generative models have promoted the development of detection methods. Previous studies in the field of DeepFake detection of generated text are dominated by deep-learning based document classification models and studies about discriminating features of generated text. GROVER (Zellers et al., 2019) detects generated text by a fine-tuned model of the generative model itself. Ippolito et al. (2019) fine-tune the BERT model for discrimination and explore how sampling strategies and text excerpt length affect the detection. GLTR (Gehrmann et al., 2019) develops a statistical method of computing per-token likelihoods and visualizes histograms over them to help deepfake detection. Badaskar et al. (2008) and Pérez-Rosas et al. (2017) study language distributional features including n-gram frequencies, text coherence and syntax features. Vijayaraghavan et al. (2020) study the effectiveness of different numeric representations (e.g., TFIDF and Word2Vec) and different neural networks (e.g., ANNs, LSTMs) for detection. Bakhtin et al. (2019) tackle the problem as a ranking task and study about the cross-architecture and cross-corpus generalization of their scoring functions. Schuster et al. (2019) indicate that simple provenance-based detection methods are insufficient for solving the problem and call for development of fact checking systems. However, existing approaches struggle to capture fine-grained factual structures among continuous sentences, which in our observation is essential in discriminating human-written text and machine-generated text. Our approach takes a step towards modeling fine-grained factual structures for deepfake detection of text.

7 Conclusion

In this paper, we present FAST, a graph-based reasoning approach utilizing fine-grained factual knowledge for DeepFake detection of text. We represent the factual structure of a document as a graph, which is utilized to learn graph-enhanced sentence representations. Sentence representations are further composed through document-level aggregation for the final prediction, where the consistency and coherence of continuous sentences are sequentially modeled. We evaluate our system on a news-style dataset and a webtext-style dataset, whose fake instances are generated by GROVER and GPT-2 respectively. Experiments show that components of our approach bring improvements and our full model significantly outperforms transformer-based baselines on both datasets. Model analysis further suggests that our model can distinguish the difference in the factual structure of machine-generated and human-written text.

A Training Details of NSP Model

In this part, we describe the training details of our next sentence prediction model. The training data of the NSP model comes from the human-written component of the webtext-style dataset or the news-style dataset depending on which dataset we are running experiments on. We construct the dataset with balanced numbers of positive instances and negative instances. Supposing a positive instance is a continuous sentence pair "A; B" from the human-written text, we construct a negative instance "$A; C$", where C is the most similar sentence in the document of B.

We tackle this problem as a binary classification task. We fine-tune the RoBERTa-Large model with standard cross-entropy loss on the binary classification task. We apply AdamW as the optimizer for model training. We set the learning rate as 1e-5, batch size as 8, and set max sequence length as 128.

B Training Details of FAST Model

In this part, we describe the training details for our experiments. We employ cross-entropy loss as the loss function. We apply AdamW as the optimizer for model training. We employ RoBERTa-Base as the backbone of our approach. The RoBERTa network and graph-based reasoning model are trained jointly. We set the learning rate as 1e-5, warmup step as 0, batch size as 4 per gpu, and set max sequence length as 512. The training time for one epoch takes 2 hours on 4 P40 GPUs for the webtext-style dataset, and 20 minutes for the news-style dataset. We set the dimension of the contextual node representation as 100. The dimension of the wikipedia2vec entity representation is 100.

MultiCQA: Zero-Shot Transfer of Self-Supervised Text Matching Models on a Massive Scale

Andreas Rücklé and **Jonas Pfeiffer** and **Iryna Gurevych**
Ubiquitous Knowledge Processing Lab (UKP)
Department of Computer Science, Technische Universität Darmstadt
www.ukp.tu-darmstadt.de

Abstract

We study the zero-shot transfer capabilities of text matching models on a massive scale, by self-supervised training on 140 source domains from community question answering forums in English. We investigate the model performances on nine benchmarks of answer selection and question similarity tasks, and show that *all* 140 models transfer surprisingly well, where the large majority of models substantially outperforms common IR baselines. We also demonstrate that considering a broad selection of source domains is crucial for obtaining the best zero-shot transfer performances, which contrasts the standard procedure that merely relies on the largest and most similar domains. In addition, we extensively study how to best combine multiple source domains. We propose to incorporate self-supervised with supervised multi-task learning on all available source domains. Our best zero-shot transfer model considerably outperforms *in-domain* BERT and the previous state of the art on six benchmarks. Fine-tuning of our model with in-domain data results in additional large gains and achieves the new state of the art on all nine benchmarks.

1 Introduction

Semantic matching of two text sequences is crucial among a wide range of NLP problems, such as question answering (Nakov et al., 2017; Wang and Jiang, 2017) or semantic textual similarity (Cer et al., 2017). Due to the ubiquity of applications, it is crucial to study how to obtain re-usable text matching models that transfer well to *unseen* domains or tasks.

Zero-shot transfer of text matching models is particularly challenging in setups of non-factoid answer selection (Cohen et al., 2018; Tay et al., 2017; Feng et al., 2015; Verberne et al., 2010) and question similarity (Nakov et al., 2017; Lei et al., 2016). These tasks compare questions and answers, or two potentially related questions in community question answering (cQA) forums, FAQ pages, and general collections of text passages. In contrast to other text matching tasks in NLP, they compare texts of different lengths—e.g., answers can be long explanations or descriptions—and often deal with expert domains. This makes it difficult to transfer models across domains (Shah et al., 2018), and to apply common approaches such as universal sentence embeddings without further domain or task adaptations (Poerner and Schütze, 2019).

Non-factoid answer selection and question similarity are also particularly *promising* to study zero-shot transfer. Reasons are that (1) there exist a large number of domains, and (2) in-domain training data is often scarce. Previous work proposed domain adaptation techniques (Poerner and Schütze, 2019; Shah et al., 2018), training with unlabeled data (Rücklé et al., 2019b), and shallow architectures (Rücklé et al., 2019a). However, these approaches result in entirely separate models that are specialized to individual target domains. One model that is re-usable and targets zero-shot transfer in similar settings is the question-answer encoder of Yang et al. (2020), which has recently been evaluated in cross-domain settings for efficient answer sentence retrieval (Guo et al., 2020). However, they do not study zero-shot transfer with a *large* number of source domains, and they do not assess how to best combine them.

In this work, we address these limitations and are—to the best of our knowledge—the first to study the zero-shot transfer capabilities of re-usable text matching models with a large number of source domains in these challenging setups.

In the **first part**, we investigate the zero-shot transfer capabilities of 140 domain-specific text matching models to nine benchmark datasets. By leveraging self-supervised training signals of ques-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2471–2486,
November 16–20, 2020.

tion title-body pairs, we analyze a large number of models specialized on diverse domains. We utilize the training method provided by Rücklé et al. (2019b) and train adapter modules (Rebuffi et al., 2017; Houlsby et al., 2019) within BERT (Devlin et al., 2019) for *each* of the 140 English StackExchange forums. Adapters considerably reduce storage requirements by training only a small number of additional parameters while keeping the pre-trained BERT weights fixed. In our extensive analysis, we show that our approach for zero-shot transfer is extremely effective—on six benchmarks *all* 140 models outperform common IR baselines. Most importantly, we revisit and analyze the traditional strategy of leveraging large data sets from intuitively similar domains to train models for zero-shot transfer. We establish that *neither* training data size *nor* domain similarity are suitable for predicting the best models, stressing the need for more elaborate strategies to identify suitable training tasks. This also demonstrates that considering a broad selection of source domains is crucial, which contrasts the standard practice of merely relying on the most similar or largest ones.

In the **second** part of this work, we study how to best *combine* multiple source domains with multi-task learning and AdapterFusion (Pfeiffer et al., 2020a). Our analysis reveals that both approaches are not affected by catastrophic interference across training sets. In particular, our combination of *all* available source domains—despite the large data imbalances, see Figure 1—is the most effective and outperforms the respective best of 140 single-domain models on six out of nine bechmarks. Finally, we combine unlabeled with labeled data for training in a self-supervised and supervised fashion, which considerably improves the zero-shot transfer performances in 16 out of 18 cases. Our best model substantially outperforms the *in-domain* BERT and RoBERTa (Liu et al., 2019) models, as well as the previous state of the art on six benchmarks, which demonstrates its versatility across tasks and domains. We also show that our model is an effective initialization for in-domain fine-tuning, which results in large gains and achieves state-of-the-art results on all nine benchmarks.

Our source code and the weights of our best multi-task model is publicly available.[1] Additionally, all 140 source domain adapters are available at AdapterHub.ml (Pfeiffer et al., 2020b).

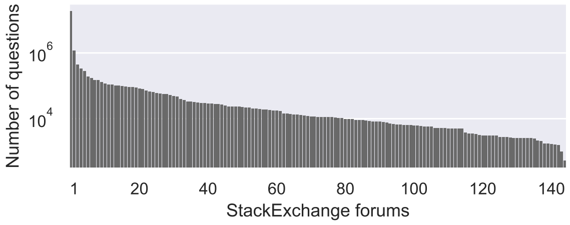

Figure 1: Number of questions in StackExchange forums (log scale) that can be used for self-supervision.

2 Related Work

The predominant method for text matching tasks such as non-factoid answer selection and question similarity is to train a neural architecture on a large quantity of labeled in-domain data. This includes CNN and LSTM models with attention (Tan et al., 2016; Dos Santos et al., 2016; Wang et al., 2016; Rücklé and Gurevych, 2017), compare-aggregate approaches (Wang and Jiang, 2017; Rücklé et al., 2019a), and, more recently, transformer-based models (Hashemi et al., 2020; Yang et al., 2020; Mass et al., 2019). Fine-tuning of large pre-trained transformers such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) currently achieves state-of-the-art performances on many related benchmarks (Garg et al., 2020; Mass et al., 2019; Rochette et al., 2019; Nogueira and Cho, 2019).

However, realistic scenarios often do not provide enough labeled data for supervised in-domain training. Thus, different recent work has focused on improving model performances in small data scenarios. Shah et al. (2018) use adversarial domain adaptation for duplicate question detection. Poerner and Schütze (2019) adapt the combination of different sentence embeddings to individual target domains. Rücklé et al. (2019b) use weakly supervised training, self-supervised training methods, and question generation. Similar approaches were also explored in ad-hoc retrieval (Zhang et al., 2020; Ma et al., 2020; MacAvaney et al., 2019). A crucial limitation of these approaches is that they result in entirely separate models for each dataset and are thus not re-usable. In this work, we therefore explore the zero-shot transfer capabilities of models, to understand how well they generalize to unseen settings.

Previous work of Yang et al. (2020) investigates this on a smaller scale. They propose USE-QA, a sentence encoder for comparing questions and

---

[1] `https://github.com/ukplab/emnlp2020-multicqa`

answers, and achieve promising zero-shot results in retrieval tasks. However, it is unclear how this model compares to the zero-shot performances of models trained on several different source domains and how best to combine the data from multiple domains. Other work addresses the generalization of models over several domains in different settings, e.g., for machine reading comprehension (Talmor and Berant, 2019; Fisch et al., 2019). More related to our work, Guo et al. (2020) propose a new evaluation suite with eight datasets for retrieval-based QA, in which they also study the effectiveness of USE-QA. In contrast to them, our work (1) deals with re-ranking setups and uses cross-encoders, which is different to their bi-encoder scenario for retrieval; (2) we deal with question and answer passages instead of answer sentences; (3) we study a large number of 140 source domains and provide important insights on zero-shot transfer performances in relation to domain similarity and data size, and extensively analyze the training of models on many source domains simultaneously.

3 Data and Setup

3.1 Training Data for 140 Domains

StackExchange is a network that consists of 172 cQA forums,[2] referred to as domains in the following, each devoted to a particular topic such as programming, traveling, finance, etc. From those 172 forums, 140 are in English and contain more than 1000 unlabeled questions.

We use data from each of these 140 English forums and train domain-specific models for semantic text matching. This has recently become feasible with self-supervised training methods such as *WS-TB* (Rücklé et al., 2019b), in which the question title is considered as a query to retrieve the question body (the detailed description of the question). This requires no labeled training instances and thus allows us to scale our experiments to 140 source domains which we can transfer from.

Formally, we train models with positive instances x^+ and negative training instances x^-:

$$x_n^+ = (\text{title}(q_n), \text{body}(q_n))$$
$$x_n^- = (\text{title}(q_n), \text{body}(q_m))$$

in which $q_n \neq q_m$. We randomly sample q_m from the entire corpus. For computational reasons, we use a maximum of 100k positive training instances. This training technique performs well for duplicate question detection and answer selection (Rücklé et al., 2019b), and similar methods have been used for ad-hoc retrieval (MacAvaney et al., 2019).

Table 1: The statistics of the evaluation benchmarks.

Our different domains are clearly separated by topic. Because not all domains are equally popular, the training sizes are heavily imbalanced, see Figure 1. This allows us to analyse the impact of data size in regard to the transfer performances.

3.2 Evaluation Benchmarks

We transfer all models to 9 benchmark datasets from different domains. We categorize them in two broad tasks, non-factoid answer selection and question similarity. See Table 1 for the statistics.

Answer selection (AS). The goal is to re-rank a pool of candidate answers A in regard to a question q. The questions in all datasets are short and do not contain additional descriptions (question bodies). Answers to non-factoid questions are often long texts such as descriptions, explanations, and advice.

- *InsuranceQA* (Feng et al., 2015) is a benchmark crawled from an FAQ community,[3] in which licensed insurance practitioners answer user questions. The domain is narrow and only contains questions about insurance topics in the US. We use the recent version 2 of the dataset with $|A| = 500$ candidate answers (retrieved with BM25). Typically, one answer is correct.
- *WikiPassageQA* (Cohen et al., 2018) was crowd-sourced from Wikipedia articles and is not restricted to a particular domain (although many questions are about history topics). Candidate answers are passages from a single doc-

---

[2] See `https://stackexchange.com/sites`. The data from all forums is publicly available `https://archive.org/details/stackexchange`

[3] `https://www.insurancelibrary.com/`

ument, on the basis of which the question was formulated. $|A| = 58$ of which 1.6 passages represent correct answers (on average).

- *Long Answer Selection (LAS)* datasets (Rücklé et al., 2019a) were crawled from apple, cooking, academia, travel, and aviation StackExchange forums. For a user question, its accepted answer is considered as correct, and negative candidates were collected by retrieving the accepted answers to similar questions (using a search engine with BM25). $|A| = 100$.

We measure mean average precision (MAP) on WikiPassageQA, and accuracy (P@1) otherwise.

Question similarity (QS). The goal is to re-rank a pool of potentially related forum questions C in regard to a query question q. All questions contain titles and bodies—which we concatenate—and are thus long multi-sentence texts. On all question similarity benchmarks we measure MAP.

- *SemEval17* (Nakov et al., 2017) refers to Task 3b of the SemEval 2017 challenge. This question similarity benchmark contains instances crawled from QatarLiving forums[4]. For each question q, $|C| = 10$ potentially related questions were retrieved with a search engine and manually labeled for relatedness in regard to q.
- *AskUbuntu* (Lei et al., 2016) is an extension of the dataset by Dos Santos et al. (2015), crawled from the AskUbuntu forum. The train split contains noisy community-labeled duplicate annotations, and the (smaller) dev/test splits were manually annotated for relevance. $|C| = 20$.

3.3 Models and Training

BERT models. We use a pointwise ranking architecture based on pre-trained language models. We concatenate the two input texts (separated with SEP token), and learn a linear classifier on top of the final CLS representation for scoring. We optimize the binary cross-entropy loss. Similar techniques achieve state-of-the-art results on many related datasets (Garg et al., 2020; Mass et al., 2019; Rücklé et al., 2019b).

For our zero-shot transfer experiments from single domains in §4, we use BERT base uncased (Devlin et al., 2019). Later in §5, we additionally investigate BERT large uncased and RoBERTa large (Liu et al., 2019). The hyperparameters for all setups are listed in Appendix A.1.

Training. We train our models with self-supervision, see §3.1. To obtain *in-domain models*, we fine-tune BERT with the respective training data of the benchmark datasets of §3.2. We train the models for 20 epochs with early stopping for in-domain BERT, and without early stopping for zero-shot transfer. We report the average result over five runs for the in-domain models in AskUbuntu and SemEval (due to small evaluation splits) and over two runs for the remaining benchmarks. Following Mass et al. (2019), we sample a maximum of 10 negative candidate answers for each question in WikiPassageQA (new samples in each epoch). For the LAS datasets we randomly sample 10 negative candidates from the corpus. For InsuranceQA and AskUbuntu, we randomly sample one negative candidate due to their larger training sizes.

Adapters. To reduce the storage requirements, and to efficiently distribute our models to the community, we train adapters (Houlsby et al., 2019; Rebuffi et al., 2017) instead of full fine-tuning for our 140 single-domain BERT models. Adapters share the parameters of a large pre-trained model—in our case BERT—and introduce a small number of task-specific parameters. With that, adapters transform the intermediate representations in every BERT layer to the training task while keeping the pre-trained model itself unchanged. We use the recent architecture of Pfeiffer et al. (2020a), which makes it possible to investigate their adapter combination technique AdapterFusion in §5. In preliminary experiments, we find that using adapters in contrast to full model fine-tuning does not decrease the model performance while drastically reducing the number of parameters (one model is ∼5 MB).

4 Zero-Shot Transfer from 140 Domains

In this section, we study the zero-shot transfer performances of all models (§4.1) and investigate whether domain similarity and training data size are suitable for predicting the best models (§4.2).

4.1 Results

In Figure 2, we show the zero-shot transfer to all nine benchmarks. Except for SemEval17, all results are for the dev split.[5] Diamonds ◇ show the performance of IR baselines[6] and in-domain BERT.

---

[4] `https://www.qatarliving.com/forum`

[5] SemEval17 does not contain a separate dev split.

[6] TF*IDF for LAS, BM25 for WikiPassageQA and InsuranceQA, and a search engine ranking for SemEval17 (which is the official challenge baseline).

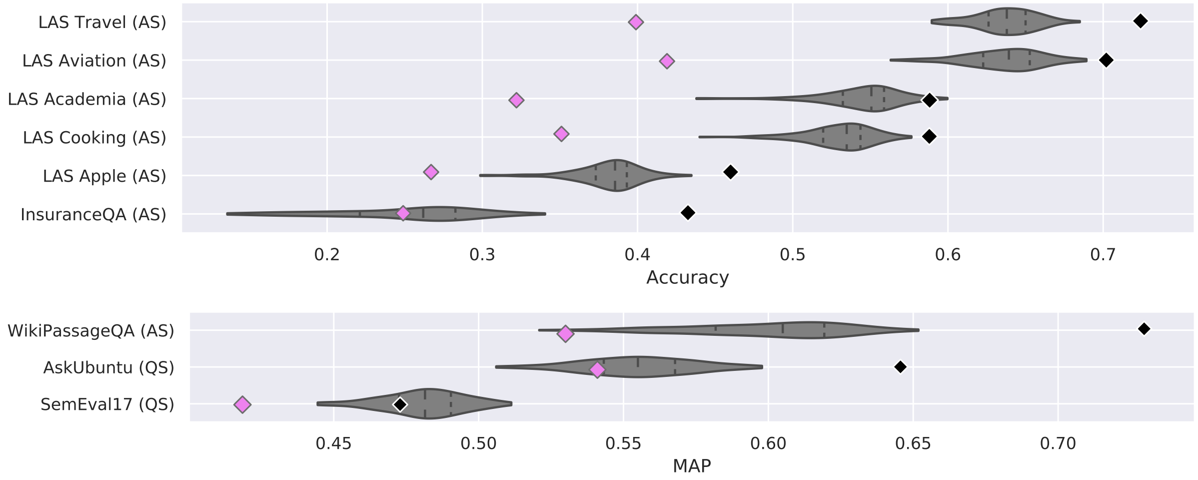

Figure 2: Zero-shot transfer performances of all 140 models to the evaluation benchmarks. For benchmarks that contain StackExchange data, we exclude the model from the respective source domain. The violin range visualizes the observed transfer scores, without extension or cut-off for extreme datapoints. Vertical lines show the mean and the quartiles. Diamonds show the performances of IR baselines (violet) and in-domain BERT models (black).

Zero-shot transfer vs. IR baselines. We observe that the wide range of domain-specific models transfer extremely well to all evaluation datasets. For instance, all models largely outperform IR baselines on six benchmarks. This suggests that learning a *general* similarity function in BERT for our type of data—i.e., short questions and long answers, or pairs of long questions—is important and indeed learned by the models. The low variances of the model performances, especially for more general domains such as Travel, Cooking, and SemEval17, indicate that the domain-specific factors either have a smaller impact, or were already learned during BERT pre-training. This is in line with recent work in ad-hoc retrieval, which showed that BERT models trained on tweets and Wikipedia data transfer surprisingly well to news articles (Akkalyoncu Yilmaz et al., 2019). Other work has shown that IR baselines are often hard to beat, e.g., most neural models trained in-domain on WikiPassageQA perform below BM25 (Cohen et al., 2018). In contrast, we show that a large number of BERT models from a variety of 140 domains outperform these baselines without requiring any in-domain supervision.

Zero-shot vs. in-domain models. BERT trained in-domain performs the best in most cases. The difference is larger for expert topics with big training sets (InsuranceQA, AskUbuntu), which shows that our setup provides a challenging test-bed for measuring the generalization capabilities of models. However, for target domains with few training instances (see Table 1), the differences of in-domain BERT to the best zero-shot transfer models are much smaller. Importantly, these setups pose crucial and realistic challenges for text matching approaches (Rücklé et al., 2019a,b). For instance, on SemEval17, this results in low performances for in-domain BERT. In contrast, our best zero-shot transfer model achieves a performance of 51.13 MAP—which is 2.13 points better than the best challenge participant in (Nakov et al., 2017).

This clearly demonstrates that zero-shot transfer is a suitable alternative for in-domain models, which also contrasts the large performance degradations often observed with traditional models such as LSTMs (Shah et al., 2018). Importantly, we find no substantial differences between question similarity and answer selection *tasks*, which are both not explicitly learned during training. We thereby take an important step towards overcoming the boundaries between individual tasks and domains.

4.2 Analysis

Due to the large number of 140 domain specific models, each trained on datasets of different sizes, we are able to perform unique analyses regarding the zero-shot transfer performances to target tasks.

Ideally, we would like to identify a small number of models that transfer well to a given dataset, without requiring costly evaluations of all models. In the following, we probe the two most commonly used domain selection techniques: (1) domain similarity and (2) training size, in regard to the transfer

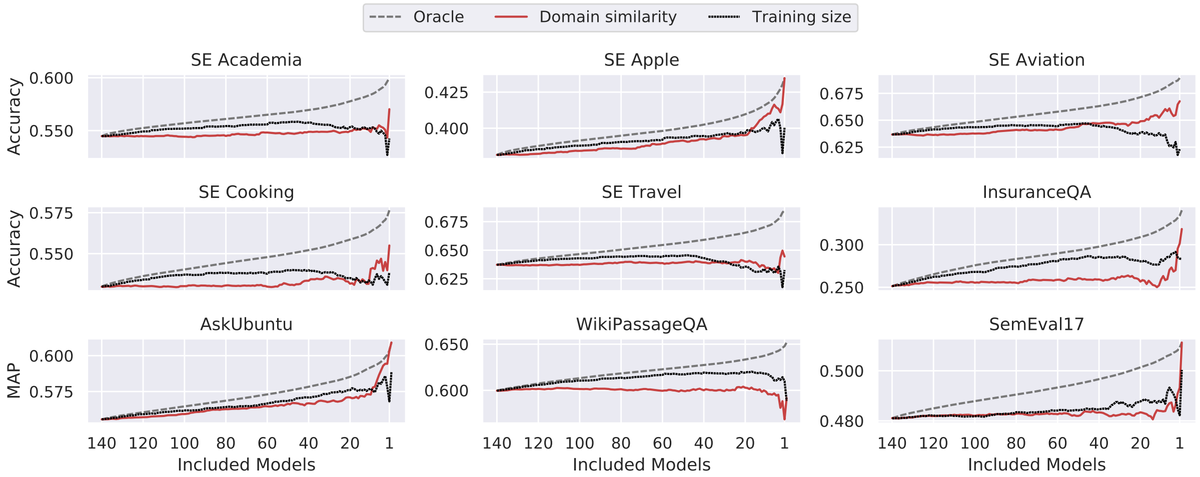

Figure 3: The average performance scores (y-axis) of subsets of models (x-axis) selected by domain similarity or training size (scores are averaged over the included models). The oracle always selects the best models.

performances. To simulate an optimal selection, we define an *oracle* that always identifies the best models. We present our findings in Figure 3.

Domain similarity. To measure the domain similarity, we embed the questions of all datasets with Sentence-RoBERTa (Reimers and Gurevych, 2019). For each dataset, we obtain the mean over all embeddings and calculate the domain similarity to other datasets with cosine similarity.

Domain similarity is most effective when selecting models for benchmarks of technical domains, e.g., AskUbuntu, LAS-Apple, and LAS-Aviation in Figure 3. However, this does not hold true for benchmarks of non-technical domains such as LAS-Travel or WikiPassageQA. In those cases, only considering the most similar source domains does not improve the average model performance. One reason might be that there do not exist many similar non-technical domains within StackExchange, from which models can transfer domain-specific idiosyncrasies. However, as we have shown in §4.1, such knowledge is not essential, i.e., a large number of models from more distant domains achieve good zero-shot transfer performances.

We provide examples of the best models and the most similar domains for three benchmarks in Table 2 (more are given in Appendix A.4). Many of the best models are from distant domains—e.g., ‘Ethereum’ for WikiPassageQA or ‘SciFi’ for LAS-Travel. This shows the importance of considering a broad selection of source domains, including ones that are not intuitively close.

Training size. The average performance of our models after removing the smallest domains improves more consistently (see WikiPassageQA and InsuranceQA in Figure 3). This shows, that the training size is more suitable for identifying models that achieve low performance scores—e.g., models that are trained on very narrow expert domains. However, the training size alone cannot identify the *best* models for zero-shot transfer. It is thus crucial to not limit the scope to the largest datasets at hand when exploring suitable training tasks. Importantly, this contrasts the common procedure of only including the largest domains for transfer (Shah et al., 2018).

Summary We have established that neither domain similarity nor training data size are suitable for predicting the best models. This shows that elaborate strategies are necessary for automatically identifying the most suitable training sets. Most importantly, we also demonstrate the importance of considering a broad selection of source domains instead of following the standard practice of merely relying on the most similar or largest domains. These insights could also be beneficial for researchers in related areas, e.g., to consider a wider range of domains and source datasets prior to domain adaptation.

5 Zero-Shot Transfer from Combinations of Multiple Domains

We now investigate how to best combine *multiple* source domains for zero-shot transfer. We denote our models as **MultiCQA**.

	Best Models	Most Similar Domains
LAS-Travel	scifi(40k, 0.61); money(18k, 0.64); diy(36k, 0.61); space(7k, 0.55); cooking(14k, 0.45);	expatriates(3k, 0.90); law(9k, 0.75); civicrm(7k, 0.75); eosio(1k, 0.73); expressionengine(7k, 0.73);
WikiPassageQA	politics(6k, 0.81); ethereum(16k, 0.61); physics(158k, 0.66); money(18k, 0.57); travel(24k, 0.60);	history(7k, 0.91); literature(2k, 0.84); movies(13k, 0.83); mythology(1k, 0.82); politics(6k, 0.81);
AskUbuntu	superuser(442k, 0.81); apple(61k, 0.79); blender(37k, 0.54); magento(70k, 0.54); electronics(85k, 0.52);	superuser(442k, 0.81); elementaryos(3k, 0.81); apple(61k, 0.79); unix(181k, 0.76); serverfault(288k, 0.76);

Table 2: The best models and the most similar domains for three benchmarks. Parentheses show the training size and the domain similarity (between 0 and 1). Underlined domains are in the top-5 of most similar and best models.

AU is AskUbuntu, IQA is InsuranceQA, WPQA is WikiPassageQA. Σ shows the average performance of benchmarks that use the same performance measure.

5.1 Setup

Combination methods. We use (1) multi-task learning and share all model layers across the domains. In each minibatch, we sample instances from a single source domain, which we select with a round-robin schedule. Models trained in this manner are denoted as **MT**.

In addition, we (2) combine knowledge from our domain adapters (§4) with AdapterFusion (**AF**; Pfeiffer et al., 2020a). This learns a weighted combination of multiple (fixed) adapters in each BERT layer and is typically trained on the target task. We adapt this approach to our zero-shot setup and train it with multi-task learning as above.[7]

Data. We use the training data of §3.1 and exclude the domains that are used in any of the evaluation datasets[8]. We use three sets of source domains: (1) the set of 18 topically **balanced** domains, consisting of the top-three domains (according to the number of questions asked) from each of the six broad categories as defined by StackExchange[9]; (2) the **largest** 18 domains according to the number of asked questions; (3) **all** included 134 domains.

We additionally study the impact of extending our training data with community-labeled instances from the source domains. For a positive instance of question title and body, we add positive instances of (a) question title and accepted answer, and (b) question title and body of a duplicate question. We name this **extended data**.

Models. If not otherwise noted, we fine-tune BERT base. We also experiment with BERT large and RoBERTa large (all uncased). For MultiCQA models this corresponds to MultiCQA^{B}, MultiCQA$^{B\text{-lg}}$, and MultiCQA$^{RBa\text{-lg}}$. The training procedure, number of runs, and hyperparameters are as in §3.3.

We additionally compare our models to the question/answer encoder USE-QA (Yang et al., 2020), which is a state-of-the-art model for retrieving answers in zero-shot transfer setups. The IR baselines are the same as in §4.1 (TF*IDF for LAS, BM25

---

[7] We use AdapterFusion without value matrix to avoid additional regularization as in (Pfeiffer et al., 2020a).

[9] Technology, culture, life, science, professional, and business. See Appendix A.5 for the list of included domains.

for WikiPassageQA and InsuranceQA, and a search engine ranking for SemEval17—the official challenge baseline).

5.2 Results

Multiple source domains. In Table 3, we show the results of MultiCQA$^{\mathrm{B}}$ with MT and AF for the different sets of source domains, and compare this to the respective best single-domain models of §4.

We observe that the balanced set of source domains achieves better results than combining domains with the largest training sets, which shows that diversity is more important than size. Most importantly, MT with data from *all* source domains outperforms the respective best single-domain model in 6 out of 9 benchmarks. This demonstrates that common problems of MT—catastrophic interference between training sets in particular—do not occur in our setup. This also reveals that combining source domains on a massive scale is possible.

MT and AF are both effective combination methods, with minor differences on most datasets. However, MT performs considerably better on InsuranceQA, which is a very narrow expert domain. The reason for this is that AF combines *fixed* domain-specific adapters, which can lead to reduced performances if all adapters are not related to the target domain. AF can also lead to better results, e.g., on LAS-Academia. We include an analysis of AF for these datasets in Appendix A.3, where we also visualize the learned fusion weights. Interestingly, we find that the fusion weights do not differ much between the two datasets. However, when we remove a single adapter, we also observe that AF automatically replaces it with another adapter from a similar source domain, indicating that this approach is robust.

Additional labeled data. In Table 3, we also see that extending the training data of MT models with additional labeled data from question-answer pairs and question duplicates considerably and consistently improves the performances in 16 of 18 cases. This improves the performance of MT all on *all nine benchmarks*, which shows that our approach is very effective when combining a large number of smaller domains. Due to these consistent improvements, we train all our large MultiCQA models with *MT all* and the extended data.

Comparison to in-domain models. In Table 4, we compare our large MultiCQA models to the in-domain state of the art. We find that the additional capacity of the models and the better initialization with RoBERTa considerably improves the zero-shot transfer performances (on average). Our best *zero-shot* MultiCQA$^{\mathrm{RBa\text{-}lg}}$ model outperforms USE-QA on eight benchmarks, and performs better than the previous *in-domain* state of the art on all LAS datasets and on SemEval17.

Our MultiCQA models are thus highly effective *and* re-usable across different domains and tasks. This clearly demonstrates the effectiveness and feasibility of training suitable models for zero-shot transfer that are widely applicable to different realistic settings.

Further in-domain fine-tuning. Finally, we show that MultiCQA$^{\mathrm{RBa\text{-}lg}}$ is an effective initialization for in-domain fine-tuning. This leads to large gains and achieves state-of-the-art results on all nine benchmarks.

6 Analysis

We manually inspect 50 instances of InsuranceQA and AskUbuntu for which our zero-shot transfer model MultiCQA$^{\mathrm{RBa\text{-}lg}}$ selects a wrong answer or an unrelated question. We find that the texts are always on-topic, i.e., many aspects of the question are included in the selected answers (InsuranceQA) or in the potentially similar questions (AskUbuntu). This includes keywords, phrases (often paraphrased), names, version numbers, etc. The most common source of error is that an important aspect of the question appears to be ignored or is (likely) not understood by the model. For instance, many aspects of the question might be mentioned in a potentially similar question on AskUbuntu, but in the wrong context. Table 5 shows an example of such a case, and we provide more examples and additional details in Appendix A.6. We find that this type of error affects 25 of 50 instances in AskUbuntu, and 10 of 50 instances InsuranceQA.[10]

Future work could thus achieve further improvements by enhancing the overall understanding of question and answer texts. Current models seemingly match similar keywords or phrases of the questions and answers, often without truly understanding them in context.

---

[10] In 8/50 cases in AskUbuntu and 30/50 cases in InsuranceQA our model actually selects relevant texts, e.g., correct answers or similar questions (which are not labeled as such).

7 Conclusion

We studied the zero-shot transfer of text matching models on a massive scale, with 140 different source domains and nine benchmark datasets of non-factoid answer selection and question similarity tasks. By investigating such a large number of models, we provided an extensive comparison and fair baselines to combination methods, and were able to extensively analyze a large sample size.

We have shown that (1) BERT models trained in a self-supervised manner on cQA forum data transfer well to all our benchmarks, even across distant domains; (2) training data size and domain similarity are not suitable for predicting the zero-shot transfer performances, revealing that a broad selection of source domains is crucial; (3) our MultiCQA approach that combines self-supervised and supervised training data across a large set of source domains outperforms many in-domain baselines and achieves state-of-the-art zero-shot performances on six benchmarks; (4) fine-tuning $\text{MultiCQA}^{\text{RBa-lg}}$ in-domain further improves the performances and achieves state-of-the-art results on all nine benchmarks.

We clearly demonstrated the effectiveness and the relevance of zero-shot transfer in many realistic scenarios and believe that our work lays foundations for a wide range of research questions. For instance, combining our approach with additional pre-training objectives such as the Inverse Cloze Task (Chang et al., 2020) could substantially increase the amount of training data for the large quantity of smaller forums. Researchers could also use our 140 domain-specific adapters and investigate further combination techniques to make them even more broadly applicable.

A Appendices

A.1 Hyperparameters

For computational and memory reasons we limit the maximum sequence length to 300 tokens (instead of the maximum of 512 in BERT) for all our models. Similar sequence lengths are commonly used on the benchmarks that we study (e.g., Mass et al., 2019; Tan et al., 2016).

For all experiments, we use a batch size of 32 and a linear warmup schedule over one epoch. We train all models for 20 epochs with early stopping of in-domain models, and without early stopping for zero-shot transfer.

For full model fine-tuning on SemEval17, we use a learning rate of 5×10^{-5}, due to the very small size of the data set. In all other cases with full model fine-tuning, we use learning rates that we optimized on WikiPassageQA and InsuranceQA. For this, we explored the manual selection of learning rates of 0.001, 0.0001, and 5×10^{-5}. The development scores on InsuranceQA are 43.25, 40.00, and 39.25 (accuracy), respectively. The development scores on WikiPassageQA are 72.69, 71.93, 72.26 (MAP), respectively. We thus chose 0.001 as a learning rate when fine-tuning BERT (and RoBERTa) models.

For the training of adapters and AdapterFusion, we use the learning rates as recommended in (Pfeiffer et al., 2020a), which are 0.0001 and 5×10^{-5}, respectively.

A.2 Computing Infrastructure

We used a heterogenous cluster with different types of GPUs for our experiments. Our most demanding experiments with RoBERTa-large were performed with one NVIDIA Tesla V100 GPU and 32GB memory (per experiment). To train the models with a batchsize of 32, we used accumulation of gradients over two smaller mini-batches of size 16. One epoch with all source domains trains for on average 97 minutes. The remaining experiments were split across NVIDIA Tesla V100/P100 GPUs (32GB), and NVIDIA Titan RTX (24GB).

A.3 AdapterFusion (AF) on LAS-Academia and InsuranceQA

AdapterFusion learns a weighted combination of adapter outputs in each BERT layer, which is dependent on the layer input. Similar to Pfeiffer et al. (2020a), we can thus plot the activations of the individual adapters for different benchmarks in order to analyze which source domains are most impactful. Further, this allows us to observe how the activations differ across different benchmarks.

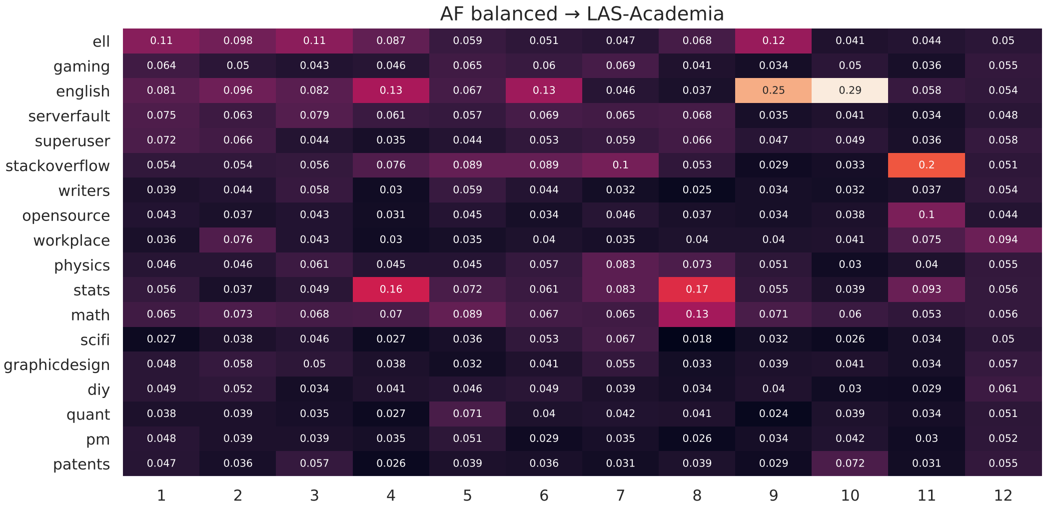
In Figure 4 and in Figure 5 we plot the activatations for *AF balanced* on LAS-Academia and on InsuranceQA, which were the best and worst transfer datasets of this approach, respectively (compared to MT; see §5.2). We find, that the activations are very similar across the two benchmarks, which indicates that our model learns to focus less on the model input. This shows that some adapters are better suited than others for individual BERT layers, e.g., the adapter for the ‘English’ domain dominates layers 9 and 10, and ‘OpenSource’ as well as ’StackExchange’ adapters dominate layer 11.

When transferring to the narrow expert domain InsuranceQA, interestingly, the same adapters are activated in BERT layers, with slightly different strengths as compared to LAS-Academia. This means that specific combinations of the same adapters are helpful for a variety of downstream tasks.

To investigate the impact of single most important adapters and how they affect the performance of AF, we *remove* the adapter of the *English* domain—which has the strongest activations in AF balanced—and plot the result for LAS-Academia in Figure 6. We observe that AF, now increases the activation of the ‘Ell’ (English language learners) adapter (see layer 9). This shows that AF has learned to utilize particular types of information encoded in adapters that exploit similar attributes, rather than combining a fixed selection of adapters. If, like in this scenario, the adapter is no longer available, AF extracts the information from other, similar adapters. This validates the effectiveness of AF as well as that different kinds of information are stored within the different layers of adapters.

A.4 Individual Transfer: Best Models and Most Similar Domains

We show the best models and most similar domains for all benchmark in Table 6 (we have provided an excerpt of that in Table 2 of the paper). In particular, we see that the best source domains vary across the different benchmarks. Often, the best models are not from intuitively close domains nor from domains with large training sets.



AF balanced → LAS-Academia

Table 6: The best models and the most similar domains for all benchmarks. Parentheses show the training size and the domain similarity (between 0 and 1). Underlined domains are in the top-5 of most similar and best models.

A.5 List of Domains in Combination Experiments

The list of all domains is available on the web: https://stackexchange.com/sites. We list the domains used for our two subsets in §5 below.

Balanced contains the top-3 domains (according to the number of asked questions) within the six broad categories as defined by StackExchange (technology, culture/recreation, life/arts, science, professional, business). The included domains are:

ell (English language learners), gaming, english, serverfault, superuser, stackoverflow, writers, opensource, workplace, physics, stats, math, scifi, graphicdesign, diy (do-it-yourself), quant (quantitative finance), pm (project management), patents

Largest contains the top-18 largest domains (according to the number of asked questions). The included domains are:

stackoverflow, math, superuser, serverfault, latex, unix, physics, statistics, electronics, gis (geographic information systems), english, salesforce, wordpress, magento, sharepoint, gaming, dba (database administrators), drupal

A.6 Examples of Wrong Predictions on InsuranceQA and AskUbuntu

We provide additional examples of mistakes made by $\text{MultiCQA}^{\text{RBa-lg}}$ (zero-shot transfer) on AskUbuntu and InsuranceQA to complement our brief analysis in Section 6.

Table 7 shows an additional example for AskUbuntu. The query question asks for the maximum number of CPUs that can be handled by a kernel. The selected similar question, however, asks for information *where* the kernel gets its information about the available CPUs—not the maximum possible number of CPUs. Tables 8 and 9 show examples of similar problems in InsuranceQA.

Query question: How many maximum CPUs does Ubuntu support by default? I think this is kernel dependent and probably will change over time depending on the kernel a release uses, correct me if wrong I'd like to know [...]
Most similar (MultiCQA$^{\text{RBa-lg}}$): Creation of /proc/stat. Which function of the kernel creates and writes the information for /proc/stat. In this, would like to know when kernel gets the CPU information (recognises number of CPUs) [...]
Ground truth: Ubuntu Linux 14.04 LTS server edition information need. I was wondering what's the maximum RAM, and maximum CPUs does the Ubuntu Linux 14.04 LTS server edition can handle [...]

Table 7: AskUbuntu example (shortened). This shows that our model mostly focuses on *number of CPUs* and *kernel* information instead of recognizing that the crucial information is the *maximum number*. We underline important aspects that differ.

Question: Can I buy a car without insurance?
Selected answer (MultiCQA$^{\text{RBa-lg}}$): You most certainly can get auto insurance without a car. if you needed toborrow, test drive, rent, or lease a vehicle for whatever reason you would purchase what is called a drive other car policy. [...]
Ground truth: Depending in the state you live in and also if your are financing the car. if you have a loan on the car the financial institution will require insurance before you even leave the car lot. if you are buying from a private party they may not require this but in most states you can not even get your license plates with out insurance.

Table 8: InsuranceQA example 1 (shortened). This shows that the model does not interpret the individual keywords within context, i.e., it does not differentiate between *car without insurance* and *insurance without car*. We underline important aspects that differ in the most similar candidate.

Query question: Why is state farm life insurance so expensive?
Selected answer (MultiCQA$^{\text{RBa-lg}}$): State farm offers life insurance, both term and permanent through their captive agents along with property and casualty insurance. However, unlike the latter types of coverage [...]
Ground truth: Every carrier has their own rates - these are based off a long calculation of actuarial values and mortality tables. Some carriers are more aggressive than others and are willing to take on more risk [...] more conservative carriers feature higher rates. So it's hard to say one carrier is just very expensive.

Table 9: InsuranceQA example 2 (shortened). The selected answer describes state farm life insurance, whereas the ground truth explains *why* it can be expensive. We underline important aspects that differ in the most similar candidate.

XL-AMR: Enabling Cross-Lingual AMR Parsing with Transfer Learning Techniques

Abstract

Abstract Meaning Representation (AMR) is a popular formalism of natural language that represents the meaning of a sentence as a semantic graph. It is agnostic about how to derive meanings from strings and for this reason it lends itself well to the encoding of semantics across languages. However, cross-lingual AMR parsing is a hard task, because training data are scarce in languages other than English and the existing English AMR parsers are not directly suited to being used in a cross-lingual setting. In this work we tackle these two problems so as to enable cross-lingual AMR parsing: we explore different transfer learning techniques for producing automatic AMR annotations across languages and develop a cross-lingual AMR parser, XL-AMR. This can be trained on the produced data and does not rely on AMR aligners or *source-copy* mechanisms as is commonly the case in English AMR parsing. The results of XL-AMR significantly surpass those previously reported in Chinese, German, Italian and Spanish. Finally we provide a qualitative analysis which sheds light on the suitability of AMR across languages. We release XL-AMR at github.com/SapienzaNLP/xl-amr.

1 Introduction

Abstract Meaning Representation (AMR) is a popular formalism for natural language (Banarescu et al., 2013). It represents sentences as rooted, directed and acyclic graphs in which nodes are concepts and edges are semantic relations among them. AMR unifies, in a single structure, a rich set of information coming from different tasks, such as Named Entity Recognition (NER), Semantic Role Labeling (SRL), Word Sense Disambiguation (WSD) and coreference resolution. Such representations are actively integrated in several Natural Language Processing (NLP) applications, *inter alia*, information extraction (Rao et al., 2017), text summarization (Hardy and Vlachos, 2018; Liao et al., 2018), paraphrase detection (Issa et al., 2018), spoken language understanding (Damonte et al., 2019), machine translation (Song et al., 2019b) and human-robot interaction (Bonial et al., 2020). It is therefore desirable to extend AMR semantic representations across languages along the lines of cross-lingual representations for grammatical annotation (de Marneffe et al., 2014), concepts (Conia and Navigli, 2020) and semantic roles (Akbik et al., 2015; Di Fabio et al., 2019). Furthermore, it could be especially useful to integrate cross-lingual semantic structures in multilingual applications of natural language understanding.

A peculiar feature of the AMR formalism is that it aims at abstracting away from word forms. AMR graphs are *unanchored*, i.e., the linkage between tokens in a sentence and nodes in the corresponding graph is not explicitly annotated. Hence, the feature of being agnostic about how to derive meanings from strings makes AMR particularly suitable for representing semantics cross-lingually. However, AMR was initially designed for encoding the meaning of English sentences. Owing to this, the available resources and modelling techniques focus mostly on English, while leaving cross-lingual AMR understudied. Some preliminary studies showed the limits of AMR as an interlingua, categorizing them as due to distinctions in the underlying ontologies or structural divergences among languages (Xue et al., 2014; Hajič et al., 2014). More recent studies, instead, have provided evidence that AMR or a simplified version of it can be used as a formalism for cross-lingual semantic representation, showing that it is possible to overcome some of the structural linguistic divergences (Damonte and Cohen, 2018; Zhu et al., 2019).

The underlying idea of this paper is that AMR can be used to represent semantic information in

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2487–2500,
November 16–20, 2020. ©2020 Association for Computational Linguistics

different languages since there exist key linguistic features that are shared across languages, such as predicates, roles and conjunctions (Von Fintel and Matthewson, 2008). However, developing an AMR parser for multiple languages is hard because the existing annotated training resources that are sufficiently large are available in English only, and, moreover, acquiring semantic annotations for a large number of sentences is well-known to be a slow and expensive process in NLP (Zhang et al., 2018; Pasini, 2020). To this end, we aim at exploiting and developing the necessary tools and resources for enabling cross-lingual AMR parsing, i.e., the task of transducing a sentence in the source language into an AMR graph based on English (Damonte and Cohen, 2018).

We present XL-AMR, a cross-lingual AMR parser, and study different transfer learning techniques to enable its training: i) model transfer which relies on language-independent features, ii) annotation projection relying on parallel corpora and available English AMR parsers, and iii) automatic translation of the training corpora which guarantees gold AMR structures. We make the following contributions:

- We develop and release XL-AMR, a cross-lingual AMR parser which disposes of word aligners, i.e., word-to-word and word-to-node, and surpasses the previously reported results on Chinese, German, Italian and Spanish, by a large margin.
- Exploration of different techniques to create cross-lingual AMR training data, showing how it is possible to transfer semantic structure information across different languages.
- Creation and release of diverse quality silver data for cross-lingual AMR parsing.
- Qualitative analysis of the ability of XL-AMR to transfer semantic structures across languages and of AMR to represent the meaning of sentences cross-lingually.

2 Related Work

Our work lies between two areas, namely, semantic parsing and cross-lingual transfer learning.

Semantic parsing Semantic parsing is a key task required to complete the puzzle of Natural Language Understanding (Navigli, 2018), and one which is receiving growing attention in the scientific community. Besides AMR, various different formalisms have been proposed over the years to encode semantic structures: Elementary Dependency Structures (Oepen and Lønning, 2006, EDS), Prague Tectogrammatical Graphs (Hajič et al., 2012, PTG), Universal Conceptual Cognitive Annotation (Abend and Rappoport, 2013, UCCA), Universal Decompositional Semantics (White et al., 2016, UDS), *inter alia*. While some frameworks, such as UCCA and UDS, have been exploited in a cross-linguistic setting (Lyu et al., 2019; Zhang et al., 2018), cross-lingual AMR has mainly been studied within the scope of annotation analysis works (Xue et al., 2014; Hajič et al., 2014). These works point out the limitations of AMR as an interlingua, and consider them partly due to the distinctions in the underlying ontologies and structural divergences among languages. Zhu et al. (2019) also evaluate the properties of AMR across languages and aim at simplifying this formalism in order to express only essential semantic features of a sentence, such as predicate roles and linguistic relations. Cross-lingual AMR *parsing*, instead, has received relatively less attention. This is largely attributable to the lack of training data and evaluation benchmarks in languages other than English. Damonte and Cohen (2018) propose, to the best of our knowledge, the only cross-lingual AMR parser to date and, moreover, their proposed cross-lingual AMR evaluation benchmark has been released only very recently (Damonte and Cohen, 2020). The authors adapt a transition-based English AMR parser (Damonte et al., 2017) for cross-lingual AMR parsing, which is trained on silver annotated data. However, the performances it has achieved are not satisfying in terms of Smatch score (Cai and Knight, 2013), mostly as a result of concept identification errors, which in turn are directly related to the usage of noisy word-to-node alignments projected from English. Throughout the literature English AMR parsers commonly rely on AMR alignments which are automatically created using heuristics (Flanigan et al., 2014), or on pretrained aligners (Pourdamghani et al., 2014; Liu et al., 2018), treated as latent variables of the model (Lyu and Titov, 2018) or implicitly modelled through *source-copy* mechanisms (Zhang et al., 2019). These alignments, however, take advantage of the fact that AMR nodes and English words are highly related.[1] This dependency is therefore not suitable for cross-lingual parsing since similarity between words in

---

[1] In AMR 2.0 roughly 60% of the nodes are English words. In addition, PropBank predicates are often similar to English words, e.g., one can heuristically align *publish-01* to *publish*.

the sentences and concepts in the graph does not hold at large. Our parser, instead, disposes of explicit and implicit AMR alignments using a *seq2seq* model for concept identification and achieves significantly higher performance on all the tested languages. On the other hand, to account for data sparsity, XL-AMR employs several common techniques in English AMR parsing literature (Konstas et al., 2017; Zhang et al., 2019), such as anonymization and recategorization, expanding them across languages by relying on multilingual resources.

Transfer learning The idea behind this method is to leverage annotations available in one language, commonly English, to enable learning models that generalize to languages where labelled resources are scarce (Ruder et al., 2019). Different techniques include annotation projection, machine translation and language-independent feature-based models. Extensive works in this direction exist, applied to different NLP tasks, i.e., WSD (Barba et al., 2020), SRL (Padó and Lapata, 2009; Kozhevnikov and Titov, 2013), Dependency Parsing (Tiedemann, 2015), concept representation (Conia and Navigli, 2020), etc. In cross-lingual AMR parsing, annotation projection is employed by Damonte and Cohen (2018), who produce cross-lingual silver AMR annotations by exploiting parallel sentences selected from the Europarl corpus (Koehn, 2005): English sentences are parsed using an English parser (Damonte et al., 2017, AMREAGER) and the resulting graphs are associated with the corresponding parallel sentences. However, the data on which AMREAGER was trained is very different from those used to produce the silver annotations, thus affecting the quality and reliability of the AMR graphs produced. Here we test two different techniques: we conduct experiments with annotation projection using Europarl for comparison, and, in addition, we use translation techniques to produce better quality training corpora. This leads to significant improvements and provides evidence that better quality data – and models – allow for using AMR as an interlingua.

3 Cross-Lingual AMR

In what follows we first formalize the task (Section 3.1) and then detail our cross-lingual AMR parser (Section 3.2) and our proposed silver data creation methods (Section 3.3). Finally, we list the pre- and postprocessing cross-lingual techniques and resources we employ (Section 3.4).

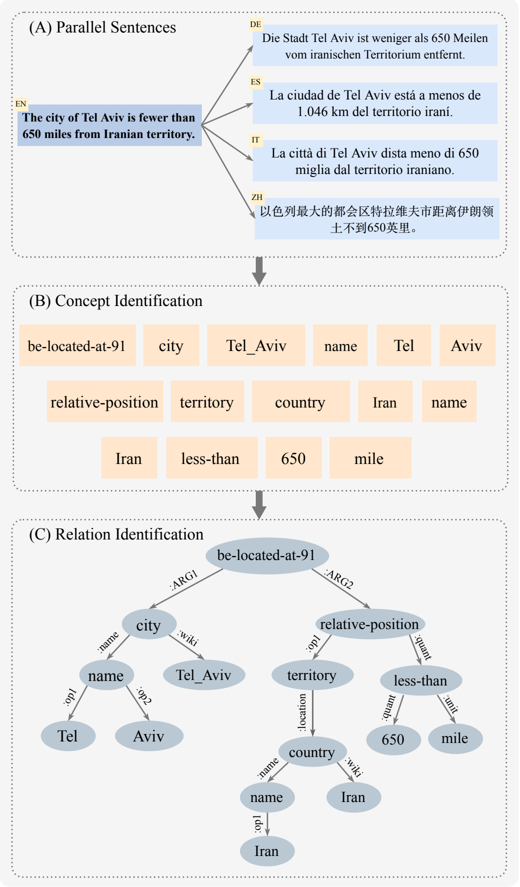

Figure 1: Cross-Lingual AMR Parsing: (A) Sentences written in different languages sharing the same meaning; (B) concepts representing the words in the sentences; (C) the final AMR graph.

3.1 The Task

Cross-lingual AMR parsing is defined as the task of transducing a sentence in any language to the AMR graph of its English translation whose nodes are either English words, PropBank framesets (Kingsbury and Palmer, 2002) or special AMR keywords.

Breaking down this definition, given an English sentence and its translation T_L in a language L, their meaning representation is ideally formalized by the same AMR, $G = (V, E)$, where V is a list of concept nodes and E is the set of semantic relations between them. Figure 1-A shows an example of a sentence in English, with its translations into Chinese, German, Italian and Spanish which have the same meaning and therefore the same abstract representation (Figure 1-C). Following state-of-the-art models for English AMR parsing (Zhang et al., 2019), we tackle cross-lingual AMR parsing as a two-stage approach, i.e., concept and relation identification, which we briefly overview here and later detail in Section 3.2. For concept identification, given the sequence $T_L = (t_1, t_2, \dots, t_j)$, t_i being a word in language L ($i \in \{1, \dots, j\}$, $L \in \{\text{EN, DE, ES, IT, ZH}\}$), we train a neural network to generate the list of nodes $V = (v_1, v_2, \dots, v_n)$, $v_i \in$ English words $\cup$ PropBank framesets $\cup$ AMR keywords. In Figure 1-B we show the list of concepts that represent the words in the sentences of Figure 1-A. The relation identification procedure, instead, is inspired by the arc-factored approaches employed in dependency parsing (Kiperwasser and Goldberg, 2016), i.e., searching for the maximum-scoring connected subgraph over the identified concepts in the previous step. Thus, given the list of predicted nodes $V = (v_1, v_2, \dots, v_n)$ and a learned score for each candidate edge, we search for the highest-scoring spanning tree and then merge the duplicate nodes based on unique node indices (see Section 3.2) to restore the final AMR graph. Figure 1-C shows the AMR representing the shared semantics of the sentences in Figure 1-A.

3.2 XL-AMR Model

XL-AMR is composed of two modules which are learned jointly, i.e., concept identification, modeled as a *seq2seq* problem, and relation identification, based on a biaffine attention classifier (Dozat and Manning, 2017). We use a *seq2seq* model to dispose of the need for an AMR alignment module. Lyu and Titov (2018) argue that alignments are important for injecting a useful inductive bias for AMR parsing and maintain that alignment-based parsers might be better than *seq2seq* for AMR parsing, owing to the relatively small amount of data available for AMR. However, aligning words to AMR nodes in cross-lingual parsing is challenging. The widely used AMR aligners are usually based on heuristics (Flanigan et al., 2014), or on the fact that AMR and English are highly cognate (Pourdamghani et al., 2014). Hence, these approaches would not be valid for cross-lingual alignment and, moreover, projecting the alignments across languages through English has shown to be noisy and to affect the parsing performance (Damonte and Cohen, 2018).

Concept identification At training time we obtain the list of nodes by first converting the graph into a tree, duplicating the nodes occurring in multiple relations, and then using a pre-order traversal over the tree. To account for reentrancies we assign a unique index to each node during traversal, similarly to Zhang et al. (2019). Following the attention-based encoder-decoder architecture proposed by Bahdanau et al. (2015), our concept identification module consists of a bidirectional RNN encoder and a decoder that attends to the source sentence at each concept decoding step.

The *encoder* employs an L-layer bidirectional RNN (Schuster and Paliwal, 1997) with LSTM cells (Hochreiter and Schmidhuber, 1997), i.e., BiLSTM, which encodes the input token embeddings e_i into hidden states h_i. Each hidden state $h_i^l = [\overrightarrow{h_i^l}; \overleftarrow{h_i^l}]$, is a concatenation of the forward hidden state and the backward hidden state at timestep i. Similarly to Zhang et al. (2019), the input token embedding e_i is a concatenation of contextualized embeddings, word embeddings, Part-of-Speech (PoS) embeddings, token anonymization indicator[2] and character-level embeddings. The subsequent BiLSTM layer, instead, takes the hidden states of the previous layer as input.

The *decoder* also consists of L recurrent neural network (unidirectional) layers with LSTM cells. The decoder embedding layer concatenates word embeddings, node index embeddings and character-level embeddings. The layer l of the decoder calculates $d_t^l = decoder_l(d_t^{l-1}, d_{t-1}^l)$, where d_t^{l-1} is the concept hidden state of the previous layer at timestep t while d_{t-1}^l that of previous timestep. d_0^l is initialized with the concatenation of the encoder's last hidden states $h^l = [\overrightarrow{h^l}; \overleftarrow{h^l}]$. We follow the *input feeding* approach of Luong et al. (2015), which concatenates the output of the decoder's embedding layer and an attentional vector computed at the previous timestep. We first compute the *source attention distribution* a_t using additive attention (Bahdanau et al., 2015) as follows:

$$
\begin{aligned}
e_{t,i} &= v^\top \tanh(W_h h_i^L + W_s d_t^L + b_s) \\
a_t &= \text{softmax}(e_t) \\
c_t &= \sum_i a_{t,i} h_i
\end{aligned}
$$

where v, W_h, W_s and b_s are model parameters, and c_t is the source context vector. Then, we compute the attentional vector, $\tilde{d}_t = \tanh(W_c[c_t; d_t^L] + b_c)$, where W_c and b_c are model parameters.

Zhang et al. (2019) used the attentional vector to allow the decoder to copy nodes predicted in the previous steps (*target-copy*), rather than only

---

[2] Tokens representing named entities are anonymized during preprocessing and restored in postprocessing (Section 3.4).

generating a new node from the vocabulary. As they provide empirical evidence that this is crucial for handling reentrancies, we employ their *target-copy* approach and use the attentional vector $\tilde{d}_t$ to i) feed in a dense layer and softmax to produce a probability distribution over the vocabulary $P_{vocab} = \text{softmax}(W_{vocab}\tilde{d}_t + b_{vocab})$, ii) to learn a *target attention distribution* $\hat{a}_t$ (similar to the *source attention distribution* above), iii) to calculate p_{copy} and $p_{generate}$ probabilities that decide either to copy one of the previously predicted nodes by sampling a node from the *target attention distribution* $\hat{a}_t$, or to generate a new node from the output vocabulary. Each newly generated node is assigned a unique index, or it is assigned the index of the node copied from the previously generated concepts. At prediction time, we employ a beam search to decode the list of nodes based on the probability distribution computed above.

Relation identification For this module, we follow Zhang et al. (2019) and use a deep biaffine classifier inspired by Dozat and Manning (2017), which takes as input the decoder states and factorizes the edge prediction in two components predicting i) whether there is an edge between a pair of nodes, and ii) the edge label for each possible edge, respectively. We direct the reader to Zhang et al. (2019) and Dozat and Manning (2017) for technical details on the biaffine attention classifier. At prediction time, to ensure the validity of the tree, given the list of predicted nodes and the score for candidate edges, we search for the highest-scoring spanning tree using the Chu-Liu-Edmonds algorithm. We then merge the duplicate nodes based on the node indices to restore the final AMR graph. The model is trained to jointly minimize the loss of reference nodes and edges.

3.3 Silver Training Data

In order to train cross-lingual AMR parsers and to evaluate the cross-lingual properties of AMR as an interlingua, we project existing AMR annotations for English sentences to target language sentences following two different approaches.

Parallel sentences - silver AMR graphs We follow Damonte and Cohen (2018) and project AMR graphs from English sentences to target language sentences through a parallel corpus. Differently from Damonte and Cohen (2018), we do not need *word-to-word* and *word-to-node* aligners for training the concept identification module. Instead we directly pair a sentence in the target language with the AMR graph corresponding to its English counterpart. In this case, while the sentences are parallel, the AMR graphs are of silver standard quality, i.e., the English sentences of the parallel corpus are parsed using an existing AMR parser. We refer to this method as PARSENTS-SILVERAMR.

Gold AMR graphs - silver translations In addition to pivoting through parallel sentences, we investigate whether considering human-annotated AMR graphs could bring more benefits than system produced AMR graphs. To this end, we make use of the existing gold standard datasets for AMR parsing, i.e., English sentence-AMR graph pairs, and use machine translation systems to translate the training sentences into the target language. This choice is motivated by the existence of reliable machine translation systems for the languages of our interest. Moreover, we validate the silver translations through a back-translation step (Sennrich et al., 2016). That is, firstly, we translate the sentences from English to the target language and, secondly, using the same neural translation model, we translate the target language translations back to English. Then, to filter out less accurate translations we apply a 1-NN strategy based on the cosine similarity between translations and source sentence semantic embeddings, similarly to Artetxe and Schwenk (2019a). If the nearest neighbour of a translation corresponds to its source English sentence, we consider it a good translation, otherwise we discard it. We employ semantic similarity since we have a two-step automatic translation, due to which lexical differences are introduced into translations compared to the original sentence. Typical machine translation metrics, e.g., BLEU, METEOR, rely on lexical similarity, which could lead good translations being discarded. In fact, we do not need the translation to be word-to-word aligned, but rather to preserve the meaning of the sentence, thus considering valid also the cases when certain words are translated into synonyms or related words. We refer to this method as GOLDAMR-SILVERTRNS.

3.4 Pre- and Postprocessing

AMR parsers in the literature rely on several pre- and postprocessing rules. We extend these rules for the cross-lingual AMR parsing task based on several multilingual resources such as Wikipedia, BabelNet 4.0 (Navigli and Ponzetto, 2010), DBpedia Spotlight API (Daiber et al., 2013) for wikifi-

Dataset	Lang	Train Insts	Dev Insts	Source

	ES	34552	1325	AMR 2.0
	IT	34521	1322	AMR 2.0
	ZH	32154	1276	AMR 2.0

Table 1: Dataset quality standard, instances per language, and the source corpus of the sentences.

cation in all languages but Chinese, for which we use Babelfy (Moro et al., 2014) instead, Stanford CoreNLP (Manning et al., 2014) for English preprocessing pipeline, the Stanza Toolkit (Qi et al., 2020) for Chinese, German and Spanish sentences, and Tint[3] (Aprosio and Moretti, 2016) for Italian.

The preprocessing steps consist of: i) lemmatization, ii) PoS tagging, iii) NER, iv) re-categorization of entities and senses, v) removal of wiki links and polarity attributes. The postprocessing steps consist of restoring i) anonymized subgraphs, ii) wikification, iii) senses, iv) polarity attributes. We give full details on pre- and postprocessing in Appendix A.

4 Experiments

We now present a set of experiments for cross-lingual AMR parsing when using different training techniques and the silver data we created (see Section 3.3). We discuss the results of our multiple settings and compare with previous approaches performing cross-lingual AMR parsing.

Test bed We evaluate on the *Abstract Meaning Representation 2.0 - Four Translations* (Damonte and Cohen, 2020), a corpus containing translations of the test split of 1371 sentences from the LDC2017T10 (AMR 2.0), in Chinese (ZH), German (DE), Italian (IT) and Spanish (ES). This data is designed for use in cross-lingual AMR parsing (available to all LDC subscribers).

Dataset In Section 3.3, we explained the two projection approaches for obtaining cross-lingual AMR data, i.e., PARSENTS-SILVERAMR and GOLDAMR-SILVERTRNS.

For the first approach, inspired by Damonte and Cohen (2018), and for comparison purposes, we choose Europarl as parallel corpus.[4] We predict the silver AMR using the model of Zhang et al. (2019).

For the second approach, instead, i.e., GOLDAMR-SILVERTRNS, we choose AMR 2.0 as gold dataset and translate the sentences into Chinese, German, Italian and Spanish. For German, Italian and Spanish, for both translating and back-translating the sentences we use the machine translation models made available by Tiedemann and Thottingal (2020, OPUS-MT).[5] For Chinese, instead, since OPUS-MT does not provide translation models, we employ the released MASS[6] (Song et al., 2019a) supervised neural translation models. Then, to filter out less accurate translations, we compute the cosine similarity between dense semantic representations of the original English sentence and its back-translated counterpart. To embed the sentences we use LASER (Artetxe and Schwenk, 2019b), a state-of-the-art model for sentence embeddings. Details on the number of instances per language and for each silver data approach are shown in Table 1.

Training configurations We conduct experiments following different training approaches:

- **Zero-shot** – the model is trained on English sentences only, relying on multilingual features, and is evaluated on all the target languages (henceforth $\emptyset$-shot).
- **Language-specific** – the model is trained only on target language data, i.e., DE, ES, IT or ZH, and evaluated in the same language.
- **Bilingual** – the model is trained on English data and one of either DE, ES, IT or ZH, and evaluated in the target language.
- **Multilingual** – the model is trained on data from all available languages per setting and evaluated on the target languages.

Systems We denote the variations of XL-AMR, based on the above training configurations, as XL-AMR^{data} where, $data \in \{par, trans, amr\}$, par referring to the data produced with PARSENTS-SILVERAMR approach, $trans$ to GOLDAMR-SILVERTRNS approach, amr to the AMR 2.0 English gold standard, and $data$+ refers to combining par or $trans$ with amr. The only existing cross-lingual AMR parser from the literature to date is

---

[3] Stanza does not provide a NER model for Italian.

[4] We do not produce silver AMR graphs for Chinese since Europarl does not cover the Chinese language.

[5] We provide the list of models we used in Appendix B.

Table 2: Smatch F1 scores on DE, ES, IT and ZH. Best scores per language are denoted in **bold**.

the one of Damonte and Cohen (2018, AMREAGER Multilingual), henceforth AMREAGER. We compare the results of the XL-AMR variants with the projection method of AMREAGER on the gold dataset, i.e., AMR *2.0 - Four Translations*. We remark that we do not consider the results of their Machine Translation[7] method, since, as emphasised by the authors, it is not informative in terms of cross-lingual properties of AMR (Damonte and Cohen, 2018) because it performs English AMR parsing. We provide details of our model hyperparameters in Appendix C.

Results In Table 2 we show the Smatch[8] score of the models. This metric computes the degree of overlap of two AMR graphs (Cai and Knight, 2013).

We point out the low score of the $\emptyset$-shot models, i.e., XL-AMR$_{\emptyset}^{amr}$ and XL-AMR$_{\emptyset}^{par+}$, which perform lower than AMREAGER, especially in the Chinese language. However, XL-AMR$_{\emptyset}^{par+}$ noticeably improves over XL-AMR$_{\emptyset}^{amr}$, which can be explained by the fact that *seq2seq* requires a large amount of data in order to generalize. This is confirmed by a fine-grained analysis showing lower accuracy of XL-AMR$_{\emptyset}^{amr}$ compared to XL-AMR$_{\emptyset}^{par+}$ in concept identification, which, we recall, is a *seq2seq* module.

Interestingly, the language-specific XL-AMR^{par}, even if trained on less instances, outperforms the $\emptyset$-shot models by a large margin. Moreover, it also surpasses AMREAGER, which is trained on the same sentences from Europarl. The results are further improved when jointly training in multiple languages, i.e., when using the multilingual and bilingual configurations. We attribute this improvement to the ability of a *seq2seq* model to learn better when provided with a larger training set. The domain of the Europarl data is very specific, which does not enable the model to generalize in sentences from other domains. In fact, the XL-AMR^{par+} models significantly improve over the XL-AMR^{par} bilingual and multilingual models. We attribute the higher performances of XL-AMR^{par+} to i) larger training dataset, ii) training on different domains, and iii) better quality of the data (AMR 2.0 data is human annotated).

The XL-AMR^{trans} models perform best: we note that the performances of the language-specific variants outperform those of the multilingual XL-AMR^{trans} models, in contrast to the behaviour of the XL-AMR^{par} models, suggesting that the addition of silver data in other languages is not beneficial. This may be due to the fact that the AMR graphs of translated sentences are the same, thus as a consequence the model does not access extra information. Moreover, the inclusion of translated sentences in other languages slightly harms the performances. This is confirmed by the removal from the training set of the most distant language, in the multilingual (-ZH) model, which in turn achieves around 2 F1 points more compared to the multilingual version including Chinese. This can be further explained by the linguistic differences between Chinese and the other languages, which prevent them from benefiting from the inclusion of Chinese instances in the training set. However, when adding English gold AMR 2.0, i.e., XL-AMR^{trans+}, the model benefits from the better quality of this dataset. In fact, the bilingual version of XL-AMR^{trans+} is the best performing across the board in German, Spanish and Italian, surpassing AMREAGER by at least 14 F1 points and both XL-AMR^{par} and XL-AMR^{par+} by at least 5 F1 points in each language. Interestingly, the best results in Chinese are achieved by the language-specific XL-AMR^{trans} surpassing AMREAGER by 8 F1 points and the $\emptyset$-shot models by more than 17 F1 points. This is once again explained by the linguistic differences of Chinese as compared to the other languages, which render the additional data non-beneficial. Table 3 shows the fine-grained evaluation of AMREAGER and our best performing models for each data creation approach, for which we

---

[7] It translates the test sentences from the target language to English and parses the translations using an English parser.

Table 3: Fine-grained F1 scores DE, ES, IT and ZH. Best scores per language are denoted in **bold**.

use the evaluation tools[9] of Damonte et al. (2017). The fine-grained results for the AMREAGER are not reported by Damonte and Cohen (2018), therefore we run the evaluation using their released models.[10] Our best model outperforms AMREAGER in all subtasks except for *Negations* in German and *Named Entities* in Chinese, which are prone to heuristic string matching errors in the pre- and postprocessing procedure of our models. XL-AMR^{trans+} achieves significantly higher performance in *Reentrancies*, *Concepts*, *SRL*, in all the tested languages, compared to AMREAGER, thus demonstrating the effectiveness of our parser and data creation approaches.

In summary, translating the gold standard training data, i.e., GOLDAMR-SILVERTRNS, leads XL-AMR to achieve higher performances than when trained on parallel sentences associated with silver AMR graphs, i.e., PARSENTS-SILVERAMR.

5 Qualitative Analysis

We manually check the predictions of XL-AMR in order to establish the nature of the mistakes based on the Smatch score between the gold and predicted AMR graphs and determine their severity. Then, we observe how XL-AMR handles the translation divergences, i.e., linguistic distinctions that make transfer across languages difficult (Dorr, 1994).

Smatch errors The parser has difficulties with some compounded words in German, e.g., *Uranproduktionsfähigkeit* (*uranium production capability*), *Kernkraftstoffkreislauf* (*nuclear fuel cycle*), for which it fails to break their meaning down to the correct subgraph, e.g., (c / cycle-02 :ARG1 (f /fuel :mod (n / nucleus))), thus predicting a generic node, i.e., (t / thing). This issue can be alleviated using a better preprocessing to split the compounds.

Several cases with low Smatch score are due to inconsistent translations of test set sentences into the target language, even though, we recall, the test set has been manually translated. This could be due to translator choices, but can lead to divergent meaning structures, e.g., *Ich kann verstehen, wie Du Dich fühlst (DE)* (*I can understand how you are feeling*) whose original English sentence from which the AMR graph is projected is *I know what you're feeling*. The gold AMR graph is thus not appropriate for the German sentence, due to the sentence's different meaning. Thus these mistakes are not due to the parser, but to the translations.

An interesting cause of drop in the Smatch arises from the prediction of concepts that are synonyms of the corresponding concepts in the gold graph, e.g., say-01 → state-01, stop-01 → halt-01, best friend → best mate, demand-01 → urge-01, etc. We notice that the predicted concepts (to the left of the arrow) are less specific than the gold concepts, yet somehow preserve the meaning. These examples show that the parser captures a close meaning even when failing to predict the exact concept.

Translation divergences We investigate how XL-AMR deals with the cases where there exist translation divergences, i.e., cases in which source and target language have different syntactic ordering properties (Dorr, 1990), as classified by Dorr (1994) using the following 7 categories: i) *thematic*, ii) *promotional*, iii) *demotional*, iv) *structural*, v) *conflational*, vi) *categorial*, vii) *lexical*.[11]

A *thematic* divergence happens when the argument-predicate structure is different across lan-

---

[9] github.com/mdtux89/amr-evaluation

[10] github.com/mdtux89/amr-eager-multilingual

[11] In absence of a larger available resource for language divergences, here we make use of some of the pre-classified examples from Dorr (1990, 1994).

guages, e.g., ***I*** *like travelling* where *I* is the subject, in Italian becomes ***Mi*** *piace viaggiare*, and *Mi* is now the object. XL-AMR overcomes this divergence and predicts the correct AMR, (l / like-01 :ARG0 (i / I) :ARG1 (t / travel :ARG0 i)).

Promotional and *demotional* divergences can be merged into the *head switching* macro-category. They arise when a modifier in one language is promoted to a main verb in the other, or vice versa, e.g., *John* ***usually*** *goes home* is *Juan* ***suele*** *ir a casa* (*John is accustomed to go home*) in Spanish. XL-AMR correctly parses the sentence into (g / go-01 :ARG0 (p / person :name (n / Juan)) :ARG4 (h / home) :mod (u / usual)).

A *structural* divergence exists when a verbal object is realized as a noun phrase (NP) in one language and as prepositional phrase (PP) in the other, e.g., *I saw* ***John*** where *John* is NP, is translated as *Vi* ***a Juan*** (*I saw to John*) in Spanish where *a Juan* is PP. This also is not a problem for our parser, which predicts the correct graph, (s / see-01 :ARG0 (i / I) :ARG1 (p / person :name (n / Juan))).

A *conflational* divergence refers to the translation of two or more words in one language into one word in the other. The above errors in German compounded words fall into this category and our model does not handle them properly. However, regarding other languages this problem is not common, e.g., *I* ***fear*** translates into *Io* ***ho paura*** (*I have fear*) in Italian and the parser correctly predicts the AMR graph, (f / fear-01 :ARG0 (i / I)).

A *categorical* divergence arises when the same meaning is expressed by different syntactic categories across languages, e.g., *I* ***agree***, where *agree* is a *verb*, is expressed by a *noun* in Italian and Spanish, *Sono d'****accordo*** and *Estoy de* ***acuerdo***. The parser correctly predicts the same AMR for both languages, (a / agree-01 :ARG0 (i / I)).

A *lexical* divergence arises when a verb in the source language is translated with a different lexical verb, e.g., *John* ***broke*** *into the room*, *Juan* ***forzó*** *la entrada al cuarto*, in which the verb *break* in English is translated with the verb *forzar* (*force*) in Spanish. XL-AMR predicts (f / force-01 :ARG0 (p / person :name (n / Juan)) :ARG2 (e / enter-01 :ARG0 p :ARG1 (r / room))) for the Spanish sentence, which, even though it is correctly parsed, does not overcome the lexical difference of the action, which results in different AMR graphs for the same meaning. This is partially due to the fact that AMR is bounded to lexical forms in English.

In summary, XL-AMR overcomes most of the foregoing structural divergences with the exception of two cases: i) the conflational divergence in German, that is caused by the language's compound words vocabulary, for the resolution of which a better preprocessing can be beneficial; ii) the lexical divergence that persists despite the parser predicting a valid graph. The latter divergence results in non-parallel structures for parallel meanings, and we believe this might be tackled by integrating a unified ontology for synonyms or related meanings within the AMR formalism, along the line of disjunctive AMR[12] (Banarescu et al., 2013). We leave exploration of this approach open for future work.

6 Conclusion

We explored transfer learning techniques to enable high performance cross-lingual AMR parsing. We created silver data based on annotation projection through parallel sentences and machine translation, on which we trained XL-AMR, a cross-lingual AMR parser that achieves the highest results reported to date on Chinese, German, Italian and Spanish. A qualitative evaluation showed that XL-AMR is able to handle most of the structural divergences among languages. The performance of XL-AMR together with the qualitative analysis suggests that carefully modeling cross-lingual AMR parsing leads to the production of suitable AMR structures across languages. It would therefore be promising to extend this line of our research to exploit larger multilingual semantic resources, in order to further improve the parsing quality. These AMR representations could then be integrated into downstream cross-lingual tasks to investigate their added value.

A Cross-Lingual AMR Pre- and Postprocessing

English AMR parsers throughout the literature rely on several pre- and postprocessing rules. We extend these rules for the cross-lingual AMR parsing task based on several multilingual resources.

Preprocessing This step consists of: i) lemmatization, ii) PoS-tagging, iii) NER, iv) re-categorization of entities and senses and v) removal of wiki links and polarity attributes. As NLP pipelines (steps i-iii) we use Stanford CoreNLP (Manning et al., 2014) for English sentences, the Stanza Toolkit (Qi et al., 2020) for Chinese, German and Spanish sentences, and Tint[13] (Aprosio and Moretti, 2016) for Italian. Re-categorization and anonymization of entities is often used in English AMR parsing to reduce data sparsity (Zhang et al., 2019; Lyu and Titov, 2018; Peng et al., 2017; Konstas et al., 2017). Here we follow Konstas et al. (2017); Zhang et al. (2019) and anonymize entity subgraphs, which are identified by an AMR entity type and the `:name` role. First, the entity subgraphs are mapped with the corresponding text span in the sentence and then the text span is replaced with the anonymized token, i.e., `ENTITY_TYPE_i`. To match the entities in the AMR graphs, which are tied to English, with the corresponding text span in non-English sentences, we first collect all the possible lexicalizations of the entity in the target language using BabelNet 4.0 (Navigli and Ponzetto, 2010), a multilingual semantic network which brings together different resources such as WordNet, Wikipedia, etc., each node of which clusters together the lexicalizations that express the same concept in different languages. Then we search for the possible text spans in the sentence written in the target language. At test time, we anonymize the text spans which have been identified during the training data preprocessing and which are tagged by the NER tagger as entities.

Postprocessing This step consists of restoring i) anonymized subgraphs, ii) wiki links, iii) senses and iv) polarity attributes. The anonymized subgraphs are restored using the anonymized text

---

[13] Stanza does not provide a NER model for Italian.

spans created during preprocessing. Then wiki links are restored using the DBpedia Spotlight API[14] (Daiber et al., 2013), commonly used in English AMR parsing (van Noord and Bos, 2017; Zhang et al., 2019; Ge et al., 2019). It provides models for multiple languages, except Chinese, for which we use Babelfy (Moro et al., 2014). Since the wiki links identified by DBpedia Spotlight API are language-specific to the text, we further use Wikipedia inter-language links to retrieve the corresponding wiki links for the English entities. We restore senses as the most frequent sense of the predicate in the training data (using -01 if unseen) similar to (Lyu and Titov, 2018; Zhang et al., 2019) and finally restore polarity attributes based on heuristic rules observed on the training data and linguistic rules specific to each language (included in the released code).

B OpusMT Translation Models

For the translation and back-translation steps of GOLDAMR-SILVERTRNS data creation approach, we use the pretrained models[15] from the huggingface transformers library[16] listed in Table 4.

Source	Target	Model
German	English	`Helsinki-NLP/opus-mt-de-en`
Italian	English	`Helsinki-NLP/opus-mt-it-en`
Spanish	English	`Helsinki-NLP/opus-mt-ROMANCE-en`
English	German	`Helsinki-NLP/opus-mt-en-de`
English	Italian	`Helsinki-NLP/opus-mt-en-it`
English	Spanish	`Helsinki-NLP/opus-mt-en-ROMANCE`

Table 4: OpusMT translation models.

C Model Hyperparameters

The input features for all the models include: i) fixed mBERT[17] (Devlin et al., 2019) as contextual embeddings (dim = 768), ii) ConceptNet Numberbatch 9.08[18] (Speer et al., 2017) multilingual static word embeddings (dim = 300) which we set as trainable except in $\emptyset$-shot models, iii) trainable PoS embeddings (dim = 100) where we use the universal PoS-tags set by Petrov et al. (2012), iv) trainable anonymization indicator embeddings (dim = 50), v) trainable character-level embeddings (dim = 100), i.e., CharCNN (Kim et al., 2016).

The encoder and decoder of the node prediction module are composed of 2 layers of 512 and 1024 LSTM units each, respectively. All the models are trained using Adam optimizer (Kingma and Ba, 2015) with learning rate 0.001, for 120 epochs and the best model hyperparameters are chosen on the basis of development set accuracy. The models are trained using 1 GeForce GTX TITAN X GPU, full training takes around 48 hours for models trained in the largest dataset XL-AMR^{trans+} ($\sim$84M trainable parameters) and XL-AMR^{par+} ($\sim$86M trainable parameters). At prediction time we set the size of beam search to 5.

Abstract

In the literature, the research on abstract meaning representation (AMR) parsing is much restricted by the size of human-curated dataset which is critical to build an AMR parser with good performance. To alleviate such data size restriction, pre-trained models have been drawing more and more attention in AMR parsing. However, previous pre-trained models, like BERT, are implemented for general purpose which may not work as expected for the specific task of AMR parsing. In this paper, we focus on sequence-to-sequence (seq2seq) AMR parsing and propose a seq2seq pre-training approach to build pre-trained models in both single and joint way on three relevant tasks, i.e., machine translation, syntactic parsing, and AMR parsing itself. Moreover, we extend the vanilla fine-tuning method to a multi-task learning fine-tuning method that optimizes for the performance of AMR parsing while endeavors to preserve the response of pre-trained models. Extensive experimental results on two English benchmark datasets show that both the single and joint pre-trained models significantly improve the performance (e.g., from 71.5 to 80.2 on AMR 2.0), which reaches the state of the art. The result is very encouraging since we achieve this with seq2seq models rather than complex models. We make our code and model available at `https://github.com/xdqkid/S2S-AMR-Parser`.

1 Introduction

Abstract meaning representation (AMR) parsing aims to translate a textual sentence into a directed and acyclic graph which consists of concept nodes and edges representing the semantic relations between the nodes (Banarescu et al., 2013). Previous studies focus on building diverse approaches to modeling the structure in AMR graphs, such as tree-based approaches (Wang et al., 2015b; Groschwitz et al., 2018), graph-based approaches (Flanigan et al., 2014; Werling et al., 2015; Cai and Lam, 2019), transition-based approaches (Damonte et al., 2017; Guo and Lu, 2018), sequence-to-sequence (seq2seq) approaches (Peng et al., 2017; van Noord and Bos, 2017; Konstas et al., 2017; Ge et al., 2019), and sequence-to-graph (seq2graph) approaches (Zhang et al., 2019a,b; Cai and Lam, 2020). Among these approaches, seq2seq-based approaches, which properly transform AMR graphs into sequences, have received much interest, due to the simplicity in implementation and the competitive performance.

Figure 1: An example of seq2seq-based AMR parsing.

Similar to many NLP tasks, the performance of AMR parsing is much restricted by the size of human-curated dataset. For example, even recent AMR 2.0 contains only 36.5K training AMRs. To alleviate the effect of such restriction, a previous attempt is to utilize large-scale unlabeled sentences with self-training (Konstas et al., 2017). Alternatively, a more recent feasible solution is to resort to pre-training which builds pre-trained models on large-scale (unlabeled) data. Linguistic knowledge captured in pre-trained models can then be properly

Task	Dataset	Source	Target
machine translation	gold	sentence	sentence
syntactic parsing	silver	sentence	tree sequence
AMR parsing	silver	sentence	AMR sequence

Table 1: Three seq2seq learning tasks explored in this paper to obtain pre-trained models. Here *silver* dataset indicates that the sequences in the target-side are generated automatically .

incorporated into the training of an AMR parser. However, the widely used pre-trained models such as ELMO (Peters et al., 2017) and BERT (Devlin et al., 2019) may not work as expected for building a state-of-the-art seq2seq AMR parser. The reasons are two-fold. On the one hand, previous studies on both seq2seq-based AMR parsing and AMR-to-text generation demonstrate the necessity of a shared vocabulary for the source and target sides (Ge et al., 2019; Zhu et al., 2019). Using pre-trained models like BERT as pre-trained encoders for AMR parsing, however, will violate the rule of sharing a vocabulary. On the other hand, pre-trained models such as BERT are basically tuned for the purpose of representing sentences instead of generating target sequences. According to Zhu et al. (2020), by contrast to using BERT directly as the encoder, a more reasonable approach is to utilize BERT as an extra feature or view BERT as an extra encoder. See Section 5.1 for more detailed discussions on the effect of BERT on AMR parsing.

In this paper, we propose to pre-train seq2seq models that aim to capture different linguistic knowledge from input sentences. To build such pre-trained models, we explore three different yet relevant seq2seq tasks, as listed in Table 1. Here, machine translation acts as the most representative seq2seq task which takes a bilingual dataset as the training data. According to Shi et al. (2016) and Li et al. (2017), a machine translation system with good performance requires the model to well derive linguistic information from input sentences. The other two tasks require auto-parsed syntactic parse trees and AMR graphs as the training data, respectively. It is worth noting that the pre-training task of AMR parsing is in the similar spirit of self-training (Konstas et al., 2017).

In order to investigate whether various seq2seq pre-trained models are complementary to each other in the sense that they can be learned jointly to achieve better performance, we further explore joint learning of several pre-training tasks and evaluate its effect on AMR parsing. In addition, motivated by Li and Hoiem (2018), we extend the vanilla fine-tuning method to optimize for both the performance of AMR parsing and response preservation of the pre-trained models. Detailed experimentation on two widely used English benchmarks shows that our approach substantially improves the performance, which greatly advances the state-of-the-art. This is very encouraging since we achieve the state-of-the-art by simply making use of the generic seq2seq framework rather than designing sophisticated AMR parsing models.

2 Baseline: AMR Parsing as Seq2Seq Learning

Seq2Seq Modeling. The encoder in the *Transformer* (Vaswani et al., 2017) consists of a stack of multiple identical layers, each of which has two sub-layers: one implements the multi-head self-attention mechanism and the other is a position-wise fully connected feed-forward network. The decoder is also composed of a stack of multiple identical layers. Each layer in the decoder consists of the same sub-layers as in the encoder layers plus an additional sub-layer that performs multi-head attention to the output of the encoder stack. See Vaswani et al. (2017) for more details.

Pre-Processing: Linearize AMR Graph to Target Sequence. As in van Noord and Bos (2017), we obtain simplified AMRs by removing variables and wiki links. Variables in AMR graphs are only necessary to indicate co-referring nodes and they do not carry any semantic information by themselves. Therefore, AMR graphs are first converted into AMR trees by removing variables and duplicating the co-referring nodes. Then newlines present in an AMR tree are replaced by spaces to get a sequence. Figure 1(c) illustrates the linearization result of the AMR graph in Figure 1(b). Based on the data of sentences paired with linearized AMR graphs, we train a seq2seq model whose outputs are also linearized AMRs.

Post-Processing: Recover AMR Graph from Target Sequence. The output from *Transformer* is an AMR sequence without variables, wiki-links, and co-occurrent variables. Moreover, the output may contain brackets that do not match, resulting incomplete concepts. To recover its full graph, the post-processing should restore information removed in pre-processing by assigning a unique variable to each concept, pruning duplicated and redundant material, performing Wikification, and restoring co-referring nodes. Meanwhile, it should fix incomplete concepts.

We use the pre-processing and post-processing scripts provided by van Noord and Bos (2017). [1]

3 Seq2Seq Pre-training for AMR Parsing

In this section, we first present our single pre-training approach, followed by the joint pre-training approach on two or more pre-training tasks. Then we present our fine-tuning methods.

3.1 Single Pre-training

To be consistent with the seq2seq model for AMR parsing, the pre-trained models in this paper are all built on the Transformer. That is, for each pre-training task listed in Table 1, we learn a seq2seq model which will be used to initialize seq2seq model for AMR parsing in the fine-tuning phase. When building the pre-trained models, we merge all the source and target sides of the three pre-training tasks, and construct a shared vocabulary. Moreover, in all the models we share vocabulary embeddings for both the source and target sides.

PTM-MT is a seq2seq neural machine translation (NMT) model which is trained on a publicly available bilingual dataset. According to findings in Goldberg (2019) and Jawahar et al. (2019), the Transformer encoder is strong in capturing syntax and semantics from source sentences, which is helpful to AMR parsing.

PTM-SynPar is a seq2seq constituent parsing model. Building such a model requires a training dataset which consists of sentences paired with constituency parse trees. To construct a silver treebank, we parse the English sentences in the bilingual data for MT by using an off-the-shelf parser. Then we linearize the automatic parse trees to get syntax sequences, as illustrated in Figure 2. Note that in the linearization, we let the output contain the words from the source sentence. The motivation here is to regard parsing as a language generation problem, similar to the idea in Choe and Charniak (2016).

PTM-SemPar is a seq2seq AMR parsing model trained on a silver corpus of auto-parsed AMR graphs. To construct such a corpus, we apply the baseline system of AMR parsing to process the English sentences in the bilingual MT corpus. Then we adopt the linearization process illustrated in Figure 1 to obtain source-target pairs. Finally, we train a seq2seq-based AMR parsing model on the silver corpus that will be used as a pre-trained model.

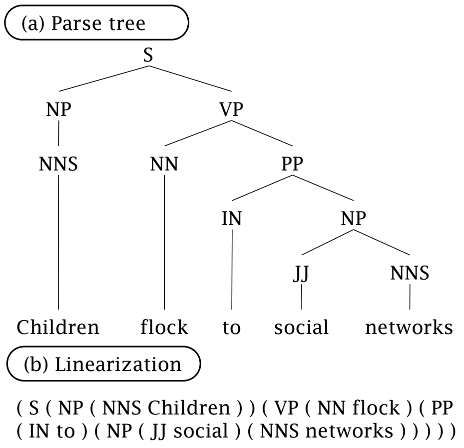

Figure 2: A linearization example of the parse tree for the sentence of *Children flock to social networks*.

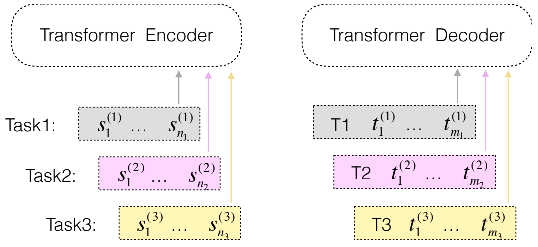

Figure 3: Illustration of the joint pre-training approach.

3.2 Joint Pre-training

Intuitively, the above described single pre-trained models can capture linguistic features from different perspectives. One question is whether these models are complementary when they are properly used to initialize a seq2seq-based AMR parser. To empirically answer this question, we propose to build pre-trained models through jointly learning multiple pre-training tasks. Inspired by the zero-shot approach proposed for multi-lingual neural machine translation (Johnson et al., 2017), we add a unique preceding tag to the target side of training data to distinguish the task of each training instance, as illustrated in Figure 3.

With such tagged training instances, multi-task learning is actually quite straightforward. We simply combine the training data of all the pre-training tasks that we are focusing on and then feed the

---

[1] https://github.com/RikVN/AMR

combined training data to the Transformer model. The training process interleaves training data from each task. For example, we update parameters on a batch of training instances from task1 and then update parameters on a batch of training instances from task2, and the process iterates. With such a joint training strategy, we obtain four joint pre-trained models, i.e., PTM-MT-SynPar, PTM-MT-SemPar, PTM-SynPar-SemPar, and PTM-MT-SynPar-SemPar. Names of the models can tell what pre-training tasks are learned jointly.

3.3 Fine-tuning Methods

Given a pre-trained model, we can directly fine-tune it on a gold AMR corpus to train an AMR parser. For this purpose we use two different fine-tuning methods. In the following we first present the vanilla fine-tuning method, and then extend it under the framework of multi-task learning. For simplicity, we refer to the latter method as Multi-Task Learning (MTL) fine-tuning hereafter.

Vanilla Fine-Tuning optimizes the parameters of an existing pre-trained seq2seq models to train AMR parsing on a gold AMR corpus. Fine-tuning adapts the shared parameters to make them more discriminative for AMR parsing, and the low learning rate is an indirect mechanism to preserve some of the representational structure captured in the pre-training models.

MTL Fine-Tuning is designed to attack the potential drawback of the vanilla fine-tuning method. In vanilla fine-tuning, optimizing model parameters to train AMR parsing presents a potential risk of overfitting. Inspired by Li and Hoiem (2018), we propose to optimize for high accuracy of AMR parsing while preserving the performance on the pre-training tasks. Preservation of the performance on the pre-training tasks can be regarded as a regularizer for the training of AMR parsing. To implement such MTL fine-tuning, we once again adopt the generic multi-task learning framework depicted in Figure 3.

Now the question left behind is how to obtain fine-tuning instances for pre-training tasks. To this end, we use the pre-trained model focused and input sentences of gold AMR corpus to generate fine-tuning instances for pre-training tasks. Formally speaking, given an instance $\{s, t^{(0)}\}$ of the fine-tuning task , and a pre-trained model learned from k pre-training tasks, we first feed the pre-trained model with input s and obtain its k outputs, i.e. $t^1, \cdots, t^k$ for the k pre-training tasks, respectively. Therefore, each input s in the fine-tuning task is now equipped with $k+1$ outputs, one for the fine-tuning task while the other k for the k pre-training tasks. Meanwhile, each output is associated with a unique preceding tag which indicates the corresponding task.

Please also note that we do not apply MTL fine-tuning to the pre-training task of AMR parsing. This is because the fine-tuning task is the same as the pre-training task. For example, for the pre-trained model PTM-MT-SynPar-SemPar, in MTL fine-tuning we only keep the pre-training tasks of MT and syntactic parsing.

4 Experimentation

In this section, we report the performance of our seq2seq pre-training approach to AMR parsing.

4.1 Experimental Settings

Pre-training Dataset and Pre-trained Models For pre-trained models, we use the WMT14 English-to-German dataset[2] which consists of about 3.9M training sentence pairs after filtering out long and imbalanced pairs. To obtain syntactic parse trees for the source sentences, we utilize toolkit AllenNLP (Gardner et al., 2017) which is trained on Penn Treebank (Marcus et al., 1993). To obtain AMR graphs for the source sentences, we utilize our baseline AMR parsing system. Then we merge English/German sentences and linearized parse trees, and AMR graphs together and segment all the tokens into subwords by byte pair encoding (BPE) (Sennrich et al., 2016) with 20K operations.

We implement above pre-trained models based on *OpenNMT-py* (Klein et al., 2017).[3] For simplicity, we unify parameters of these models as the Transformer-base model in Vaswani et al. (2017). The number of layers in encoder and decoder is 6 while the number of heads is 8. Both the embedding size and the hidden size are 512 while the size of feedforward network is 2048. Moreover, we use Adam optimizer (Kingma and Ba, 2015) with β_1 of 0.9 and β_2 of 0.998. Warm_up step, learning rate, dropout rate and label smoothing epsilon are 16000, 2.0, 0.1 and 0.1 respectively. In addition, we set the batch token-size to 8,192. We train the models for 300K steps and choose the model

---

[3] `https://github.com/OpenNMT/OpenNMT-py`

with the best performance on WMT2014 English-to-German development set as the final pre-trained model.

AMR Parsing Benchmarks We evaluate AMR performance on AMR 1.0 (LDC2015E86) and AMR 2.0 (LDC2017T10). The two datasets contain 16,833 and 36,521 training AMRs, respectively, and share 1,368 development AMRs and 1,371 testing AMRs. All the source sentences and linearized AMRs are segmented into subwords by using the BPE trained for the pre-trained models.

To fine-tune the pre-trained models for AMR parsing, we follow the settings of hyper-parameters used for training pre-trained models.

Evaluation Metrics For evaluation purpose, we use the AMR-evaluation toolkit to evaluate parsing performance in Smatch and other fine-grained metrics (Cai and Knight, 2013; Damonte et al., 2017). We report results of single models that are tuned on the development set.

4.2 Experimental Results

Table 2 presents the comparison of our approach and related studies on the test sets of AMR 1.0 and AMR 2.0. From the results, we have the following observations:

- Pre-trained models on a single task (i.e., from #2 to #6) significantly improve the performance of AMR parsing, indicating seq2seq pre-training is helpful for seq2seq-based AMR parsing. We also note that the pre-trained model of NMT achieves the best performance, followed by the pre-trained models on AMR parsing and on syntactic parsing. This indicates that seq2seq AMR parsing benefits more from pre-training tasks that require the encoder be able to capture the semantics from source sentences.

- Joint pre-trained models on two or more pre-training tasks further improve the performance of AMR parsing. However, in the presence of NMT pre-training task, the benefits from joint pre-training with either AMR parsing, syntactic parsing or both are shrunk.

- MTL fine-tuning consistently outperforms the vanilla fine-tuning method. For example, on single pre-training tasks, MTL outperforms vanilla fine-tuning by 1.5 $\sim$ 2.0 Smatch F1 scores while on joint pre-training tasks, the improvements of MTL over vanilla fine-tuning instead decrease.

- With twice training sentences in AMR 2.0, overall the performance on AMR 2.0 is higher than that on AMR 1.0. However, the gap between the performance on AMR 2.0 and AMR 1.0 gets smaller when we move from single pre-training models to joint pre-training models. For example, based on PTM-MT-SynPar-SemPar, the performance gap is 1.1 in Smatch F1 scores, much less than the performance gap 6.9 between their corresponding baselines.

- Finally, our approach achieves the best reported performance on AMR 1.0 and the performance on AMR 2.0 is higher than or close to that achieved by previous studies which use BERT. This is very encouraging taking into consideration the fact that our seq2seq model is much simper than the graph-based models proposed in related studies (Zhang et al., 2019a,b; Naseem et al., 2019; Cai and Lam, 2020).

Table 3 compares the performance of our best system and the systems reported recently with fine-grained metrics. We obtain the best performance for Reentrancies, NER, and SRL. Compared to the systems of Z'19a, Z'19b, and C'20, we achieve lower performance for Wiki and Negations. One possible reason for our relatively lower performance on Wiki and Negations is that unlike above three systems, in this paper we do not anonymize named entities and do not use an extra algorithm to add polarity attributes.

5 Analysis and Discussion

In this section, we conduct more analysis on AMR parsing with pre-trained models. In the following all the results are obtained on AMR 2.0.

5.1 Effect of BERT on Seq2Seq AMR Parsing

To explore the effect of BERT on seq2seq AMR parsing, motivated by Zhu et al. (2020), we use BERT in various ways to boost the performance of AMR parsing.

Given an input sentence $x = (x_1, \cdots, x_n)$ with n words, the BERT tokenizer segments it into a subword sequence $x' = (x'_1, \cdots, x'_m)$ with m

subwords. Then BERT returns a hidden state sequence $b = (b_1, \cdots, b_m)$ in shape $\mathbb{R}^{m \times d_{BERT}}$, where d_{BERT} is the size of BERT hidden states (e.g., d_{BERT}=768 in our experiment). Figure 4 illustrates the process of obtaining BERT hidden states for an input sentence. Next we use the following methods to properly incorporate BERT hidden states b into Transformer-based AMR parsing.

- BERT as embedding, which uses $f\left(bW^B\right)$ as input of the the Transformer encoder, where $W^B \in \mathbb{R}^{d_{BERT} \times d}$ are model parameters to be learned, d is the model size for seq2seq AMR parsing, and f is the activation function *ReLu*.
- BERT as encoder, which uses $f\left(bW^B\right)$ as the output of the Transformer encoder. That is to say, we replace the Transformer encoder with BERT.
- BERT as extra feature, which views b as extra features for an input sentence x'. The input of the Transformer encoder is defined as $f\left([b, (Emb\left(x'\right) + Pos\left(x'\right))]W^E\right)$, where $[\cdot, \cdot]$ represents the operation of concatenation, $Emb\left(x'\right)$ and $Pos\left(x'\right)$ return the word embeddings and position embeddings of x' respectively, and $W^E \in \mathbb{R}^{(d+d_{BERT}) \times d}$ are model parameters to be learned.
- BERT as extra encoder, which adds a sub-layer, i.e, BERT-context-attention sub-layer, in the Transformer decoder after the masked-self-attention sub-layer and the context-attention sub-layer. The BERT-context-attention sub-layer works in a similar way as the context-attention sub-layer by attending to BERT hidden states $f\left(bW^B\right)$.

#	Methods	P.	R.	F1
1	None	73.5	66.9	70.0

3	BERT as encoder	75.5	68.0	71.5
4	BERT as extra feature	79.2	71.5	75.2
5	BERT as extra encoder	75.1	68.2	71.5

Table 4: Smatch scores on AMR 2.0 when incorporate BERT in various methods.

Meanwhile, we also provide another Transformer-based baseline in which we segment input sentences into subwords with the BERT tokenizer. For all above experiments, the source-side vocabulary is the set of subwords in training sentences segmented by the BERT tokenizer while the target-side vocabulary is the set of subwords in training AMRs segmented by BPE mentioned in Section 4.1.

Table 4 compares the performance of AMR parsing when incorporating BERT in various methods. By comparing the performance of #1 in Table 4 against the baseline #1 in Table 2, we observe a drop of Smatch F1 score from 71.5 to 70.0, indicating that it is important to share vocabulary for seq2seq AMR parsing. Based on the baseline of not sharing vocabulary, the four different methods of incorporating BERT result in very different performance ranging from 71.5 to 75.2 in Smatch F1 score. Among them, incorporating BERT as embedding or extra feature achieves similar performance, which is much higher than the performance of incorporating BERT as either encoder or extra encoder. This suggests that rather than straightly feeding BERT hidden states into a decoder, it is important to feed them into an encoder first. However, our pre-trained seq2seq models, even on a single pre-training task (i.e., #3, #5, #6) outperform using BERT, indicating the effectiveness of pre-trained seq2seq models for AMR parsing.

5.2 Effect of Training Data Sizes on Pre-training Models

In this section we investigate the impact of the size of pre-training data to check whether AMR parsing benefits more from pre-trained models that are trained on larger datasets. To this end, we randomly use 20%, 40%, 60%, and 80% of the full pre-training instances to train the pre-trained models, respectively.

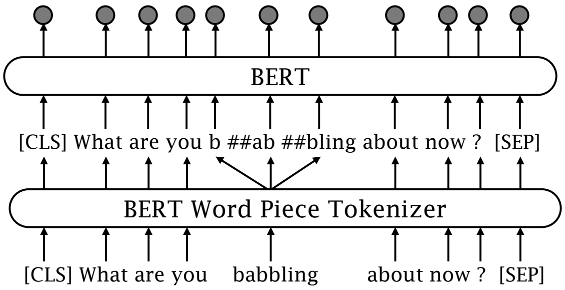

Figure 4: Illustration of obtaining BERT hidden states for an given sentence.

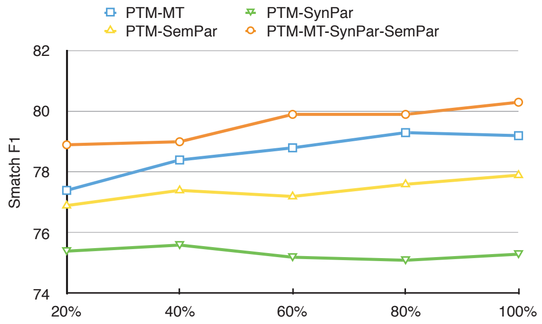

Figure 5: Learning curve over the number of training sentences in pre-training datasets.

As shown in Figure 5, except syntactic parsing (i.e., PTM-SynPar), the pre-training models on the other three kinds of pre-training tasks achieve higher AMR parsing performance with the increasing of training data sizes. Based on the learning curve, we suspect there still exists much room for further improvements if we enlarge the training data of pre-training tasks.

5.3 Effect of Different Pre-Training Components on Seq2Seq AMR Parsing

When adapt a pre-trained model to AMR parsing, we initialize the whole seq2seq Transformer model of AMR parsing with the counterpart of the pre-trained model. However, it is unveiled what part of initialization contributes most. To this end, we decompose the whole seq2seq model into three components, i.e., (shared) word embedding, encoder and decoder. The three components take account of 31.1%, 29.5% and 39.4% of parameters, respectively. Then we do ablation study by accumulating the initialization using the pre-trained model while the other components will be randomly initialized.

We use the PTM-MT-SynPar-SemPar pre-trained model as representative (i.e., #14 in Table 2). Table 5 presents the performance. From the table, we observe that with well-learned word em-

Pre-trained Initialization	P.	R.	F1
None	75.8	67.7	71.5
Embedding	80.7	76.3	78.4
Embedding + Encoder	81.3	77.2	79.2
Embedding + Decoder	80.7	76.5	78.5
All	**82.3**	**78.3**	**80.2**

Table 5: Smatch F1 scores on the test sets of AMR2.0 when initialize different components of seq2seq model with a pre-trained model. Here we use MTL as fine-tuning method.

bedding, we substantially boost the performance from 71.5 in Smatch F1 score to 78.4 while initializing the other two components with the pre-trained model leads to another 1.8 improvement in Smatch F1 score (i.e., from 78.4 to 80.2).

5.4 Effect of Pre-trained Models Trained on Different Datasets

As shown in Table 2, the pre-trained model of PTM-SynPar (or PTM-SemPar) significantly improves the performance AMR parsing from 71.5 to 75.3 (or 77.9) in Smatch F1 score. However, in the presence of PTM-MT, joint pre-training with either PTM-SynPar, PTM-SemPar, or both gives another up to 1.0 improvement, suggesting that complementarity among the pre-trained models does exist but is relatively limited. We suspect that the overlapping is mainly due to the fact that we pre-train these models on the same source-side dataset. We conjecture that more improvement is potentially reachable if the pre-training tasks are trained on different datasets.

To test the conjecture, we construct another silver dataset for both syntactic parsing and AMR parsing that is in the same size (i.e., 3.9M) as before. This is done by randomly selecting 3.9M English sentences from WMT14 English monolingual language model training data.[4] Table 6 compares the Smatch F1 scores. From it, we observe consistent improvement if the pre-trained models are jointly trained on different datasets. For example, by replacing the pre-training dataset of AMR parsing with the new constructed dataset, we improve AMR parsing from 80.1 in Smatch F1 score to 81.4. This suggests that assigning different pre-training tasks with different datasets improves the performance of AMR parsing.

#	Pre-trained Model	F1
1	PTM-MT (WMT14B)	79.1
2	PTM-MT(WMT14B)-SemPar(WMT14B)	80.1
3	PTM-MT(WMT14B)-SemPar(WMT14M)	**81.4**
4	PTM-MT(WMT14B)-SynPar(WMT14B)	79.5
5	PTM-MT(WMT14B)-SynPar(WMT14M)	79.9

Table 6: Smatch F1 scores on the test set of AMR 2.0 when the pre-training tasks are trained on different datasets. Here WMT14B is for WMT14 English-to-German dataset while WMT14M is for WMT14 English monolingual dataset.

#	Pre-trained Model		F1
1	PTM-MT on EN-DE	Vanilla	77.1
2		MTL	79.1
3	PTM-MT on EN-FR	Vanilla	77.5
4		MTL	**79.4**

Table 7: Smatch F1 scores on the test set of AMR 2.0 when the pre-training tasks are trained on different bilingual dataset.

5.5 Effect of Different Bilingual Datasets

For the pre-training task of machine translation, we have chosen English-to-German (EN-DE) with 3.9M sentence pairs. However, it is still unclear whether it is critical to choose the right language pair. To this end, we move to WMT14 Englilsh-to-French (EN-FR) translation and randomly select 3.9M sentence pairs from its training dataset, as the same size of EN-DE translation. Table 7 compares the Smatch F1 scores when the pre-trained models are trained on different bilingual datasets. From it, we observe that pre-training on EN-FR dataset achieves even slight higher performance than that on EN-DE dataset. This further confirms our finding that AMR parsing can greatly benefit from machine translation.

6 Related Work

We describe related work from two perspectives: pre-training and AMR parsing.

Pre-training. Pre-training a universal model and then fine-tuning the model on a downstream task have recently become a popular strategy in the field of natural language processing. Previous works on pre-training can be roughly grouped into two categories. One category of approaches is to learn static word embeddings such as word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) while the other group builds dynamic pre-trained models that would also be used in downstream tasks. Representative examples in the latter group in-

---

clude Dai and Le (2015), CoVe (McCann et al., 2017), ELMo (Peters et al., 2017; Edunov et al., 2019), OpenAI GPT (Radford et al., 2018), and BERT (Devlin et al., 2019). Besides the aforementioned encoder-only (e.g., BERT) or decoder-only (e.g., GPT) pre-training approaches, recent studies also propose approaches to pre-training seq2seq models, such as MASS (Song et al., 2019), PoDA (Wang et al., 2019), PEGASUS (Zhang et al., 2020), BART (Lewis et al., 2020), and T5 (Raffel et al., 2020).

AMR Parsing. As a semantic parsing task that translates texts into AMR graphs, AMR parsing has received much attention in recent years. Diverse approaches have been applied to the task. Flanigan et al. (2014) pioneer the research work on AMR parsing by using a a two-stage approach: node identification followed by relation recognition. Werling et al. (2015) improve the first stage in the parser of Flanigan et al. (2014) by generating subgraph aligned to lexical items. To avoid conducting AMR parsing from scratch, Wang et al. (2015b) propose to obtain AMR graphs from dependency trees by using a transition-based method. Wang et al. (2015a) extend their previous work by introducing a new transition action to get better performance. Damonte et al. (2017) propose a complete transition-based approach that parses sentences left-to-right in linear time. The recent neural AMR parsing could be roughly grouped into two categories. On the one hand, the generic seq2seq-based approaches have been widely used for AMR parsing which show competitive performance (Peng et al., 2017; van Noord and Bos, 2017; Konstas et al., 2017; Ge et al., 2019). On the other hand, to better model the graph structure on the target side, graph-based models are well studies for AMR parsing which achieve the state-of-the-art-performance (Lyu and Titov, 2018; Guo and Lu, 2018; Groschwitz et al., 2018; Zhang et al., 2019a,b; Cai and Lam, 2020).

7 Conclusion

In this paper we proposed a seq2seq-based pre-training approach to improving the performance of seq2seq-based AMR parsing. To this end, we designed three relevant seq2seq learning tasks, including machine translation, syntactic parsing, and AMR parsing itself. Then we built seq2seq pre-trained models through either single or joint pre-training tasks. Detail experimentation shows that both the single and joint pre-trained models substantially improve our baseline and the performance reaches the state of the art. The accomplishment is encouraging since we achieve this simply by using the generic seq2seq framework rather than complex models.

Hate-Speech and Offensive Language Detection in Roman Urdu

Hammad Rizwan, Muhammad Haroon Shakeel, Asim Karim
Department of Computer Science,
Lahore University of Management Sciences (LUMS),
Lahore, Pakistan
{hammad.rizwan, m.shakeel, akarim}@lums.edu.pk

Abstract

The task of automatic hate-speech and offensive language detection in social media content is of utmost importance due to its implications in unprejudiced society concerning race, gender, or religion. Existing research in this area, however, is mainly focused on the English language, limiting the applicability to particular demographics. Despite its prevalence, Roman Urdu (RU) lacks language resources, annotated datasets, and language models for this task. In this study, we: (1) Present a lexicon of hateful words in RU, (2) Develop an annotated dataset called RUHSOLD consisting of $10,012$ tweets in RU with both coarse-grained and fine-grained labels of hate-speech and offensive language, (3) Explore the feasibility of transfer learning of five existing embedding models to RU, (4) Propose a novel deep learning architecture called CNN-gram for hate-speech and offensive language detection and compare its performance with seven current baseline approaches on RUHSOLD dataset, and (5) Train domain-specific embeddings on more than 4.7 million tweets and make them publicly available. We conclude that transfer learning is more beneficial as compared to training embedding from scratch and that the proposed model exhibits greater robustness as compared to the baselines.

1 Introduction

In the last decade, online social media platforms have become extremely popular, with users growing exponentially. These platforms provide users with the freedom to express their opinions and ability to interact with people of diverse groups. On one hand, this has resulted in exchanges of ideas and fostered relationships, while on the other, it is exploited to spread, incite, promote, or justify hatred, violence, and discrimination against users based on their gender, religion, race, affiliation with certain groups, and views related to certain events or subjects (e.g., politics) through hateful, offensive, derogatory, or obscene language. If such content is left unaddressed, it has known to lead to acts of violence and conflicts on a broader scale, resulting in problems for the protection of human rights, the rule of law, and freedom of speech, which are essentials for the development of an unprejudiced democratic society.

Most of the social media platforms address this issue by employing techniques such as reporting and manual review by humans, which is limited by the reviewer's speed, ability to understand the evolution of slang, jargon, and familiarity with multilingual content. Apart from these issues, this process generally takes 24 hours, and by that time, the intended damage has already taken place. Moreover, the manual process also poses problems related to the subjective notions of what constitutes hate-speech and offensive language, which might result in misuse of this process to silence minorities and to suppress criticism of official policies, political opposition, or religious beliefs. Thus, an automated system to detect hate speech and offensive language is inevitable.

In the last few years a string of events in Pakistan, such as the lynching of a student due to online anti-religious propaganda against him [1], smearing campaigns against famous political leaders and social media personalities, women being regularly targeted and harassed for sharing their viewpoints online, and the targeting of religious minorities to hurt their religious sentiment has prompted the government to make legislation against online hate-speech such as "National Action Plan" and "The Prevention of Electronic Crime Bill". Such measures speak volumes for the problems related to online hate-speech faced in the country and the need for automated systems to help counter such content.

The majority of the initial research on hate-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2512–2522,
November 16–20, 2020.

speech and offensive language detection is mainly focused on the English language. Although English is the official language of Pakistan, Urdu is treated as the National language. People tend to write Urdu using Latin scripts and code-switch between two languages in the same conversation (i.e., alternative use of RU and English languages within the same speech, clause/sentence or constituent/element) (Noor et al., 2015; Fatima et al., 2018).

This unique and informal dialect of communication is known as Roman Urdu (RU). It is a significantly more challenging language to model as compared to formal languages (i.e. languages that follow proper grammatical structure and standard dictionary) due to factors such as colloquial verbiage, improper grammar, spelling variations, self-made abbreviations, and code-switching (Shakeel and Karim, 2020). It is known that the nature of hate-speech content changes with demographics, thus, language resources, labeled datasets, and models for multiple languages are crucial to facilitate the research in this area (Mandl et al., 2019). However, despite its prevalence, RU is under-resourced in this context. To this end, we make following contributions.

- First, we provide a lexicon base of 621 hateful words for the RU language.
- Second, we develop a gold-standard dataset, called Roman Urdu Hate-Speech and Offensive Language Detection (RUHSOLD), from tweets in RU with binary coarse-grained as well as multi-class fine-grained labels.
- Third, we explore the transfer learning capabilities of five existing multilingual embedding models to RU language through extensive experiments.
- Fourth, we propose a novel deep learning model called Convolutional Neural Network n-gram (CNN-gram) and compare its performance with seven baseline models on the RUHSOLD dataset. In our presentation, we demonstrate that CNN-gram displays a greater robustness across both coarse-grained as well as fine-grained classification tasks.
- Fifth, to exhibit contrast with transfer learning of embedding models, we train domain-specific embeddings called “RomUrEm” on more than 4.7 million tweets and compare its performance with five existing pre-trained embeddings in terms of macro F1-score on both tasks of RUHSOLD dataset.

Rest of the paper is organized as follows. Section 2 presents a discussion on the background of the problem. In Section 3, details of the RUHSOLD dataset, it’s annotation process, and definition of labels is discussed. Section 4 presents the experimental design and details of baseline models. The proposed model is introduced in Section 5 while we present the results and discussion in Section 6. Finally, we give concluding remarks in Section 7.

2 Background

Research in automatic hate-speech detection has been evolving rapidly over the last five years. Much of the existing research consists of diverse yet related tasks. For instance Waseem and Hovy (2016); Waseem (2016) focus on detection of racism and sexism on Twitter, Davidson et al. (2017) work on differentiating offensive language from hate-speech on Twitter, and de Gibert et al. (2018) focused on hateful and non-hateful speech in a white supremacy forum. Such a diverse set of terminologies has given a rise to problems such as duplication of research, absence of interrelationships, and the lack of re-usability across different strands of the hate-speech and offensive language detection tasks (Kumar et al., 2018). To address this issue Founta et al. (2018) studies these terminologies to find interrelationship between them and provide a selection of labels that eliminate ambiguities of perceivable overlap between them.

In an effort to develop resources, datasets, and models for hate-speech and offensive language detection in multiple languages, a shared task called Hate-Speech and Offensive Content Identification (HASOC) in Indo-European Languages is organized under Forum for Information Retrieval Evaluation (FIRE) (Mandl et al., 2019). This task focuses on Hindi, German and English languages. In the last couple of years, several datasets have been made public in languages such as German (Wiegand et al., 2018), Polish (Ptaszynski et al., 2019), Portuguese (Fortuna et al., 2019), Indonesian (Ibrohim and Budi, 2019), Hindi (Kumar et al., 2018; Mathur et al., 2018), etc. However, despite its prevalence, there is no publicly available dataset for RU to the best of our knowledge.

With regards to language models for hate-speech and offensive language detection, Davidson et al. (2017) have used features such as POS tags, tf-idf vectors, emotion lexicon, and n-grams with multiple classifiers such as logistic regression, naive Bayes, SVM, Decision Tree, and Random Forest. Such approaches rely on local information and are therefore unable to capture context and long-term dependencies in texts where hate-speech is subtle and cannot be judged without taking the entire span of the text into account. With the advent of larger datasets, researchers have shifted to data-hungry deep learning based approaches which are better at learning semantics, contexts, and long-term dependencies (Badjatiya et al., 2017; Agrawal and Awekar, 2018).

Lee et al. (2018) performed a comparative study for machine learning and deep learning models and concluded that deep learning models are more accurate. They also highlighted the fact that different features are important for each hate-speech label, all of which cannot be captured by a single model. Thus, ensemble methods have been used by studies such as Park and Fung (2017), who have used a hybrid-Convolutional Neural Network (CNN) which combines word and character level CNN, Pitsilis et al. (2018), who have used an ensemble of Long Short-term Memory (LSTM) classifiers with majority voting and confidence based aggregation, and Mahata et al. (2019), who used an ensemble of CNN and LSTM based classifiers to capture both salient local information and long term contexts. However, ensembles are carefully selected task-specific combinations which might not generalize well and are computationally expensive. Thus a single model with a greater robustness and generalization is desirable.

The rising success of transfer learning in other deep learning domains such as computer vision and the success of transformer models in many Natural Language Processing (NLP) domains has led to its adoption by many of the researchers who took part in the recent HASOC track at FIRE 2019. These models have outperformed other modeling techniques in five out of eight sub-tasks for different languages. Their success can mainly be attributed to either using ensemble models or performing transfer learning using a pre-trained multilingual transformer embedding model called BERT (Devlin et al., 2019). Keeping these developments in view, we also examine the transfer learning capabilities of five existing embedding models.

3 Roman Urdu Hate-Speech and Offensive Language Detection (RUHSOLD) Dataset

In the literature, researchers create hate-speech datasets by extracting hateful content from online resources by means of a collection of language-specific lexicons of hateful words (Waseem and Hovy, 2016; Basile et al., 2019; Davidson et al., 2017). Despite `Hatebase.org` having the largest collection of multilingual hateful words, it lacks such lexicon base for RU. To this end, we have constructed our own lexicon of hateful words (by searching for such keywords online and interviewing people). this lexicon consists of abusive and derogatory terms along with slurs or terms pertaining to religious hate and sexist language. Using this lexicon along with a separate collection of RU common words, we search and collect $20,000$ tweets and perform a manual preliminary analysis to find new slang, abuses, and identify frequently occurring common terms. The choice to add common RU words is made in order to extract random inoffensive tweets and the tweets that are offensive but do not contain any offensive words e.g.,

> **Tweet**: *Aap apni behan. Beti.. maan ... aur bivi ka march karwa do phir*
>
> **Translation**: *Then do a march of you sister, daughter, mom and wife.*

The tweet is offensive as it targets close relations and tries to demean them but does not contain any hateful/offensive terms/lexicon.

We discard words or terms for which the number of extractable tweets are too few.

Using this updated lexicon we search and collect $50,000$ new tweets. From this updated tweet base, around $10,000$ tweets are randomly sampled for annotations. To avoid issues related to user distribution bias as highlighted by Arango et al. (2019), we restrict a maximum of 120 tweets per user.

To create a gold-standard, the data is manually labeled by three independent annotators and is called Roman Urdu Hate-Speech and Offensive Language Detection (RUHSOLD) dataset. During the annotation process, all conflicts are resolved by a majority vote among three annotators. Tweets on which a consensus cannot be reached or that are reckoned to provide insufficient information for labeling are discarded and replaced by new randomly sampled

Tweet	Translation	Target Label
randi ke bache tu apne hashar ki fikar kar	you son of a prostitute, you should worry for what will happen to you.	Abusive/Offensive
Hindu bhenchod hi ki gaand ma hi keerra hota hay Tum hindu ho hi harami tumhara kabhi 1 baap nhi hota	There are always insects in asses of Hindu sisterfu**kers. These hindus have multple fathers instead of 1	Religious Hate
No wonder you can't make it to First Lady. At least you managed to grab the title of FIRST RANDDI	No wonder you can't make it to First Lady. At least you managed to grab the title of FIRST PROSTITUTE	Sexism

Table 1: Samples of tweets for each label from RUHSOLD dataset

tweets from the data collection. We develop the gold-standard for two sub-tasks. First sub-task is based on binary labels of *Hate-Offensive content* and *Normal content* (i.e., inoffensive language). These labels are self-explanatory. We refer to this sub-task as "coarse-grained classification". Second sub-task defines Hate-Offensive content with four labels at a granular level. These labels are the most relevant for the demographic of users who converse in RU and are defined in related literature. We refer to this sub-task as "fine-grained classification". The objective behind creating two gold-standards is to enable the researchers to evaluate the hate-speech detection approaches on both easier (coarse-grained) and challenging (fine-grained) scenarios. All labels and their definitions are summarized as follows:

Abusive/Offensive: Profanity, strongly impolite, rude or vulgar language expressed with fighting or hurtful words in order to insult a targeted individual or group (Nobata et al., 2016; Founta et al., 2018; Mathur et al., 2018).

Sexism: Language used to express hatred towards a targeted individual or group based on gender or sexual orientation (Waseem and Hovy, 2016; Waseem, 2016; Warner and Hirschberg, 2012).

Religious Hate: Language used to express hatred towards a targeted individual or group based on their religious beliefs or lack of any religious beliefs and the use of religion to incite violence or propagate hatred against a targeted individuals or group (Albadi et al., 2018; Warner and Hirschberg, 2012). e.g

Profane: The use of vulgar, foul or obscene language without an intended target (Davidson et al., 2017; Mandl et al., 2019).

Lablel	Tweet Count
Abusive/Offensive	$2,402$
Sexism	839
Religious Hate	782
Profane	640
Normal	$5,349$
Total	$10,012$

Table 2: Tweet counts with respect to labels for fine-grained classification task

Normal: This contains text that don't fall into the above categories.

Table 1 shows sample tweets for each of the previously described labels along with their English translation.

Religious Hate and Sexism can be combined under the umbrella of the single "Hate-Speech" tag as defined in (Davidson et al., 2017; Golbeck et al., 2017). However, in our case, this defeats the purpose of identifying hate-speech and offensive content at a granular level while at the same time differentiating between the subject matter of abusive content. Thus we refrain from merging any labels.

Table 2 shows the tweet labels and their respective counts. The mode, mean, max, and min length of the tweets are 42, 18, 73, and 1 respectively.

We split the data in train, test, and validation sets with 70,20,10 split ratio using stratification based on fine-grained labels. The use of stratified sampling is deemed necessary to preserve the same labels ratio across all splits. This way, train split contains $7,209$ tweets while test and validation splits have 2003, and 801 tweets respectively. These standard splits along with RU lexicon base is made publicly available to further the research in this direction [2].

4 Experimental Design

In this section, we describe the details of the experiments designed to evaluate the performance of different embeddings, baseline models, and the proposed model for both tasks (i.e., coarse-grained and fine-grained classification).

It is shown in literature that using pre-trained word embeddings for NLP tasks improves the predictive performance of the models (Shakeel et al., 2019). Although, for many years, robust pre-trained embeddings were mainly limited to the English language, in recent years, multilingual embeddings are also made publicly available. These embeddings include LASER (Artetxe and Schwenk, 2019), ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2019), and FastText (Bojanowski et al., 2017). Thus we first compare the out-of-the-box performance of these five pre-trained embeddings. We also fine-tune these embeddings on RUHSOLD dataset in order to gauge their capability of transfer learning to a different domain and language. We use tokenizers for all embedding models from HuggingFace library [3] while for BERT, "base" version is used. To exhibit the contrast to transfer learning, the domain-specific embeddings called *RomUrEm* are also trained. We use Twitter API to collect $4,770,677$ random and hate-speech tweets and use word2vec (Mikolov et al., 2013) to train 200 dimensional embeddings. We set the window size to 5, minimum word count to 2, and the number of iterations in pre-training to 10. These embeddings are also made publicly available along with dataset.

Secondly, we compare the performance of seven baseline models through extensive experimentation. The comprehensive details of each model are described below.

4.1 Baseline Models

The baseline models are selected based on their reported good performance for hate-speech detection on multiple datasets. We re-implement these models from the companion code or detailed description, whichever is available.

LSTM+GBDT: Badjatiya et al. (2017) perform multiple experiments using traditional machine learning and deep learning approaches along with various pre-trained embeddings and different ensembles on sexism and racism Twitter dataset in the English Language (Waseem and Hovy, 2016). They conclude that LSTM+GBDT, which utilizes random embeddings followed by an ensemble of LSTM and Gradient Boosting Decision Tree (GBDT) outperforms 16 other models in terms of predictive performance.

FastText+CNN: Kumar et al. (2018) held an open task to model a dataset of Hindi tweets (in both Roman and Devanagari script). Team "DA-LD-Hildesheim" (Modha et al., 2018) employed Fasttext embeddings along with CNN, which outperformed 18 other submitted approaches.

Bi-LSTM with Attention: Bi-LSTM along with attention mechanism have been used consistently for hate-speech detection tasks and is able to achieve top performance on fox news comment dataset (Gao and Huang, 2017).

The rest of the models describe below are taken from HASOC track at FIRE.

BERT+LAMB: Team "3-idiots" (Mishra and Mishra, 2019) utilized pre-trained BERT embedding with LAMB optimizer and achieved top performance for tasks B and C in English language and task B (fine-grained hate speech detection) in Hindi language.

SVM+RF+AB: Team "A3-108" (Mujadia et al., 2019) utilized an ensemble of Linear SVM, Adaboost, and Random Forest along with soft and hard voting mechanism and achieved top performance on Hindi language task C (targeted/untargeted offense).

Domain Embeddings+CNN: Team "QutNocturnal" (Bashar and Nayak, 2019) utilized CNN along with embeddings trained on $494,311$ random tweets in Hindi and $5,251$ sarcasm tweets in "Hinglish". This architecture was able to achieve top performance on Hindi language task A (binary hate speech detection). To replicate their embeddings, we use RomUrEm.

BERT+LASER+GBDT: Team "HateMonitors" (Saha et al., 2019) utilized pre-trained multilingual BERT and LASER embedding with LGBM classifier in order to achieve top performance for German language task A.

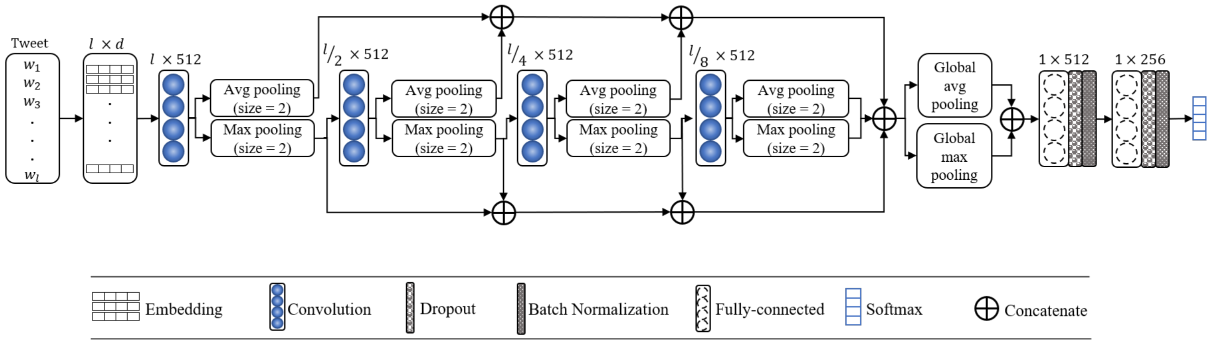

Figure 1: CNN-gram model for hate-speech and offensive language detection in Roman Urdu

5 Proposed Model

In NLP, n-gram information can efficiently be used to learn a certain pattern from text (Attia et al., 2018). The proposed model named Convolutional Neural Network n-gram (CNN-gram) learns patterns based on unigram, bigram, trigram, and quadgram. Complete model architecture is illustrated in Figure 1. Each tweet is first converted to $l \times d$ embedding matrix, where l represents the number of words in the tweet while d is the embedding vector dimension for each word. Four CNN layers are then employed to learn the feature maps. The first CNN layer uses a kernel size of 1 with *ReLU* activation function to learn unigram features followed by max-pooling and average-pooling layers with a pool size of 2. Max-pooling is utilized to drop low activation values from learned representations, which also acts as dimensionality reduction by downsampling the output. The average-pooling is utilized to capture average activations of features. The max-pooled output is then forwarded to another CNN layer which uses kernel size of 2 to learn bigram patterns. This is followed by another set of max-pooling and average-pooling layers identical to the first layer. Similarly, third and fourth CNN layers are used to learn trigram and quadgram patterns respectively. Note that these are not bigram, trigram, and quadgram patterns in “true” sense as one of the two activations is dropped during max-pooling process with a pool size of 2 after every CNN layer. However, on forwarded high activations, the notion of bigram, trigram, and quadgram holds true. Outputs of all four max-pooling and average-pooling layers are concatenated followed by a global average-pooling and global max-pooling layers in parallel, which takes the average and maximum value as the feature corresponding to each filter. These average and maximum feature values are concatenated and are forwarded to a small fully-connected network with two fully-connected layers to squash the information to smaller dimensions. Dropout and batch-normalization after each fully-connected layer is also utilized to avoid feature co-adaptation, followed by *softmax* activation function for final prediction of the label. The categorical cross-entropy is used as the loss function.

All the implementation is done in Python using Keras library with Tensorflow backend running on Nvidia 1080Ti GPU. All weights of the networks are initialized randomly and to mitigate the effect of randomness, random seed is fixed across all experiments. In each of the experiments, the model is trained for 200 epochs. A checkpoint of the learned weights is saved at epoch with best predictive performance on the validation split and is later used to evaluate the test split. The training is stopped if validation error does not decrease for 15 epochs.

5.1 Hyper-parameters Tuning

In the proposed model, the choices of the number of convolutional filters and the number of units in dense layers are made empirically. Figure 1 shows these choices for CNN-gram. The rest of the hyper-parameters were selected by performing a grid search on validation split and utilizing RomUrEm embeddings without finetuning. For available choices of $[0.1, 0.2, 0.3, 0.4, 0.5]$ for dropout rate, 0.5 was found to be most optimal. While for optimizer, “Adam” was chosen over “Adadelta” and “SGD”. Finally, 0.002 learning rate turned out to be the optimal choice among $[0.001, 0.002, 0.003.0.004, 0.005]$.

5.2 Evaluation Metrics

We employed the standard metrics that are widely adopted in the literature for measuring the classifi-

Embedding	Without Fine-tuning				With Fine-tuning			
	Accuracy	Precision	Recall	F1-score	Accuracy	Precision	Recall	F1-score
LASER	0.74	0.74	0.74	0.74	0.76	0.76	0.76	0.76
ELMo	0.80	0.80	0.80	0.80	0.79	0.79	0.79	0.79
BERT	0.68	0.70	0.68	0.67	**0.89**	**0.90**	**0.89**	**0.89**
XLM-RoBERTa	0.53	0.27	0.50	0.35	0.85	0.85	0.85	0.85
FastText	0.74	0.75	0.73	0.73	0.88	0.88	0.88	0.88
RomUrEm	**0.85**	**0.84**	**0.84**	**0.84**	0.88	0.88	0.88	0.88

Table 3: Out-of-the-box performance of different embeddings for coarse-grained classification

	Accuracy	Precision	Recall	F1-score
LSTM+GBDT	0.54	0.58	0.51	0.38
BERT+LASER+GBDT	0.89	0.89	0.89	0.89
FastText+CNN	0.87	0.87	0.87	0.87
SVM+RF+AB	**0.90**	**0.90**	**0.90**	**0.90**
BERT+LAMB	**0.90**	**0.90**	0.89	0.89
Domain Embeddings+CNN	0.88	0.89	0.88	0.88
BiLSTM with Attention	0.86	0.86	0.85	0.85
BERT+CNN-gram	**0.90**	**0.90**	**0.90**	**0.90**
XLM-RoBERTa+CNN-gram	0.88	0.88	0.88	0.88
FastText+CNN-gram	0.81	0.81	0.80	0.80
RomUrEm+CNN-gram	0.89	0.89	0.89	0.89

Table 4: Comparisons of the proposed approach with baseline models on coarse-grained classification

cation performance involving imbalanced dataset. These metrics are *accuracy, macro precision, macro recall,* and *macro F1-score* (Attia et al., 2018). In RUHSOLD dataset, "Normal" class is the dominant while other classes are underrepresented. Thus, it is prudent to use macro-averaging to reflect the model performances as it is insensitive to skewness in class distribution.

6 Results and Discussion

In this section, we discuss the findings of our experiments. Subsequent two subsections present the results on test split of RUHSOLD dataset for coarse-grained and fine-grained classification respectively.

6.1 Coarse-grained Classification

Table 3 summarizes the results for the out-of-the-box predictive performance of the pre-trained embeddings (without utilizing any downstream model). This experiment is intended to highlight the ability of pre-trained embeddings to be adapted for different domains, languages, and tasks. We evaluate the predictive performance in terms of macro F1-score. However, for completeness sake, accuracy, macro precision, and macro recall are also given. We show the results of both variants i.e., without and with fine-tuning (i.e. transfer learning). In case where fine-tuning is not allowed, the domain-specific RomUrEm embeddings, that are trained on a parallel corpora (recall section 4), outperform all other pre-trained embeddings by a significant margin. It yields an F1-score of 0.84, which is followed by ELMo with an F1-score of 0.80. LASER and FastText show comparable performance with F1-scores of 0.74 and 0.73 respectively. The XLM-RoBERTa embeddings yield the poorest performance among all the embeddings with an F1-score of 0.35. The highest performance of RomUrEm can be attributed to the fact that it is trained on tweets having both random and hateful content, while the other embeddings are trained on common texts. Thus, to make a fair comparison, we perform fine-tuning for all embeddings on RUHSOLD dataset in order to perform transfer learning from one domain to the other.

With fine-tuning, the highest F1-score of 0.89 is shown by BERT, which is closely followed by an F1-score of 0.88 of FastText and RomUrEm embeddings. It is worthwhile to note that by allowing fine-tuning, the F1-score is increased from 0.67 to 0.89 for BERT. The highest improvement, however, is shown by XLM-RoBERTa for which, fine-tuning boosts F1-score from 0.35 to 0.85, which is a significant increment of 0.50. These results lead us to deduce that BERT, FastText, and XLM-RoBERTa have a higher potential for transfer learning, thus, are plausible candidates to be used as embeddings for any downstream model for the task of hate-speech detection. These results however, need to be interpreted with caution. As RomUrEm is already trained on a corpora of hate-speech tweets, the same cannot be concluded for this particular embedding. However, it's results can act as a standard to gauge the transfer learning potential of other embeddings. In that regard, BERT embedding has an advantage which exhibits a higher capability for domain adaptation and transfer learning.

Table 4 presents the comparison of the proposed approach with baseline models. In baseline models, LSTM+GBDT has the least F1-score of 0.38. LSTM captures long-term dependencies and order

Embedding	Without Fine-tuning				With Fine-tuning			
	Accuracy	Precision	Recall	F1-score	Accuracy	Precision	Recall	F1-score
LASER	0.66	0.62	0.42	0.46	0.67	0.59	0.52	0.54
ELMo	**0.70**	0.64	**0.52**	**0.56**	0.60	0.66	0.50	0.55
BERT	0.61	0.60	0.36	0.37	0.77	0.72	0.65	0.67
XLM-RoBERTa	0.53	0.11	0.20	0.14	**0.79**	0.70	**0.75**	**0.72**
FastText	0.62	0.55	0.33	0.35	0.77	0.69	0.63	0.66
RomUrEm	**0.70**	**0.69**	0.51	**0.56**	**0.79**	**0.76**	0.63	0.67

Table 5: Out-of-the-box performance of different embeddings for fine-grained classification

of the words and it is evident that this information is not rich enough for the task of hate-speech detection with respect to this dataset. It is interesting to note that complex ensemble models yield a higher F1-score. For instance, SVM+RF+AB shows an F1-score of 0.90, which is the highest amongst all the baseline approaches. This is closely followed by two other ensemble models i.e., BERT+LASER+GBDT and BERT+LAMB, with an F1-score of 0.89. Other baseline models show similar performance with a variation of ±0.03 score. Turning now to the proposed model, we employ four embeddings for our experiments by keeping in the view results presented in Table 3. The variation with BERT embedding show the highest F1-score of 0.90, closely followed by the variations with RomUrEm and XLM-RoBERTa, which yields F1-score of 0.89 and 0.88 respectively. The least performance is achieved by using FastText embedding which gives an F1-score of 0.80. Note that the results of the best performing variation of the proposed model are identical to the baseline of SVM+RF+AB. Interestingly, BERT performs similarly to the domain specific RomUrEm embeddings which is consistent with the findings of Table 3 that BERT can be a convincing replacement for domain specific embeddings. However, it is relatively an easier task as compared to fine-grained classification. Thus, more concrete conclusions can be drawn by analyzing the results on fine-grained classification task.

6.2 Fine-grained Classification

Table 5 shows that without fine-tuning, ELMo embedding performs par with domain specific RomUrEm embeddings with an F1-score of 0.56. This is followed by LASER embedding that yields 0.46 F1-score. Other pre-trained embeddings, however, show a poorer performance. For instance, BERT, FastText, and XLM-RoBERTa yield an F1-score of 0.37, 0.35, and 0.14 respectively. Conversely, allowing fine-tuning makes the XLM-RoBERTa top performer amongst the bunch. This is closely followed by BERT and RomUrEm. In general, all embedding models, except ELMo, benefit from fine-tuning. Much like coarse-grained classification, highest improvement with fine-tuning is shown by XLM-RoBERTa with a difference of 0.58. It is interesting to note that RomUrEm is able to achieve an F1-score of 0.67 on this challenging task, which is identical to BERT. These results strengthen our confidence in BERT and XLM-RoBERTa that these models are able to capture the complexity of natural language semantics to a greater or equal extent of domain-specific embedding trained from scratch.

	Accuracy	Precision	Recall	F1-score
LSTM+GBDT	0.53	0.20	0.20	0.15
BERT+LASER+GBDT	0.80	0.73	0.70	0.71
FastText+CNN	0.78	0.70	0.67	0.68
SVM+RF+AB	0.77	0.73	0.62	0.67
BERT+LAMB	0.80	0.72	0.73	0.72
Domain Embeddings+CNN	0.72	0.63	0.52	0.55
BiLSTM with Attention	0.76	0.67	0.63	0.65
BERT+CNN-gram	**0.82**	**0.75**	**0.74**	**0.75**
XLM-RoBERTa+CNN-gram	0.81	0.74	0.71	0.72
FastText+CNN-gram	0.66	0.45	0.41	0.42
RomUrEm+CNN-gram	0.75	0.68	0.61	0.64

Table 6: Comparisons of the proposed approach with baseline models on fine-grained classification

Let us now look at the results of baseline and the proposed model shown in Table 6. As this is a difficult task as compared to coarse-grained classification, it reflects the true learning capabilities of the models. It is evident from the results that LSTM+GBDT is the poorest performer among all the baselines with an F1-score of 0.15, which is in line with the results of coarse-grained classification task. This is followed by Domain Embeddings+CNN, which yield an F1-score of 0.55. These results reflect the difficulty that simpler models face in the identification of hate-speech at fine-grained level. The more complex models such as BERT+LASER+GBDT and BERT+LAMB yield a higher F1-score of 0.71 and 0.72 respectively. We note from Table 4 and 6 that all baseline models utilizing BERT embeddings show a consistent

Table 7: Fine-grained classification predictions of best performing baseline and the proposed model

performance across both tasks.

As far as the performance of the variants of the proposed model is concerned, the BERT+CNN-gram has the highest F1-score of 0.75, which is an improvement over the baseline. This result corroborates with the result of coarse-grained classification task presented in Table 4. XLM-RoBERTa based variation exhibit the second highest score of 0.72, which is identical to the baseline BERT+LAMB model. The lowest performance is shown by FastText+CNN-gram with an F1-score of 0.42 while RomUrEm based variant has the F1-score of 0.64. These results substantiate the findings on coarse-grained classification task which suggest that instead of training embeddings, using existing pre-trained embeddings by fine-tuning them on the task in hand is a more perceptive choice. However, a carefully tailored model on top of these embeddings is advantageous. The results of both coarse-grained and fine-grained classification experiments support this conclusion.

We show some examples of fine-grained classification predictions in Table 7 for best performing baseline and proposed model variation to showcase challenges faced with respect to classification at the granular level. It is observed that the models are more "confused" between Abusive/Offensive and Profane as compared to other labels. It shows the limitation of the models with respect to intricacies of human language for subtle differences between profane language and targeted abuse or offensive language.

7 Conclusion and Future Work

In this work, we presented a dataset in Roman Urdu for the task of hate-speech detection in social media content, annotated with five fine-grained labels. We also make publicly available domain-specific embeddings trained on a parallel corpora of more than 4.7 million tweets. Furthermore, an extensive experimentation with respect to multiple embeddings, their power of transfer learning, and comparison with existing baseline models is carried out. As a future research, semantically challenging cases at fine-grained level with respect to complexities of Abusive/Offensive (targeted) and Profane (untargeted) language demand further investigation.

Suicidal Risk Detection for Military Personnel

Abstract

We analyze social media for detecting the suicidal risk of military personnel, which is especially crucial for countries with compulsory military service such as the Republic of Korea. From a widely-used Korean social Q&A site, we collect posts containing military-relevant content written by active-duty military personnel. We then annotate the posts with two groups of experts: military experts and mental health experts. Our dataset includes 2,791 posts with 13,955 corresponding expert annotations of suicidal risk levels, and this dataset is available to researchers who consent to research ethics agreement. Using various fine-tuned state-of-the-art language models, we predict the level of suicide risk, reaching .88 F1 score for classifying the risks.

1 Introduction

Suicide is one of the major causes of death in the military. In some countries where military service is compulsory because of a conscription system, active-duty military personnel live in physical separation from their family and friends for an extended period of time, often against their will. In the Republic of Korea, for example, most men have the obligation to serve in the military for about a year and half, leading to a large population of about 600,000 in active duty as of this year. Many of them experience difficulty adapting to the isolated environment, and some of them are at risk of suicide.

One approach to detect the suicide risk signs of active-duty soldiers is the analysis of social media posts, similar to the approach used for detecting suicide risk of the general public (Milne et al., 2016; Yates et al., 2017; Zirikly et al., 2019). However, research on military suicide finds that there are distinct risk factors, such as combat exposure, injury, bereavement, and negative unit climate associated only with military service (Nock et al., 2013). For this reason, we cannot directly apply the findings of suicide risk research of the general public to the military personnel. In this paper, we take on the challenge of collecting social media posts related to military service in the Republic of Korea, annotating and analyzing them using NLP methods for detecting suicide risk of active-duty soldiers.

The first and most challenging step is to create an annotated dataset of military-related social media posts written by active-duty soldiers. We collect posts from a popular social question and answering (Q&A) platform. Anonymous posts are allowed, so we find that there is a considerable amount of military-related posts that contain possible suicide risk and other mental health issues. Annotation poses a challenge, as the mental health and suicide risk of soldiers should be analyzed by mental health experts experienced in the military setting. It is difficult, though, to find such experts, so we reached out to two separate groups of experts, military experts and mental health experts. We asked both groups for annotation, and our analysis includes the results of the annotation, as well as the results of the prediction of suicide risk.

Our focused contribution is in building a dataset of 2,791 social media posts written by military personnel in Korean with corresponding 13,955 expert annotations of suicidal risk levels. We fine-tune various state-of-the-art language models to classify the risks for developing simple yet effective baselines, achieving up to .88 F1 score.

2 Constructing Annotated Dataset

We describe the steps in collecting relevant posts, preprocessing, and annotations. We also explain

November 16–20, 2020.

Risk Level	Description
Imminent Risk (3)	• Expressing to self-harm or suicide directly and explicitly. • Making concrete plans for suicide: seeking access to hazardous tools or pills • Existence of triggering events, make a will, etc.
High Risk (2)	• Expressing to self-harm or suicide indirectly and implicitly • Desire for suicidal behavior, suicidal ideation, self-harming • Risk factors becoming severe due to stressful events, relationship problems, etc.
Low Risk (1)	• Expressing depressed, stressed, anxiety due to environmental or internal factors • Maladaptation to (military) service, but would become adaptable through adequate measures • Requiring continuous treatment with the therapist or psychiatrist
No Risk (0)	• No help required due to no risky sign detected • Expressing mild sadness • Simple questions

Table 1: Risk annotation criteria. All posts are annotated with risk leve lof 0 to 3. *Imminent Risk (3)*: the writer of the post needs urgent help. The post might show concrete plans to commit suicide, or triggering events. *High Risk (2)*: the writer needs attention, reporting and help. The writer expresses desire and thinking about suicide, and/or self-harming behaviors. *Low Risk (1)*: the writer needs help but not urgently. *No Risk (0)*: no risk of suicide.

how we dealt with research ethics concerns.

2.1 Data Collection

Collecting Posts. We collect relevant posts from Naver Knowledge iN, an online Korean Q&A (Question and Answering) platform in 2019. Like Quora.com, people ask questions through anonymous posts without length constraints. In some cases, users disclose their personal matters to obtain advice from others. To collect the relevant posts, we use 58 military-related keywords plus suicide or self-harm related terms. For instance, we use 'military force', 'army + self-harm', 'army + suicide', and so on. For every keyword, we collect the most recent 1,000 posts without any meta-data such as username and timestamp because these features could make person identification quite easy. Through this process, we collect 44,108 posts.

Preprocessing. We preprocess the collected posts in three steps. Since 58 search keywords return many duplicated posts, so we first remove duplicates which reduces the data size.

Then we manually remove any post that is written by family or friends of the soldier, or by anyone unrelated to military. We retain only posts written by soldiers themselves so that the trained model can detect suicide risk signals of the active military personnel based on their first-person account.

Next, we manually remove personally identifiable information and all named entities in the text. We found 44 unit names, 7 school names, 10 number of grades, 2 region names, and 2 personal names and user ids and replaced them with unidentifiable placeholders. After preprocessing, we are left with 2,791 posts. The average length of a post is 92.7 words.

Ethical Concerns. We carefully consider any potential ethical concerns with the entire process of this research. We collect posts only if they are publicly available from Naver Knowledge iN, and we do not collect any metadata of the posts because they can potentially be used to identify authorship. Also, we manually inspect every post to remove personally identifiable information, masking all named entities. These processes are costly and make it very difficult to build a large-scale corpus. Annotators are shown only anonymized posts, and annotated data will be available to researchers with express consent not to contact or de-anonymize any of the posts.[1] This study is reviewed and approved by the KAIST Institutional Review Board (#KH2019-122).

2.2 Annotating Suicidal Risk

5 annotators evaluated the degree of suicidal risk of writers (military personnel) in the anonymized posts. We annotate the risk at the *post-level* because anonymous posts do not have user names from the start, and the other posts are anonymized by removing user names due to the ethical concerns.

Annotation Criteria. Table. 1 shows our annotation criteria, which came from existing shared task settings (Milne et al., 2016; Zirikly et al., 2019) and guidelines such as 'Classification criteria of *soldiers in need*' issued by the Ministry of National Defense. All posts are annotated with the risk level from 0 to 3, from lowest to highest level of detected

	E1	**E2**	**I1**	**I2**	**I3**
0	2,453	2,157	1,213	881	1,255
1	205	542	1,132	1,592	1,434
2	93	79	434	242	71
3	40	13	12	76	31

Table 2: Risk level distributions among annotators. External annotator group tends to evaluate most posts as *No Risk*, and internal annotator group labels more posts as *Low Risk*. The proportion of posts labeled as class *High Risk* and *Imminent Risk* is about 3-10%.

suicidal risk.

Annotation Perspective. Evaluating suicidal risk of military personnel requires professional clinical knowledge as well as military experience because of various factors unique for the military setting (Nock et al., 2013; Oh and Lee, 2017). So we separate and consider the two perspectives: first of military experts and second of clinical experts. Military experts evaluate the risk as an insider of the special population, since they are familiar with military situational factors through their experiences living and working with 'soldiers in need'. We refer to it as the *internal* perspective. On the other hand, clinicians would view the posts and patients from outside of military service with their clinical experience and knowledge. So we refer to it as the *external* perspective. The difference of perspective for each expert group and detailed annotated examples are in Table. 4.

Annotation Process. We recruit two *external* expert annotators (E1 (Psychiatrist), E2 (Psychotherapist)) and three *internal* expert annotators (I1 (Military Counselor), I2 (Commander), I3 (Commander)). Each annotator independently evaluated the level of the risk detected in the 2,791 posts into the 4 classes. With posts that show disagreement within each group, annotators were asked to evaluate the risk of those items once again independently. Annotators could choose whether to change their initial evaluation, but in most cases they did not change the first evaluation.

2.3 Annotation Results

Here we show risk level frequencies for each annotator, and degrees of agreement among them.

Distribution of Risk Levels. As shown in Table. 2, most posts are labeled as *No Risk* or *Low Risk*. External annotators tend to evaluate most posts as *No Risk*, and internal annotators label more posts as *Low Risk* rather than *No Risk*. The proportion of posts labeled as *High Risk* and *Imminent Risk* is about 3-10%, showing skewed frequency distribution among classes.

	E1	**E2**	**I1**	**I2**	**I3**
E1	1.00				
E2	0.54	1.00			
I1	0.22	0.33	1.00		
I2	0.19	0.24	0.45	1.00	
I3	0.25	0.36	0.45	0.55	1.00

Table 3: Cohen's inter-annotator Agreement (IAA) coefficients across annotators. The overall IAA shows fair agreement. Agreement within each group is higher than that of between groups.

Inter-Annotator Agreement (IAA). Table. 3 presents Cohen's IAA among annotators. We find the agreement of within group is higher than that of between groups.

In detail, within each group, the external annotators show fair agreement (Krippendorff's α=0.58), and the internal annotators fair agreement as well. (Krippendorff's α=0.55) The overall agreement among the five annotators is lower (Krippendorff's α=0.37) than that of within group agreements. In addition, if annotations are binarized to 'Flagged', the Krippendorff's αs are internal's α=0.53, external's α=0.52, overall α=0.30. Again, we observe fair agreement within groups, but the level of agreement of all annotators is rather low because of the difference between groups.

Comparison between Perspectives. Table. 4 shows a few manually selected examples of risk annotation between groups. For the first and second examples, two groups annotated the same scores. The first example explicitly expresses suicidal thoughts and even a failed suicide attempt, so all annotators agreed the writer seems to require immediate help. The second example asks merely for a skin problem, and both groups annotated as *No Risk* for this post.

Through third and fourth examples, we can see the difference between the two perspectives. For the third example, the internal annotators rated relatively higher than the external annotators. This is because the writer is under stress due to the problems adjusting to military life, suffering from depression and thinking about suicide. Also, they think this would have highly negative effect on the poster's life in the unit, so they judge the risk factor is relatively high, and the military must pay attention from the perspective of the commander responsible for this soldier's life and work in the military.

Annotation	Example
E (High, 3.00) I (High, 3.00)	I'm a soldier now.. I'm so tired of depression, insomnia, and hallucination. Every day I try to sleep, some voices tell me not to sleep, so I can't sleep without medicine... When I'm in a group of people, my heart beats fast, hard to breathe, head hurts, and I feel dizzy. And when I look in the mirror, I'm so surprised to see someone behind me, even though nobody's there. It was a shock to me... because I can definitely hear and see it. I feel like I'm lying. I don't know what's happening. I feel so sorry to my family, but after I die, hard time would be just a moment. I heard that 'Actifed' is bad for people with high blood pressure like me. I bought 100 pills at the pharmacy. I took all tablets of Actifed, but just throwing up 4 times and being paralyzed for an hour. I still feel pain when I move. I'm sorry I couldn't die.
E (No, 0.00) I (No, 0.00)	Although I'm in the military, I can go on vacation more often so I can take care of my skin. So far, I haven't cared much about my skin but then.. Should I take care of it since I'm on duty? Or after being discharged?
E (Low, 0.50) I (High, 2.00)	After a few days I was assigned to my platoon, I have felt weird symptoms. Due to the rebuke and curse from senior soldiers, I was so nervous that I couldn't carry out my mission efficiently, and couldn't think or judge well just like a teenager. I hate to be with others, and I didn't really want to live every day. I usually come up with suicidal ideas, but I try hard to withstand the situation by thinking of my parents, and shedding tears alone. I have a continuous headache with dizziness, get to sleep irregularly, and I'm in a daze. It feels like what I'm doing isn't mine, and I feel depressed all day long. I don't even have an appetite. But unit says it's difficult to discharge me early because my situation is not bad enough, and it doesn't look very serious. My unit's refusing though my medical report says "Consider maladaptation to service." I'm having a hard time every day. I want to get out of the unit and get counseling and proceed with treatment.
E (High, 2.00) I (Low, 0.67)	I wanna kill myself How can I stand military life for 9 more months.. I could be reminiscing looking back on this later. I don't know if I can do it well

Table 4: Examples of risk annotation between groups. The first and second examples show the same evaluation of the risk for the post. For the third and fourth examples, there is disagreement of the evaluated risk between the two expert groups.

However, the external annotators expect that there is little suicidal risk because the writer wants to visit a therapist or psychiatrists anyway rather than moving onto suicidal behavior. The fourth example expresses thoughts about killing oneself, so the external annotators give a higher risk score to this example. But the internal annotators see less risk from the post because they have commonly heard this type of negative expression about the mandatory military service among the soldiers.

Considering these examples and others, we conclude that both perspectives should be considered together and separately while predicting the suicidal risk of military personnel using a computational model.

3 Experiments

We classify the posts by annotated risk levels at the post-level. We first compute the *maximum* value of risk annotations to aggregate multiple annotations for each post with the aim to give alert if there is *any* possibility of suicidal risk. This might increase false positives, but the experts view that in practice, false positives are better than false negatives.

Classification Types. We classify posts in three ways: 1) the four risk levels, 2) `Flagged` or not, and 3) `Urgent` or not. For binary classification, we consider *Low, High, Imminent Risk* posts as `Flagged` and *No Risk* as `Not Flagged`, and *High, Imminent Risk* as `Urgent` and *Low, No Risk* posts as `Not Urgent` (Milne et al., 2016).

Models. We leverage two type of models: 1) Convolutional Neural Network (CNN) and 2) pre-trained language models, which are used in the relevant shared task (Zirikly et al., 2019). The teams that participated in the shared task demonstrated that CNN is effective for the risk classification task (Morales et al., 2019). Also, ASU (Ambalavanan et al., 2019) shows fine-tuning pre-trained language model is highly effective. Note that our dataset contains Korean posts with post-level risk annotations, so these previous models should be adjusted to our dataset.

Specifically, we use CNN with pre-trained Korean subword-level word embeddings for the input of the two convolution layers (Park et al., 2018). In case of using pre-trained language models, we have a choice to use *multilingual* models trained

Model	All annotators			Internal expert			External expert		
	`4-level` F1 (Acc.)	`Flagged` F1 (Acc.)	`Urgent` F1 (Acc.)	`4-level` F1 (Acc.)	`Flagged` F1 (Acc.)	`Urgent` F1 (Acc.)	`4-level` F1 (Acc.)	`Flagged` F1 (Acc.)	`Urgent` F1 (Acc.)
CNN	0.56 (0.71)	0.87 (0.90)	0.76 (0.82)	0.52 (0.72)	0.88 (0.91)	0.76 (0.84)	0.46 (0.81)	0.81 (0.86)	0.72 (0.94)
BERT-Multilingual	0.65 (0.72)	0.85 (0.89)	0.74 (0.84)	0.63 (0.71)	0.84 (0.89)	0.71 (0.84)	0.51 (0.84)	0.82 (0.87)	0.81 (0.96)
KoBERT	**0.72** (0.76)	**0.88** (0.91)	**0.80** (0.86)	**0.68** (0.75)	**0.88** (0.92)	**0.80** (0.87)	0.55 (0.84)	**0.85** (0.88)	0.81 (0.96)
XLM-R	0.70 (0.75)	0.87 (0.90)	**0.80** (0.86)	**0.68** (0.75)	0.87 (0.90)	**0.80** (0.86)	**0.56** (0.85)	**0.85** (0.88)	**0.83** (0.96)

Table 5: Results of classification models. Fine-tuning BERT for Korean (KoBERT) or multilingual RoBERTa (XLM-R) shows better performance compared to BERT-multilingual and CNN. We emphasize that fine-tuned language models can correctly classify the post which needs *urgent* help with 0.80 F1 score and 86% accuracy.

with a corpus that includes Korean (Multilingual-BERT (Devlin et al., 2018), XLM-R (Conneau et al., 2020)) , or a model pre-trained over only Korean corpus (KoBERT [2]). Since we classify the risk at the post-level, these models are fine-tuned by post-level supervisions without aggregation of posts to the user-level. Detailed experimental settings for reproducibility are in the Appendix.

Results. The results are shown in Table. 5. We report accuracy as well as macro F1 to consider precision and recall on the test sets. Overall, KoBERT and XLM-R outperform the others. Corresponding results on the validation set and most frequent baselines are in Appendix.

For classifying posts with maximum risk levels from all annotators, KoBERT outperforms in classifying posts at the four risk levels (F1 = 0.72, acc = 0.76), and whether the post is `Flagged` or not. (F1 = 0.88, acc = 0.91) XLM-R shows comparable performance in classifying the `Urgent` posts. (F1 = 0.80, acc = 0.86) This tendency is shown in classifying the internal expert risk level annotations. For External expert's risk classification, XLM-R shows slightly better performance.

Among the annotator groups, internal expert group tends to obtain high scores in overall for both F1 and accuracy (F1 = 0.88, acc = 0.92), while external expert group shows the lowest F1 in average in 4-level risk classification. (F1 = 0.56, acc = 0.85) This is caused by the small number of *Imminent risk* in the external annotator's evaluations.

Also, `Flagged` posts classification performance is higher than that of 4-level or `Urgent` post classification, which implies our model identifies well the posts with any level of risk from posts with *No Risk*. In the 'Flagged' condition, label (1), (2) and (3) are combined as a single class, so imbalance between classes is partially relieved, which leads to a better F1 score. In practice, this would be quite helpful for consideration of intervention.

4 Discussion and Conclusions

In this paper, we tackle the problem of suicidal risk of military personnel from their social media posts. We focus on the specific population of military personnel in compulsory service because it requires a unique approach to fully understand their suicidal risk. As our first step, we collect 2,791 military-relevant posts in a social Q&A platform that are written by at-risk active-duty soldiers and remove any identifying information from the data. Then five annotators (three military experts and two clinicians) evaluate the degree of suicidal risk of the posts. After the dataset is constructed, we fine-tune a pre-trained language models, achieving at most 0.88 F1 score.

Our research can be the first step toward proper intervention programs and institutional support for soldiers with mental health issues. Such follow-up would maximize the value of our model and data. We also plan to add domain-specific features to our model, collect more data, integrate existing suicidal risk datasets with various languages to improve performance.

A Experimental Details

A.1 Comparison Models

We compare the classification performance of comparison models trained on our dataset. We use accuracy and F1 score as evaluation metrics, computing them using scikit-learn. (Pedregosa et al., 2011)

Convolutional Neural Networks. (CNN) We use CNN for text classification. For the input of the convolutional layer, we use 300 dimension pre-trained Korean subword-level word embeddings (Park et al., 2018), and set the number of layers as 2, the number of filters as 256. On the top of the layers, we add sigmoid or softmax activation function for classification

Multilingual BERT. Since our dataset consists of Korean posts, we use Multilingual version of BERT-base cased model. (Devlin et al., 2018) We add a trainable linear layer and sigmoid or softmax activation over the classification head ([CLS]). Then the entire model is fine-tuned by minimizing the cross entropy loss between the predicted label and the target labels, using BertAdam optimizer (Devlin et al., 2018). Most hyperparameters are chosen in original paper. (Devlin et al., 2018) The number of trainable parameters is 110M.

KoBERT. A BERT-base model trained on a corpus consisting of Korean Wikipedia corpus and news data to improve the performance of the multilingual BERT. This is a pre-trained model which is publicly available in GitHub. We use this model to fine-tune on our data. We set all details the same as described in Multilingual BERT above. The number of trainable parameters is 110M.

XLM-R. A state-of-the-art pre-trained cross-lingual language model which trained on corpus including Korean Documents. (Conneau et al., 2020) The model is based on RoBERTa architecture, and the pre-trained model is shown to be highly effective cross-lingual language understanding tasks. Like other BERTs, we fine-tune this model on our data with adding the same classification layer. The number of trainable parameters is 275M.

A.2 Hyperparameters

Batch size is set to 32, and the maximum sequence length to 512 in CNN, Multiligual BERT, KoBERT, and XLM-R. The learning rate of all models are set to 3e-5 like previous settings. (Devlin et al., 2018; Conneau et al., 2020) The batch size and the sequence length is manually chosen to fit the models to our computing infrastructure. All models are trained on single RTX 2080Ti GPU. For every run, a model converged at most within 3 hours.

A.3 Data Splits

We train the classifiers on the training set which consists of 1,674 posts, and evaluated on the 559 posts of the test set. The number of examples in each splits are shown in Table. 7-9 We use a validation set which contains 558 posts for tuning the hyperparameters of our models.

A.4 Most Frequent Baselines

When aggregating all 5 annotators' labels in 4 risk levels, *Low Risk* label accounts for 54.28% of all posts. In binarized label as `Flagged` or not, `Flagged` is relatively more frequent (75.24%) than `Not flagged`, and another binarized label as Urgent or not, `Not urgent` accounts for 78.68%.

Aggregating labels of 3 internal experts shows similar tendency with all 5 annotators' result. `Low Risk` label is the most frequent class which accounts for 54.32% in 4 risk levels. `Flagged` posts are more frequent (75.42%) than `Not flagged`, and `Not urgent` posts are relatively more frequent(78.90%) than `Urgent` post.

2 External experts' annotations are quite different from other group's results. In 4 levels of risk, the ratio of *No Risk* posts reaches to 78.68%, which is the most frequent, and this ratio is obviously same in `Not flagged` posts. When dividing labels into `Urgent` or not, `Not urgent` occupies 94.66%.

Comparing to the most frequent class baseline, the results of our classification models are higher in terms of accuracy.

B Related Work

Detecting Mental Illness in Social Media. Social media posts are widely used in mental illness research using computational methods. One common approach is detecting mental illness related variables from the posts automatically, such as depression (De Choudhury et al., 2013; Schwartz et al., 2014; Guntuku et al., 2017; Eichstaedt et al., 2018), self-harm (Milne et al., 2016; Yates et al., 2017), and suicidal risk (Homan et al., 2014; O'Dea et al., 2015; De Choudhury et al., 2016; Coppersmith et al., 2018; Cao et al., 2019; Aragón et al., 2019; Jung et al., 2019). These approaches usually aim to help people in need immediately. More

general mental health research includes predicting mental health conditions (Benton et al., 2017), mental well-being (Bagroy et al., 2017), physical illness (Wang et al., 2017), and medical conditions (Merchant et al., 2019).

This kind of research requires annotated data, so much effort has been made toward data collection and dissemination. The 2nd Workshop on Computational Linguistics and Clinical Psychology (CLPsych'15) introduced a shared task (Coppersmith et al., 2015) to identify depression and post-traumatic stress disorder (PTSD) users using a Twitter dataset. The shared task for CLPsych'19 introduced an assessment of suicide risk based on social media postings using data from Reddit to identify the four levels of risk (Zirikly et al., 2019). Yates et al. (2017) introduced a large-scale Reddit dataset containing 9,000 users with self-reported depression diagnoses, along with over 107,000 control users. Another research created a general Reddit dataset for the assessment of suicide risk via online postings (Shing et al., 2018).

Unlike previous studies, our work focus on a specific at-risk population. Suicidal risk of military personnel could more easily result in tragic consequences because of their easier access to firearms (Nock et al., 2013; Oh and Lee, 2017).

Mental Health Problems of Military Personnel. Since mental health problems in military are different from those of the general population, they should be treated distinctly. Previous research in soldiers' mental health looks into patients with PTSD and other traumatic experiences. This line of research mainly investigates the patients' medical records, questionnaires, psychological measurement tools, interviews, or administrative data (Kim et al., 2011; Bryan et al., 2013a; Thompson et al., 2014; Bryan et al., 2013b; Reger et al., 2018; Anestis et al., 2019; Start et al., 2019).

A study using social media posts investigates the temporal changes in military personnel's posts during the year preceding their death, through content coding method and multilevel models (Bryan et al., 2018). This work focuses on explaining the factors of suicide from posts, rather than train a model to predict the risks from unseen data.

Our work applies a computational method to social media posts to predict suicidal risks from unseen posts without additional manual coding. This research opens up an important new direction in computational analysis of mental health in a special at-risk population.

Comparative Evaluation of Label-Agnostic Selection Bias in Multilingual Hate Speech Datasets

Nedjma Ousidhoum, Yangqiu Song, Dit-Yan Yeung
Department of Computer Science and Engineering
The Hong Kong University of Science and Technology
nousidhoum@cse.ust.hk, yqsong@cse.ust.hk, dyyeung@cse.ust.hk

Abstract

Work on bias in hate speech typically aims to improve classification performance while relatively overlooking the quality of the data. We examine selection bias in hate speech in a language and label independent fashion. We first use topic models to discover latent semantics in eleven hate speech corpora, then, we present two bias evaluation metrics based on the semantic similarity between topics and search words frequently used to build corpora. We discuss the possibility of revising the data collection process by comparing datasets and analyzing contrastive case studies.

1 Introduction

Hate speech in social media dehumanizes minorities through direct attacks or incitement to defamation and aggression. Despite its scarcity in comparison to normal web content, Mathew et al. (2019) demonstrated that it tends to reach large audiences faster due to dense connections between users who share such content. Hence, a search based on generic hate speech keywords or controversial hashtags may result in a set of social media posts generated by a limited number of users (Arango et al., 2019). This would lead to an inherent bias in hate speech datasets similar to other tasks involving social data (Olteanu et al., 2019) as opposed to a *selection bias* (Heckman, 1977) particular to hate speech data.

Mitigation methods usually point out the classification performance and investigate how to debias the detection given false positives caused by gender group identity words such as "women" (Park et al., 2018), racial terms reclaimed by communities in certain contexts (Davidson et al., 2019), or names of groups that belong to the intersection of gender and racial terms such as "black men" (Kim et al., 2020). The various aspects of the dataset construction are less studied though it has recently been shown, by looking at historical documents, that we may somehow neglect the data collection process (Jo and Gebru, 2020). Thus, in the present work, we are interested in improving hate speech data collection with evaluation before focusing on classification performance.

We conduct a comparative study on English, French, German, Arabic, Italian, Portuguese, and Indonesian datasets using topic models, specifically Latent Dirichlet Allocation (LDA) (Blei et al., 2003). We use multilingual word embeddings or word associations to compute the semantic similarity scores between topic words and predefined keywords and define two metrics that calculate bias in hate speech based on these measures. We use the same list of keywords reported by Ross et al. (2016) for German, Sanguinetti et al. (2018) for Italian, Ibrohim and Budi (2019) for Indonesian, Fortuna et al. (2019) for Portuguese; allow more flexibility in both English (Waseem and Hovy, 2016; Founta et al., 2018; Ousidhoum et al., 2019) and Arabic (Albadi et al., 2018; Mulki et al., 2019; Ousidhoum et al., 2019) in order to compare different datasets based on shared concepts that have been reported in their respective paper descriptions; and for French, we make use of a subset of keywords that covers most of the targets reported by Ousidhoum et al. (2019). Our first bias evaluation metric measures the average similarity between topics and the whole set of keywords, and the second one evaluates how often keywords appear in topics. We analyze our methods through different use cases which explain how we can benefit from the assessment.

Our main contributions consist of (1) designing bias metrics that evaluate hateful web content using topic models; (2) examining selection bias in eleven datasets; and (3) turning present hate speech corpora into an insightful resource that may help us balance training data and reduce bias in the future.

2 Related Work

Hate speech labeling schemes depend on the general purpose of the dataset. The annotations may include hateful vs. non hateful (Basile et al., 2019), racist, sexist, and none (Waseem and Hovy, 2016); as well as discriminating target attributes (ElSherief et al., 2018), the degree of intensity (Sanguinetti et al., 2018), and the annotator's sentiment towards the tweets (Ousidhoum et al., 2019). Besides English (Basile et al., 2019; Waseem and Hovy, 2016; Davidson et al., 2017; ElSherief et al., 2018; Founta et al., 2018; Qian et al., 2018), we notice a growing interest in the study of hate speech in other languages, such as Portuguese (Fortuna et al., 2019), Italian (Sanguinetti et al., 2018), German (Ross et al., 2016), Indonesian (Ibrohim and Budi, 2019), French (Ousidhoum et al., 2019), Dutch (Hee et al., 2015), and Arabic (Albadi et al., 2018; Mulki et al., 2019; Ousidhoum et al., 2019). Challenging questions being tackled in this area involve the way abusive language spreads online (Mathew et al., 2019), fast changing topics during data collection (Liu et al., 2019), user bias in publicly available datasets (Arango et al., 2019), bias in hate speech classification and different methods to reduce it (Park et al., 2018; Davidson et al., 2019; Kennedy et al., 2020).

Bias in social data is broad and addresses a wide range of issues (Olteanu et al., 2019; Papakyriakopoulos et al., 2020). Shah et al. (2020) present a framework to predict the origin of different types of bias including label bias (Sap et al., 2019), selection bias (Garimella et al., 2019), model overamplification (Zhao et al., 2017), and semantic bias (Garg et al., 2018). Existing work deals with bias through the construction of large datasets and the definition of social frames (Sap et al., 2020), the investigation of how current NLP models might be non-inclusive of marginalized groups such as people with disabilities (Hutchinson et al., 2020), mitigation (Dixon et al., 2018; Sun et al., 2019), or better data splits (Gorman and Bedrick, 2019). However, Blodgett et al. (2020) report a missing normative process to inspect the initial reasons behind bias in NLP without the main focus being on the performance which is why we choose to investigate the data collection process in the first place.

In order to operationalize the evaluation of selection bias, we use topic models to capture latent semantics. Regularly used topic modeling techniques such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003) have proven their efficiency to handle several NLP applications such as data exploration (Rodriguez and Storer, 2020), Twitter hashtag recommendation (Godin et al., 2013), authorship attribution (Seroussi et al., 2014), and text categorization (Zhou et al., 2009).

In order to evaluate the consistency of the generated topics, Newman et al. (2010) used crowdsourcing and semantic similarity metrics, essentially based on Pointwise Mutual Information (PMI), to assess the coherence; Mimno et al. (2011) estimated coherence scores using conditional log-probability instead of PMI; Lau et al. (2014) enhanced this formulation based on normalized PMI (NPMI); and Lau and Baldwin (2016) investigated the effect of cardinality on topic generation. Similarly, we use topics and semantic similarity metrics to determine the quality of hate speech datasets, and test on corpora that vary in language, size, and general collection purposes for the sake of examining bias up to different facets.

3 Bias Estimation Method

The construction of toxic language and hate speech corpora is commonly conducted based on keywords and/or hashtags. However, the lack of an unequivocal definition of hate speech, the use of slurs in friendly conversations as opposed to sarcasm and metaphors in elusive hate speech (Malmasi and Zampieri, 2018), and the data collection timeline (Liu et al., 2019) contribute to the complexity and imbalance of the available datasets. Therefore, training hate speech classifiers easily produces false positives when tested on posts that contain controversial or search-related identity words (Park et al., 2018; Sap et al., 2019; Davidson et al., 2019; Kim et al., 2020).

To claim whether a dataset is rather robust to keyword-based selection or not, we present two label-agnostic metrics to evaluate bias using topic models. First, we generate topics using Latent Dirichlet Allocation (LDA) (Blei et al., 2003). Then, we compare topics to predefined sets of keywords using a semantic similarity measure. We test our methods on different numbers of topics and topic words.

3.1 Predefined Keywords

In contrast to Waseem (2016), who legitimately questions the labeling process by comparing ama-

teur and professional annotations, we investigate how we could improve the collection without taking the annotations into account. In other terms, how the data selection contributes to the propagation of bias and therefore, false positives during first, the annotation step, then the classification.

We define $\mathbf{B_1}$ and $\mathbf{B_2}$ assess how the obtained social media posts semantically relate to predefined keywords. The bias metric $\mathbf{B_1}$ measures this relatedness on average, while $\mathbf{B_2}$ evaluates how likely topics are to contain keywords. We use predefined sets of keywords that can be found in the hate speech resource paper descriptions (Waseem and Hovy, 2016; Ross et al., 2016; Sanguinetti et al., 2018; Founta et al., 2018; Albadi et al., 2018; Fortuna et al., 2019; Mulki et al., 2019), appeared on reported websites[1], or seen along with the corpus (Ibrohim and Budi, 2019; Ousidhoum et al., 2019).

Table 1 shows examples of keywords utilized to gather toxic posts[2]. The list of keywords provided by Ibrohim and Budi (2019), which contains 126 words, is the largest we experiment with. The Portuguese, Italian, and German lists are originally small since they focus on particular target groups[3], whereas the remaining lists have been reduced slightly to meet the objectives presented in the descriptions of all the corpora we used.

3.2 Topic Models

Table 2 shows examples of topics that were generated from the chosen datasets. Although Founta et al. (2018) report collecting data based on controversial hashtags and a large dictionary of slurs, Waseem and Hovy (2016) on other hashtags, and Ousidhoum et al. (2019) on a different set of keywords, we can initially notice a recurring term in two English topics, and potentially more if we generate larger topics.

Moreover, Ousidhoum et al. (2019)'s Arabic dataset contains the word *pigs* used to insult people, a slang word, and the word *camels* as a part of a demeaning expression that means *"camels urine drinkers"* which is usually used to humiliate people from the Arabian Peninsula. The three words exist in the predefined list of keywords similarly to all French, Portuguese, Italian and most German and Idonesian topic words.

Italian, German and Portuguese topics are composed of words related to immigrants and refugees as they correspond to the main targets of these datasets. The French topic also contains the name of a political ideology typically associated with more liberal immigration policies.

---

[1] Such as the HateBase`https://hatebase.org/`.

[2] We will make both the lists and links to their sources available to the research community.

[3] The target groups are women, immigrants, and refugees.

Other than slurs, named entities can be observed in Waseem and Hovy (2016)'s topic, which includes the name of a person who participated in an Australian TV show that was discussed in the tweets [4]; the German topic includes the name of the German Chancellor *Merkel* since she was repeatedly mentioned in tweets about the refugee crisis (Ross et al., 2016); Mulki et al. (2019)'s topic contains the name of the Lebanese political figure *Gebran Bassil* since they collected their dataset based on Twitter accounts of Syrian and Lebanese political figures; as well as names of religious groups in Albadi et al. (2018)'s topic in conformity with their collection strategy based on names of sects.

Despite their short length, the example topics can provide us with a general idea about the type of bias present in different datasets. For instance, topics generated from datasets in languages which are mainly spoken in Europe and the USA commonly target immigrants and refugees, in contrast to Arabic and Indonesian topics which focus on other cultural, social, and religious issues. Overall, all topics show a degree of potentially quantifiable relatedness to some predefined key concepts.

3.3 Bias Metrics

Mimno et al. (2011), Lau et al. (2014), and Röder et al. (2015) evaluate the quality of topics through coherence metrics that use Pointwise Mutual Information (PMI) and other similarity measures. Similarly, we would like to assess topic bias in hate speech based on the semantic similarity between high scoring words in each topic and the set of search keywords used to collect data.

Given a set of topics $\mathbf{T}=\{\mathbf{t_1}, \ldots, \mathbf{t_{|T|}}\}$ generated by LDA, with each topic $\mathbf{t_i}=\{\mathbf{w_1}, \ldots, \mathbf{w_n}\}$ composed of n words, and a predefined list of keywords $\mathbf{w'}$ of size m such as $\mathbf{w'}=\{\mathbf{w'_1}, \ldots, \mathbf{w'_m}\}$, we define the two bias functions $\mathbf{B_1}$ and $\mathbf{B_2}$ based on $\mathbf{Sim_1}$ and $\mathbf{Sim_2}$, respectively.

$\mathbf{Sim_1}$ measures the similarity between two words $\mathbf{w_j} \in \mathbf{t_i}$ and $\mathbf{w'_k} \in \mathbf{w'}$ for $\mathbf{t_i} \in \mathbf{T}$, with $0 < i \leq |\mathbf{T}|$, such as:

$$\mathbf{Sim_1}(\mathbf{t_i}, \mathbf{w'}) = \frac{1}{n}\frac{1}{m}\sum_{j=1}^{n}\sum_{k=1}^{m} \mathbf{Sim}(\mathbf{w_j}, \mathbf{w'_k}) \quad (1)$$

$\mathbf{B_1}$ computes the mean similarity between each $\mathbf{w_j} \in \mathbf{t_i}$ and $\mathbf{w'_k} \in \mathbf{w'}$, then the mean given all generated topics, such as:

$$\mathbf{B_1}(\mathbf{T}, \mathbf{w'}) = \frac{1}{|\mathbf{T}|}\sum_{i=1}^{|\mathbf{T}|} \mathbf{Sim_1}(\mathbf{t_i}, \mathbf{w'}) \quad (2)$$

$\mathbf{Sim_2}$ measures the maximum similarity of each word $\mathbf{w_j} \in \mathbf{t_i}$ and keyword $\mathbf{w'_k} \in \mathbf{w'}$, w_j, such as $\forall \mathbf{w_j} \in \mathbf{t_i}$ and $\forall \mathbf{w'_k} \in \mathbf{w'}$ with $0 < j \leq n$ and $0 < k \leq m$:

$$\mathbf{Sim_2}(\mathbf{t_i}, \mathbf{w'}) = \max \mathbf{Sim}(\mathbf{w_j}, \mathbf{w'_k}) \quad (3)$$

Then, we calculate $\mathbf{B_2}$ similarly to $\mathbf{B_1}$:

$$\mathbf{B_2}(\mathbf{T}, \mathbf{w'}) = \frac{1}{|\mathbf{T}|}\sum_{i=1}^{|\mathbf{T}|} \mathbf{Sim_2}(\mathbf{t_i}, \mathbf{w'}) \quad (4)$$

Both $\mathbf{B_1}$ and $\mathbf{B_2}$ scores aim to capture how the word distribution of a given dataset can lead to false positives. $\mathbf{B_1}$ evaluates how the whole set of keywords $\mathbf{w'}$ semantically relates to the whole set of topics $\mathbf{T}$ by measuring their relatedness to each topic word $\mathbf{w_j} \in \mathbf{t_i}$, then to each topic $\mathbf{t_i} \in \mathbf{T}$. Whereas $\mathbf{B_2}$ verifies whether each topic word $\mathbf{w_j} \in \mathbf{t_i}$ is similar or identical to a keyword $\mathbf{w'_k} \in \mathbf{w'}$. In summary, $\mathbf{B_1}$ determines the average stability of topics given keywords, and $\mathbf{B_2}$ how regularly keywords appear in topics.

4 Results

In this section, we demonstrate the impact of our evaluation metrics applied to various datasets and using different similarity measures.

4.1 Experimental Settings

The preprocessing steps we apply to all the datasets consist of (1) the anonymization of the tweets by changing @*mentions* to @*user*, then deleting @*user*s, and (2) the use of NLTK[5] to skip stopwords. Then, we run the Gensim (Řehůřek and Sojka, 2010) implementation of LDA (Blei et al., 2003) to generate topics. We vary the number of topics and words within the range [2,100] to take the inherent variability of topic models into account.

In the general cases presented in Figures 1, 2, 3, and 4, we fix the number of topics to be equal to 8 when we alter the number of topic words and likewise, we fix the number of topic words to be equal to 8 when we experiment with different numbers

---

[4] Waseem and Hovy (2016) report collecting tweets about *My Kitchen Rules (mkr)*.

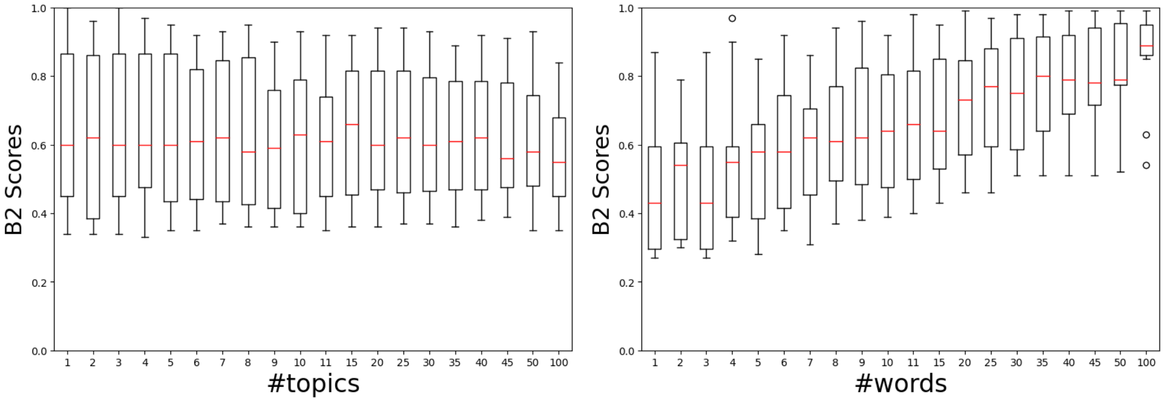
(a) $\mathbf{B_1}$ variations per number of topics. (b) $\mathbf{B_1}$ variations per number of words.

Figure 1: Average $\mathbf{B_1}$ scores based on topic and word numbers in the interval [2, 100]. We fix the number of topics to 8 when we alter the number of words and similarly, we fix the number of words to 8 when we change the number of topics. We use the **multilingual Babylon embeddings** to compute the semantic similarity between words.



(a) $\mathbf{B_2}$ variations per number of topics. (b) $\mathbf{B_2}$ variations per number of words.

Figure 2: Average $\mathbf{B_2}$ scores based on topic and word numbers in the interval [2, 100]. We fix the number of topics to 8 when we alter the number of words and similarly, we fix the number of words to 8 when we change the number of topics. We use the **multilingual Babylon embeddings** to compute the semantic similarity between words.

of topics. We define the semantic similarity measure $\mathbf{Sim}$ between each topic word and keyword to be the cosine similarity between their embedding vectors in the space of the multilingual pretrained Babylon embeddings (Smith et al., 2017) with respect to each of the seven languages we examine.

4.2 Robustness Towards The Variability of Topic Models

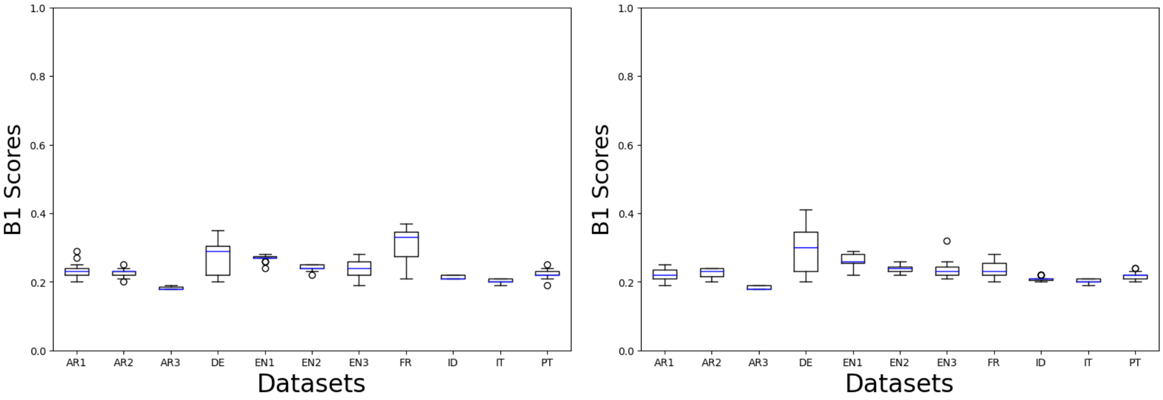
Figures 1 and 2 show the average $\mathbf{B_1}$ and $\mathbf{B_2}$ score variations given all the datasets. The scores are given numbers of topics and topic words within the range [2,100], respectively.

Despite $\mathbf{B_1}$ scores being similar on average, we notice that the larger the number of topics, the more outliers we observe. In parallel, the smaller the number of words, the more outliers we see. This is due to possible randomness when large topics are generated.

On the other hand, $\mathbf{B_2}$ scores are larger on average due to the high probability of keywords appearing in topics regardless of the dataset. This naturally translates to $\mathbf{B_2}$ showing more stability regarding the change in topic numbers in comparison to topic words.

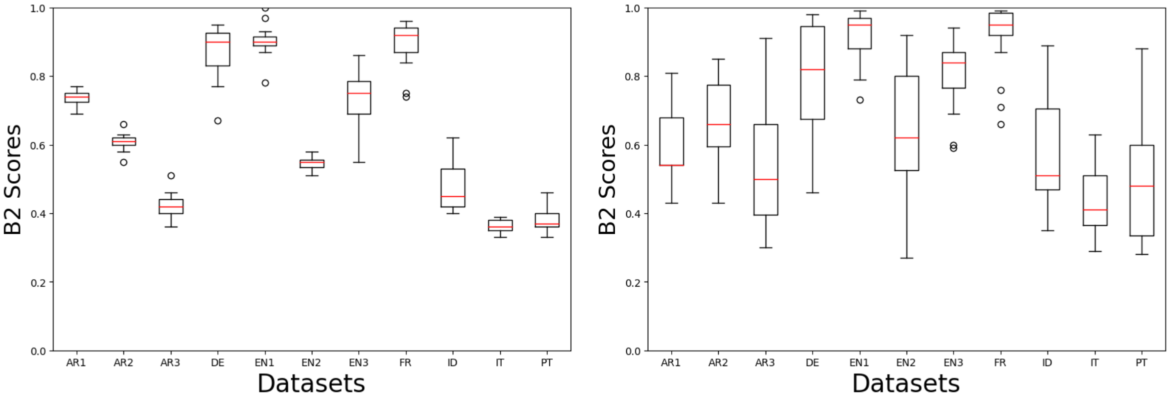
4.3 Robustness of Keyword-based Selection

Figure 3 illustrates the variations of each dataset given the numbers of topics and topic words within the interval [2,100], respectively. In general, changes in $\mathbf{B_1}$ scores are small, such as the largest difference we observe is in the German



(a) $\mathbf{B_1}$ scores per number of topics for different datasets. (b) $\mathbf{B_1}$ scores per number of words for different datasets.

Figure 3: $\mathbf{B_1}$ score variations for different datasets. The numbers of topics and words in topics are in the range [2, 100]. We use **multilingual Babylon embeddings** to compute the semantic similarity between words. EN1,EN2,EN3 refer to Ousidhoum et al. (2019); Waseem and Hovy (2016); Founta et al. (2018); and AR1, AR2, AR3 to Ousidhoum et al. (2019); Albadi et al. (2018); Mulki et al. (2019) respectively.



(a) $\mathbf{B_2}$ scores per number of topics. (b) $\mathbf{B_2}$ scores per number of topics.

Figure 4: $\mathbf{B_2}$ score variations for different datasets. The numbers of topics and words in topics are in the range [2, 100]. We use **multilingual Babylon embeddings** to compute the semantic similarity between words. EN1,EN2,EN3 refer to Ousidhoum et al. (2019); Waseem and Hovy (2016); Founta et al. (2018); and AR1, AR2, AR3 to Ousidhoum et al. (2019); Albadi et al. (2018); Mulki et al. (2019) respectively.

dataset (Ross et al., 2016). In German, we reach the maximum 0.41 when the number of words in each topic equals 2, and the minimum when it equals 100. On the other hand, we observe the most noticeable changes when we vary the number of topics in French (Ousidhoum et al., 2019) such that $\mathbf{B_1} = 0.34$ when $|\mathbf{T}| = 2$ versus 0.21 when $|\mathbf{T}| = 7$ and back to 0.37 when $|\mathbf{T}| = 100$.

However, we remark overall cohesion despite the change in topic numbers especially in the case of Italian and Portuguese caused by the limited numbers of search keywords, that equal 5 and 7 respectively.

Moreover, the account-based dataset of (Mulki et al., 2019), referred to as AR3 in Figures 3 and 4 shows more robustness towards keywords. Nevertheless, such a collection strategy may generate a linguistic bias that goes with the same stylistic features used by the targeted accounts, similarly to Waseem and Hovy (2016)'s user bias reported by Arango et al. (2019).

4.4 Hate Speech Embeddings

Besides using multilingual Babylon embeddings, we train hate speech embeddings with Word2Vec (Mikolov et al., 2013) to examine whether this can help us tackle the problem of out-of-the-vocabulary words caused by slang, slurs, named entities, and ambiguity.

Since we test on single French, German, Ital-

	DATASET	ORIG	REL	GEN
EN	Founta et al. (2018)	0.94	0.80	0.80
	Ousidhoum et al. (2019)	0.92	0.79	0.96
	Waseem and Hovy (2016)	0.95	0.82	0.82
AR	Albadi et al. (2018)	0.70	0.72	0.75
	Mulki et al. (2019)	0.64	0.66	0.69
	Ousidhoum et al. (2019)	0.66	0.67	0.72

Table 3: $\mathbf{B_1}$ scores based on trained **hate speech embeddings** for 10 topics. We have manually clustered the keywords released by Ousidhoum et al. (2019) based on discriminating target attributes. For instance, the word *ni**er* belongs to the origin (ORIG) category, *raghead* to religion (REL), and *c**t* to gender (GEN). For normalization purposes, we skipped disability since we did not find Arabic keywords that target people with disabilities.

ian, Indonesian, and Portuguese datasets, we do not train embeddings on these languages due to the lack of data diversity. In contrast, we train English hate speech embeddings on Waseem and Hovy (2016), Founta et al. (2018)[6], the SEMEVAL data (Basile et al., 2019), and Ousidhoum et al. (2019)'s datasets. We train Arabic embeddings in the same way using Albadi et al. (2018)'s sectarian dataset, (Mulki et al., 2019)'s Levantine Arabic dataset, and Ousidhoum et al. (2019)'s heterogeneous dataset. The size of the data is relatively small but the different datasets are composed of tweets that have been collected for different purposes within more than one year apart.

We test on window sizes of 3, 5, 10, 15, and 50, embedding sizes of 50, 100, 200, and 300, and we manually classify keywords released by Ousidhoum et al. (2019) based on discriminating target attributes to analyze the metric $\mathbf{B_1}$.

The $\mathbf{B_1}$ scores reported in Table 3 are larger than the ones reported in Figures 1 and 3 resulting from the difference between the size of the embedding space of Babylon and hate speech embeddings. Our embeddings are trained on a limited amount of data but, we can still notice slight differences in the scores. Interestingly, $\mathbf{B_1}$ scores reveal potentially overlooked targets as in Albadi et al. (2018)'s sectarian dataset that is supposed to target people based on their religious affiliations, yet its $\mathbf{B_1}$ scores given all discriminating attributes are comparable.

DATASET	ORIG	REL	GEN
Founta et al. (2018)	0.27	0.27	0.26
Ousidhoum et al. (2019)	0.33	0.28	0.35
Waseem and Hovy (2016)	0.27	0.26	0.27

Table 4: $\mathbf{B_1}$ scores for English hate speech datasets using **WordNet** given 10 topics and keywords clustered based on origin (ORIG), religion (REL), and gender (GEN). The scores are reported for tweets that have not been labeled *non-hateful* or *normal*. Although we initially attempted to study the differences of pretrained word embeddings and word associations, we found that many $(\mathbf{w_j}, \mathbf{w'_k})$ pairs involve out-of-the-vocabulary words. In such cases $(\mathbf{w_j}, \mathbf{w'_k})$ would have a WordNet Similarity score $\mathbf{WUP} = 0$ which is why the scores are in the range [0.25, 0.35].

4.5 General versus Corpus-Specific Lists of Keywords

We consider two examples in the following use case: (1) Waseem and Hovy (2016) who report building their dataset based on hashtags such as *mkr, victim card, and race card*, and (2) Albadi et al. (2018) who report building their sectarian dataset based on religious group names such as *Judaism, Islam, Shia, Sunni and Christianity*. The initial list of predefined keywords such as the ones we have shown in Table 1 carries additional words in English and Arabic. Therefore, for these two datasets, we have measured bias using two predefined lists of keywords: the initial list and one that is specific to the dataset in question.

The scores given the general set of keywords are reported in Figures 3 and 4, such as AR2 refers to Albadi et al. (2018) and EN2 to Waseem and Hovy (2016). The $\mathbf{B_1}$ and $\mathbf{B_2}$ scores given corpus-specific lists of keywords are either the same or ±0.01 the reported scores. We observed a maximum difference of 0.03, which is why reporting these scores would have been repetitive.

In conclusion, this is a symptom of high similarity in present English and Arabic hate speech datasets despite their seemingly different collection strategies and timelines.

4.6 WordNet and Targeted Hate Bias

In addition to word embeddings, we test our evaluation metrics on WordNet (Fellbaum, 1998)'s $\mathbf{WUP}$ (Wu and Palmer, 1994) similarity. $\mathbf{WUP}$ evaluates the relatedness of two synsets, or word senses, c_1 and c_2, based on hypernym relations. Synsets with short path distances are more related

---

[6] we use Tweepy `http://docs.tweepy.org/en/latest/api.html` to retrieve tweets that have not been deleted.

than those with longer ones. Wu and Palmer (1994) scale the depth of the two synset nodes by the depth of their Least Common Subsumer (LCS) or the most specific concept that is an ancestor of c_1 and c_2 (Newman et al., 2010).

In this use case, we aim to present a prospective label bias extension of our metrics by testing $\mathbf{B_1}$ on toxic tweets only. Consequently, we consider tweets that were not annotated normal or non-hateful. We question the present annotation schemes by computing $\mathbf{B_1}$ with $\mathbf{Sim{=}WUP}$.

Waseem and Hovy (2016), Founta et al. (2018) and Ousidhoum et al. (2019) report using different keywords and hashtags to collect tweets. However, the scores shown in Table 4 indicate that the datasets might carry similar meanings, specifically because $\mathbf{WUP}$ relies on hypernymy rather than common vocabulary use. The comparison of $\mathbf{B_1}$ scores given target-specific keywords also implies that the annotations could be non-precise. We may therefore consider fine-grained labeling schemes in which we explicitly involve race, disability, or religious affiliation as target attributes, rather than general labels such as *racist* or *hateful*.

4.7 Case Study

Figures 5(a) and 5(b) show bias scores generated for the German dataset (Ross et al., 2016) which contains 469 tweets collected based on 10 keywords related to the refugee crisis in Germany. We notice that $\mathbf{B_1}$ scores fluctuate in the beginning, reach a threshold, then get lower when the number of topics increases. $\mathbf{B_1}$ remains stable within different numbers of words as opposed to $\mathbf{B_2}$ scores that increase when more topic words are generated since eventually, all topics would include at least one keyword.

On the other hand, Figures 5(c) and 5(d) show bias scores generated for the Indonesian dataset (Ibrohim and Budi, 2019) which contains more than 13,000 tweets collected based on a heterogeneous set of 126 keywords. In such settings, $\mathbf{B_1}$ is almost constant for both the number of topics and topic words, contrary to $\mathbf{B_2}$ sores that arise when many topics are generated since new topics would include words that did not appear in the previously generated ones.

5 Discussion

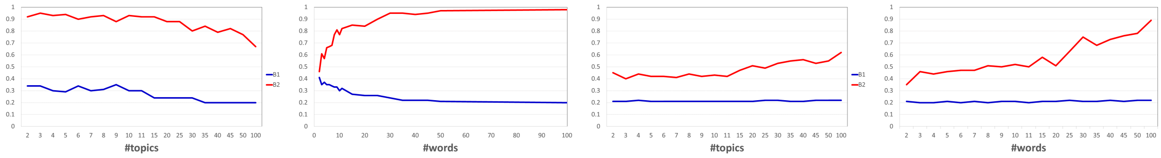
We consider our bias evaluation metrics to be label-agnostic and tested this claim in the different use cases we presented in section 4. Table 5 reports the Spearman's correlation scores between the properties of each dataset and its average $\mathbf{B_1}$ and $\mathbf{B_2}$ scores given different numbers of topics and topic words. The correlation scores show that, on average, our metrics do not depend on summary statistics either. We observe low correlation scores between the different features and $\mathbf{B_1}$ scores. $\mathbf{B_1}$ correlates the best with the number of keywords and the vocabulary size whereas $\mathbf{B_2}$ correlates the best with the average cosine similarity between keywords.

	$\mathbf{w'_{Sim}}$	**#TWEETS**	$\mathbf{\lvert w' \rvert}$	**VOCAB**	**TWEET**
#TOPICS					
$\mathbf{B_1}$	0.08	0.06	0.22	0.18	-0.03
$\mathbf{B_2}$	0.25	0.01	0.12	0.07	-0.14
#WORDS					
$\mathbf{B_1}$	0.12	-0.08	0.23	0.20	-0.02
$\mathbf{B_2}$	-0.36	-0.19	0.10	-0.09	-0.04

Table 5: Given the average $\mathbf{B_1}$ and $\mathbf{B_2}$ scores generated for each dataset, based on topics (**#TOPICS**) and topic words (**#WORDS**) in the interval [2,100], respectively, we compute Spearman's correlation scores between $\mathbf{B_1}$ and $\mathbf{B_2}$ and (1) the number of keywords $\mathbf{\lvert w' \rvert}$ and average cosine similarity between keywords $\mathbf{w'_{Sim}}$ given the language of the dataset; in addition to (2) the number of collected tweets **#TWEETS**, their average size **TWEET**, and size of vocabulary **VOCAB** in each dataset.

Although our bias metrics do not take annotations into account, we notice a global trend of overgeneralizing labels as presented in Section 4.6. Despite the fact that this is partly due to the absence of a formal definition of hate speech, we do believe that there could be a general framework which specifies several aspects that must be annotated.

Moreover, we notice recurring topics in many languages, such as those centered around immigrants and refugees which may later lead to false positives during the classification and hurt the detection performance. Hence, we believe that our evaluation metrics can help us recognize complementary biases in various datasets, facilitate transfer learning, as well as enable the enhancement of the quality of the data during collection by performing an evaluation step at the end of each search round.



(a) Variations of $\mathbf{B_1}$ and $\mathbf{B_2}$ scores given #topics in the German dataset.

(b) Variations of $\mathbf{B_1}$ and $\mathbf{B_2}$ scores given #words in the German dataset.

(c) Variations of $\mathbf{B_1}$ and $\mathbf{B_2}$ scores given #topics in the Indonesian dataset.

(d) Variations of $\mathbf{B_1}$ and $\mathbf{B_2}$ scores given #words in the Indonesian dataset.

Figure 5: Variations of $\mathbf{B_1}$ (in blue) and $\mathbf{B_2}$ (in red) scores on the German and Indonesian datasets.

6 Conclusion

We proposed two label-agnostic metrics to evaluate bias in eleven hate speech datasets that differ in language, size, and content. The results reveal potential similarities across available hate speech datasets which may hurt the classification performance.

As unpreventable as selection bias in social data can be, we believe there is a way to mitigate it by incorporating evaluation as a step which directs the construction of a new dataset or when combining existing corpora.

Our metrics are extensible to other forms of bias such as user, label, and semantic biases, and could be adapted in cross-lingual contexts using different similarity measures.

Abstract

In the computational detection of cyberbullying, existing work largely focused on building generic classifiers that rely exclusively on text analysis of social media sessions. Despite their empirical success, we argue that a critical missing piece is the model explainability, i.e., why a particular piece of media session is detected as cyberbullying. In this paper, therefore, we propose a novel deep model, HEterogeneous Neural Interaction Networks (HENIN), for explainable cyberbullying detection. HENIN contains the following components: a comment encoder, a post-comment co-attention sub-network, and session-session and post-post interaction extractors. Extensive experiments conducted on real datasets exhibit not only the promising performance of HENIN, but also highlight evidential comments so that one can understand why a media session is identified as cyberbullying.

1 Introduction

Figure 1: An illustration of a media session containing an image/video/posted text and a sequence of comments. A cyberbullying session is typically composed of multiple insulting comments.

In recent years, cyberbullying has become one of the most pressing online risks among youth and raised serious concerns in society. Cyberbullying is commonly defined as the electronic transmission of insulting or embarrassing comments, photos or videos, as illustrated in Figure 1. Harmful bullying behavior can include posting rumors, threats, pejorative labels, and sexual remarks. Research from the American Psychological Association and the White House has revealed more than 40% of young people in the US indicate that they have been bullied on social media platforms (Dinakar et al., 2012). Such a growing prevalence of cyberbullying on social media has detrimental societal effects, such as victims may experience lower self-esteem, increased suicidal ideation, and a variety of negative emotional responses (Hinduja and Patchin, 2014). Therefore, it has become critically important to be able to detect and prevent cyberbullying on social media. Research in computer science aimed at identifying, predicting, and ultimately preventing cyberbullying through better understanding the nature and key characteristics of online cyberbullying.

In the literature, existing efforts toward automatically detecting cyberbullying have primarily focused on textual analysis of user comments, including keywords (Dadvar et al., 2012; Nahar et al., 2013; Nand et al., 2016) and sentiments analysis (Dani et al., 2017). These studies attempt to build a generic binary classifier by taking high-dimensional text features as the input and make predictions accordingly. Despite their satisfactory detection performance in practice, these models largely overlooked temporal information of cyberbullying behaviors. They also ignore user interactions in social networks. Furthermore, the majority of these methods focus on detecting cyberbullying sessions effectively but cannot explain "why" a media session was detected as cyberbullying. Given a sequence of comments with user attributes, we think sequential learning can allow us to better exploit and model the evolution and correlations among individual comments. Besides, graph-based learning can enable us to represent and learn how users interact with each other in a session.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2543–2552,
November 16–20, 2020.

This work aims to detect cyberbullying by jointly exploring explainable information from user comments on social media. To this end, we build an explainable cyberbullying detection framework, **HE**terogeneous **N**eural **I**nteraction **N**etworks (**HENIN**), through a coherent process. HENIN consists of three main components that learn various interactions among heterogeneous information displayed in social media sessions. A comment encoder is created to learn the representations of user comments through a hierarchical self-attention neural network so that the semantic and syntactic cues on cyberbullying can be captured. We create a post-comment co-attention mechanism to learn the interactions between a posted text and its comments. Moreover, two graph convolutional networks are leveraged to learn the latent representations depicting how sessions interact with one another in terms of users, and how posts are correlated with each other in terms of words.

Specifically, we address several challenges in this work: (a) how to perform explainable cyberbullying detection that can boost detection performance, (b) how to highlight explainable comments without the ground truth, (c) how to model the correlation between posted text and user comments, and (d) how to model the interactions between sessions in terms of users, and the interactions between textual posts in terms of words. Our solutions to these challenges result in a novel framework HENIN.

Our contributions are summarized as follows. (1) We study a novel problem of explainable cyberbullying detection on social media. (2) We provide a novel model, HENIN [1], which jointly exploits posted text, user comments, and the interactions between sessions and between posts to learn the latent representations for cyberbullying detection. (3) Experiments conducted on Instagram and Vine datasets exhibit the promising performance of HENIN, and the evidential comments and words highlighted by HENIN, for detecting cyberbullying media sessions with explanations.

2 Related Work

Relevant studies can be categories into social contexts-based and user comment-based approaches. **Social contexts-based approaches** utilize three categories of features, user-based, post-based, and network-based. (a) Post-based features rely on text analysis to identify cyberbullying evidences (e.g., profane words) on social media (Dadvar et al., 2012; Nahar et al., 2013; Nand et al., 2016). Xu et al. (2012) point out Latent Semantic Analysis(LSA) and Latent Dirichlet Allocation (LDA) can be used to learn latent representations of posts. In addition, *SICD* (Dani et al., 2017) further models post sentiments for cyberbullying detection. (b) User-based features are extracted from user profiles to measure their characteristics. Gender-specific features, user's past posts, account registration time, and frequently-used words are useful user-based features (Dadvar and De Jong, 2012; Dadvar et al., 2013). (c) Existing studies (Cheng et al., 2019b; Tu et al., 2018; Wang et al., 2017) also prove that network-based features are effective in detecting cyberbullying. These features are learned by constructing propagation networks or interaction networks that depict how posts are spread and how users interact with each other. **User comment-based approaches** utilize the sequence of user comments to detect cyberbullying of the source post. CONcISE (Yao et al., 2019) is a sequential hypothesis testing method conducted on the comment sequence to select the significant comment features. Raisi and Huang (2018) detect harassment-based cyberbullying by identifying expert-provided key phrases from user comments.

3 Problem Statement

Let $S = \{s_1, s_2, ..., s_M\}$ denote a corpus of M social media sessions. Each media session contains the posted text and its subsequent comments. Let P be a posted text, consisting of N words $\{w_i\}_{i=1}^{N}$. Let $C = \{c_1, c_2, ..., c_T\}$ be a set of T comments related to the post P, where each comment $c_j = \{w_1^j, w_2^j, ...w_{Q_j}^j\}$ contains Q_j words. Let $G_{ss} = (V_S, E_S)$ be a session-session weighted graph, in which we consider each media session as a node $s \in V_S$ and the similarity between sessions as an edge weight $e_{(s_i,s_j)} \in E_S$. Let $G_{pp} = (V_P, E_P)$ be a post-post weighted graph, in which we consider each posted text as a node $p \in V_P$ and the similarity between posts as an edge weight $e_{(p_i,p_j)} \in E_P$. We treat the cyberbullying detection problem as the binary classification problem, i.e., each media session is associated with a binary label $y = \{0, 1\}$ with 1 representing a bullying session, and 0 representing a non-bullying session. At the same time, we aim to learn a rank

---

[1] The Code of HENIN model is available at: `https://github.com/HsinYu7330/HENIN`

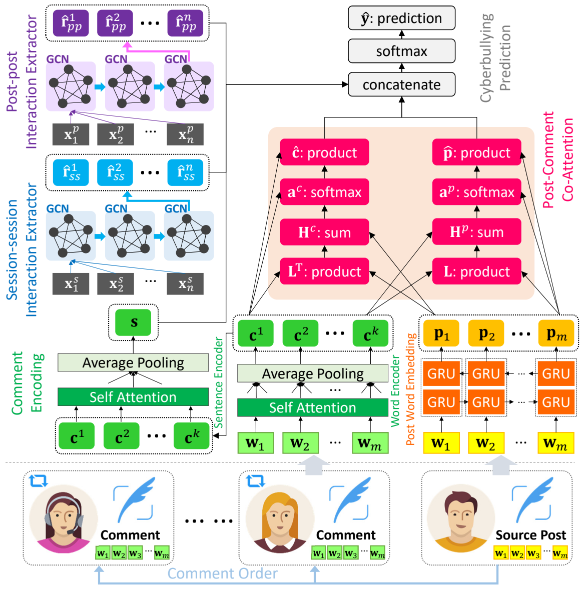

Figure 2: The proposed HENIN model, which contains four components: a joint word-level and sentence-level comment encoder, a post-comment co-attention mechanism, session-session and post-post interaction extractors, and the final cyberbullying prediction.

list RC from all comments in $\{c_j\}_{j=1}^{T}$, according to the degree of explainability, where RC_k denotes the k_{th} most explainable comment. The explainability of comments denotes the impact degree of detecting the media session is cyberbullying or not. Formally, we can represent the problem as *Explainable Cyberbullying Detection*.

Problem: Given a posted text P, a set of related comments C, the session graph G_{ss} and the post graph G_{pp}, the goal is to learn a cyberbullying detection function $f : f(P, C, G_{ss}, G_{pp}) \to (\hat{y}, RC)$, such that it maximizes the prediction accuracy with explainable comments ranked highest in RC.

4 The proposed HENIN Model

In this section, we present the details of the proposed HENIN, which jointly learns the hierarchical self-attention and graph convolutional neural networks for cyberbullying detection. It consists of four major components (Figure 2): (1) a comment encoder (including word-level and sentence-level), (2) a post-comment co-attention mechanism, (3) session-session and post-post interaction extractors, and (4) a cyberbullying prediction component.

The comment encoder component depicts the modeling from the comment linguistic features to latent representation features through hierarchical word-level and sentence-level self-attention networks. The explainability degree of comments is learned through the attention weights within sentence-level self-attention learning. The post-comment co-attention mechanism is performed in the level of word embeddings. The mutual interactions between the posted text and comments can be learned through the post-comment co-attention. On the other hand, the session-session interaction extractor and the post-post interaction extractor aim at modeling how users interact across media sessions, and how words are correlated across posts, through two graph convolutional neural networks. Finally, the cyberbullying prediction is made by concatenating the representations of the aforementioned three components.

4.1 Comment Encoding

A set of comments related to the given media session contains linguistic cues at the word and sentence levels. Textual usages in comments provide different degrees of importance for explainability of why the session is detected as cyberbullying. For example, in a cyberbullying media session extracted from the Instagram dataset (see Section 5.1), the comment *"how the fuck are you even a fucking fan you cunt if you just talk shit about harry fuck you kaitlyn!"*, the words "fuck" and "shit" contribute more signals to reflect apparent and evidential emotion sense, compared to other ones. Meanwhile, this comment strongly expresses malicious remarks to someone, and therefore it is not only more explainable but also useful to determine whether it is a cyberbullying session.

Several studies have shown that improved document representations with highlighting important words and sentences for classification can be learned by hierarchical attention neural networks (Yang et al., 2016; Cheng et al., 2019a). Inspired by (Yang et al., 2016), we adopt a hierarchical neural network to model word-level and sentence-level representations through self-attention mechanisms. Specifically, we first learn the comment embedding vector by utilizing the word encoder with self-attention. Then we learn the comment representations through the sentence encoder with self-attention.

Word Encoder. Given a comment c_j with m words, we first embed the words to a latent space via the pre-trained word2vec model (Mikolov et al., 2013). Then we capture words' contextual relations among comments by calculating scaled dot-product attention (Vaswani et al., 2017). Specifically first, let word embeddings as input vectors $\mathbf{x}_i$. The query vector sequence $\mathbf{q}_i$, the key vector sequence $\mathbf{k}_i$, and the value vector sequence $\mathbf{v}_i$ can be obtained by linear transformation, i.e., $\mathbf{q}_i = \mathbf{w}_q\mathbf{x}_i$, $\mathbf{k}_i = \mathbf{w}_k\mathbf{x}_i$, and $\mathbf{v}_i = \mathbf{w}_v\mathbf{x}_i$, where $\mathbf{w}_q, \mathbf{w}_k, \mathbf{w}_v$ are the learnable parameters through the networks. Next we compute the dot products of the query with all keys, divide each by $\sqrt{d_k}$ (d_k is the dimension of keys), and apply a softmax function to obtain the attention weights on the values: $\mathbf{a}_i = \text{softmax}(\frac{\mathbf{q}_i\mathbf{k}_i^\top}{\sqrt{d_k}})$, where $\mathbf{a}_i$ is an attention weight vector that measures the importance of each word in the comment. Finally, each word's hidden representation can be obtained by computing the dot products of attention weights $\mathbf{a}_i$ and the value vector sequence $\mathbf{v}_i$. We take the average of the learned representations to generate the comment vector $\mathbf{c}^j$, given by: $\mathbf{c}^j = \frac{\sum_{i=1}^{m}\mathbf{a}_i\mathbf{v}_i}{m}$.

Sentence Encoder. Similar to the word encoder, we utilize the scaled dot-product attention to encode each media session. The aim is to capture the context information at the sentence level, and to generate the media session representation of post P_i, denoted by $\mathbf{s}^i$, from the learned comment embedding vectors $\{\mathbf{c}^1, \mathbf{c}^2, ..., \mathbf{c}^k\}$. Every post's sentence embedding $\mathbf{s}$ will be used as features for cyberbullying prediction.

4.2 Post-Comment Co-attention Mechanism

To model the interaction between posted text and comments, we propose a post-comment co-attention mechanism that learns the semantic word-level correlation between posted text and comments. That said, we intend to simultaneously learn and derive the attention weights of words on posted text and comments. Specifically first, similar to comment encoding, word embeddings of a posted text are obtained by a pre-trained word2vec model. We adopt recurrent neural networks with bidirectional gated recurrent units (GRU) to model word sequences from both directions of words. The bidirectional GRU contains the forward GRU $\overrightarrow{f}$ that reads posted text p^i from word w_1^i to w_m^i and the backward GRU $\overleftarrow{f}$ that reads posted text p^i from word w_m^i to w_1^i, given by: $\overrightarrow{\mathbf{h}_t^i} = \overrightarrow{GRU}(\mathbf{w}_t^i)(t \in \{1, ..., m\})$ and $\overleftarrow{\mathbf{h}_t^i} = \overleftarrow{GRU}(\mathbf{w}_t^i)(t \in \{m, ..., 1\})$. We obtain the embedding of word p_t^i in a posted text by concatenating its forward and backward hidden states $\overrightarrow{\mathbf{h}_t^i}$ and $\overleftarrow{\mathbf{h}_t^i}$, i.e., $\mathbf{p}_t^i = [\overrightarrow{\mathbf{h}_t^i}, \overleftarrow{\mathbf{h}_t^i}]$. Then we can construct the feature matrix of words of posted text $\mathbf{P} = [\mathbf{p}^1, ..., \mathbf{p}^N]$. Similarly the feature matrix of comments $\mathbf{C} = [\mathbf{c}^1, ..., \mathbf{c}^T]$ can be derived.

The proposed co-attention mechanism attends to the posted text words and the comment simultaneously. By extending the co-attention formulation (Lu et al., 2016; Cui et al., 2019), we first compute the affinity matrix $\mathbf{L} \in \mathbb{R}^{T\times N}$: $\mathbf{L} = \tanh(\mathbf{C}^\top\mathbf{W}_l\mathbf{P})$, where $\mathbf{W}_l$ is a matrix of learnable weights. The affinity matrix $\mathbf{L}$ is used to transform the comment attention space to the posted text attention space, and vice versa for $\mathbf{L}^\top$. As a result, we can consider the affinity matrix as a feature matrix, and learn to predict the posted text and comment attention maps $\mathbf{H}^p$ and $\mathbf{H}^c$, as follows: $\mathbf{H}^p = \tanh(\mathbf{W}_p\mathbf{P} + (\mathbf{W}_c\mathbf{C})\mathbf{L})$, and $\mathbf{H}^c = \tanh(\mathbf{W}_c\mathbf{C} + (\mathbf{W}_p\mathbf{P})\mathbf{L}^\top)$, where $\mathbf{W}_p, \mathbf{W}_c$ are the matrices of learnable parameters. The attention weights of posted text and comments, $\mathbf{a}^p$ and $\mathbf{a}^c$, can be obtained by: $\mathbf{a}^p = \text{softmax}(\mathbf{w}_{hp}^\top\mathbf{H}^p)$, $\mathbf{a}^c = \text{softmax}(\mathbf{w}_{hc}^\top\mathbf{H}^c)$, where $\mathbf{w}_{hp}^\top$ and $\mathbf{w}_{hc}^\top$ are vectors of learnable weight parameters. Based on the above attention weights, the posted text and comment attention vectors are obtained by calculating the weighted sum of the posted text features and comment features via: $\hat{\mathbf{p}} = \sum_{i=1}^{N}\mathbf{a}_i^p\mathbf{p}^i$ and $\hat{\mathbf{c}} = \sum_{i=1}^{T}\mathbf{a}_i^c\mathbf{c}^i$,, where $\hat{\mathbf{p}}$ and $\hat{\mathbf{c}}$ are the learned features vectors for posted text and comments, respectively, through the co-attention mechanism.

4.3 Interaction Extractors

To learn and represent the potential interactions between two sessions as well as two text posts, we utilize multilayer neural networks that operate on graph data based on the layers of graph convolutional networks (GCN) (Kipf and Welling, 2016). GCN is able to induce embedding vectors of nodes based on features of their neighborhoods. We create two multi-layer GCNs to learn the embeddings of the given session s_i and its posted text P_i from the session-session graph G_{ss} and the post-post graph G_{pp}, respectively.

Session-session Interaction Extractor. Let $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n) \in \mathbb{R}^{n\times p}$ be the vectors of user participation in all sessions, where n is the number of all sessions and p is the number of users. Each vector $\mathbf{x}_i$ is a multi-hot encoding that depicts how session s_i is participated by all users. Let matrix $\hat{\mathbf{R}}_{ss}$ be the representations of all sessions learned from the session-session graph $G_{ss} = (\mathbf{X}, \mathbf{A})$, where $\mathbf{A} \in \mathbb{R}^{n\times n}$ encodes the pairwise relationships (such as cosine similarity, which is used by default) between sessions. We exploit GCN to learn $\hat{\mathbf{R}}_{ss}$. GCN contains one input layer, several propagation layers, and the final output layer (Kipf and Welling, 2016). At deeper layers, the nodes indirectly receive more information from farther nodes in the graph. Given the input feature matrix $\mathbf{X}^{(0)} = \mathbf{X}$ and the graph structure matrix $\mathbf{A}$, GCN performs the layer-wise propagation in hidden layers via $\mathbf{X}^{(k+1)} = \rho(\hat{\mathbf{A}}\mathbf{X}^{(k)}\mathbf{W}^{(k)})$, where $k = 0, 1, ..., K-1$ and $\mathbf{W}^{(k)}$ is the matrix of learnable parameters in the k-th layer. ρ is a non-linear activation function, such as ReLU, and $\mathbf{X}^{(k+1)}$ denotes the activation output in the k-th layer. $\hat{\mathbf{A}}$ is the normalized symmetric adjacency matrix, $\hat{\mathbf{A}} = \mathbf{D}^{-\frac{1}{2}}\mathbf{A}\mathbf{D}^{-\frac{1}{2}}$, where $\mathbf{D} = diag(d_1, d_2, ..., d_n)$ is a diagonal matrix with $d_i = \sum_{j=1}^{n} \mathbf{A}_{ij}$. Finally, the graph representations $\hat{\mathbf{R}}_{ss} = [\hat{\mathbf{r}}_{ss}]$ can be obtained from the output layer that uses *softmax* as the activation function.

Post-post Interaction Extractor. Similar to *session-session interaction extractor*, we depict each posted text in the graph G_{pp} as a real-valued vector $\mathbf{x}_i$ by using the word embedding vector of post P_i as the initial feature. By performing GCNs as aforementioned, we can derive the graph representations of all posts, denoted by $\hat{\mathbf{R}}_{pp} = [\hat{\mathbf{r}}_{pp}]$.

4.4 Cyberbullying Prediction

By concatenating the sentence embedding vector $\mathbf{s}$, the post-comment co-attention feature vectors $\hat{\mathbf{p}}$ and $\hat{\mathbf{c}}$, the session interaction representation $\hat{\mathbf{r}}_{ss}$, and the post interaction representation $\hat{\mathbf{r}}_{pp}$, we generate the prediction via a fully-connected layer, given by: $\hat{\mathbf{y}} = \sigma([\hat{\mathbf{p}}, \hat{\mathbf{c}}, \mathbf{s}, \hat{\mathbf{r}}_{ss}, \hat{\mathbf{r}}_{pp}]\mathbf{W}_f + \mathbf{b}_f)$, where $\hat{\mathbf{y}}$ is the predicted probability vector indicating the predicted probability of label 1 (i.e., cyberbullying). $\mathbf{W}_f$ and $\mathbf{b}_f$ are the learnable parameters and biases. σ is the sigmoid function. $y \in \{0, 1\}$ denotes the ground-truth label of media sessions. The goal is to minimize the cross-entropy loss function: $\mathcal{L}(\Theta) = -y \log(\hat{\mathbf{y}}) - (1 - y) \log(1 - \hat{\mathbf{y}})$, where Θ denotes all parameters of the network. The parameters in the network are learned through the *Adam* optimizer (Kingma and Ba, 2014), which is an adaptive learning rate method that uses estimations of first and second moments of gradient to adapt the learning rate for each weight of the neural network. We choose *Adam* since it is generally regarded as being fairly robust and effective to the choice of the hyperparameters, and it is widely used for training neural networks.

Table 1: Statistics of Instagram and Vine datasets.

Datasets	Instagram	Vine
# Sessions	2,211	882
# Bullying	676	283
# Non-Bullying	1,535	599
# Comments	159,277	70,385
# Users	72,176	25,699

5 Experiments

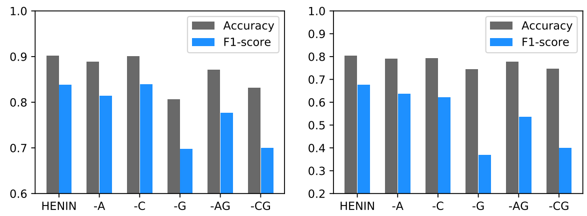
We aim to answer the following evaluation questions. **EQ1:** Can HENIN improve the cyberbullying media session *classification performance*? **EQ2:** How effective is *each component* of HENIN? **EQ3:** Is HENIN able to perform accurate *early* detection of cyberbullying sessions? **EQ4:** Can HENIN highlight comments that can *explain why* a media session is detected as cyberbullying?

5.1 Datasets and Settings

We use two social media datasets whose statistics is shown in Table 1. One is Instagram dataset (Hosseinmardi et al., 2015, 2016), which contains image description and user comments. The other is Vine (Rafiq et al., 2015, 2016), which is a mobile application website that allows users to record and edit a few seconds looping videos. The texts of both datasets are in English.

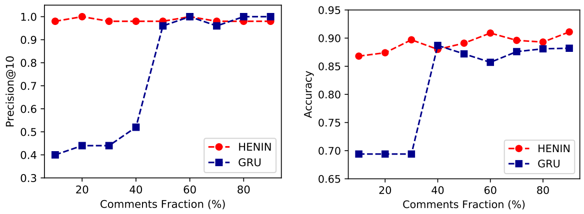
We compare our HENIN model with several methods, including classification models such as Logistic Regression (**LR**) (Hosseinmardi et al., 2015, 2016) and Random Forest (**RF**) (Rafiq et al., 2015, 2016). We collect posted text and all related comments of the session as a document to embed the session to a latent space via pre-trained doc2vec model (Le and Mikolov, 2014). Then we leverage the session representations as input features to train LR and RF classifiers. In addition, we also compare HENIN with three end-to-end deep learning models, including **RNN**, **GRU**, and GRU with attention **GRU+A**. We also compare HENIN with a recent advance **CONcISE** (Yao et al., 2019), which has a sequential hypothesis testing-based mechanism to produce timely and accurate detection of cyberbullying. For a fair comparison with CONcISE, we follow their settings by using their suggested key terms: “ugly”, “shut”, “suck”, “gay”, “beautiful”, “sick”, ‘bitch”, ‘work”, “hate”, and “fuck.”

We provide the hyperparameter settings to enable the reproducibility. (1) The maximum number of words per comment `MAX_COM_WORD_LEN=10`



(a) Instagram (b) Vine

Figure 3: Results of ablation analysis for HENIN.



(a) Precision@10 (b) Accuracy

(a) Precision@10 (b) Accuracy

Figure 5: Effect of comments' fraction on Vine.

and `6` on Instagram and Vine, respectively, according to the median of all comments' length. (2) The maximum length of user comments `MAX_COM_LEN=75` and `80` on Instagram and Vine, respectively. (3) The dimension of word embeddings `d=300`. (4) The number of GCN layers is `3`. (5) The matrix **A** for GCN is constructed by pairwise cosine similarity between posts and sessions.

5.2 Cyberbullying Detection Performance

To answer **EQ1**, we first compare our HENIN with baseline methods. To evaluate the performance of cyberbullying detection methods, we use the following metrics, which are commonly used to evaluate classifiers: Accuracy (Acc), Precision (Pre), Recall (Rec), and F1-Score (F1). To have the experiments be more robust and reliable, we randomly choose 80% of media sessions for training and the remaining 20% for testing. We repeat the process 5 times, and report the average values. The results are shown in Table 2. We can find that the proposed HENIN consistently outperforms the competing methods across two datasets on Accuracy, Recall, and F1, i.e., except for the metric of Precision. Although RF and RNN lead to higher scores in Precision in Instagram and Vince datasets, respectively, their performance in other metrics is not stable. It is also worthwhile to notice that models considering attention mechanisms, i.e., HENIN and GRU+A, tend to produce better performance. This implies the importance of modeling contextual correlation and contribution at either word or sentence level on the detection of cyberbullying.

5.3 Ablation Analysis for HENIN

To answer **EQ2**, we further investigate the effect of each component in the proposed HENIN model. We aim at evaluating the following reduced variants of HENIN. (1) **-A**: HENIN without the Post-Comment co-attention component, (2) **-G**: HENIN without the GCN components, (3) **-C**: HENIN without the Comment Encoder, (4) **-AG**: HENIN without the Post-Comment co-attention and GCN components, and (5) **-CG**: HENIN without the Comment Encoder and GCN components.

The results are shown in Figure 3. The ablation analysis of HENIN brings two insights. First, all of the three components (i.e., comment encoder, session-session and post-post interactions, and posted text-comment co-attention) contribute apparently to the performance improvement. Second, When the model without considering the representations learned from session and post interactions, the performance reduces 14% and 9.6% in terms of F1-Score and Accuracy metrics on Instagram, and 30.7% and 6% on Vine. In other words, "-G" models hurt the performance most. The results suggest that modeling interactions between sessions and between posts through GCNs in HENIN is important.

5.4 Early Detection of Cyberbullying

To answer **EQ3**, we examine whether HENIN can accurately detect cyberbullying sessions at early stages. In other words, we aim to understand how a model performs given only a partial proportion of observed comments. Here we choose GRU as the baseline for comparison. Specifically, for each media session, we sort all comments by response time, then choose various fractions of comments into the training and testing sets. We utilize *Precision@k* and *Accuracy* as the evaluation metrics,

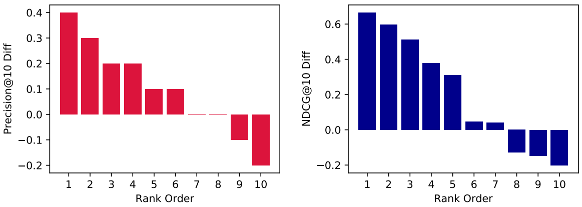
Table 2: The main performance comparison in four metrics for cyberbullying detection on two datasets. Note that the best model and the second model are highlighted by **bold** and underline, respectively.

Datasets	Metrics	CONcISE	RNN	GRU	GRU+A	LR	RF	HENIN
Instagram	Acc	0.627	0.782	0.815	0.884	0.840	0.805	**0.902**
	Pre	0.388	0.817	0.846	0.835	0.792	**0.901**	0.889
	Rec	0.381	0.376	0.496	0.781	0.652	0.405	**0.829**
	F1	0.384	0.507	0.569	0.805	0.715	0.559	**0.838**
Vine	Acc	0.603	0.706	0.747	0.797	0.788	0.786	**0.804**
	Pre	0.363	**0.830**	0.773	0.757	0.748	0.751	0.821
	Rec	0.376	0.190	0.309	0.559	0.512	0.498	**0.643**
	F1	0.369	0.245	0.418	0.636	0.608	0.597	**0.676**

where $k = 10$. The results are shown in Figure 4 and Figure 5. From the figures, we can see that, our proposed HENIN can achieve much better performance when the observed comments are quite a few (i.e., the fraction of comments is low than 40%). In contrast, GRU model needs at least 50% comments on both datasets to obtain the same good performance as HENIN. In short, we prove that HENIN is able to produce quite accurate early detection of cyberbullying sessions.

5.5 Explainability and Case Study

Explainability. To answer **EQ4**, we evaluate the performance of the explainability of our *HENIN* model from the perspective of comments. We choose *GRU+A* as the baselines for comment explainability since it can learn attention weights for comments as a kind of explainability. Specifically, we want to see if the top-ranked explainable comments determined by our HENIN are more likely to be related to the major contexts in cyberbullying media sessions. We randomly choose 10 media sessions, which contains at least 20 but not more than 50 comments, to evaluate the explainability ranking list of the comment *RC*. Then we denote the ground-truth ranking list by rating the explainability score from $\{0, 1, 2, 3, 4\}$ for each comment, where 0 means "not explainable at all", 1 means "not explainable", 2 means "neutral", 3 means "somewhat explainable", and 4 means "highly explainable (highly malicious)." We invite three domain experts to perform the ground-truth ratings for every comment. The average rating scores are used to generate the ranking list. Therefore, for each media session, we have two lists of top-k comments, $L^{(1)} = \{L_1^{(1)}, L_2^{(1)}, ..., L_k^{(1)}\}$ by HENIN, and $L^{(2)} = \{L_1^{(2)}, L_2^{(2)}, ..., L_k^{(2)}\}$ by GRU+A. The top-k comments are ranked and selected using the comment attention weights from high to low. To estimate the rank-aware explainability of comments, we utilize *Normalized Discounted Cumulative Gain* (NDCG) (Järvelin and Kekäläinen, 2002) and *Precision@k* as the evaluation metrics. We empirically set $k = 10$.



(a) Precision@10 (b) NDCG@10

Figure 6: The discrepancy histograms of mean Precision@10 and mean NDCG@10 (in the y-axis) for the results between HENIN and GRU+A in Vine dataset.

The results are shown in Figure 6, where media sessions are sorted by the discrepancy in the metrics between two methods, i.e., NDCG@k(HENIN)−NDCG@k(GRU+A), in a descending order. From the figures, we can have two observations. First, among 10 Vine media sessions, HENIN obtains higher precision scores than GRU+A for 6 cases. The overall mean precision scores over 10 cases for HENIN and GRU+A are 0.51 and 0.41, respectively. Second, similar results can be found on NDCG scores. HENIN is superior to GRU+A on 7 cases, and two cases have equal NDCG scores. The overall mean NDCG scores over 10 cases for HENIN and GRU+A are 0.57 and 0.36, respectively. These results demonstrate that the attention weights of HENIN are able to highlight more evidential comments than GRU+A, and its explainability can be verified.

Case Study. We further demonstrate the explainable comments that HENIN correctly ranks high

Lets go in the hallway right now bitch

30 comments

Top-7 comments ranked by HENIN

Rank	AttW	Comments
1	**1.421**	*What a bitch tell him to hmu and ill kill his bitch ass for hitting a woman*
2	**0.219**	*if a bitch hit a nigga wit a object damn right we gon retaliate*
3	0.127	*When ugly girl try play flight with cute boiltshanabishh Axi Esete*
4	0.077	*That weak ass punch lmao Michael Featherston*
5	0.074	*She had no business hitting him wit anything period*
6	0.072	*Laurie us to the kid with the mole on his face*
7	**0.070**	*Court-dawg Jimecia Bandy Donishia Phillips*

Figure 7: The top-7 comments highlighted by HENIN.

but GRU+A misses. These cases are presented in Figure 7. We can find that: (1) our HENIN can rank more evidential comments higher than non-explainable comments. For example, the top-1 comment *"What a bitch tell him to hmu and ill kill his bitch ass for hitting a woman"* contains explicit vulgar and malicious texts that can explain why this media session detected as cyberbullying. (2) We can give higher attention weights to explainable comments than those neutral and unrelated comments. For example, the unrelated comment *"Court-dawg Jimecia Bandy Donishia Phillips"* has an attention weight 0.070, which is lower than an explainable comment *"if a bitch hit a nigga wit a object damn right we gon retaliate"* with attention weight 0.219. Therefore, the latter comment is selected to be a more important evidence for cyberbullying prediction. In short, HENIN is able to not only accurately detect cyberbullying sessions, but also highlight evidential comments as explanations.

5.6 HENIN Hyperparameter Analysis

Since we have shown that the graph-based interactions between sessions and between posts have a great impact on the detection (Section 5.3), we further aim to investigate how different hyperparameters of GCNs affect the performance. Here we study two hyperparameters. One is the number of GCN layers. The other is the choice of similarity measures in constructing the matrix $\mathbf{A}$ for GCN. The results on stacking the different number of GCN layers are shown in Table 3. We can see that stacking more GCN layers leads to performance improvement by around 1.1% in terms of F1 on Instagram and 2.2% on Vine.

The weight matrix $\mathbf{A}$ for GCN is obtained by calculating the similarity for all pairs of nodes in the graph. We compare three commonly similarity measures, Cosine similarity: $\cos(\mathbf{x}_i, \mathbf{x}_j) = \frac{\mathbf{x}_i \cdot \mathbf{x}_j}{\|\mathbf{x}_i\| \|\mathbf{x}_j\|}$, Jaccard similarity: $\text{jac}(\mathbf{x}_i, \mathbf{x}_j) = \frac{\mathbf{x}_i \mathbf{x}_j}{\sum \mathbf{x}_i \sum \mathbf{x}_j - \sum \mathbf{x}_i \mathbf{x}_j}$, and Euclidean similarity: $\text{euc} = 1 - \bar{\text{euc}}(\mathbf{x}_i, \mathbf{x}_j) = 1 - \bar{N}(\sqrt{\sum (\mathbf{x}_i - \mathbf{x}_j)^2})$ ($\bar{\text{euc}}$ and $\bar{N}$ denote normalization to [0,1]). The results are shown in Table 4. We can see that on the Instagram dataset, using Euclidean similarity can improve the performance by 4.9% and 2.8% in terms of F1 and Accuracy, respectively. On the Vine dataset, using Jaccard similarity outperform than the other two measures by improving 1.2% and 1.7% in terms of F1 and Accuracy, respectively. The results suggest that in different datasets, we need to choose the proper similarity measure to construct the weight matrix as the performance can be affected.

Table 3: Effect of the number of GCN layers.

Dataset	Instagram		Vine	
	Acc	F1	Acc	F1
#layers=1	0.896	0.827	0.803	0.672
#layers=2	0.896	0.829	0.797	0.654
#layers=3	**0.902**	**0.838**	**0.804**	**0.676**

Table 4: Effect of similarity measures in constructing matrix $\mathbf{A}$ depicting the graph for GCN.

Dataset	Instagram		Vine	
$\mathbf{A}_{ij}$	Acc	F1	Acc	F1
$\cos(\mathbf{x}_i, \mathbf{x}_j)$	0.894	0.823	0.806	0.668
$\text{jac}(\mathbf{x}_i, \mathbf{x}_j)$	0.893	0.824	**0.811**	**0.673**
$\text{euc}(\mathbf{x}_i, \mathbf{x}_j)$	**0.922**	**0.872**	0.794	0.661

6 Conclusion

Cyberbullying detection on social media attracts growing attention in recent years. It is also crucial to understand why a media session is detected as cyberbullying. Thus we study the novel problem of explainable cyberbullying detection that aims at improving detection performance and highlighting explainable comments. We propose a novel deep learning-based model, HEterogeneous Neural Interaction Networks (HENIN), to learn various feature representations from comment encodings, post-comment co-attention, and graph-based interactions between sessions and posts. Experimental results exhibit both promising performance and evidential explanation of HENIN. We also find that the learning of graph-based session-session and post-post interactions contributes most to the performance. Such results can encourage future studies to develop advanced graph neural networks in better representing the interactions between heterogeneous information. In addition, it is worthwhile to further model information propagation and temporal correlation of comments in the future.

Reactive Supervision: A New Method for Collecting Sarcasm Data

Boaz Shmueli[1,2,3,*], **Lun-Wei Ku**[2] and **Soumya Ray**[3]
[1]Social Networks and Human-Centered Computing, Taiwan International Graduate Program
[2]Institute of Information Science, Academia Sinica
[3]Institute of Service Science, National Tsing Hua University

Abstract

Sarcasm detection is an important task in affective computing, requiring large amounts of labeled data. We introduce **reactive supervision**, a novel data collection method that utilizes the dynamics of online conversations to overcome the limitations of existing data collection techniques. We use the new method to create and release a first-of-its-kind large dataset of tweets with sarcasm perspective labels and new contextual features. The dataset is expected to advance sarcasm detection research. Our method can be adapted to other affective computing domains, thus opening up new research opportunities.

1 Introduction

Sarcasm is ubiquitous in human conversations. As a form of insincere speech, the intent behind a sarcastic utterance is integral to its meaning. Perceiving a sarcastic utterance as genuine will often result in a complete reversal of the intended meaning, and vice versa (Gibbs, 1986). It is therefore crucial for affective computing systems and tasks, such as sentiment analysis and dialogue systems, to automatically detect sarcasm from the perspective of the author as well as the reader in order to avoid misunderstandings. Oprea and Magdy (2019) recently pioneered the study of *intended sarcasm* (by the author) vs. *perceived sarcasm* (by the reader) in the context of sarcasm detection tasks. The training of models for these tasks requires large amounts of labeled sarcasm data, with Twitter becoming a major source due to its popularity as a social network as well as the huge amounts of conversational text its users generate. Previous works describe three methods for collecting sarcasm data: distant supervision, manual annotation, and manual collection.

Distant supervision automatically collects "in-the-wild" sarcastic tweets by leveraging author-generated labels such as the #sarcasm hashtag (Davidov et al., 2010; Ptáček et al., 2014). This method generates large amounts of data at low cost, but labels are often noisy and biased (Bamman and Smith, 2015).

To improve quality, **manual annotation** asks humans to label given tweets as sarcastic or not. Since finding sarcasm in a large corpus is "a needle-in-a-haystack problem" (Liebrecht et al., 2013), manual annotation can be combined with distant supervision (Riloff et al., 2013). Still, low inter-annotator reliability is often reported (Swanson et al., 2014), resulting not only from the subjective nature of sarcasm but also the lack of cultural context (Joshi et al., 2016). Moreover, neither method collects both sarcasm perspectives: distant supervision collects intended sarcasm, while manual annotation can only collect perceived sarcasm.

Lastly, in **manual collection**, humans are asked to gather and report sarcastic texts, either their own (Oprea and Magdy, 2020) or by others (Filatova, 2012). However, both manual methods are slower and more expensive than distant supervision, resulting in smaller datasets.

To overcome the above limitations, we propose **reactive supervision**, a novel conversation-based method that offers automated, high-volume, "in-the-wild" collection of high-quality intended and perceived sarcasm data. We use our method to create and release the SPIRS sarcasm dataset[1].

2 Reactive Supervision

Reactive supervision exploits the frequent use in online conversations of a **cue tweet** — a reply that highlights sarcasm in a prior tweet. Figure 1 (left panel) shows a typical exchange on Twitter: C posts a sarcastic tweet. Unaware of C's sarcastic intent, B replies with an oblivious tweet. Lastly, A

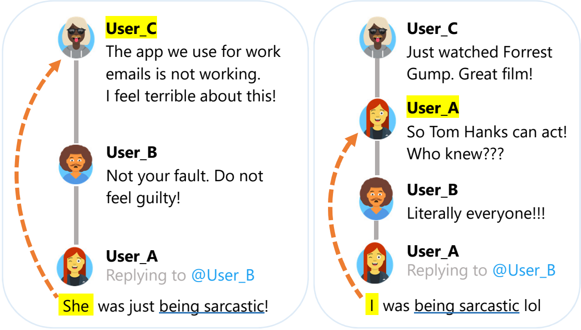
Person	Example Cue	Regular Expression	Example Author Sequences
1st	*I was only being sarcastic lol*	`^A[^A]*`**`(A)`**`[^A]*$`	$AB\boldsymbol{A}$, $AB\boldsymbol{A}C$, $AB\boldsymbol{A}B$
2nd	*Why are you being sarcastic?*	`^AA*`**`(B)`**`A*$`	$A\boldsymbol{B}$, $A\boldsymbol{B}A$, $A\boldsymbol{B}AA$
3rd	*She was just being sarcastic!*	`^AA*B[AB]*`**`(C)`**`[AB]*$`	$AB\boldsymbol{C}$, $AB\boldsymbol{C}B$, $ABA\boldsymbol{C}$

Table 1: The three grammatical person classes, with example cue tweets, corresponding regular expressions, and examples of matching author sequences. The bold author letter corresponds to the position of the sarcastic tweet.



User_C
The app we use for work emails is not working. I feel terrible about this!

User_B
Not your fault. Do not feel guilty!

User_A
Replying to @User_B
She was just being sarcastic!

User_C
Just watched Forrest Gump. Great film!

User_A
So Tom Hanks can act! Who knew???

User_B
Literally everyone!!!

User_A
Replying to @User_B
I was being sarcastic lol

Figure 1: Conversation threads. Left panel: 3rd-person cue with author sequence ABC. Right panel: 1st-person cue with author sequence $ABAC$.

alerts B by replying with a cue tweet (*She was just being sarcastic!*). Since A replies to B but refers to the sarcastic author in the 3rd person (*She*), C is necessarily the author of the perceived sarcastic tweet. Similarly, Figure 1 (right panel) shows how a 1st person cue (*I was just being sarcastic!*) can be used to unequivocally label intended sarcasm.

To capture sarcastic tweets, we thus first search for cue tweets (using the query phrase "being sarcastic", often used in responses to sarcastic tweets), then carefully examine each cue tweet to identify the corresponding sarcastic tweet.

The following formalizes our method.

2.1 Method

Definitions We define a thread to be a sequence of tweets $\{t_n, t_{n-1}, \ldots, t_1\}$, where t_{i+1} is a reply to t_i, $i = 1, \ldots, n-1$. Tweets are listed in reverse chronological order, with t_1 being the root tweet. The corresponding author sequence is $a_n a_{n-1} \ldots a_1$, were we replace the original author names with consecutive capital letters $(A, B, C, \ldots)$, starting with $a_n = A$. For example, Figure 1 (right panel) depicts a thread of length $n = 4$ with author sequence $ABAC$. Here $a_4 = a_2 = A$, $a_3 = B$, and $a_1 = C$ is the author of the root tweet.

Algorithm Given a thread $\{t_n, t_{n-1}, \ldots, t_1\}$ with cue tweet t_n by $a_n = A$, our aim is to identify the sarcastic tweet among $\{t_{n-1}, \ldots, t_1\}$. We first examine the personal subject pronoun used in the cue (I, you, s/he) and map it to a grammatical person class (1st, 2nd, 3rd). This informs us whether the sarcastic author is also the author of the cue (1st), its addressee (2nd), or another party (3rd). For each person class we then apply a heuristic to identify the sarcastic tweet.

For example, for a 1st-person cue tweet (e.g., *I was just being sarcastic!*), the sarcastic tweet must also be authored by A. If the earlier tweets in T contain exactly one tweet from A, it is unambiguously the sarcastic tweet. Otherwise, if there are two or more earlier tweets from A (or none), the sarcastic tweet cannot be unambiguously pinpointed and the entire thread is discarded. We formalize this rule by requiring the author sequence to match the regular expression `/^A[^A]*`**`(A)`**`[^A]*$/`, where the capturing group **`(A)`** corresponds to the sarcastic tweet[2]. We are able to use regular expressions because we use a string of letters to represent the author sequence. 2nd- and 3rd-person cues produce corresponding rules and patterns. Table 1 lists the three person classes, corresponding regular expressions, and example author sequences.

2.2 Advantages

Additional Tweet Types Along with each sarcastic tweet, we collect the **oblivious tweet** (the unsuspecting reply to the sarcastic tweet) when available. As far as we know, this is the first work that identifies and collects oblivious texts, a new type of data that can improve research on the (mis)understanding of sarcasm, with applications such as automated assistive systems for people with emotional or cognitive disabilities. If the sarcastic tweet is a reply, we also capture the **eliciting tweet**, which is the tweet that evoked the sarcastic reply. We provide more details in Appendix A.

---

[2] We use Perl-Compatible Regular Expressions (PCRE).

Extraction of Semantic Relations Being able to identify the various tweets types (cue, oblivious, sarcastic, eliciting), reactive supervision can be understood more abstractly as capturing *semantic dependency relations* between *utterances*[3]. Reactive supervision can thus be useful in the context of discourse analysis.

Context-Aware Annotation Our method uses cues from thread participants, who therefore serve as *de facto* annotators. As participants are familiar with the conversation's context, we overcome some quality issues of using external annotators, who are often unfamiliar with the conversation context due to cultural and social gaps (Joshi et al., 2016).

Sarcasm Perspective Previous datasets contain either intended or perceived sarcasm, but not both (Oprea and Magdy, 2019). Our method identifies and labels *both* intended and perceived sarcasm *within the same data context*: by their essence, 1st-person cue tweets capture intended sarcasm, while 2nd- and 3rd-person cues capture perceived sarcasm. We label a tweet as perceived sarcasm when at least one reader perceives the tweet as sarcastic and posts a cue tweet. Detecting perceived sarcasm is useful, for example, for training algorithms that flag sensitive texts which might be (mis)perceived as sarcastic (even by a single reader).

Faster Data Collection We tested González-Ibáñez et al. (2011)'s distant supervision method of collecting tweets ending with #sarcasm and related hashtags, fetching 171 tweets/day on average. During the same period, our method collected 312 tweets/day on average, an 82% rate improvement.

Summary of Advantages Table 2 summarizes the advantages of our best-of-all-worlds method over other approaches. Reactive supervision offers automated, in-the-wild, and context-aware detection of intended and perceived sarcasm data.

Method → **Feature** ↓	Distant Supervision	Manual Annotation	Manual Collection	**Reactive Supervision**
Automatic	✓	✗	✗	✔
In-the-wild	✓	✗	✗	✔
Oblivious Tweet	✗	✗	✗	✔
Context-Aware	✓	Maybe	Maybe	✔
Perspective	Intended	Perceived	Either	**Both**
Samples/Day	171	Manual	Manual	**312**

Table 2: Comparison of data collection methods.

```
Result: Set $S$ of Sarcastic Tweets
$S \leftarrow \{\}$
$candidates$ ← Fetch('being sarcastic')
for $cue$ in $candidates$ do
    switch Classify($cue$) do
        case 1st person do
            regexp ← ^A[^A]*(A)[^A]*$
        case 2nd person do
            regexp ← ^AA*(B)A*$
        case 3rd person do
            regexp ← ^AA*B[AB]*(C)[AB]*$
        case unknown do
            continue
    end
    $\{t_n(= cue), t_{n-1}, \ldots, t_1\}$ ← Traverse($cue$)
    $a_n a_{n-1} \ldots a_1$ ← authors($\{t_n, t_{n-1}, \ldots, t_1\}$)
    if $i$ ← Match(regexp, $a_n a_{n-1} \ldots a_1$) then
        $S \leftarrow S \cup \{t_i\}$
    end
end
```

3 SPIRS Dataset

We implemented reactive supervision using a 4-step pipeline (see Algorithm 1):

1. **Fetch** calls the Twitter Search API to collect cue tweets, using "being sarcastic" as the query.

2. **Classify** is a rule-based, precision-oriented classifier that classifies cues as 1st-, 2nd-, or 3rd-person according to the referred pronoun (I, you, s/he). If the cue cannot be accurately classified (e.g., a pronoun cannot be found, the cue contains multiple pronouns, negation words are present), the cue is classified as *unknown* and discarded.

3. **Traverse** calls the Twitter Lookup API to retrieve the thread by starting from the cue tweet and repeatedly fetching the parent tweet up to the root tweet.

4. Finally, **Match** matches the thread's author sequence with the corresponding regular expression. Unmatched sequences are discarded. Otherwise, the sarcastic tweet is identified and saved along with the cue tweet, as well as the eliciting and oblivious tweets when available.

The pipeline collected 65K cue tweets containing the phrase "being sarcastic" and corresponding threads during 48 days in October and November 2019. 77% of the cues were classified as *unknown* and discarded, ending with 15 000 English sarcastic tweets. In addition, 10 648 oblivious and 9 156 eliciting tweets were automatically captured. Table 3 summarizes the SPIRS dataset. We added 15 000 negative instances by sampling random English tweets captured during the same period, discarding tweets with sarcasm-related words or hashtags.

---

[3] It is worth noting that Hearst (1992) uses patterns to automatically extract *lexical relations* between *words*.

		# Tweets		
Person	**Perspective**	**Sarcastic**	**Oblivious**	**Eliciting**
1st	Intended	10 300	9 065	8 075
2nd	Perceived	3 000	—	842
3rd	Perceived	1 700	1583	239
Total		**15 000**	**10 648**	**9 156**

Table 3: SPIRS data breakdown by person class.

Sarcastic tweets can be either root tweets or replies. We found that the majority of intended sarcasm tweets are replies (78.4%), while the majority of perceived sarcasm tweets are root tweets (77.0%). Further dataset statistics on author sequence and tweet position distributions are available in Appendices B and C.

Reliability To assess our method's reliability in capturing sarcastic tweets, we manually inspected 200 random sarcastic tweets, along with their cue tweets, from each person class. The accuracy of sarcastic tweet labeling was high: 98.5%, 98%, and 97% for 1st-, 2nd-, and 3rd-person cue tweets, respectively. Table 4 shows samples of correct and incorrect cue tweet classifications.

Cue Tweet	**Pers.**	**Correct?**
Shudda been more clear...I was being sarcastic	1st	✓
I'm almost always being sarcastic, but this was real	1st	✗
Take it you are being sarcastic	2nd	✓
You do realize @user was being sarcastic right?	2nd	✗
She was being sarcastic. You missed the joke	3rd	✓
Mind blown. Had no idea he was being sarcastic	3rd	✗

Table 4: Correctly and incorrectly classified cue tweets.

4 Experiments and Analysis

We present dataset baselines for three tasks: sarcasm detection, sarcasm detection with conversation context, and sarcasm perspective classification, a new task enabled by our dataset.

4.1 Sarcasm Detection

The first experiment is sarcasm detection. We trained a total of three models: CNN (100 filters with a kernel size 3) and BiLSTM (100 units), both max-pooled and Adam-optimized with a learning rate of 0.0005; data was preprocessed as described in Tay et al. (2018); the embedding layer was preloaded with GloVe embeddings (Twitter data, 100 dimensions) (Pennington et al., 2014). We also fine-tuned a pre-trained base uncased BERT model (Devlin et al., 2019). For all three models, we used 5-fold cross-validation for training, holding out 20% of the data for testing.

Results are shown in Table 5 (top panel). BERT is the best performing model, with 70.3% accuracy. We compared SPIRS's classification results to the Ptáček et al. (2014) dataset, commonly used in sarcasm benchmarks. We found that Ptáček's accuracy is significantly higher (86.6%). We posit that it is because sarcasm is confounded with locale in the Ptáček (sarcastic tweets are from worldwide users; non-sarcastic tweets are from users near Prague), and thus classifiers learn features correlated to locale. We tested our hypothesis by replacing our negative samples with Ptáček's, which indeed resulted in boosting the accuracy by 19.1%.

4.2 Detection with Conversation Context

Our second sarcasm classification experiment uses conversation context by adding eliciting and oblivious tweets to the model. As far as we know, this is the first sarcasm-related task that uses oblivious texts. Our model concatenated the outputs of three identical 100-unit BiLSTMs (one per tweet: sarcastic, oblivious, eliciting) before feeding it into dense layers for classification. Tweets without surrounding context were not used in this task. Results are shown in Table 5 (middle panel). Accuracy for the full-context model was 74.7% (MCC 0.398).

Ablation Study We conducted context ablation experiments to identify the contribution of each tweet type. We found that removing the eliciting tweets reduces accuracy by 0.5% and MCC by 0.026. Removing the oblivious tweets, however, lowered accuracy by 3.4% to 71.4%, and the MCC dropped significantly by 31%, from 0.398 to 0.275. This illustrates the importance of the new oblivious text data provided in the dataset and suggests its usefulness in sarcasm-related tasks.

4.3 Perspective Classification

Taking advantage of the new labels in our dataset, we propose a new task to classify a sarcastic text's perspective: intended vs. perceived. Our results are displayed in Table 5 (bottom panel), demonstrating the superiority of BERT over the other models, with an accuracy of 68.2% and MCC of 0.366.

Error Analysis We carefully examined the errors to analyze the causes of perspective misclassification. We observed that misclassified-as-intended tweets (e.g., "You're lost!", "Omg that was so

Task	Dataset	Model	P	R	F1	Acc	MCC

Table 5: Baselines. We report precision, recall, macro-F1, accuracy, and MCC (Matthews correlation coefficient). Mean and standard deviation were calculated using 5-fold cross-validation. N is the number of instances after preprocessing. *Dataset classes were balanced using majority class downsampling.

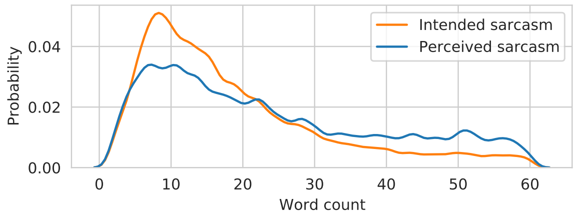

Figure 2: Word count distribution in SPIRS

funny") had, on average, almost half the word count of misclassified-as-perceived tweets (17.2 vs. 27.8). We posit that longer, more informative texts make sarcasm easier to perceive; hence, short perceived sarcasm or long intended sarcasm might introduce errors. Analysis of the dataset's word count distribution supports our hypothesis (see Figure 2).

Looking for further error sources, we inspected *short* intended tweets that were misclassified, for example "great friends i have!" and "My mom is so beautiful". These tweets can be read as root tweets and not as replies, yet most intended sarcasm tweets are replies while most perceived sarcasm tweets are root tweets (see Section 3). We hypothesize that the classifier learns discourse-related features (original tweet vs. reply tweet), which can lead to these errors. Further analysis of sarcasm perspective and its interplay with sarcasm pragmatics is a promising avenue for future research.

5 Conclusion

We present an innovative method for collecting sarcasm data that exploits the natural dynamics of online conversations. Our approach has multiple advantages over all existing methods. We used it to create and release SPIRS, a large sarcasm dataset with multiple novel features. These new features, including labels for sarcasm perspective and unique context (e.g., oblivious texts), offer opportunities for advances in sarcasm detection.

Reactive supervision is generalizable. By modifying the cue tweet selection criteria, our method can be adapted to related domains such as sentiment analysis and emotion detection, thereby advancing the quality and quantity of data collection and offering new research directions in affective computing.

A Search Pattern Production

We construct the regular expression for capturing all tweet types — sarcastic, oblivious, and eliciting — given a 3rd-person cue tweet. Similar logic produces the patterns for 1st- and 2nd-person cues.

The cue tweet author (A) refers to the sarcastic tweet author in the 3rd person (e.g., *She was being sarcastic!*); we thus assume that A's tweet is a response to a second author B, but refers to a third author C (the sarcastic author). To unambiguously pinpoint the sarcastic tweet, C can only appear once in the author sequence. Moreover, only A, B, and C can participate in the thread. Finally, C's tweet can either be a root tweet or a reply to another tweet. The combination of these constraints leads to the regular expression `/^(A)(A*B[AB]*)(C)([AB]*)$/`.

`(A)` is the cue tweet. `(A*B[AB]*)` forces at least one tweet from B (to which A responded). `(C)` is the sarcastic tweet. Finally, `([AB]*)` represents optional tweets from A or B. If the author sequence matches the regular expression, we can unambiguously identify the sarcastic author and the corresponding sarcastic tweet. We also use the search pattern to find the oblivious and eliciting tweets. We assume that the cue tweet `(A)` is triggered by an oblivious tweet from B. Thus, if `(A*B[AB]*)` contains *exactly* one B, we designate the corresponding tweet as oblivious. Likewise, `([AB]*)` contains the eliciting tweet.

Table 6 lists the search patterns for the three person classes. Note that the 2nd-person pattern does not include an oblivious tweet because A's cue tweet is a response to a sarcastic tweet from B, i.e., it is not triggered by an oblivious tweet.

Person	Regular Expression
1st	`^(A)([^A]*)(A)([^A]*)$`
2nd	`^(A)A*(B)(A*)$`
3rd	`^(A)(A*B[AB]*)(C)([AB]*)$`

Table 6: Person classes and their search patterns. The capturing groups' colors correspond to the locations of the cue, oblivious, sarcastic and eliciting tweets.

B Author Sequence Distribution

Table 7 shows the most common author sequences in SPIRS. The different colors correspond to the different tweet types. The most common pattern for 1st-person cues is $ABAC$ (as in Figure 1, right panel). AB is the most common pattern for 2nd-person cues, which denote a sarcastic root tweet followed immediately by a cue tweet (e.g., *Why are you being sarcastic?*). For 3rd-person cues, the most common pattern is ABC (as in Figure 1, left panel). Note that some patterns appear in more than one person class. For example, ABA appears in both 1st- and 2nd-person classes, while $ABAC$ appears in both 1st- and 3rd-person.

		# Tweets		
Person	**Patterns**	**Sarcast.**	**Obliv.**	**Elicit.**
1st (Intended)	$ABAC$	2 841	2 841	2 841
	ABA	1 818	1 818	—
	$ABAB$	1 551	1 551	1 551
	Other	4 090	2 855	2 683
	Subtotal	**10 300**	**9 065**	**8 075**
2nd (Perceived)	AB	2 122	—	—
	ABA	782	—	782
	Other	96	—	60
	Subtotal	**3 000**	**—**	**842**
3rd (Perceived)	ABC	1 235	1 235	—

C Tweet Position Distribution

Reactive supervision enables the measurement of conversation position statistics for sarcastic tweets on Twitter. Given a thread $\{t_n, \ldots, t_i = s, \ldots, t_1\}$ with cue tweet t_n, sarcastic tweet $t_i = s$, and root tweet t_1, we define the *position* of the sarcastic tweet as the distance $i - 1$ between the sarcastic tweet and the root. Furthermore, the *cue lag* is the distance $n - i$ between the cue and the sarcastic tweet. Table 8 shows the distribution of sarcastic tweets by position and cue lag in the SPIRS dataset.

Root tweets (*position* $= 0$) account for 39% of sarcastic tweets. A further 39% of sarcastic tweets are direct replies to root tweets (*position* $= 1$). Interestingly, only 25% of cue tweets are direct replies to their sarcastic targets (*lag* $= 1$), while an overwhelming 71% have a lag of 2, mostly reflecting a response to an intermediate oblivious tweet. We further find that the average thread length is 3.9 tweets, while the average lag is 1.8 tweets.

	Distance from the root tweet						
Cue lag	0	1	2	3	4	5+	**Total**
1	16.5	7.2	0.9	0.3	0.1	0.2	25.1
2	20.6	30.6	11.4	3.8	1.7	2.3	70.4
3+	1.9	1.3	0.7	0.3	0.1	0.2	4.5
Total	**39.0**	**39.1**	**13.0**	**4.3**	**1.9**	**2.7**	**100.0**

Abstract

Self-supervised neural machine translation (SSNMT) jointly learns to identify and select suitable training data from comparable (rather than parallel) corpora and to translate, in a way that the two tasks support each other in a virtuous circle. In this study, we provide an in-depth analysis of the sampling choices the SSNMT model makes during training. We show how, without it having been told to do so, the model self-selects samples of increasing (*i*) complexity and (*ii*) task-relevance in combination with (*iii*) performing a denoising curriculum. We observe that the dynamics of the mutual-supervision signals of both system internal representation types are vital for the extraction and translation performance. We show that in terms of the Gunning-Fog Readability index, SSNMT starts extracting and learning from Wikipedia data suitable for high school students and quickly moves towards content suitable for first year undergraduate students.

1 Introduction

Human learners, when faced with a new task, generally focus on simple examples before applying what they learned to more complex instances. This approach to learning based on sampling from a curriculum of increasing complexity has also been shown to be beneficial for machines and is referred to as *curriculum learning* (CL) (Bengio et al., 2009). Previous research on curriculum learning has focused on selecting the best distribution of data, i.e. order, difficulty and closeness to the final task, to train a system. In such a setting, data is externally prepared for the system to ease the learning task. In our work, we follow a complementary approach: we design a system that selects by itself the data to train on, and we analyse the selected distribution of data, order, difficulty and closeness to the final task, without imposing it beforehand. Our method resembles *self-paced learning* (SPL) (Kumar et al., 2010), in that it uses the emerging model hypothesis to select samples online that fit into its space as opposed to most curriculum learning approaches that rely on judgements by the target hypothesis, i.e. an external *teacher* (Hacohen and Weinshall, 2019) to design the curriculum.

We focus on machine translation (MT), in particular, self-supervised machine translation (SSNMT) (Ruiter et al., 2019), which exploits the internal representations of an emergent neural machine translation (NMT) system to select useful data for training, where each selection decision is dependent on the current state of the model. Self-supervised learning (Raina et al., 2007; Bengio et al., 2013) involves a primary task, for which labelled data is not available, and an auxiliary task that enables the primary task to be learned by exploiting supervisory signals within the data. In SSNMT, both tasks, data extraction and learning MT, enable and enhance each other. This and the mutual supervision of the two system internal representations lead to a self-induced curriculum, which is the subject of our investigation.

In Section 2 we describe related work on CL, focusing on MT. Section 3 introduces the main aspects of self-supervised neural machine translation. Here, we analyse the performance of both the primary and the auxiliary tasks. This is followed by a detailed study of the self-induced curriculum in Section 4 where we analyse the characteristics of the distribution of training data obtained in the auxiliary task of the system. We conclude and present ideas for further work in Section 5.

2 Related Work

Machine translation has experienced major improvements in translation quality due to the introduction of neural architectures (Cho et al., 2014;

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2560–2571,
November 16–20, 2020.

Bahdanau et al., 2015; Vaswani et al., 2017). However, these rely on the availability of large amounts of parallel data. To overcome the need for labelled data, unsupervised neural machine translation (USNMT) (Lample et al., 2018a; Artetxe et al., 2018b; Yang et al., 2018) focuses on the exploitation of very large amounts of monolingual sentences by combining denoising autoencoders with back-translation and multilingual encoders. Further combining these with phrase tables from statistical machine translation leads to impressive results (Lample et al., 2018b; Artetxe et al., 2018a; Ren et al., 2019; Artetxe et al., 2019). USNMT can be combined with pre-trained language models (LMs) (Conneau and Lample, 2019; Song et al., 2019; Liu et al., 2020). Brown et al. (2020) train a very large LM on billions of monolingual sentences which allows them to perform NMT in a few-shot setting. Self-supervised NMT (SSNMT) (Ruiter et al., 2019) is an alternative approach focusing on *comparable*, rather than *parallel* data. The internal representations of an emergent NMT system are used to identify useful sentence pairs in comparable documents. Selection depends on the current state of the model, resembling a type of self-paced learning (Kumar et al., 2010).

Data selection in SSNMT is directly related to **curriculum learning**, the idea of presenting training samples in a *meaningful* order to benefit learning, e.g. in the form of faster convergence or improved performance (Bengio et al., 2009). Inspired by human learners, Elman (1993) argues that a neural network's optimization can be accelerated by providing samples in order of increasing complexity. While **sample difficulty** is an intuitive measure on which to base a learning schedule, curricula may focus on other metrics such as **task-relevance** or **noise**.

To date, **curriculum learning in NMT** has had a strong focus on the relevance of training samples to a given translation task, e.g. in domain adaptation. van der Wees et al. (2017) train on increasingly relevant samples while gradually excluding irrelevant ones. They observed an increase in BLEU over a static NMT baseline and a significant speed-up in training as the data size is incrementally reduced. Zhang et al. (2019) adapt an NMT model to a domain by introducing increasingly domain-distant (*difficult*) samples. This seemingly contradictory behavior of benefiting from both increasingly difficult (domain-distant) *and* easy (domain-relevant) samples has been analyzed by Weinshall et al. (2018), showing that the initial phases of training benefit from easy samples with respect to a hypothetical competent model (*target hypothesis*), while also being *boosted* (Freund and Schapire, 1996) by samples that are difficult with respect to the current state of the model (Hacohen and Weinshall, 2019). In Wang et al. (2019), both domain-relevance and denoising are combined into a single curriculum.

The denoising curriculum for NMT proposed by Wang et al. (2018) is related to our approach in that they also use *online data selection* to build the curriculum based on the current state of the model. However, the noise scores for the dataset at each training step depend on fine-tuning the model on a small selection of clean data, which comes with a high computational cost. To alleviate this cost, Kumar et al. (2019) use reinforcement learning on the pre-scored noisy corpus to jointly learn the denoising curriculum with NMT. In Section 3.2 we show that our model exploits its self-supervised nature to perform denoising by selecting parallel pairs with increasing accuracy, without the need of additional noise metrics.

Difficulty-based curricula for NMT that take into account sentence length and vocabulary frequency have been shown to improve translation quality when samples are presented in increasing complexity (Kocmi and Bojar, 2017). Platanios et al. (2019) link the introduction of difficult samples with the NMT models' *competence*. Other difficulty-orderings have been explored extensively in Zhang et al. (2018), showing that they, too, can speed-up training without a loss in translation performance.

SSNMT jointly learns to find and extract similar sentence pairs from comparable data and to translate. The extractions can be compared to those obtained by **parallel data mining** systems where strictly parallel sentences are expected. Beating early feature-based approaches, sentence representations obtained from NMT systems or tailored architectures are achieving a new state-of-the-art in parallel sentence extraction and filtering (España-Bonet et al., 2017; Grégoire and Langlais, 2018; Artetxe and Schwenk, 2019; Hangya and Fraser, 2019; Chaudhary et al., 2019). Using a highly multilingual sentence encoder, Schwenk et al. (2019) scored Wikipedia sentence pairs across various language combinations (*WikiMatrix*). Due to its multilingual aspect and the close similarity with the raw Wikipedia data we use, we also use scored WikiMatrix data for one of the comparisons (Section 3.2).

3 Self-Supervised Neural Machine Translation (SSNMT)

SSNMT is a joint data selection and training framework for machine translation, introduced in Ruiter et al. (2019). SSNMT enables learning NMT from *comparable* rather than parallel data, where comparable data is a collection of multilingual topic-aligned documents.[1] Its basic architecture uses the semantic information encoded in the internal representations of a standard NMT system to determine at training time if an input sentence pair is *similar enough* or not, and therefore whether it should be used for training or not. Selection is made online, so, the more the semantic representations improve during training, the more truly parallel sentence pairs are selected. Because of this, the nature of the selected pairs naturally evolves during training, and this evolution is what we analyze as self-induced curriculum learning in Section 4.

SSNMT is based on a bidirectional NMT system $\{L1, L2\}\rightarrow\{L2, L1\}$ where the engine learns to translate simultaneously from a language $L1$ into another language $L2$ and vice-versa with a single encoder and a single decoder. This is important in the self-supervised architecture because it represents the two languages in the same semantic space. In principle, the input data to train the system is a monolingual corpus of sentences in $L1$ and a monolingual corpus of sentences in $L2$ and the system learns to find and select similar sentence pairs. In order to speed-up training, we use a comparable corpus such as Wikipedia, where we can safely assume that there are comparable (similar) and parallel sentence pairs in related documents D_{L1}, D_{L2}.

Given a document pair D_{L1}, D_{L2}, the SSNMT system encodes each sentence of each document into two fixed-length vectors C_w and C_h

$$C_w = \sum_t w_t, \qquad C_h = \sum_t h_t, \qquad (1)$$

where w_t is the word embedding and h_t the encoder output at time step t. For each of the *sentence representations* s, all combinations of sentences $s_{L1}\times s_{L2} \parallel s_{L1} \in D_{L1}$ and $s_{L2} \in D_{L2}$ are encoded and scored using the *margin-based* measure by Artetxe and Schwenk (2019) with $k = 4$.

What follows is a selection process, that identifies the top scoring s_{L2} for each s_{L1} and vice-versa. If a pair $\{s_{L1}, s_{L2}\}$ is top scoring for both language directions *and* for both sentence representations, it is accepted without involving any hyperparameter or threshold. This is the high precision, medium recall approach in Ruiter et al. (2019). Whenever enough pairs have been collected to create a batch, the system trains on it, updating its weights, improving both its translation and extraction ability to fill the next batch.

3.1 Translation Quality

Experimental Setup We use Wikipedia (WP) as a comparable corpus and download the English, French, German and Spanish dumps,[2] pre-process them and extract comparable articles per language pair using `WikiTailor`[3] (Barrón-Cedeño et al., 2015; España-Bonet et al., 2020). All articles are normalized, tokenized and truecased using standard `Moses` (Koehn et al., 2007) scripts. For each language pair, a shared byte-pair encoding (BPE) (Sennrich et al., 2016) of 100 k merge operations is applied. Following Johnson et al. (2017), a language tag is added to the beginning of each sequence.

The number of sentences, tokens and average article length is reported in Table 1. For validation we use *newstest2012* (NT12) and for testing *newstest2013* (NT13) for *en–es* and *newstest2014* (NT14) or *newstest2016* (NT16) for *en*–$\{fr, de\}$. The SSNMT implementation[4] builds on the transformer base (Vaswani et al., 2017) in `OpenNMT` (Klein et al., 2017). All systems are trained using a batch size of 50 sentences with maximum length of 50 tokens.

Monolingual embeddings trained using `word2vec` (Mikolov et al., 2013)[5] on the complete WP editions are projected into a common multilingual space via `vecmap`[6] (Artetxe et al., 2017) to attain bilingual embeddings between *en*–$\{fr$,*de*,*es*$\}$. These initialise the NMT word embeddings (C_w).

---

[1] Wikipedia is an example; the French article on *Paris* is different from the German one. They are not translations of each other, but they are on the same topic.

Table 2: Automatic evaluation of SSNMT on NT14 (fr) NT16 (de) NT13 (es). Most right columns show the comparison with three SotA systems for supervised NMT (Edunov et al., 2018) / USNMT (Lample et al., 2018b) / pre-trained+LM USNMT (Song et al., 2019).

As a control experiment and purely in order to analyse the quality of the SSNMT data selection auxiliary task, we use the Europarl (EP) corpus (Koehn, 2005). The corpus is pre-processed in the same way as WP, and we create a synthetic comparable corpus from it as explained in Section 3.2. For these experiments, we use the same data for validation and testing as mentioned above.

Automatic Evaluation We use BLEU (Papineni et al., 2002), TER (Snover et al., 2006) and METEOR (Lavie and Agarwal, 2007) to evaluate translation quality. For calculating BLEU, we use `multi-bleu.perl`, while TER and METEOR are calculated using the `scoring` package[7] which also provides confidence scores. SSNMT translation performance training on the en–$\{fr, de, es\}$ comparable Wikipedia data is reported in Table 2 together with a comparison to the current state-of-the-art (SotA) in supervised and (pre-trained) USNMT. SSNMT is on par with the current SotA in USNMT, outperforming it by 3–4 BLEU points in en–fr with lower performance on en–de ($\sim$3 BLEU). Note that unsupervised systems such as Lample et al. (2018b) use more than 400 M monolingual sentences for training while SSNMT uses an order of magnitude less by exploiting comparable corpora. However, once unsupervised NMT is combined with LM pre-training, it outperforms SSNMT (which does not use LM pre-training) by large margins, i.e. around 7 BLEU points for en–fr and 13 BLEU for en–de.

3.2 Data Extraction Quality

Experimental Setup To get an idea of the data extraction performance of an SSNMT system, we perform control experiments on synthetic comparable corpora, as there is no underlying ground truth to Wikipedia. For these purposes, we use the en–$\{fr,de,es\}$ versions of Europarl. After setting aside $1M$ parallel pairs as *true* samples to evaluate SSNMT data extraction performance, the target sides of all remaining source-target pairs in EP are scrambled to create non-parallel (*false*) source-target pairs. In order to keep the synthetic comparable corpora close to the statistics of the original comparable Wikipedias, we control the EP true:false (parallel:non-parallel) sentence pair ratio to mimic the ratios we observe in our extractions from WP. We assume that all WP sentences accepted by SSNMT are true (parallel) examples, and that the number of false examples (non-parallel) are the rejected ones. With this, we estimate base true:false ratios of 1:4 for en–$\{fr,es\}$ and 1:8 for en–de.[8] The false samples created from EP are oversampled in order to meet this ratio given that there are $1M$ true samples. Further, we calculate the average article length of the comparable WPs and split the synthetic comparable samples into pseudo-articles with this length. The statistics of

---

[7] `kheafield.com/code/scoring.tar.gz`

[8] In a manual evaluation annotating 10 randomly sampled WP articles for L1 and L2 in en–$\{fr,es,de\}$ each, the true:false ratios resulted 3:8 for en–fr, 1:4 for en–es and 1:8 for en–de which validate the assumption.

the synthetic pseudo-comparable EPs are reported in Table 1. We then train and evaluate the SSNMT system on the synthetic comparable data.

Automatic Evaluation The pairs SSNMT extracts from the pseudo-comparable EP articles at each epoch are compared to the $1M$ ground truth pairs to calculate *epoch-wise* extraction precision (P) and recall (R). Further, we also take the concatenation of all extracted sentences from the very beginning up to a certain epoch in training in order to report *accumulated* P and R. As we are interested in the final extraction decision based on the intersection of both representations C_w and C_h (*dual*), but also in the decisions of each single representation (C_w, C_h), we report the performance for all three representation combinations on EP$_{enfr}$ in Figure 1. Similar curves are observed for EP$_{ende}$ and EP$_{enes}$, which are considered in the discussion below.

At the beginning of training, the extraction **precision** of each representation itself is fairly low with P∈[0.45,0.66] for C_w and P∈[0.14,0.40] for C_h. The fact that C_w is initialized using pre-trained embeddings, while C_h is not, leads to the large difference in initial precision between the two. As both representations are combined via their intersections, the final decision of the model is high precision already at the beginning of training with values between 0.78–0.87. As training progresses and the internal representations are adapted to the task, the precision of C_h is greatly improved, leading to an overall high precision extraction which converges at 0.96–0.99. This development of extracting parallel pairs with increasing precision is in fact an instantiation of a **denoising curriculum** as described by Wang et al. (2018).

The **recall** of the model, being bounded by the performance of the weakest representation, is very low at the beginning of training (R∈ [0.03,0.04]) due to the lack of task knowledge in C_h. However, as training progresses and C_h improves, the accumulated extraction recall of the model rises to high values of 0.95–0.98. Interestingly, the epoch-wise recall is much lower than the accumulated, which provides evidence for the hypothesis that SSNMT models extracts different *relevant* samples at different points in training, such that it has identified most of the relevant samples at some point during training, but not at every epoch.

It should be stressed that the successful extraction of increasingly precise pairs in combination with high recall is the result of the dynamics of both internal representations C_w and C_h. As C_h is less informative at the beginning of training, C_w guides the final decision at such early stages to ensure high precision; and as C_w is high in recall throughout training, C_h ensures a gentle growth in final recall by setting a good lower bound. The intersection of both ensures that errors committed by one can be caught by the other; effectively a mutual supervision between representations. The results in Figure 1 show that the SSNMT self-induced curriculum is able to identify parallel data in comparable data with high precision and recall.

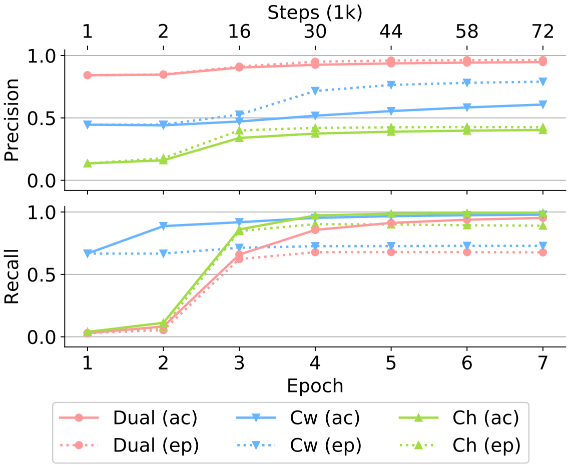

Figure 1: Accumulated (ac) and epoch-wise (ep) precision and recall on the en–fr EP-based synthetic comparable data.

Comparison with WikiMatrix Because of the close similarity with our WP data, we compare on the en–$\{fr, de, es\}$ corpora in WikiMatrix (Schwenk et al., 2019), which we pre-process as described in Section 3.1. As these data sets consist of preselected mined sentence pairs together with their similarity scores, a manual threshold θ needs to be set to extract sentence pairs for training supervised NMT. We run the extraction script using $\theta = 1.04$, which Schwenk et al. (2019) recommend as a *good choice for most language pairs*, and use the resulting data to train a supervised NMT system.

The results are summarized in the bottom two rows in Table 3. Confidence intervals ($p = 95\%$) are calculated using bootstrap resampling (Koehn, 2004). For en–fr, the supervised system trained on WikiMatrix outperforms SSNMT trained on WP by 3–4 BLEU points, while the opposite is the case for en–de, where SSNMT achieves 1–5

	#Pairs$_{enfr}$	$en2fr$	$fr2en$	#Pairs$_{ende}$	$en2de$	$de2en$	#Pairs$_{enes}$	$en2es$	$es2en$

Table 3: BLEU scores of a supervised NMT system trained on the unique pairs collected by SSNMT in the first (NMT$_{init}$), intermediate (NMT$_{mid}$), final (NMT$_{end}$) and all (NMT$_{all}$) epochs of training tested on N13/N14.

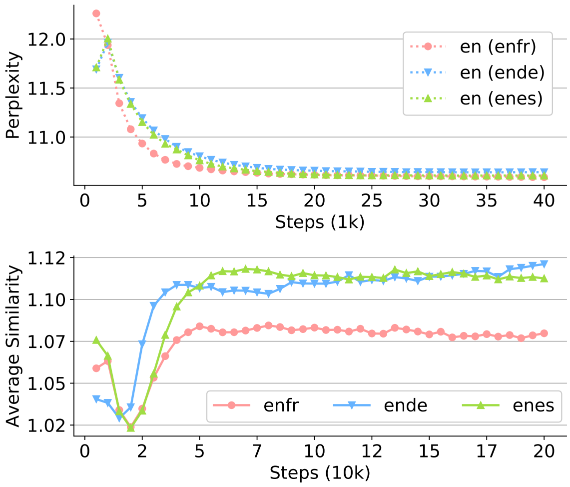

Figure 2: Perplexities on the English data extracted by SSNMT (top) and average similarity scores of the accepted pairs (bottom).

BLEU points more. For *en–es*, both approaches are not statistically significantly different. The variable performance of the two approaches may be due to the varying appropriateness of the extraction threshold θ in WikiMatrix. For each language and corpus, a new optimal threshold needs to be found; a problem that SSNMT avoids by its use of two representation types that complement each other during extraction without the need of a manually set threshold. The results show that SSNMT's self-induced extraction and training curriculum is able to deliver translation quality on a par with supervised NMT trained on externally preselected mined parallel data (WikiMatrix).

4 Self-Induced SSNMT Curricula

4.1 Order & Closeness to the MT Task

As a first indicator of the existence of a preferred choice in the order of the extracted sentence pairs, we compare the performance of SSNMT with different supervised NMT models trained on the WP data extracted by SSNMT at different points in training. We consider specific per-epoch data sets extracted in the first, intermediate and final epochs of training, as well as cumulative data of all unique sentence pairs extracted over all epochs. We then train four supervised NMT systems (NMT$_{init}$, NMT$_{mid}$, NMT$_{end}$, NMT$_{all}$) on these data sets. The difference in the **translation quality** using only the data selected at different epochs reflects the evolving closeness of the data to the final translation task: we expect data extracted in later epochs of the SSNMT training to include more sentences which are parallel, as demanded by a translation task, and therefore to achieve a higher translation quality.

For each language pair and system, the first four rows in Table 3 show the number of sentence pairs extracted for training and the BLEU score achieved. The evolving SSNMT training curriculum outperforms all supervised versions across all tested languages. Notably, performance is 1–3 BLEU points above the supervised system trained on all extracted data, despite the fact that the SSNMT system is able to extract only a small amount of data in its first epochs, compared to the fully supervised NMT$_{all}$, that, at every epoch, has access to all data that was ever extracted at any of the SSNMT epochs. This suggests that the SSNMT system is able to exclude previously accepted false positives in later epochs, while training supervised NMT on the complete data extracted by SSNMT leads to a recurring visitation at each epoch of the same erroneous samples. Similar to a **denoising curriculum**, the quality and quantity of the extracted data grows as training continues for all languages, as the concatenation of the data extracted across epochs (NMT$_{all}$) is always outperformed by the last and thus largest epoch (NMT$_{end}$), despite the data for NMT$_{all}$ being much larger in size.

An indicator of the **closeness of the curriculum to the final task** is the **similarity** between the selected sentence pairs during training. We

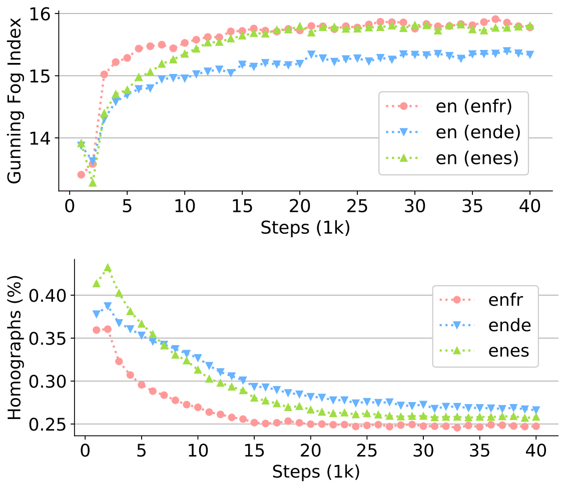

Figure 3: Gunning Fog Index (top) and percentage of homographs (bottom) of extracted English data seen during the first 40 k steps in training.

estimate similarity between pairs by their margin-based scores (Artetxe and Schwenk, 2019) during training. At the beginning of training, the average similarity between extracted pairs is low, but it quickly rises within the first 100 k training steps to values close to $margin$ 1.07 (en–fr) and $margin$ 1.12 (en–$\{de,es\}$). This evolution is depicted in Figure 2 (bottom). The increase in mean similarity of the accepted pairs provides empirical evidence for our hypothesis that internal representations of translations grow closer in the cross-lingual space, and the system is able to exploit this by extracting increasingly similar and accurate pairs.

4.2 Order & Complexity

Establishing the complexity of a sentence is a complex task by itself. Complexity can be estimated by the loss of an instance with respect to the gold or target. In our self-supervised approach, there is no target for the sentence extraction task, so we try to infer complexity by other means.

First, we study the behaviour of the average **perplexity** throughout training. Perplexities of the extracted data are estimated using a LM trained with `KenLM` (Heafield, 2011) on the monolingual WPs for the four languages in our study. We observe the same behaviour in the four cases illustrated by the English curves plotted in Figure 2 (top). Perplexity drops heavily within the first 10 k steps for all languages and models. This indicates that the data extracted in the first epoch includes more *outliers*, and the distribution of extracted sentences moves closer to the average observed in the monolingual WPs as training advances. The larger number of outliers at the beginning of training can be attributed to the larger number of homographs (bottom Figure 3) and short sentences at the beginning of training, leading to a skewed distribution of selected sentences.

The presence of **homographs** is vital for the self-supervised system in its initialization phase. At the beginning of training, only word embeddings, and therefore C_w, are initialized with pre-trained data, while C_h is randomly initialized. Thus, words that have the same index in the shared vocabulary, homographs, play an important role in identifying similar sentences using C_h, making up around 1/3 of all tokens observed in the first epoch. As training progresses, and both C_w and C_h are adapted to the training data, the prevalence of homographs drops and the extraction is now less dependent on a shared vocabulary. The importance of homographs for the initialization raises questions on how SSNMT performs on languages that do not share a script and it is left for future work.

Finally, we analyze the complexity of the sentences that an SSNMT system selects at different points of training by measuring their **readability**. For this, we apply a modified version of the **Gunning Fog Index** (GF) (Gunning, 1952), which is a measure predicting the years of schooling needed to understand a written text given the complexity of its sentences and vocabulary. It is defined as:

$$\mathrm{GF} = 0.4\left[\left(\frac{w}{s}\right) + 100\left(\frac{c}{w}\right)\right] \tag{2}$$

where w and s are the number of words and sentences in a text. c is the number of *complex words*, which are defined as words containing more than 2 syllables. The original formula excluded several linguistic phenomena from the complex word definition such as compound words, inflectional suffixes or familiar jargon; we do not apply all the language-dependent linguistic analysis.

Since our training data is based on Wikipedia articles, the diversity in the complexity of the sentences is limited to the range of complexities observed in Wikipedia. Figure 4 (right) shows the per-sentence GF distributions over the sentences found in the monolingual WPs. We plot the probability density function for the sentence-level GF Index for the four WP editions estimated via a kernel density estimation. Each distribution is made up of two overlapping distributions: one at the lower end of the sentence complexity scale containing short

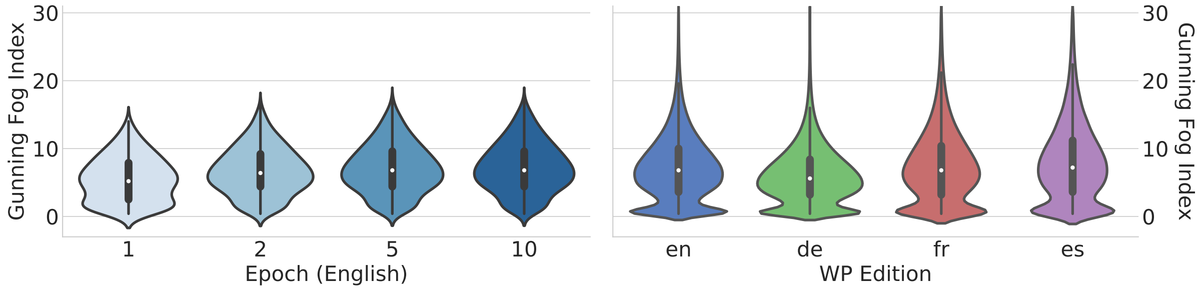

Figure 4: Kernel density estimated Gunning Fog distributions and box plots over extracted *en* (*en*–*de*) sentences at different points in training (left) and over the monolingual Wikipedias (right).

article titles and headers, and one with a higher average complexity and larger standard deviation containing content sentences.

To study the behaviour during training, we compare the Gunning Fog distributions of the English data extracted at the beginning, middle and end of training SSNMT$_{ende}$ with that of the original WP$_{en}$. In the extracted data, we observe that compared with WP the overlapping distributions are less pronounced and that there is no trail of highly complex sentences. This is due to (*i*) the pre-processing of the input data, which removes sentences containing less than 6 tokens, thus removing most WP titles and short sentences, and (*ii*) the length accepted in our batches, which is constrained to 50 tokens per sentence, removing highly complex strings. Apart from this, the distributions in the middle and the end of training come close to the underlying one, but we observe a large number of very simple sentences in the first epoch. This shows that the system extracts mostly simple content at the beginning of training, but soon moves towards complex sentences that were previously not yet identifiable as parallel.

A more detailed evolution is depicted in Figure 3 (top). We collect extracted sentences for each 1 k training steps and report their "text"-level GF scores.[9] Here we observe how the complexity of the sentences extracted rises strongly within the first 20 k steps of training. For English, most models start with text that is suitable for high school students (grade 10–11) and quickly turn to more complex sentences suited for first year undergraduate students (∼13 years of schooling); a **curriculum of growing complexity**. The GF mean of the full set of sentences in the English Wikipedia is ∼12, which corresponds to a high school senior. For all other languages, a similar trend of growing sentence complexity is observed.

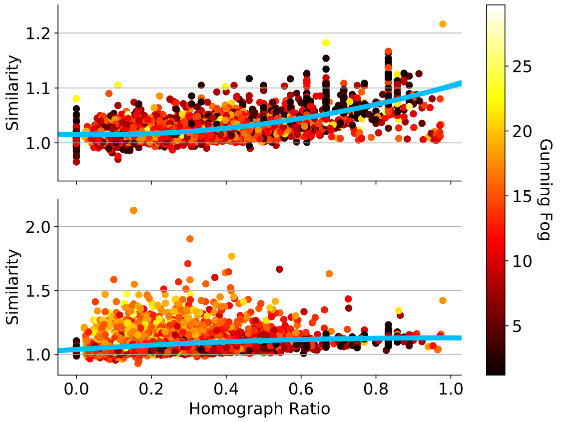

Figure 5: Margin-based similarity, homograph ratio and Gunning Fog index for the first 10 k extracted sentences in the first (top) and last (bottom) epoch of *en*–*fr* training. The solid blue line shows a second order polynomial regression between the homograph ratio and similarity.

4.3 Correlation Analysis

So far, the variables under study, similarity and complexity —GF and homograph ratio—, have been observed as a function of the training steps. In order to uncover the correlations between the variables themselves, we calculate the Pearson Correlation Coefficient (r) between them on the extracted pairs of the *en*–*fr* SSNMT model during its first and last epoch. As shown in the previous sections of the paper, most differences appear in the first epoch and the behaviour across languages is comparable.

At the beginning of training (Figure 5, top) there is a positive correlation ($r = 0.43$) between homograph ratio and similarity, naturally pointing to the importance of homographs for identifying

---

[9] Note that GF is a text level score. In Figure 4 we show sentence level GF distributions, while in Figure 3 (top) we show GF scores for "texts" consisting of sentences extracted over a 1 k training step period.

similar pairs at the beginning of training. This is supported by a weak negative correlation between GF and homograph ratio ($r = -0.28$), indicating that sentences with more homographs tend to be less complex. While there is no significant correlation between GF and similarity in the first epoch ($r = -0.07$), in the last epoch of training (Figure 5, bottom), we observe a moderate positive relationship indicating that more complex sentences tend to come with a higher similarity ($r = 0.30$). At this point, homographs become less important for the extraction and sentences without homographs are now also extracted in large numbers, indicated in terms of a weaker positive correlation between the homograph ratio and the similarity ($r = 0.25$). The relationship between the homograph ratio and the GF stays stable ($r = -0.27$), as can be expected since the two values are not dependent on the MT model's state (C_w and C_h), as opposed to the similarity score.

5 Summary and Conclusions

This paper explores self-supervised NMT systems which jointly learn the MT model and how to find its supervision signal in comparable data; i.e. how to identify and select similar sentences. This association makes the system naturally and internally evolve its own curriculum without it having been externally enforced. We observe that the dynamics of mutual-supervision of both system internal representations, C_w and C_h, is imperative to the high recall and precision parallel data extraction of SSNMT. Their combination for data selection over time instantiates a **denoising curriculum** in that the percentage of non-matching pairs, i.e. non-translations, decreases from 18% to 2%, with an especially fast descent at the beginning of training.

Even if the quality of extraction increases over time, lower-similarity sentence pairs used at the beginning of training are still relevant for the development of the translation engine. We analyze the translation quality of a supervised NMT system trained on the epoch-wise data extracted by SSNMT and observe a continuous increase in BLEU. Analogously, we also analyze the similarity scores of extracted sentences and observe that they also increase over time. As extracted pairs are increasingly similar, and precise, the extraction itself instantiates a secondary **curriculum of growing task-relevance**, where the task at hand is NMT learning with parallel sentences.

A tertiary **curriculum of increased sample complexity** is observed via an analysis of the extracted data's Gunning Fog indices. Here, the system starts with sentences suitable for initial high school students and quickly moves towards content suitable for first year undergraduate students: an overachiever indeed as the norm over the complete WP is end of high school level.

Lastly, by estimating the perplexity with an external LM trained on WP, we observe a steep decrease in perplexity at the beginning of training with fast convergence. This indicates that the extracted data quickly starts to resemble the underlying distribution of all WP data, with a larger amount of outliers at the beginning. These outliers can be accounted for by the importance of homographs at that point. This raises the question of how SSNMT will perform on really distant languages (less homographs) or when using smaller BPE sizes (more homographs), which is something that we will examine in our future work.

Towards Reasonably-Sized Character-Level Transformer NMT by Finetuning Subword Systems

Jindřich Libovický and **Alexander Fraser**
Center for Information and Speech Processing
Ludwig Maximilian University of Munich
Munich, Germany
{libovicky, fraser}@cis.lmu.de

Abstract

Applying the Transformer architecture on the character level usually requires very deep architectures that are difficult and slow to train. These problems can be partially overcome by incorporating a segmentation into tokens in the model. We show that by initially training a subword model and then finetuning it on characters, we can obtain a neural machine translation model that works at the character level without requiring token segmentation. We use only the vanilla 6-layer Transformer Base architecture. Our character-level models better capture morphological phenomena and show more robustness to noise at the expense of somewhat worse overall translation quality. Our study is a significant step towards high-performance and easy to train character-based models that are not extremely large.

1 Introduction

State-of-the-art neural machine translation (NMT) models operate almost end-to-end except for input and output text segmentation. The segmentation is done by first employing rule-based tokenization and then splitting into subword units using statistical heuristics such as byte-pair encoding (BPE; Sennrich et al., 2016) or SentencePiece (Kudo and Richardson, 2018).

Recurrent sequence-to-sequence (S2S) models can learn translation end-to-end (at the character level) without changes in the architecture (Cherry et al., 2018), given sufficient model depth. Training character-level Transformer S2S models (Vaswani et al., 2017) is more complicated because the self-attention size is quadratic in the sequence length.

In this paper, we empirically evaluate Transformer S2S models. We observe that training a character-level model directly from random initialization suffers from instabilities, often preventing it from converging. Instead, we propose finetuning subword-based models to get a model without explicit segmentation. Our character-level models show slightly worse translation quality, but have better robustness towards input noise and better capture morphological phenomena. Our approach is important because previous approaches have relied on very large transformers, which are out of reach for much of the research community.

2 Related Work

Character-level decoding seemed to be relatively easy with recurrent S2S models (Chung et al., 2016). But early attempts at achieving segmentation-free NMT with recurrent networks used input hidden states covering a constant character span (Lee et al., 2017). Cherry et al. (2018) showed that with a sufficiently deep recurrent model, no changes in the model are necessary, and they can still reach translation quality that is on par with subword models. Luong and Manning (2016) and Ataman et al. (2019) can leverage character-level information but they require tokenized text as an input and only have access to the character-level embeddings of predefined tokens.

Training character-level transformers is more challenging. Choe et al. (2019) successfully trained a character-level left-to-right Transformer language model that performs on par with a subword-level model. However, they needed a large model with 40 layers trained on a billion-word corpus, with prohibitive computational costs.

In the most related work to ours, Gupta et al. (2019) managed to train a character-level NMT with the Transformer model using Transparent Attention (Bapna et al., 2018). Transparent attention attends to all encoder layers simultaneously, making the model more densely connected but also more computationally expensive. During training, this improves the gradient flow from the decoder to the encoder. Gupta et al. (2019) claim that Trans-

parent Attention is crucial for training character-level models, and show results on very deep networks, with similar results in terms of translation quality and model robustness to ours. In contrast, our model, which is not very deep, trains quickly. It also supports fast inference and uses less RAM, both of which are important for deployment.

Gao et al. (2020) recently proposed adding a convolutional sub-layer in the Transformer layers. At the cost of a 30% increase of model parameter count, they managed to narrow the gap between subword- and character-based models by half. Similar results were also reported by Banar et al. (2020), who reused the convolutional preprocessing layer with constant step segments Lee et al. (2017) in a Transformer model.

3 Our Method

We train our character-level models by finetuning subword models, which does not increase the number of model parameters. Similar to the transfer learning experiments of Kocmi and Bojar (2018), we start with a fully trained subword model and continue training with the same data segmented using only a subset of the original vocabulary.

To stop the initial subword models from relying on sophisticated tokenization rules, we opt for the loss-less tokenization algorithm from SentencePiece (Kudo and Richardson, 2018). First, we replace all spaces with the ▁ sign and do splits before all non-alphanumerical characters (first line of Table 1). In further segmentation, the special space sign ▁ is treated identically to other characters.

We use BPE (Sennrich et al., 2016) for subword segmentation because it generates the merge operations in a deterministic order. Therefore, a vocabulary based on a smaller number of merges is a subset of a vocabulary based on more merges estimated from the same training data. Examples of the segmentation are provided in Table 1. Quantitative effects of different segmentation on the data are presented in Table 2, showing that character sequences are on average more than 4 times longer than subword sequences with 32k vocabulary.

We experiment both with deterministic segmentation and stochastic segmentation using BPE Dropout (Provilkov et al., 2020). At training time, BPE Dropout randomly discards BPE merges with probability p, a hyperparameter of the method. As a result of this, the text gets stochastically segmented into smaller units. BPE Dropout increases translation robustness on the source side but typically has a negative effect when used on the target side. In our experiments, we use BPE Dropout both on the source and target side. In this way, the character-segmented inputs will appear already at training time, making the transfer learning easier.

We test two methods for finetuning subword models to reach character-level models: first, direct finetuning of subword models, and second, iteratively removing BPE merges in several steps in a curriculum learning setup (Bengio et al., 2009). In both cases we always finetune models until they are fully converged, using early stopping.

4 Experiments

To cover target languages of various morphological complexity, we conduct our main experiments on two resource-rich language pairs, English-German and English-Czech; and on a low-resource pair, English-Turkish. Rich inflection in Czech, compounding in German, and agglutination in Turkish are examples of interesting phenomena for character models. We train and evaluate the English-German translation using the 4.5M parallel sen-

Table 3: Quantitative results of the experiments with deterministic segmentation. The left part of the table shows subword-based models trained from random initialization, the right part shows character-level models trained by finetuning. The yellower the background color, the better the value. Small numbers denote the difference from the best model, ∗ is the best model. For finetuning experiments (on the right) we report both difference from the best model and from the parent model. Validation BLEU score are in in the Appendix.

tences of the WMT14 data (Bojar et al., 2014). Czech-English is trained on 15.8M sentence pairs of the CzEng 1.7 corpus (Bojar et al., 2016) and tested on WMT18 data (Bojar et al., 2018). English-to-Turkish translation is trained on 207k sentences of the SETIMES2 corpus (Tiedemann, 2012) and evaluated on the WMT18 test set.

We follow the original hyperparameters for the Transformer Base model (Vaswani et al., 2017), including the learning rate schedule. For finetuning, we use Adam (Kingma and Ba, 2015) with a constant learning rate 10^{-5}. All models are trained using Marian (Junczys-Dowmunt et al., 2018). We also present results for character-level English-German models having about the same number of parameters as the best-performing subword models. In experiments with BPE Dropout, we set dropout probability $p = 0.1$.

We evaluate the translation quality using BLEU (Papineni et al., 2002), chrF (Popović, 2015), and METEOR 1.5 (Denkowski and Lavie, 2014). Following Gupta et al. (2019), we also conduct a noise-sensitivity evaluation to natural noise as introduced by Belinkov and Bisk (2018). With probability p words are replaced with their variants from a misspelling corpus. Following Gupta et al. (2019), we assume the BLEU scores measured with input can be explained by a linear approximation with intercept α and slope β using the noise probability p: BLEU $\approx \beta p + \alpha$. However, unlike them, we report the relative translation quality degradation β/α instead of only β. Parameter β corresponds to absolute BLEU score degradation and is thus higher given lower-quality systems, making them seemingly more robust.

To look at morphological generalization, we evaluate translation into Czech and German using MorphEval (Burlot and Yvon, 2017). MorphEval consists of 13k sentence pairs that differ in exactly one morphological category. The score is the percentage of pairs where the correct sentence is preferred.

5 Results

The results of the experiments are presented in Table 3. The translation quality only slightly decreases when drastically decreasing the vocabulary. However, there is a gap between the character-

level and subword-level model of 1–2 BLEU points. With the exception of Turkish, models trained by finetuning reach by a large margin better translation quality than character-level models trained from scratch.

In accordance with Provilkov et al. (2020), we found that BPE Dropout applied both on the source and target side leads to slightly worse translation quality, presumably because the stochastic segmentation leads to multimodal target distributions. The detailed results are presented in Appendix A. However, for most language pairs, we found a small positive effect of BPE dropout on the finetuned systems (see Table 4).

For English-to-Czech translation, we observe a large drop in BLEU score with the decreasing vocabulary size, but almost no drop in terms of METEOR score, whereas for other language pairs, all metrics are in agreement. The differences between the subword and character-level models are less pronounced in the low-resourced English-to-Turkish translation.

Whereas the number of parameters in transformer layers in all models is constant at 35 million, the number of parameters in the embeddings decreases 30× from over 15M to only slightly over 0.5M, with overall a 30% parameter count reduction. However, matching the number of parameters by increasing the model capacity narrows close the performance gap, as shown in Table 5.

In our first set of experiments, we finetuned the model using the character-level input directly. Experiments with parent models of various vocabulary sizes (column “Direct finetuning” in Table 3) suggest the larger the parent vocabulary, the worse the character-level translation quality. This result led us to hypothesize that gradually decreasing the vocabulary size in several steps might lead to better translation quality. In the follow-up experiment, we gradually reduced the vocabulary size by 500 and always finetuned until convergence. But we observed a small drop in translation quality in every step, and the overall translation quality was slightly worse than with direct finetuning (column “In steps” in Table 3).

With our character-level models, we achieved higher robustness towards source-side noise (Figure 1). Models trained with a smaller vocabulary tend to be more robust towards source-side noise.

Character-level models tend to perform slightly better in the MorphEval benchmark. Detailed results are shown in Table 6. In German, this is due to better capturing of agreement in coordination and future tense. This result is unexpected because these phenomena involve long-distance dependencies. On the other hand, the character-level models perform worse on compounds, which are a local phenomenon. Ataman et al. (2019) observed similar results on compounds in their hybrid character-word-level method. We suspect this might be caused by poor memorization of some compounds in the character models.

In Czech, models with a smaller vocabulary better cover agreement in gender and number in pronouns, probably due to direct access to inflective endings. Unlike German, character-level models capture worse agreement in coordinations, presum-

ably due to there being a longer distance in characters.

Training and inference times are shown in Table 7. Significantly longer sequences also manifest in slower training and inference. Table 7 shows that our character-level models are 5–6× slower than subword models with 32k units. Doubling the number of layers, which had a similar effect on translation quality as the proposed finetuning (Gupta et al., 2019), increases the inference time approximately 2–3× in our setup.

6 Conclusions

We presented a simple approach for training character-level models by finetuning subword models. Our approach does not require computationally expensive architecture changes and does not require dramatically increased model depth. Subword-based models can be finetuned to work on the character level without explicit segmentation with somewhat of a drop in translation quality. The models are robust to input noise and better capture some morphological phenomena. This is important for research groups that need to train and deploy character Transformer models without access to very large computational resources.

A Effect of BPE Dropout

We discussed the effect of BPE dropout in Section 3. Table 8 shows the comparison of the main quantitative results with and without BPE dropout.

B Notes on Reproducibility

The training times were measured on machines with GeForce GTX 1080 Ti GPUs and with Intel Xeon E5–2630v4 CPUs (2.20GHz). The parent models were trained on 4 GPUs simultaneously, the finetuning experiments were done on a single GPU.

We used model hyperparameters used by previous work and did not experiment with the hyperparameters of the architecture and training of the initial models. The only hyperparameter that we tuned was the learning rate of the finetuning. We set the value to 10^{-5} after several experiments with English-to-German translation with values between 10^{-7} and 10^{-3} based on the BLEU score on validation data.

We downloaded the training data from the official WMT web (`http://www.statmt.org/wmt18/`).The test and validation sets were downloaded using SacreBleu (`https://github.com/mjpost/sacreBLEU`). The BPE segmentation is done using FastBPE (`https://github.com/glample/fastBPE`). For BPE Dropout, we used YouTokenToMe (`https://github.com/VKCOM/YouTokenToMe`). A script that downloads and pre-processes the data is attached to the source code. It also includes generating the noisy synthetic data (using `https://github.com/ybisk/charNMT-noise`) and preparing data and tools required by MorphEval (`https://github.com/franckbrl/morpheval`).

The models were trained and evaluated with Marian v1.7.0 (`https://github.com/marian-nmt/marian/releases/tag/1.7.0`).

Validation BLEU scores are tabulated in Table 9.

Abstract

Multilingual transformer models like mBERT and XLM-RoBERTa have obtained great improvements for many NLP tasks on a variety of languages. However, recent works also showed that results from high-resource languages could not be easily transferred to realistic, low-resource scenarios. In this work, we study trends in performance for different amounts of available resources for the three African languages Hausa, isiXhosa and Yorùbá on both NER and topic classification. We show that in combination with transfer learning or distant supervision, these models can achieve with as little as 10 or 100 labeled sentences the same performance as baselines with much more supervised training data. However, we also find settings where this does not hold. Our discussions and additional experiments on assumptions such as time and hardware restrictions highlight challenges and opportunities in low-resource learning.

1 Introduction

Deep learning techniques, including contextualized word embeddings based on transformers and pretrained on language modelling, have resulted in considerable improvements for many NLP tasks. However, they often require large amounts of labeled training data, and there is also growing evidence that transferring approaches from high to low-resource settings is not straightforward. In (Loubser and Puttkammer, 2020a), rule-based or linguistically motivated CRFs still outperform RNN-based methods on several tasks for South African languages. For pretraining approaches where labeled data exists in a high-resource language, and the information is transferred to a low-resource language, Hu et al. (2020) find a significant gap between performance on English and the cross-lingually transferred models. In a recent study, Lauscher et al. (2020) find that the transfer for multilingual transformer models is less effective for resource-lean settings and distant languages. A popular technique to obtain labeled data quickly and cheaply is distant and weak supervision. Kann et al. (2020) recently inspected POS classifiers trained on weak supervision. They found that in contrast to scenarios with simulated low-resource settings of high-resource languages, in truly low-resource settings this is still a difficult problem. These findings also highlight the importance of aiming for realistic experiments when studying low-resource scenarios.

In this work, we analyse multilingual transformer models, namely mBERT (Devlin et al., 2019; Devlin, 2019) and XLM-RoBERTa (Conneau et al., 2019). We evaluate both sequence and token classification tasks in the form of news title topic classification and named entity recognition (NER). A variety of approaches have been proposed to improve performance in low-resource settings. In this work, we study (i) transfer learning from a high-resource language and (ii) distant supervision. We selected these as they are two of the most popular techniques in the recent literature and are rather independent of a specific model architecture. Both need auxiliary data. For transfer learning, this is labeled data in a high-resource language, and for distant supervision, this is expert insight and a mechanism to (semi-)automatically generate labels. We see them, therefore, as orthogonal and depending on the scenario and the data availability, either one or the other approach might be applicable.

Our study is performed on three, linguistically different African languages: Hausa, isiXhosa and Yorùbá. These represent languages with millions of users and active use of digital infrastructure, but with only very limited support for NLP technologies. For this aim, we also collected three new

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2580–2591,

datasets that are made publicly available alongside the code and additional material.[1]

We show both challenges and opportunities when working with multilingual transformer models evaluating trends for different levels of resource scarcity. The paper is structured into the following questions we are interested in:

- How do more complex transformer models compare to established RNNs?
- How can transfer-learning be used effectively?
- Is distant supervision helpful?
- What assumptions do we have to consider when targeting a realistic treatment of low-resource scenarios?

2 Languages and Datasets

In this work, we evaluate on three African languages, namely Hausa, isiXhosa and Yorùbá. Hausa is from the Afro-Asiatic family while isiXhosa and Yorùbá belong to different branches of the large Niger-Congo family. Hausa and Yorùbá are the second and third most spoken languages in Africa, and isiXhosa is recognized as one of the official languages in South Africa and Zimbabwe. Yorùbá has been part of the unlabeled training data for the mBERT multilingual, contextual word embeddings. Texts in Hausa and isiXhosa have been part of the XLM-RoBERTa training.

The three languages have few or no labeled datasets online for popular NLP tasks like named entity recognition (NER) and topic classification. We use the NER dataset by Eiselen (2016) for isiXhosa and the one by Alabi et al. (2020) for Yorùbá. We collected and manually annotated a NER dataset for Hausa and news title topic classification datasets for Hausa and Yorùbá. Table 1 gives a summary of the datasets. More information about the languages, the datasets and their creation process can be found in the Appendix.

3 Experimental Settings

To evaluate different amounts of resource-availability, we use subsets of the training data with increasing sizes from ten to the maximally available number of sentences. All the models are trained on their corresponding language-model pre-training. Except if specified otherwise, the models are not fine-tuned on any other task-specific, labeled data from other languages. We report mean F1-score on the test sets over ten repetitions with standard error on the error bars. Additional experimental details are given in the following sections and the Appendix. The code is made publicly available online as well as a table with the scores for all the runs.

Dataset Name	**Data Source**	**Full Train/ Val/ Test sentences**
Hausa NER*	VOA Hausa	1,014 / 145 / 291
Hausa Topic Class.*	VOA Hausa	2,045 / 290 /582
isiXhosa NER (Eiselen, 2016)	SADiLaR	5,138 / 608 / 537
Yorùbá NER (Alabi et al., 2020)	GlobalVoices	816 / 116 / 236
Yorùbá Topic Class.*	BBC Yoruba	1,340 / 189 / 379

Table 1: Datasets Summary. *Created for this work.

4 Comparing to RNNs

Loubser and Puttkammer (2020a) showed that models with comparatively few parameters, like CRFs, can still outperform more complex, neural RNNs models for several task and low-resource language combinations. This motivates the question whether model complexity is an issue for these low-resource NLP models. We compare to simple GRU based (Cho et al., 2014) models as well as the popular (non-transformer) combination of LSTM-CNN-CRF (Ma and Hovy, 2016) for NER and to the RCNN architecture (Lai et al., 2015) for topic classification. For these models, we use pre-trained, non-contextual word embeddings trained for the specific language. Figures 1a+b show that an increase in model complexity is not an issue in these experiments. For Hausa and Yorùbá and for the low resource settings for isiXhosa, BERT and XLM-RoBERTa actually outperform the other baselines, possibly due to the larger amounts of background knowledge through the language model pre-training. For larger amounts of task-specific training data, the LSTM-CNN-CRF and the transformer models perform similarly. One should note that for isiXhosa, the linguistically motivated CRF (Eiselen, 2016) still outperforms all approaches on the full dataset.

5 Transfer Learning

The mBERT and XLM-RoBERTa models are trained with tasks that can be obtained from unlabeled text, like masked language modelling. Addi-

tionally, the multilingual models can be fine-tuned on task-specific, supervised data but from a different, high-resource language. There is evidence that the multilingual transformer models can learn parallel concepts across languages (Pires et al., 2019; Wu and Dredze, 2019; Hu et al., 2020). This allows to then apply or evaluate the model directly without having been fine-tuned on any labeled data in the target language (zero-shot) or on only a small amount of labeled data in the target language (few-shot).

For NER, we pre-train on the English CoNLL03 NER dataset (Tjong Kim Sang and De Meulder, 2003). For topic classification, the models are pre-trained on the English AG News corpus (Zhang et al., 2015). The texts in the high-resource English and the low-resource Hausa and Yorùbá target datasets share the same domain (news texts). One issue that is visible in these experiments is the discrepancy between classes. While some classes like “Politics” are shared, the topic classification datasets also have language- and location-specific classes like “Nigeria” and “Africa” which are not part of the English fine-tuning dataset. In our experiments, we use the intersection of labels for NER (excluding DATE and MISC for Hausa and Yorùbá) and the union of labels for topic classification.

The results in Figure 1c and in the Appendix confirm the benefits of fine-tuning on high-resource languages already shown in past research. They show, however, also the large gains in performance that can be obtained by training on a minimal number of target instances. While the zero-shot setting in (Hu et al., 2020) is interesting from a methodological perspective, using a small training set for the target language seems much more beneficial for a practical application. In our experiments, we get - with only ten labeled sentences - an improvement of at least 10 points in the F1-score for a shared label set on NER. For topic classification (Figure 1b) the transfer learning is not beneficial, which might be due to the mismatch in the label sets.

6 Distant Supervision

Distant and weak supervision are popular techniques when labeled data is lacking. It allows a domain expert to insert their knowledge without having to label every instance manually. The expert can, e.g. create a set of rules that are then used to label the data automatically (Ratner et al., 2020) or information from an external knowledge source can be used (Rijhwani et al., 2020). This kind of (semi-) automatic supervision tends to contain more errors which can hurt the performance of classifiers (see e.g. (Fang and Cohn, 2016)). To avoid this, it can be combined with label noise handling techniques. This pipeline has been shown to be effective for several NLP tasks (Lange et al., 2019; Paul et al., 2019; Wang et al., 2019; Chen et al., 2019; Mayhew et al., 2019), however, mostly for RNN based approaches. As we have seen in Section 4 that these have a lower baseline performance, we are interested in whether distant supervision is still useful for the better performing transformer models. Several of the past works evaluated their approach only on high-resource languages or simulated low-resource scenarios. We are, therefore, also interested in how the distant supervision performs for the actual resource-lean African languages we study.

To create the distant supervision, native speakers with a background in NLP were asked to write labeling rules. For the NER labels PER, ORG and LOC, we match the tokens against lists of entity names. These were extracted from the corresponding categories from Wikidata. For the DATE label, the insight is used that date expressions are usually preceded by date keywords in Yorùbá, as reported by Adelani et al. (2020). We find similar patterns in Hausa like "*ranar*"(day), "*watan*" (month), and "*shekarar*"(year). For example, *"18th of May, 2019"* in Hausa translates to *"ranar 18 ga watan Mayu, shekarar 2019"*. The annotation rules are based on these keywords and further heuristics. Directly applying this distant supervision on the NER test sets results in an F1-score of 54% and 62% on Hausa and Yorùbá, respectively.

For the topic classification task, the distant supervision rules are based on a dictionary of words relating to each of the classes. To induce the dictionaries, we collected terms related to different classes from web sources. For example, for the "Sport" label, names of sportspeople and sport-related organizations were collected and similarly for the "Africa" label, names of countries, their capitals and major cities and their politicians. To label a news headline, the intersection between each class-dictionary and the text was computed, and a class was selected with a majority voting scheme. We obtain an F1-score of 49% and 55% on the Hausa and Yorùbá test set respectively when applying the distant supervision directly to the topic classification test sets. Additional details on the distant supervision are given in the Appendix.

For label noise handling we use the confusion matrix approach for NER by Hedderich and Klakow (2018), marked as *cm* in the plots. Additionally, we propose to combine it with the smoothing concept by Lv et al. (2020).

The Figures 2a and in the Appendix show that when only a small amount of manually labeled data is available, distant supervision can be a helpful addition. E.g. for the NER task in Yorùbá, combining distant supervision and noise handling with 100 labeled sentences achieves similar performance to using 400 manually labeled sentences. For label noise handling, combining the confusion matrix with the smoothing approach might be beneficial because the estimated confusion matrix is flawed when only small amounts of labeled data are given. When more manually labeled data is available, the noisy annotations lose their benefit and can become harmful to performance. Improved noise-handling techniques might be able to mitigate this.

7 Questioning Assumptions

In this section, we want to discuss certain assumptions taken by us and previous work in low-resource learning to see if these hold and what challenges and opportunities they could bring for future work.

7.1 Development Set

Kann et al. (2019) criticized that research on low-resource often assumes the existence of a development set. Addressing this, we perform hyper-parameter optimization on high-resource English data. For early-stopping (to avoid overfitting), the authors experiment with obtaining an early-stop-epoch from the average of several other languages. To avoid this multi-language set-up and the need to obtain labeled data for multiple languages, we suggest using instead a development set downsized by the same factor as the training data. This approach keeps the ratio between training and development set giving the development set a reasonable size to obtain in a low-resource setting. For the setting with ten labeled sentences for training, the same amount was used for the dev set. The results in Figure 2b and in the Appendix show that this has only a small effect on the training performance.

7.2 Hardware Resources

While the multilingual transformer models show impressive improvements over the RNN baselines, they also require more hardware resources. The LSTM-CNN-CRF model, e.g. has ca. 5M parameters compared to mBERT's over 150M parameters. The computing capabilities for training and deploying such models might not always be given in low-resource scenarios. Through personal conversations with researchers from African countries, we found that this can be an issue. There are approaches to reduce model size while keeping a similar performance quality, e.g. the 25% smaller DistilBERT (Sanh et al., 2019). Figure 2c shows that this performs indeed similar in many cases but that there is a significant drop in performance for NER when only few training sentences are available.

7.3 Annotation Time

In (Hu et al., 2020) and (Kann et al., 2020), it is assumed that no labeled training data is available for the target language. In the previous sections, we showed that even with ten labeled target sentences, reasonable model quality can be achieved. For our annotation efforts, we measured on average 1 minute per annotator per sentence for NER and 6 seconds per sentence for topic classification. We, therefore, think that it is reasonable to assume the availability of small amounts of labeled data. Especially, as we would argue that it is beneficial to have a native speaker or language expert involved when developing a model for a specific language.

For distant supervision, a trade-off arises given these annotation times. While extracting named entities from knowledge bases requires minimal manual effort assuming a set-up system, manual crafting rules took 30 minutes for the DATE label and 2.5 hours for each topic classification dataset. When reporting results for distant supervision, the performance benefits should therefore also be compared against manual annotation in the same time frame.

8 Conclusions

In this work, we evaluated transfer learning and distant supervision on multilingual transformer models, studying realistic low-resource settings for African languages. We show that even with a small amount of labeled data, reasonable performance can be achieved. We hope that our new datasets and our reflections on assumptions in low-resource settings help to foster future research in this area.

Acknowledgments

We would like to thank Toyin Aina and Emmanuel Olawuyi for their support in annotating the Hausa data. We also thank Thomas Niesler for his helpful insights as well as Alexander Blatt and the anonymous reviewers for their feedback. A Languages

In this work, we consider three languages: Hausa, isiXhosa and Yorùbá. These languages are from two language families: Niger-Congo and Afro-Asiatic, according to Ethnologue (Eberhard et al., 2019), where the Niger-Congo family has over 20% of the world languages.

The Hausa language is native to the northern part of Nigeria and the southern part of the Republic of Niger with more than 45 million native speakers (Eberhard et al., 2019). It is the second most spoken language in Africa after Swahili. Hausa is a tonal language, but this is not marked in written text. The language is written in a modified Latin alphabet.

Yorùbá, on the other hand, is native to south-western Nigeria and the Republic of Benin. It has over 35 million native speakers (Eberhard et al., 2019) and is the third most spoken language in Africa. Yorùbá is a tonal language with three tones: low, middle and high. These tones are represented by the grave ("\"), optional macron ("−") and acute ("/") accents respectively. The tones are represented in written texts along with a modified Latin alphabet.

Lastly, we consider isiXhosa, a Bantu language that is native to South Africa and also recognized as one of the official languages in South Africa and Zimbabwe. It is spoken by over 8 million native speakers (Eberhard et al., 2019). isiXhosa is a tonal language, but the tones are not marked in written text. The text is written with the Latin alphabet.

Kann et al. (2020) used as an indicator for a low-resource language the availability of data in the Universal Dependency project (Nivre et al., 2020). The languages we study suit their indicator having less than 10k (Yorùbá) or no data (Hausa, isiXhosa) at the time of writing.

B Datasets

B.1 Existing Datasets

The WikiAnn corpus (Pan et al., 2017) provides NER datasets for 282 languages available on Wikipedia. These are, however, only silver-standard annotations and for Hausa and isiXhosa less than 4k and 1k tokens respectively are provided. The LORELEI project announced the release of NER datasets for several African languages via LDC (Strassel and Tracey, 2016; Tracey et al., 2019) but have not yet done so for Hausa and Yorùbá at the time of writing.

Eiselen and Puttkammer (2014) and Eiselen (2016) created NLP datasets for South African languages. We use the latter's NER dataset for isiXhosa. For the Yorùbá NER dataset (Alabi et al., 2020), we use the authors' split into training, dev and test set of the cased version of their data.[2] For the isiXhosa dataset[3], we use an 80%/10%/10% split following the instructions in (Loubser and Puttkammer, 2020b). The split is based on token-count, splitting only after the end of the sentence (information obtained through personal conversation with the authors). For the fine-tuning of the zero- and few-shot models, the standard CoNLL03 NER (Tjong Kim Sang and De Meulder, 2003) and AG News (Zhang et al., 2015) datasets are used with their existing splits.

B.2 New Datasets

B.2.1 Hausa NER

For the Hausa NER annotation, we collected 250 articles from VOA Hausa[4], 50 articles each from the five pre-defined categories of the news website. The categories are Najeriya (Nigeria), Afirka (Africa), Amurka (USA), Sauran Duniya (the rest of the world) and Kiwon Lafiya (Health). We removed articles with less than 50 tokens which results in 188 news articles (over 37K tokens). We asked two volunteers who are native Hausa speakers to annotate the corpus separately. Each volunteer was supervised by someone with experience in NER annotation. Following the named entity annotation in Yorùbá by Alabi et al. (2020), we annotated PER, ORG, LOC and DATE (dates and times) for Hausa. The annotation was based on the MUC-6 Named Entity Task Definition guide.[5] Comparing the annotations of the volunteers, we observe a conflict for 1302 tokens (out of 4838 tokens) excluding the non-entity words (i.e. words with 'O' labels). One of the annotators was better

[4] https://www.voahausa.com

[5] https://cs.nyu.edu/faculty/grishman/NEtask20.book_1.html

in annotating DATE, while the other was better in annotating ORG especially for multi-word expressions of entities. We resolved all the conflicts after discussion with one of the volunteers. The split of annotated data of the Yoruba and Hausa NER data is 70%/10%/20% for training, validation and test sentences.

B.2.2 Hausa and Yorùbá Text classification

For the topic classification datasets, news titles were collected from VOA Hausa and the BBC Yoruba news website[6]. Two native speakers of the language annotated each dataset. We categorized the Yorùbá news headlines into 7 categories, namely "Nigeria", "Africa", "World", "Entertainment", "Health", "Sport", "Politics". Similarly, we annotated 5 (of the 7) categories for Hausa news headlines, excluding "Sport" and "Entertainment" as there was only a limited number of examples. The "Politics" category in the annotation is only for Nigerian political news headlines. Comparing the two annotators, there was a conflict rate of 7.5% for Hausa and 5.8% for Yorùbá. The total number of news titles after resolving conflicts was 2,917 for Hausa and 1,908 for Yorùbá.

C Word Embeddings

For the RNN models, we make use of word features obtained from Word2Vec embeddings for the Hausa language and FastText embeddings for Yorùbá and isiXhosa languages. We utilize the better quality embeddings recently released by Abdulmumin and Galadanci (2019) and Alabi et al. (2020) for Hausa and Yorùbá respectively instead of the pre-trained embeddings by Facebook that were trained on a smaller and lower quality dataset from Wikipedia. For isiXhosa, we did not find any existing word embeddings, therefore, we trained FastText embeddings from data collected from the I'solezwe[7] news website and the *OPUS*[8] parallel translation website. The corpus size for isiXhosa is 1.4M sentences (around 15M tokens). We trained FastText embeddings for isiXhosa using *Gensim*[9] with the following hyper-parameters: embedding size of 300, context window size of 5, minimum word count of 3, number of negative samples ten and number of iterations 10.

D Distant Supervision

D.1 Distant supervision for Personal names, Organisation and Locations

We make use of lists of entities to annotate PER, ORG and LOC automatically. In this paper, we extract personal names, organizations and locations from Wikidata as entity lists and assign a corresponding named entity label if tokens from an unlabeled text match an entry in an entity list.

For NER, we use manual heuristics to improve matching. For Yorùbá, a minimum token length of 3 was set for extraction of LOC and PER, while the minimum length for ORG was set to 2. This reduces the false positive rate, e.g. preventing matches with function words like "of".

Applying this on the test set, we obtained a precision of 80%, 38% and 28% for LOC, ORG and PER respectively; a recall of 73%, 52% and 14% for LOC, ORG and PER respectively; and an F1-score of 76%, 44% and 19% for LOC, ORG and PER respectively.

For Hausa NER, a minimum token length of 4 was set for extraction of LOC, ORG and PER. Based on these manual heuristics, on the test set, we obtained a precision of 67%, 12% and 47% for LOC, ORG and PER respectively; a recall of 63%, 37% and 56% for LOC, ORG and PER respectively; and an F1-score of 65%, 18% and 51% for LOC, ORG and PER respectively.

D.2 DATE rules for NER

Rules allow us to apply the knowledge of domain experts without the manual effort of labeling each instance. We asked native speakers with knowledge of NLP to write DATE rules for Hausa and Yorùbá. In both languages, date expressions are preceded by date keywords, like "*ranar*" / "*ọjọ́*" (day), "*watan*" / "*oṣù*" (month), and "*shekarar*" / "*ọdụ́*n" (year) in Hausa/Yorùbá. For example, *"18th of December, 2019"* in Hausa / Yorùbá translates to " *ranar 18 ga watan Disamba, shekarar 2019*" / "*ọjọ́ 18 oṣù Ọpẹ̀, ọdún 2019*". The annotation rules are based on these three criteria: (1) A token is a date keyword or follows a date keyword in a sequence. (2) A token is a digit, and (3) other heuristics to capture relative dates and date periods connected by conjunctions e.g between July 2019 and March 2020. Applying these rules result in a precision of 49.30%/51.35%, a recall of 60.61%/79.17% and an F1-score of 54.42%/62.30% on Hausa /Yorùbá test set respectively.

[9] `https://radimrehurek.com/gensim/`

D.3 Rules for Topic classification

For the Yorùbá topic classification task, we collected terms that correspond to the different classes into sets. For example, the set for the class Nigeria contains names of agencies and organizations, states and cities in Nigeria. The set for the World class is made up of the name of countries of the world, their capitals and major cities and world affairs related organizations. Names of sporting clubs and sportspeople across the world were used for the Sports class and list of artists and actresses and entertainment-related terms for the Entertainment class. Given a news headline to be annotated, we get the union set of 1- and 2-grams and obtain the intersection with the class dictionaries we have. The class with the highest number of intersecting elements is selected. In the case of a tie, we randomly pick a class out the classes with a tie. Just as we did for Yorùbá, we collected the class-related tokens for the Hausa text classification. We, however, split the classification into two steps, checking some important tokens and using the same approach as we used for Yorùbá. If a headline contains the word *cutar* (disease) , it is classified as Health, if it contains tokens such as *inec*, *zaben*, *pdp*,*apc* (which are all politics related tokens) it is classified as Politics. Furthermore, sentences with any of the following tokens *buhari*, *legas*, *kano*, *kaduna*, *sokoto* are classified as Nigeria while sentences with *afurka*, *kamaru* and *nijar* are classified as Africa. If none of the tokens highlighted above is found, we apply the same approach as we did for the Yorùbá setting, which is majority voting of the intersection set of the news headline with a keyword set for each class. Applying these rules results in a precision of $59.54\%/60.05\%$, a recall of $46.04\%/53.66\%$ and an F1-score of $48.52\%/54.93\%$ on the Hausa /Yorùbá test set respectively.

E Experimental Settings

E.1 General

All experiments were repeated ten times with varying random seeds but with the same data (subsets). We report mean F1 test score and standard error ($\sigma/\sqrt{10}$). For NER, the score was computed following the standard CoNLL approach (Tjong Kim Sang and De Meulder, 2003) using the *seqeval* implementation.[10] Labels are in the BIO2-scheme. For evaluating topic classification, the implementation by *scikit-learn* was used.[11] All models are trained for 50 epochs, and the model that performed best on the (possibly size-reduced) development set is used for evaluation.

E.2 BERT and XLM-RoBERTa

As multilingual transformer models, mBert and XLM-RoBERTa are used, both in the implementation by Wolf et al. (2019). The specific model IDs are *bert-base-multilingual-cased* and *xlm-roberta-base*.[12] For the DistilBERT experiment it is *distilbert-base-multilingual-cased*. As is standard, the last layer (language model head) is replaced with a classification layer (either for sequence or token classification). Models were trained with the Adam optimizer and a learning rate of $5e^{-5}$. Gradient clipping of value 1 is applied. The batch size is 32 for NER and 128 for topic classification. For distant supervision and XLM-RoBERTa on the Hausa topic classification data with 100 or more labeled sentences, we observed convergence issues where the trained model would just predict the majority classes. We, therefore, excluded for this task runs where *on the development set* the class-specific F1 score was 0.0 for two or more classes. The experiments were then repeated with a different seed.

E.3 Other Architectures

For the GRU and LSTM-CNN-CRF model, we use the implementation by Chernodub et al. (2019) with modifications to support FastText embeddings and the *seqeval* evaluation library. Both model architectures are bidirectional. Dropout of 0.5 is applied. The batch-size is 10 and SGD with a learning rate of 0.01, and a decay of 0.05 and momentum of 0.9 is used. Gradients are clipped with a value of 5. The RNN dimension is 300. For the CNN, the character embedding dimension is 25 with 30 filters and a window-size of 3.

For the topic classification task, we experiment with the RCNN model proposed by (Lai et al., 2015). The hidden size in the Bi-LSTM is 100 for each direction. The linear layer after the Bi-LSTM reduces the dimension to 64. The model is trained for 50 epochs.

E.4 Transfer Learning

For transfer learning, the model is first fine-tuned on labeled data from a high-resource language. Following (Hu et al., 2020), we use the English CoNLL03 NER dataset (Tjong Kim Sang and De Meulder, 2003) for NER. It consists of ca. 8k training sentences. The model is trained for 50 epochs and the weights of the best epoch according to the development set are taken. The training parameters are the same as before. On the English CoNLL03 test set, the model achieves a performance of 0.90 F1-score. As the Hausa and Yorùbá datasets have slightly different label sets, we only use their intersection, resulting in the labels PER, LOC and ORG and excluding MISC from CoNLL03 and the DATE label from Hausa/Yorùbá. For isiXhosa, the label sets are identical (i.e. also including MISC). After fine-tuning the model on the high-resource data, the model is directly evaluated on the African test set (for zero-shot) or fine-tuned and then evaluated on the African data (for few-shot).

For topic classification, the AG News corpus is used (Zhang et al., 2015). It consists of 120k training sentences. The model is trained for 20 epochs and the weights of the best epoch according to the test set are used. On this set, an F1-score of 0.93 is achieved. The training procedure is the same as above. For the labels, we use the union of the labels of the AG News corpus (Sports, World, Business and Sci/Tech) and the African datasets.

E.5 Label Noise Handling

We use a confusion matrix which is a common approach for handling noisy labels (see, e.g. (Fang and Cohn, 2016; Luo et al., 2017; Lange et al., 2019; Wang et al., 2019)). The confusion matrix models the relationship between the true, clean label of an instance and its corresponding noisy label. When training on noisy instances, the confusion matrix is added to the output of the main model (that usually predicts clean labels) changing the output label distribution from the clean to the noisy one. This allows to then train on noisily labeled instances without a detrimental loss obtained by predicting the true, clean label but having noisy, incorrect labels as targets.

We use the specific approach by Hedderich and Klakow (2018) that was developed to work with small amounts of manually labeled, clean data and a large amount of automatically annotated, noisy labels obtained through distant supervision. To get the confusion matrix of the noise, the distant supervision is applied on the small set of clean training instances. From the resulting pairs of clean and noisy labels, the confusion matrix can be estimated.

In a setting where only a few instances are available, the estimated confusion matrix might not be close to the actual change in the noise distribution. We, therefore, combine it with the smoothing approach by Lv et al. (2020). Each entry of the probabilistic confusion matrix is raised to the power of β and then row-wise normalized.

As studied by Hedderich and Klakow (2018), we do not use the full amount of available, distantly supervised instances in each epoch. Instead, in each epoch, only a randomly selected subset of the size of the clean, manually labeled training data is used to lessen the negative effects of the noisy labels additionally. For smoothing, $\beta = 0.8$ is used as this performed best for Lv et al. (2020).

Translation Quality Estimation by Jointly Learning to Score and Rank

Jingyi Zhang[1] **and Josef van Genabith**[1,2]

Abstract

The translation quality estimation (QE) task, particularly the *QE as a Metric* task, aims to evaluate the general quality of a translation based on the translation and the source sentence without using reference translations. Supervised learning of this QE task requires human evaluation of translation quality as training data. Human evaluation of translation quality can be performed in different ways, including assigning an absolute score to a translation or ranking different translations. In order to make use of different types of human evaluation data for supervised learning, we present a multi-task learning QE model that jointly learns two tasks: score a translation and rank two translations. Our QE model exploits cross-lingual sentence embeddings from pretrained multilingual language models. We obtain new state-of-the-art results on the WMT 2019 *QE as a Metric* task and outperform sentBLEU on the WMT 2019 Metrics task.

1 Introduction

The translation quality estimation (QE) task (Fonseca et al., 2019) aims to evaluate the quality of a translation based on the translation and the source sentence without using reference translations. The QE task includes *word-level QE*, *sentence-level QE*, *document-level QE* and *QE as a Metric* tasks. The *QE as a Metric* task requires QE models to score a translation on the sentence level similar to the *sentence-level QE* task, but these two tasks are different as the goal of the *sentence-level QE* task (Martins et al., 2017) is to predict the percentage of edits needed to fix the translation for post-editing purposes while the goal of the *QE as a Metric* task is to estimate the general quality of the translation like machine translation (MT) evaluation metrics, such as BLEU (Papineni et al., 2002) and Meteor (Denkowski and Lavie, 2014), except without using reference translations.

Supervised learning of the *QE as a Metric* task requires human evaluation of translation quality as training data. Human evaluation of translation quality is generally very costly and can be performed in different ways, such as Direct Assessment (DA: requiring human assessors to assign an absolute score to a translation) (Barrault et al., 2019; Graham et al., 2013, 2014, 2017) or Relative Ranking (RR: requiring human assessors to rank different translations) (Bojar et al., 2015). Since the *QE as a Metric* task requires QE models to assign an absolute score to a translation, DA human evaluation data can be straightforwardly used as training data for the *QE as a Metric* task. In order to also make use of the RR human evaluation data, we propose a multi-task learning QE model that jointly learns two tasks, score a translation and rank two translations. Multi-task learning of these two closely related tasks enables us to use both DA and RR human evaluation data for training the QE model and improve performance compared to learning these two tasks separately. Our model performs translation quality estimation based on cross-lingual sentence embeddings from pretrained multilingual language models (Devlin et al., 2019; Conneau et al., 2019) and does not need reference translations. We obtain new state-of-the-art results on the WMT 2019 *QE as a Metric* task and outperform sentBLEU on the WMT 2019 Metrics task (Ma et al., 2019).

A number of previous works also used sentence embeddings for evaluating translation quality (Shimanaka et al., 2018; Guzmán et al., 2015; Gupta et al., 2015). However, Shimanaka et al. (2018); Gupta et al. (2015)'s models only learn to score a translation and Guzmán et al. (2015)'s model only learns to rank two translations while our model jointly learns to score a translation and rank two translations in order to make use of different types of human evaluation data for model training. In

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2592–2598,
November 16–20, 2020.

addition, Shimanaka et al. (2018); Guzmán et al. (2015); Gupta et al. (2015)'s models use the reference translation for evaluating translation quality while our QE model does not require reference translations. There are existing QE models (Lo, 2019; Yankovskaya et al., 2019) that do not need the reference translation and perform translation quality estimation based on cross-lingual word/sentence embeddings, but these QE models give relatively poor and unstable results for different language pairs (Ma et al., 2019) while our QE model achieves more robust and better results. In addition, Lo (2019); Yankovskaya et al. (2019)'s QE models only score a translation while our QE model jointly learns to score a translation and rank two translations via multi-task learning.

2 Our Approach

We propose a multi-task learning QE model that jointly learns two tasks: score a translation and rank two translations. Our QE model is based on cross-lingual sentence embeddings from multilingual BERT (M-BERT) (Devlin et al., 2019; Reimers and Gurevych, 2019). To compute the sentence embedding for a given sentence, we feed this sentence into M-BERT and then perform MEAN pooling over the output of M-BERT to obtain fixed-size sentence embedding. We fine-tune M-BERT for the QE tasks.

The scoring task To score a translation t given the source sentence s, we use the cosine similarity between the source sentence embedding $\vec{s}$ and the target sentence embedding $\vec{t}$ as the score of the translation.[1] Equation 1 gives the loss function for the scoring task, where Y_{human} ($0 \leq Y_{human} \leq 1$) is the normalized DA score of the translation assigned by human assessors.

$$L_{score} = \left(cos\_sim\left(\vec{s}, \vec{t}\right) - Y_{human}\right)^2 \tag{1}$$

The ranking task To rank two translations t_1 and t_2 given the source sentence s, we compute Euclidean distances between source and target sentence embeddings $Euc\_dis\left(\vec{s}, \vec{t_1}\right)$ and $Euc\_dis\left(\vec{s}, \vec{t_2}\right)$. The translation that has a smaller Euclidean distance with the source is predicted to be the better translation.[2] Equation 2 gives the loss function for the ranking task, where t_b is the better translation and t_w is the worse translation according to the human ranking. By minimizing L_{rank}, we want $Euc\_dis\left(\vec{s}, \vec{t_b}\right)$ to be at least ε less than $Euc\_dis\left(\vec{s}, \vec{t_w}\right)$. We tuned ε on the development set and finally set $\varepsilon = 1$ in our experiments.[3]

$$L_{rank} = ReLU\left(Euc\_dis\left(\vec{s}, \vec{t_b}\right) - Euc\_dis\left(\vec{s}, \vec{t_w}\right) + \varepsilon\right) \tag{2}$$

Multi-task learning We train our QE model to jointly learn the scoring task and the ranking task via multi-task learning. Each training step includes two training batches: one training batch for the scoring task and one training batch for the ranking task. Direct Assessment (DA) human evaluation data which requires human assessors to assign an absolute score to a translation is used as training data for the scoring task; Relative Ranking (RR) human evaluation data which requires human assessors to rank different translations is used as training data for the ranking task.

The main advantage of multi-task learning for these two closely related tasks is that we can use both DA and RR human evaluation data for training the QE model and improve performance compared to learning these two tasks separately. We test our method on the WMT 2019 *QE as a Metric* task which requires QE models to assign an absolute score to a translation. We show that, on the *QE as a Metric* task, our multi-task learning method can achieve significantly better results compared to only training the QE model to learn the scoring task with DA human evaluation data.

3 Experiments

3.1 Settings

We evaluated the performance of our QE model on the WMT 2019 *QE as a Metric* task[4]. For model training, we used human evaluation data of WMT NEWS translation tasks. Since 2016, WMT performed human evaluation for submissions of NEWS translation tasks via Direct Assessment

---

[1] Instead of using cosine similarity as the translation score, we also tried to use a 1-layer feed forward network (FFN) to compute the translation score and use $\left[\vec{s}, \vec{t}\right]$ (concatenation of the source and target sentence embeddings) as the input of the FFN. Compared to cosine similarity, the FFN achieved slightly worse results on the test sets.

[2] Note that we can also use cosine similarity instead of Euclidean distance to rank the two translations in the ranking task. However, we find that using Euclidean distance for the ranking task achieved better QE results in our experiments.

[3] For tuning ε, we tried $\varepsilon = 0.2, 0.5, 1, 2, 3$ and found $\varepsilon = 1$ achieved the highest Pearson correlation on the development set.

		Number
Direct Assessment	WMT 2016	141,905
	WMT 2018	228,409
Relative Ranking	WMT 2014	254,000
	WMT 2015	258,749

Table 3: Numbers of training examples.

(DA) (Barrault et al., 2019; Graham et al., 2013, 2014, 2017). Direct Assessment requires human assessors to assign an absolute score (between 0 and 100) to a translation based on general translation quality. We normalize DA scores to $[0, 1]$ for training our model for the scoring task. Before 2016, WMT performed human evaluation for NEWS translation tasks via Relative Ranking (Bojar et al., 2015). Relative Ranking requires human assessors to rank different translations based on general translation quality. The rank results of any two translations that are not tied can be used to train our model for the ranking task. Table 3 gives numbers of training examples for our model.

We trained our model via multi-task learning.[5] Each training step includes one training batch from DA data and one training batch from RR data. Each training batch contains 8 training examples. We set the learning rate to 2e-7 and the number of training epochs to 20. The DA data (4,787 human scores) of WMT 2017 NEWS task was used as the development set. The development set does not include any RR data because the final goal of our model is to assign an absolute score to each translation as required by the *QE as a Metric* task. We evaluated our model on the development set after every 1000 training batches and saved the checkpoint that achieved the highest Pearson correlation on the development set.

Table 4: Segment-level metric results for language pairs not involving English in newstest2019: Kendalls Tau formulation of segment-level metric scores with DA scores. **Bold**: best results for the *QE as a Metric* task.

As described in the previous section, our model

---

[5] Code for reproducing our results can be found here https://github.com/jingyiz/sentence-transformers

is based on cross-lingual sentence embeddings from M-BERT (Devlin et al., 2019). Other than M-BERT, we also tested another pretrained multilingual language model XLM-RoBERTa (Conneau et al., 2019) which achieves better results than M-BERT on various cross-lingual tasks. Finally, we trained six QE models for comparison,

1. QE_M-BERT_NO-TRAIN (M_NO)
2. QE_M-BERT_DA-ONLY (M_DA)
3. QE_M-BERT_MULTI-TASK (M_MU)
4. QE_XLM-RoBERTa_NO-TRAIN (X_NO)
5. QE_XLM-RoBERTa_DA-ONLY (X_DA)
6. QE_XLM-RoBERTa_MULTI-TASK (X_MU)

where models 1, 2 and 3 use M-BERT for sentence embedding; models 4, 5 and 6 use XLM-RoBERTa for sentence embedding; NO-TRAIN means we do not fine-tune M-BERT (XLM-RoBERTa) for the QE tasks and simply use the pretrained model for sentence embedding; DA-ONLY means we only train the QE model to learn the scoring task with DA data; MULTI-TASK means we train the QE model with both DA and RR data to jointly learn the scoring task and the ranking task via multi-task learning.

3.2 Segment-Level Results

Tables 1, 2 and 4 give results of our models and the winning systems of the WMT 2019 *QE as a Metric* task (segment-level). We also show results of sentBLEU and the winning systems of the WMT 2019 Metrics task. Compared to the *QE as a Metric* task, the Metrics task allows the usage of the reference translation for translation quality estimation.

In Tables 1, 2 and 4, M_NO and X_NO had bad results, which shows that pretrained multilingual language models without fine-tuning do not perform well on the QE task; X_MU (M_MU) generally outperformed X_DA (M_DA), which shows that training the QE model with both DA and RR data to jointly learn the scoring and ranking tasks via multi-task learning can achieve better quality estimation results than only training the QE model to learn the scoring task with the DA data. Results also show that XLM-RoBERTa outperformed M-BERT for the QE task. Our best model X_MU[6] achieved new state-of-the-art results for all language pairs on WMT 2019 *QE as a Metric* task and outperformed sentBLEU for 14 out of 18 language pairs on WMT 2019 Metrics task. Particularly, among all the languages in the test sets, Gujarati (gu) and Lithuanian (lt) do not occur in the training data of the QE task. Nevertheless, our model still got good results (outperforming sentBLEU) for gu-en, lt-en, en-gu and en-lt tasks. In contrast, UNI (Ma et al., 2019), UNI+ (Ma et al., 2019), YiSi-2 (Lo, 2019) and YiSi-2_srl (Lo, 2019) give significantly worse and unstable results for different language pairs.

	MAX	CLS	MEAN
M_MU	0.641	0.646	0.648
X_MU	0.647	0.667	0.694

Table 5: Results (segment-level Pearson correlation) on the development set by using different pooling strategies for sentence embedding.

	cos_sim	Euc_dis
M_DA	0.633	
X_DA	0.651	
M_MU	0.647	0.648
X_MU	0.690	0.694

Table 6: Results (segment-level Pearson correlation) on the development set by using different loss functions for the ranking task.

Pooling Strategy Other than performing MEAN pooling to obtain sentence embeddings, we also tested MAX pooling or using the CLS token representation as the sentence embedding (Devlin et al., 2019). Results in Table 5 show that MEAN pooling achieved the best results for the QE task.

Cosine Similarity for the Ranking Task We also tried to use cosine similarity instead of Euclidean distance for ranking the two translations in the ranking task. That is we used Equation 3 instead of Equation 2 as the loss function for the ranking task. ω was tuned to be 0.1.[7] Results are shown in Table 6. Our multi-task learning QE model X_MU (M_MU) achieved better results when using Euc_dis for the ranking task compared to using cos_sim for the ranking task; X_MU (M_MU) always outperformed X_DA (M_DA) no matter Euc_dis or cos_sim was used for the ranking task.

$$L_{rank} = ReLU\left(cos\_sim\left(\vec{s}, \vec{t_w}\right) - cos\_sim\left(\vec{s}, \vec{t_b}\right) + \omega\right) \tag{3}$$

3.3 System-Level Results

Tables 7, 8 and 9 give results of our best model (X_MU) and the winning systems of the WMT

---

[6] The training process of X_MU takes 3 days with 1 GPU.

[7] For tuning ω, we tried $\omega = 0.02, 0.05, 0.1, 0.2, 0.3$ and found $\omega = 0.1$ achieved the highest Pearson correlation on the development set.

Table 9: Pearson correlation of system-level metrics for language pairs not involving English with DA human assessment in newstest2019. Best results for the *QE as a Metric* task are highlighted in bold.

2019 *QE as a Metric* task (system-level). We also show results of BLEU and the winning systems of the WMT 2019 Metrics task. For system-level evaluation, metrics which can use the reference translations for quality estimation, such as BLEU, generally achieved consistently high correlation with human evaluation for all language pairs. In contrast, QE models (including our QE model and submitted systems for the *QE as a Metric* task) are not allowed to use the reference translations for quality estimation and tend to generate more unstable results: high correlation with human evaluation for some language pairs but very low or even negative Pearson correlation with human evaluation for some other language pairs. For example, our QE model beat BLEU for zh-en, en-de and en-kk directions but got negative Pearson correlation with human evaluation for gu-en, ru-en, en-ru and fr-de directions. Among all QE models which do not use the reference translations, our model achieved the highest Pearson correlation with human evaluation for 13 out of 18 language pairs. Compared to Tables 1, 2 and 4, our model tends to produce more unstable results for system-level evaluation than segment-level evaluation, likely because the segment-level correlation is computed using about 2000 segments for a language pair while the system-level correlation is computed using only about 10 systems for a language pair, therefore the segment-level correlation is more stable.

4 Conclusion

This paper presents a multi-task leaning QE model that jointly learns two tasks, score a translation and rank two translations. The scoring and ranking results performed by human assessors can be used as training data for learning the scoring and ranking tasks respectively. Multi-task learning of these two closely related tasks enables us to make use of both types of human evaluation data for model training and improve performance compared to learning these two tasks separately. Our model obtains new state-of-the-art results on the WMT 2019 *QE as a Metric* task and outperforms sentBLEU on the WMT 2019 Metrics task.

Abstract

The cascade approach to Speech Translation (ST) is based on a pipeline that concatenates an Automatic Speech Recognition (ASR) system followed by a Machine Translation (MT) system. These systems are usually connected by a segmenter that splits the ASR output into, hopefully, semantically self-contained chunks to be fed into the MT system. This is specially challenging in the case of streaming ST, where latency requirements must also be taken into account. This work proposes novel segmentation models for streaming ST that incorporate not only textual, but also acoustic information to decide when the ASR output is split into a chunk. An extensive and thorough experimental setup is carried out on the Europarl-ST dataset to prove the contribution of acoustic information to the performance of the segmentation model in terms of BLEU score in a streaming ST scenario. Finally, comparative results with previous work also show the superiority of the segmentation models proposed in this work.

1 Introduction

ST is a field that is very closely aligned with ASR and MT, as it is their natural evolution to combine the advances in both areas. Thus, the goal is to obtain the translation of an utterance that has been spoken in a different language, without necessarily requiring the intermediate transcription. At the same time, it is desirable to have high quality translations without compromising the speed of the system. Although research into ST started in the nineties (Waibel et al., 1991), the field did not really take off until significant breakthroughs were achieved in ASR (Chan et al., 2016; Irie et al., 2019; Park et al., 2019; Jorge et al., 2020) and MT (Bahdanau et al., 2015; Sennrich et al., 2016b,a; Vaswani et al., 2017), mainly due to the introduction of deep neural networks (NN). Thanks to this, the field has recently attracted significant amounts of attention from both the research and industry communities, as the field is now mature enough that it has tangible and well-performing applications (Ma et al., 2019; Jia et al., 2019).

Currently, there are two main approaches to ST: cascade and end-to-end models. The goal of the end-to-end approach is to train a single system that is able to carry out the the entire translation process (Weiss et al., 2017; Berard et al., 2018; Gangi et al., 2019). This has only recently been possible thanks to advances in neural modeling. Due to a lack of ST data, different techniques such as pre-training and data augmentation (Bahar et al., 2019; Pino et al., 2019) have been used in order to alleviate this lack of data. It is important to remark that the currently proposed end-to-end models work in an offline manner and must process the entire input sequence. Therefore they cannot be used for a streaming scenario.

In the cascade approach, an ASR system transcribes the input speech signal, and this is fed to a downstream MT system that carries out the translation. The provided input to the MT step can be the 1-best hypothesis, but also n-best lists (Ng et al., 2016) or even lattices (Matusov and Ney, 2011; Sperber et al., 2019). Additional techniques can also be used to improve the performance of the pipeline by better adapting the MT system to the expected input, such as training with transcribed text (Peitz et al., 2012) or chunking (Sperber et al., 2017). The cascade approach can be used to take advantage of independent developments in ASR and MT, and it is significantly easier to train due to greater data availability. Thus, it is very relevant to study improvements for the ST cascade pipeline.

This work focuses on the effects of segmentation in streaming ST, as cascade systems still outperform end-to-end systems in standard setups (Niehues et al., 2019; Pino et al., 2019). Fol-

lowing a cascade approach, a streaming ST setup can be achieved with individual streaming ASR and MT components. Advances in neural streaming ASR (Zeyer et al., 2016; Jorge et al., 2019, 2020) allow the training of streaming models whose performance is very similar to offline ones. Recent advances in simultaneous MT show promise (Arivazhagan et al., 2019; Ma et al., 2019; Zheng et al., 2019), but current models have additional modelling and training complexity, and are not ready for translation of long streams of input text. For the scenario to be considered (translation of parliamentary speeches, with an average duration of 100s), it is required for the ST systems to have a minimum throughput, but simultaneous translation is not required, so the translation of chunks[1] is still acceptable. In this case we prioritize quality over simultaneous translation, with a streaming ASR system followed by a standard offline MT system. This way, the resulting ST cascade system can provide transcribed words in real-time, that are eventually split into chunks to be translated by the offline MT system.

Following this approach, it is necessary to incorporate a segmentation component in the middle in order to split the output of the ASR system into (hopefully semantically self-contained) chunks that can be successfully processed by the MT model, while maintaining a balance between latency and quality. In (Cho et al., 2012, 2015, 2017), the authors approach this problem by training a monolingual MT system that predicts punctuation marks, and then the ASR output is segmented into chunks based on this punctuation. Another approach is to segment the ASR output by using a language model (LM) that estimates the probability of a new chunk to start (Stolcke and Shriberg, 1996; Wang et al., 2016, 2019). Binary classifiers with Part of Speech and reordering features have also been proposed (Oda et al., 2014; Siahbani et al., 2018). It is also possible to segment the ASR output using handcrafted heuristics such as those based on a fixed number of words per chunk (Cettolo and Federico, 2006) or acoustic information (Fügen et al., 2007). These heuristic approaches present the disadvantage of being very domain and speaker specific. Alternatively, segmentation can be integrated into the decoder, so that it is carried out at the target side rather than the source side (Kolss et al., 2008).

This work introduces a statistical framework for the problem of segmentation in ST, which incorporates both textual and acoustic information. Jointly with this, we propose a set of novel models that follow this framework, and a series of extensive experiments are carried out, which show how these new models outperform previously proposed segmentation models. In addition, we study the effect of the preprocessing scheme applied to the input of the MT system, the performance degradation explained by transcription and/or segmentation errors, and the latency due to the components of the ST system.

This paper is organized as follows. The next section describes the statistical framework of the segmenter in the streaming ST scenario. Section 3 follows, detailing how our proposed models are instantiated in this framework. Then, Section 4 describes the Europarl-ST dataset that is used in the experiments and the three main components of our streaming ST system based on a cascade approach: ASR and MT systems, and the segmentation models. Next, Section 5 reports a detailed evaluation in terms of BLEU score on the Europarl-ST dataset and comparative results with previous work, and latency figures. Finally, Section 6 draws the main conclusions of this work and devises future research lines.

2 Statistical framework

We define the streaming ST segmentation as a problem in which a continuous sequence of words provided as the output of an ASR system is segmented into chunks. These chunks will then be translated by a downstream MT system. The goal of the segmentation is to maximize the resulting translation accuracy while keeping latency under the response-time requirements of our streaming scenario.

Formally, the segmentation problem is the task of dividing a sequence of input words x_1^J into non-overlapping chunks. We will represent this with a sequence of split/non-split decisions, y_1^J, with $y_j = 1$ if the associated word x_j is the word that ends a chunk; and $y_j = 0$, otherwise. Optionally, additional input features can be used. In this work, we use word-based acoustic features (a_1^J) aligned with the sequence of words output by the ASR system.

Ideally, we would choose the segmentation $\hat{y}_1^J$

---

[1] A chunk must be understood as a sequence of words.

such that,

$$\begin{aligned}\hat{y}_1^J &= \arg\max_{y_1^J} p(y_1^J \mid x_1^J,\, a_1^J) \\ &= \arg\max_{y_1^J} \prod_{j=1}^{J} p(y_j \mid y_1^{j-1},\, x_1^J,\, a_1^J). \quad (1)\end{aligned}$$

However, in a streaming setup, we need to bound the sequence to w words into the future (hereafter, *future window*) to meet latency requirements

$$\hat{y}_1^J = \arg\max_{y_1^J} \prod_{j=1}^{J} p(y_j \mid y_1^{j-1},\, x_1^{j+w},\, a_1^{j+w}). \quad (2)$$

Indeed, for computational reasons, the sequence is also bounded to h words into the past (hereafter, *history size*)

$$\hat{y}_1^J = \arg\max_{y_1^J} \prod_{j=1}^{J} p(y_j \mid y_{j-h}^{j-1},\, x_{j-h}^{j+w},\, a_{j-h}^{j+w}). \quad (3)$$

Previous works in the literature can be stated as a particular case of the statistical framework defined above under certain assumptions.

LM based segmentation (Stolcke and Shriberg, 1996; Wang et al., 2016, 2019). In this approach, an n-gram LM is used to compute the probability

$$P(y_j) = p(x_{j-n+1}^{j-1}, y_{j-n+1}^{j-1}, x_j, y_j, x_{j+1}^{j+n-1}) \quad (4)$$

where y_j is zero or one depending on the non-split or split decision to be taken, respectively. Split and non-split probabilities are combined into a function to decide whether a new chunk is defined after x_j

$$\hat{y}_j = \arg\max_{y_j} f(P(y_j)). \quad (5)$$

Monolingual MT segmentation (Cho et al., 2012, 2015, 2017). Following this setup, a monolingual MT model translates from the original, (unpunctuated) words x_1^J into a new sequence z_1^J that contains segmentation information (via puntuaction marks). Each z_j can be understood as a pair (x_j, y_j), so the segmentation can be defined as an MT problem

$$\hat{z}_1^J = \arg\max_{z_1^J} p(z_1^J \mid x_1^J), \quad (6)$$

that basically reverts to

$$\hat{y}_1^J = \arg\max_{y_1^J} p(y_1^J \mid x_1^J) \quad (7)$$

since x_1^J is given.

In contrast with previous approaches, which treats segmentation as a by-product of a more general task, we propose a model that directly represents the probability of the split/non-split decision.

3 Direct Segmentation Model

Now that we have introduced the theoretical framework, we are going to describe our proposed segmentation model. This approach has the advantage of allowing a future dependency and consider not only textual, but also acoustic features. This provides the model with additional evidence for taking a better split/non-split decision.

First, the *Text* model computes text state vectors s_j^{j+w} that consider each word in x_{j-h}^{j+w} using an embedding function $e()$ and one or more recurrent layers, represented by the function $f_1()$. In order to incorporate information about previous decisions y_{j-h}^{j-1}, we create a new sequence $\tilde{x}_{j-h}^{j+w}$ by inserting an end-of-chunk token into the text input sequence every time a split decision has been taken. This sequence is bounded in length by h.

$$\tilde{x}_{j-h}^{j+w} = f_c(x_{j-h}^{j+w}, y_{j-h}^{j-1}). \quad (8)$$

Then, the state vectors are defined as follows

$$s_j^{j+w} = f_1(e(\tilde{x}_{j-h}^{j+w}))). \quad (9)$$

Next, the split probability is computed by concatenating the state vectors of the current word and those in the future window, and passing them through a series of feedforward layers $f_2()$

$$p(y_j \mid y_{j-h}^{j-1}, x_{j-h}^{j+w}) = f_2([s_j^{j+w}]). \quad (10)$$

If we include acoustic information, acoustic state vectors are computed using function $f_3()$

$$c_j^{j+w} = f_3(a_{j-h}^{j+w}) \quad (11)$$

and are concatenated with the text state vectors in order to compute the split/non-split probability

$$p(y_j \mid y_{j-h}^{j-1}, x_{j-h}^{j+w}, a_{j-h}^{j+w}) = f_2([s_j^{j+w}; c_j^{j+w}]). \quad (12)$$

In the case of audio information, we assess two variants, depending whether the acoustic sequence is passed through a RNN (*Audio w/ RNN*) or not (*Audio w/o RNN*). These word-based acoustic feature vectors are obtained as follows. The Audio w/o RNN (also referred to as *copy*) option extracts three acoustic features associated to each word: duration of the current word, duration of the previous silence (if any), and duration of the next silence (if any). The three features were selected due to effectiveness (indeed, they improve system performance) as well as being word-based features which therefore can be directly integrated into the proposed model. At training time, these features are obtained by carrying out a forced alignment between the audio and the reference transcription, while at testing time are directly provided by the ASR system. The Audio w/ RNN option adds an independent RNN as f_3, to process the sequence a_{j-h}^{j+w} of three-dimensional acoustic feature vectors just described, and the acoustic state vectors are concatenated at word level with the text state vectors. Whenever acoustic features are used, first the Text model is pre-trained and frozen, and then the feedforward network is updated with the acoustic data.

$$f_3(a_{j-h}^{j+w}) = \begin{cases} RNN(a_{j-h}^{j+w}) & \text{Audio w/ RNN} \\ a_j^{j+w} & \text{Audio w/o RNN} \end{cases} \qquad (13)$$

Figure 1 provides an overview of the proposed model architecture behind the streaming ST segmenter. The part of the model inside the dashed-line boundary represents the Text model (Equations 8,9), while the complete model that additionally considers acoustic information is represented outside the boundary for the Audio w/ RNN and Audio w/o RNN cases (Equations 11, 13). State vectors are concatenated before the feed-forward network (FFN). Equation 10 computes the split probability for the Text-only model, and Equation 12 does the same for the Audio models.

4 Experimental setup

To study the effects of our streaming ST segmenter in terms of BLEU score (Papineni et al., 2002), state-of-the-art ASR and MT systems were trained to perform ST from German (De), Spanish (Es) and French (Fr) into English (En), and vice versa. ASR and MT systems were treated as black boxes in order to focus our efforts on evaluating the proposed streaming ST segmentation models on the recently released and publicly available Europarl-ST corpus (Iranzo-Sánchez et al., 2020). Basic statistics of the six language pairs of the Europarl-ST corpus involved in the evaluation are shown in Table 1.

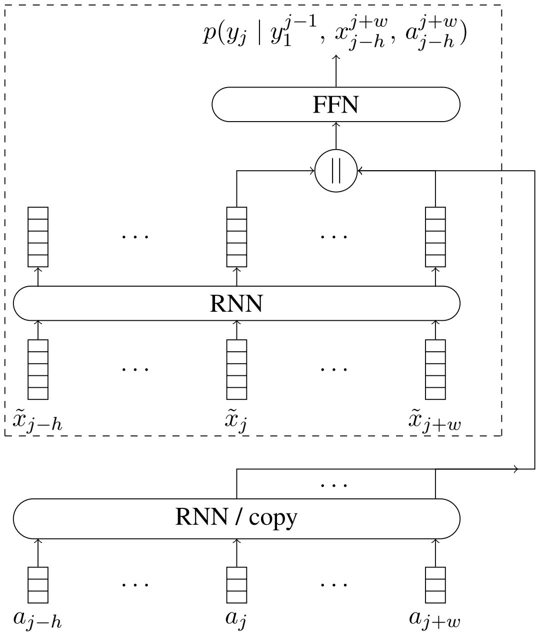

Figure 1: Overview of the model architecture for the streaming ST segmenter. The dashed-line boundary separates the Text model including word embeddings, RNN and state vectors, from the two possible Audio models, RNN and copy, outside the boundary.

4.1 ASR systems

In our cascade ST setting, input speech signal is segmented into speech/non-speech regions using a Gaussian Mixture Model - Hidden Markov Model based voice activity detection (VAD) system (Silvestre-Cerdà et al., 2012), which will be referred to as the baseline segmentation system. Detected speech chunks are delivered to our general-purpose hybrid ASR systems for German (De), English (En), Spanish (Es) and French (Fr).

On the one hand, acoustic models (AM) were generated using the TLK toolkit (del Agua et al., 2014) to train Feed-Forward deep neural Network - Hidden Markov Models (FFN-HMM). These models were used to bootstrap bidirectional long-short term memory (BLSTM) NN models (Zeyer et al., 2017), trained using Tensorflow (Abadi et al., 2015), except for the French ASR system which only features FFNs. These AMs were trained with 0.9K (De), 5.6K (En), 3.9K (Es), and 0.7K (Fr) hours of speech data from multiple sources and domains.

On the other hand, language models (LM) consist of a linear interpolation of several n-gram LMs trained with SRILM (Stolcke, 2002), combined with a recurrent NN (RNN) LM trained using the RNNLM toolkit (Mikolov, 2011) (De, Fr),

Table 1: Basic statistics of the Europarl-ST corpus for the training, development and test partitions for the six language pairs involved in the evaluation.

ST Direction	Training			Development			Test		
	Videos	Kwords		Videos	Kwords		Videos	Kwords	
		Source	Target		Source	Target		Source	Target
En-De	2937	753	730	134	29	28	126	28	27
En-Es	2926	738	800	131	29	31	127	28	31
En-Fr	2918	738	901	132	29	34	124	72	33
De-En	1082	245	289	218	50	58	226	52	59
Es-En	727	203	200	202	53	53	206	50	50
Fr-En	1053	328	395	148	39	36	166	48	45

or an LSTM LM trained with the CUED-RNNLM toolkit (Chen et al., 2016) (Es, En). The vocabulary of LMs was restricted to 200K words. As training monolingual text data, we disposed of 0.8G (De), 300G (En), 0.7G (Es) and 1.8G (Fr) tokens.

Regarding ASR performance, these systems show 19.8 (De), 17.2 (En), 10.9 (Es) and 24.3 (Fr) Word Error Rate% (WER%) figures in their corresponding test sets of the Europarl-ST corpus.

4.2 MT systems

Neural MT systems were trained for each of the translation directions to be studied using the fairseq toolkit (Ott et al., 2019). The initial models are general out-of-domain systems trained with millions (M) of sentences: 21.0M for De↔En, 21.1M for En↔Es and 38.2M for En↔Fr. These models followed the sentence-level Transformer (Vaswani et al., 2017) BASE configuration, and were fine-tuned using the Europarl-ST training data.

Two MT systems were trained for each translation direction depending on the preprocessing scheme applied to the source sentences in the training set. The first scheme uses a conventional MT preprocessing (tokenization, truecasing, etc.), while the second scheme applies a special ST preprocessing to the source side of the training set, by lowercasing, transliterating and removing punctuation marks from all sentences (Matusov et al., 2018). This latter preprocessing scheme guarantees that the same conditions for the MT input are found at training and inference time. Since conventional MT preprocessing was applied to the target side, our hope is that the model is also able to learn to recover casing and punctuation information from the source to the target side. Both preprocessing schemes were evaluated by translating ASR hypotheses provided in chunks given by the baseline VAD segmenter. Results are shown in Table 2. As the segmentation is different from that of the reference, the evaluation is carried out by re-segmenting the translations so that they match the segmentation of the reference (Matusov et al., 2005).

As shown in Table 2, BLEU score improvements of the ST scheme over the MT scheme range from 4.1 (En-De) to 7.5 (En-Es), due to the fact that the ST source processing scheme fixes the mismatch between training and inference time. At the same time, MT systems are able to recover punctuation information that was not available in the ASR output. Thus, the special ST preprocessing scheme was applied in the rest of experiments.

4.3 Segmentation models

Depending on the segmentation model, text and optionally audio belonging to Europarl-ST were used as training data. As a preprocessing step, an end-of-chunk token was inserted in the text training data after each punctuation mark, such as full point, question/exclamation marks, etc., delimiting a chunk. In addition, the ST preprocessing scheme was applied to the annotated reference transcriptions in order to obtain training data that mimics ASR output. In the case of Audio models, as mentioned before, audio and reference transcriptions were forced-aligned using the AMs described in Section 4.1 in order to compute word and silence durations as acoustic features.

Due to the class imbalance present in the segmentation problem, (95% of samples belong to the non-split class), training batches were prepared by weighted random sampling so that on average, one third of the samples belongs to the split class. Otherwise, the model degenerates to always classifying into the non-split class.

The Text model consists of 256-unit word-

Table 2: BLEU scores of the cascade ST on the Europarl-ST test sets depending on the preprocessing scheme.

Source prep. scheme	En-De	En-Es	En-Fr	Es-En	Fr-En	De-En
Conventional MT	22.4	28.0	23.4	26.5	25.4	21.3
Special ST	26.5	35.5	29.3	33.8	29.9	25.8

embedding layer, followed by a forward GRU-based RNN of 256 units. Second, for the Audio w/ RNN model, acoustic features are processed by a forward GRU-based RNN of 8 units. State vectors from Text, and optionally Audio w/ RNN, are fed into a two-layer FFN of 128 units and RELU activation. A dropout of 0.3 is applied after the RNN and FFN layers. Architecture decisions were taken on the basis of the BLEU results obtained on the dev set.

Given the sequential nature of the split/non-split decision process as a streaming ASR output is processed, greedy and beam search decoding algorithms were implemented and compared, but negligible differences were observed between them.

5 Evaluation

In order to perform an evaluation that simulates real conditions, the ASR hypothesis of an entire speech (intervention made by a MEP, with an average duration of 100 seconds) is fed to the segmentation model whose generated chunks are translated by the MT system. The chunks are translated independently from each other. The quality of the MT output, in terms of BLEU score, provides a clear indication of the performance of the streaming ST segmenter and allows us to compare different segmenters.

Figure 2 shows BLEU scores as a function of the length of the future window for the English-German (En-De) and Spanish-English (Es-En) dev sets. On the left-hand side, the three segmenters (Text, Audio w/ RNN and Audio w/o RNN) are compared averaging their BLEU scores over history sizes 5, 10 and 15 for the sake of clarity. On the right-hand side, the effect of history sizes is analysed for the Audio w/o RNN segmenter. In both cases, reference transcriptions were used as input to the segmenter.

As observed, the length of the future window is a very significant parameter to decide whether to split or not, which validates our decision to use a model that considers not only past history, but also a future window. In the case of En-De, adding a future window significantly improves the results, up to 5.8 and 3.5 BLEU points on average, in the Text and Audio models, respectively. Similarly for Es-En, but at a lower magnitude, a gain of up to 3.7 and 3.4 BLEU points on average in the Text and Audio models, respectively, is obtained at larger future windows.

When comparing the segmenters (Figure 2 on the left), the Text segmenter provides a performance that is clearly lower than the Audio-based segmenters for the English-German pair, and similar or lower for the Spanish-English pair. Audio-based segmenters offers nearly the same BLEU scores for English-German and Spanish-English. However, the Audio w/o RNN being a simpler model reaches slightly better BLEU scores using future window of length 4. This window length presents an appropriate trade-off between system latency and accuracy in our streaming scenario. Focusing on the Audio w/o RNN segmenter (Figure 2 on the right), longer history sizes such as 10 and 15 clearly provide better BLEU scores than the shorter history size ($h = 5$). A history size of 10 reaches the best BLEU scores for English-German, and similar performance is achieved between 10 and 15 in Spanish-English for future window of length 4. Based on these results, a history size of 10 and a future window of length 4 were selected for the rest of the experiments.

Table 3 presents BLEU scores of conventional cascade ST systems, in which the ASR output is segmented using the three proposed models and passed down to the MT system, from English into German, Spanish and French, and vice versa. As an upper-bound reference, results on an oracle segmenter are provided, which we have approximated by splitting the text into chunks using punctuation marks. The oracle segmenter shows which are the best BLEU scores that can be achieved with our current ASR and MT systems.

BLEU scores show how, except for Spanish-English, the models with acoustic features are able to outperform those that are only text-based. The largest improvement is in the English-German case, with a 0.8 BLEU-point improvement of Audio models over the Text model. When comparing the

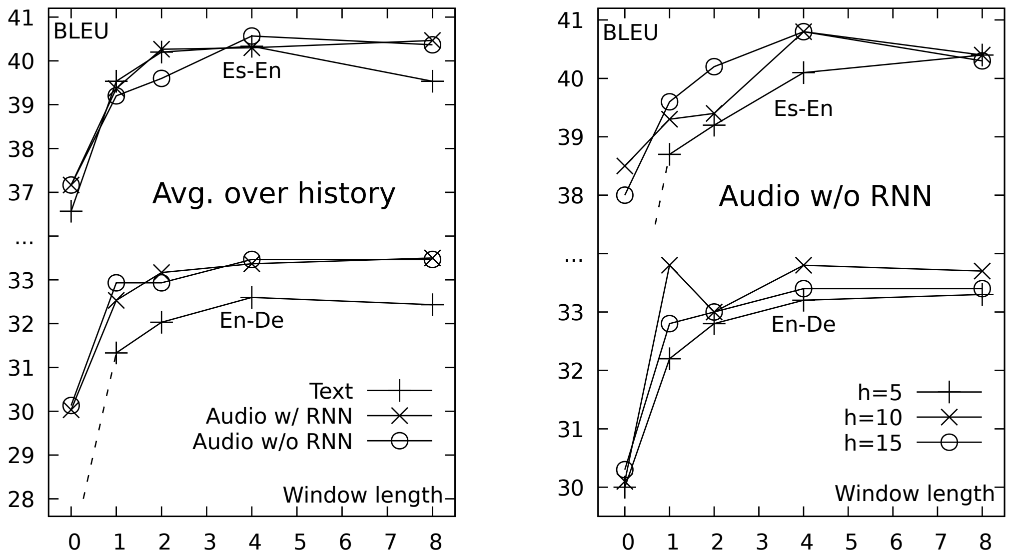

Figure 2: BLEU scores in the English-German (En-De) and Spanish-English (Es-En) dev sets as a function of future window length, averaged over history sizes for the three segmenters on the left-hand side, and on history sizes 5, 10 and 15 for the Audio w/o RNN segmenter on the right-hand side.

Table 3: BLEU scores on the test sets provided by the conventional cascade ST system with ASR output.

Segmenter	En-De	En-Es	En-Fr	Es-En	Fr-En	De-En
Baseline (VAD)	26.5	35.5	29.3	33.8	29.9	25.8
Text	27.6	37.0	29.4	34.7	31.6	28.1
Audio w/o RNN	28.4	37.2	30.0	34.4	32.1	28.3
Audio w/ RNN	28.4	37.3	30.1	33.9	32.1	28.2
Oracle	31.6	41.3	33.6	38.1	35.3	31.3

Audio models, there does not seem to be an improvement of using RNN to process the acoustic features with respect to directly feeding the acoustic features to the FFN. In the case of the Es-En, our analysis shows that, as one one set of hyperparameters was optimized and then shared among all language directions, the resulting segments produced by the Es-En Audio models are around 60% longer than segments in other pairs, which results in reduced performance of the sentence-based MT model.

Table 4 shows BLEU scores when the ASR output is replaced by the reference transcription, so that errors are only due to the segmenter and the MT systems. These results follow the trend of those in Table 3, with improvements of Audio over Text models, and no significant differences between both Audio models. Unlike the previous case, the Es-En Audio w/o RNN system does improve the results of the Text model. Interestingly enough, the oracle segmentation allows us to observe the performance degradation specifically due to the segmentation model, that is, between 2.7 and 5.3 BLEU points. Those oracle results show the best-case scenario that can be achieved with the current MT systems, using the reference transcriptions and the reference segmentation. As the addition of the RNN to process the acoustic features does not improve the performance, the simpler Audio w/o RNN will be used in the remaining experiments.

5.1 Comparison with previous work

In this section, we compare our results with previous work in the literature described in Section 2: the n-gram LM based segmenter included in the SRILM toolkit (Stolcke, 2002), and the monolingual MT segmentation (Cho et al., 2017) whose implementation is also publicly available[2].

Table 5 shows BLEU scores of a cascade ST system for the English-German Europarl-ST test set, comparing the two segmenters mentioned above, the Audio w/o RNN model proposed in this work, and the oracle segmenter that provides the refer-

ence segmentation. Except for the oracle, these segmenters were trained using only the Europarl-ST (EP-ST) training set, or the Europarl-ST training set plus additional training data from the IWSLT 2012 evaluation campaign (Cettolo et al., 2012) , in order to study the performance of the segmenter when additional, out-of-domain text data is available. Results translating both, ASR hypotheses as well as reference transcriptions, are provided.

The results show the same trend across inputs to the MT system, ASR outputs, and reference transcriptions; but differences in BLEU over segmenters are more noticeable when segmenting the references. The LM based segmenter provides the lowest BLEU scores and is not able to take advantage of additional IWSLT training data. The monolingual MT model is at a middle ground between the LM based segmenter and our segmenter, but it is able to take advantage of the additional IWSLT training data. However, our segmenter outperforms all other segmenters in both training data settings. More precisely, when incorporating IWSLT training data, our segmenter outperforms by 0.4 BLEU (ASR output) and 0.9 BLEU (reference transcriptions) the best results of previous work obtained using the monolingual MT model, mainly thanks to the ability to use acoustic information. Additionally, our proposed model shrinks the gap with respect to the oracle segmentation to 3.1 BLEU points working with ASR output, and 2.2 BLEU points when reference transcriptions are provided.

5.2 Latency evaluation

We will now measure the latency of our cascade ST system in a streaming scenario. Following (Li et al., 2020), we define accumulative chunk-level latencies at three points in the system, as the time elapsed between the last word of a chunk being spoken, and: 1) The moment the consolidated hypothesis for that chunk is provided by the ASR system; 2) The moment the segmenter defines that chunk on the ASR consolidated hypothesis; 3) The moment the MT system translates the chunk defined by the segmenter. These three latency figures, in terms of mean and standard deviation, are shown in Table 6. It should be noticed that this ST system is working with ASR consolidated hypotheses in the sense that these hypotheses will not change as the audio stream is further processed.

The difference of 1.1 seconds between the ASR and the segmenter is mostly due to the need to wait for the words in the future window to be consolidated, as the time taken by the segmenter to decide whether to split or not is negligible ($\simeq 0.01$s). Lastly, the MT system has a delay of 0.5 seconds. The total latency is dominated by the ASR system, since the long-range dependencies of the RNN-based LM delay the consolidation of the hypothesis, which is needed by the segmenter and the MT system in order to output the definitive translation.

In practice, however, the ST system could work with non-consolidated hypotheses, since these hypotheses very rarely change with respect to those consolidated. In this case, the latency of the ASR system is significantly reduced to 0.8 ± 0.2 seconds, while the latency experienced by the user for the whole ST system is 1.3 ± 0.4 seconds, as the segmenter does not wait for the words in the future window to be consolidated.

6 Conclusions

This work introduces a statistical framework for the problem of ASR output segmentation in stream-

Table 6: Accumulative chunk-level latencies in seconds (mean ± std. dev.) for the ASR, Segmenter and MT components of the Es-En ST cascade model.

	Latency (seconds)
ASR	4.1 ± 1.6
+ Seg.	5.2 ± 2.2
+ MT	5.7 ± 2.2

ing ST, as well as three possible models to instantiate this framework. In contrast to previous works, these models not only consider text, but also acoustic information. The experimental results reported provide two key insights. Firstly, we have confirmed how the preprocessing of the MT training data has a significant effect for ST, and how a special preprocessing that is closer to the inference conditions is able to obtain significant improvements. Secondly, we have shown the importance of including acoustic information in the segmentation process, as the inclusion of these features improves system performance. The proposed model improves the results of previous works on the Europarl-ST test set when evaluated with two training data setups.

In terms of future work, there are many ways of improving the segmenter system that has been presented here. We plan to look into additional acoustic features as well as possible ways to incorporate ASR information to the segmentation process. The segmenter model itself could also benefit from the incorporation of additional text data as well as pre-training procedures. We also devise two supplementary research lines, the integration of the segmentation into the translation process, so the system learns how to segment and translate at the same time, and moving from an offline MT system to a streaming MT system to improve response time, but without performance degradation.

A Reproducibility

The source code of the Direct Segmentation Model, as well as the ASR hypothesis and acoustic features used in the experiments are attached as supplementary materials. Combined with the instructions provided for training the MT systems, this allows for faithful reproduction of our experiments.

B ASR Systems

The acoustic models were trained using the datasets listed on Table 7, and the architecture of the models is summarized in Table 8.

The language models were trained using the datasets listed on Table 9. The number of English words includes 294G words from Google Books counts. As for the models themselves, they are an interpolation between 4-gram LM and a RNNLM. For German and French, the RNN is trained with the RNNLM toolkit and has a hidden layer of 400 units. For Spanish and English, the RNN is a LSTM trained with the CUED toolkit, with an embbeding layer of 256 units and a hidden layer of 2048 units. The vocabulary was limited to the most common 200K words.

C MT Systems

The models were trained using the datasets listed on Table 10.

The following fairseq command was used to train the systems:

```
fairseq-train $CORPUS_FOLDER \
 -s $SOURCE_LANG_SUFFIX \
 -t $TARGET_LANG_SUFFIX \
 --arch transformer \
 --share-all-embeddings \
 --optimizer adam \
 --adam-betas '(0.9, 0.98)' \
 --clip-norm 0.0 \
 --lr-scheduler inverse_sqrt \
 --warmup-init-lr 1e-07 \
 --warmup-updates 4000 \
 --lr 0.0005 \
 --min-lr 1e-09 \
 --dropout 0.3 \
 --weight-decay 0.0 \
 --criterion \
  label_smoothed_cross_entropy \
 --label-smoothing 0.1 \
 --max-tokens 4000 \
 --update-freq 8 \
 --save-dir $OUTPUT_FOLDER \
 --no-progress-bar \
 --log-interval 100 \
 --save-interval-updates 10000 \
 --keep-interval-updates 20 \
 --ddp-backend=no_c10d \
 --fp16
```

For finetuning, we change the following:

```
--optimizer sgd \
--lr-scheduler fixed \
--lr 5e-5 \
```

D Segmentation Systems

The different hyperparameters values that were tried for the segmentation models are shown on Table 11. In total, no more than 75 combinations were tested in order to conduct the experiments reported on this paper.

Not Low-Resource Anymore: Aligner Ensembling, Batch Filtering, and New Datasets for Bengali-English Machine Translation

Tahmid Hasan[*], **Abhik Bhattacharjee**[*], **Kazi Samin, Masum Hasan, Madhusudan Basak,**

Abstract

Despite being the seventh most widely spoken language in the world, Bengali has received much less attention in machine translation literature due to being low in resources. Most publicly available parallel corpora for Bengali are not large enough; and have rather poor quality, mostly because of incorrect sentence alignments resulting from erroneous sentence segmentation, and also because of a high volume of noise present in them. In this work, we build a customized sentence segmenter for Bengali and propose two novel methods for parallel corpus creation on low-resource setups: aligner ensembling and batch filtering. With the segmenter and the two methods combined, we compile a high-quality Bengali-English parallel corpus comprising of 2.75 million sentence pairs, more than 2 million of which were not available before. Training on neural models, we achieve an improvement of more than 9 BLEU score over previous approaches to Bengali-English machine translation. We also evaluate on a new test set of 1000 pairs made with extensive quality control. We release the segmenter, parallel corpus, and the evaluation set, thus elevating Bengali from its low-resource status. To the best of our knowledge, this is the first ever large scale study on Bengali-English machine translation. We believe our study will pave the way for future research on Bengali-English machine translation as well as other low-resource languages. Our data and code are available at `https://github.com/csebuetnlp/banglanmt`.

1 Introduction

Recent advances in deep learning (Bahdanau et al., 2015; Wu et al., 2016; Vaswani et al., 2017) have aided in the development of neural machine translation (NMT) models to achieve state-of-the-art results in several language pairs. But a large number of high-quality sentence pairs must be fed into these models to train them effectively (Koehn and Knowles, 2017); and in fact lack of such a corpus affects the performance thereof severely. Although there have been efforts to improve machine translation in low-resource contexts, particularly using, for example, comparable corpora (Irvine and Callison-Burch, 2013), small parallel corpora (Gu et al., 2018) or zero-shot multilingual translation (Johnson et al., 2017), such languages are yet to achieve noteworthy results (Koehn et al., 2019) compared to high-resource ones. Unfortunately, Bengali, the seventh (fifth) most widely spoken language in the world by the number of (native[1]) speakers,[2] has still remained a low-resource language. As of now, only a few parallel corpora for Bengali language are publicly available (Tiedemann, 2012) and those too suffer from poor sentence segmentation, resulting in poor alignments. They also contain much noise, which, in turn, hurts translation quality (Khayrallah and Koehn, 2018). No previous work on Bengali-English machine translation addresses any of these issues.

With the above backdrop, in this work, we develop a customized sentence segmenter for Bengali language while keeping uniformity with the English side segmentation. We experimentally show that better sentence segmentation that maintains homogeneity on both sides results in better alignments. We further empirically show that the choice of sentence aligner plays a significant role in the quantity of parallel sentences extracted from document pairs. In particular, we study three aligners and show that combining their results, which we name 'Aligner Ensembling', increases recall. We introduce 'Batch Filtering', a fast and effective method for filtering out incorrect alignments. Using our new segmenter, aligner ensemble, and batch filter, we collect a total of 2.75 million high-quality parallel sentences from a wide variety of domains,

November 16–20, 2020.

more than 2 million of which were not previously available. Training our corpus on NMT models, we outperform previous approaches to Bengali-English machine translation by more than 9 BLEU (Papineni et al., 2002) points and also show competitive performance with automatic translators. We also prepare a new test corpus containing 1000 pairs made with extensive manual and automated quality checks. Furthermore, we perform an ablation study to validate the soundness of our design choices.

We release all our tools, datasets, and models for public use. To the best of our knowledge, this is the first ever large scale study on machine translation for Bengali-English pair. We believe that the insights brought to light through our work may give new life to Bengali-English MT that suffered so far for being low in resources. We also believe that our findings will also help design more efficient methods for other low-resource languages.

2 Sentence Segmentation

Proper sentence segmentation is an essential prerequisite for sentence aligners to produce coherent alignments. However, segmenting a text into sentences is not a trivial task, since the end-of-sentence punctuation marks are ambiguous. For example, in English, the end-of-sentence period, abbreviations, ellipsis, decimal point, etc. use the same symbol (.). Since either side of a document pair can contain Bengali/English/foreign text, we need a sentence segmenter to produce consistent segmentation in a language-independent manner.

Input:

কাজী মুহম্মদ ওয়াজেদের একমাত্র পুত্র ছিলেন এ. কে. ফজলুল হক।

Output:

1. কাজী মুহম্মদ ওয়াজেদের একমাত্র পুত্র ছিলেন এ.
2. কে.
3. ফজলুল হক।

Figure 1: Erroneous sentence segmentation by Polyglot

Available libraries supporting both Bengali and English segmentation, e.g., Polyglot (Al-Rfou' et al., 2013), do not work particularly well for Bengali sentences with abbreviations, which is common in many domains. For instance, Polyglot inaccurately splits the input sentence in Figure 1 into three segments, whereas the English side can successfully detect the non-breaking tokens. Not only does this corrupt the first alignment, but also causes the two broken pieces to be aligned with other sentences, creating a chain of incorrect alignments.

SegTok,[3] a rule-based segmentation library, does an excellent job of segmenting English texts. SegTok uses regular expressions to handle many complex cases, e.g., technical texts, URLs, abbreviations. We extended SegTok's code to have the same functionality for Bengali texts by adding new rules (e.g., quotations, parentheses, bullet points) and abbreviations identified through analyzing both Bengali and English side of our corpus, side-by-side enhancing SegTok's English segmentation correctness as well. Our segmenter can now address the issues like the example mentioned and provide consistent outputs in a language-agnostic manner.

We compared the performance of our segmenter on different aligners against Polyglot. We found that despite the number of aligned pairs decreased by 1.37%, the total number of words on both sides increased by 5.39%, making the resulting parallel corpus richer in content than before. This also bolsters our hypothesis that Polyglot creates unnecessary sentence fragmentation.

3 Aligner Selection and Ensembling

3.1 Aligner Descriptions

Most available resources for building parallel corpora come in the form of parallel documents which are exact or near-exact translations of one another. Sentence aligners are used to extract parallel sentences from them, which are then used as training examples for MT models. Abdul-Rauf et al. (2012) conducted a comparative evaluation of five aligners and showed that the choice of aligner had considerable performance gain by the models trained on the resultant bitexts. They identified three aligners with superior performance: Hunalign (Varga et al., 2005), Gargantua (Braune and Fraser, 2010), and Bleualign (Sennrich and Volk, 2010).

However, their results showed performance only in terms of BLEU score, with no indication of any explicit comparison metric between the aligners (e.g., precision, recall). As such, to make an intrinsic evaluation, we sampled 50 documents from four of our sources (detailed in section 4.2) with their sentence counts on either side ranging from 20 to 150. We aligned sentences from these documents manually (i.e., the gold alignment) and removed duplicates, which resulted in 3,383 unique sentence pairs. We then aligned the documents again with

L(1.02)	90.86	80.34	85.28
HG+L(0.96)	**94.09**	86.86	90.33
GB+L(0.98)	92.31	91.52	91.91
BH+L(0.96)	91.91	**93.60**	**92.75**
HGB+L(0.98)	91.52	93.23	92.37

Table 3: Performance metrics of filtered ensembles

the three aligners using our custom segmenter. Table 1 shows performance metrics of the aligners.

3.2 Aligner Ensembling and Filtering

From the results in Table 1, it might seem that Hunalign should be the most ideal aligner choice. But upon closer inspection, we found that each aligner was able to correctly align some pairs that the other two had failed to do. Since we had started from a low-resource setup, it would be in our best interest if we could combine the data extracted by all aligners. As such, we 'ensembled' the results of the aligners as follows. For each combination of the aligners (4 combinations in total; see Table 2), we took the union of sentence pairs extracted by each constituent aligner of the said combination for each document. The performance of the aligner ensembles is shown in Table 2. We concatenated the first letters of the constituent aligners to name each ensemble (e.g., HGB refers to the combination of all three of them).

Table 2 shows that BH achieved the best F_1 score among all ensembles, even 0.89% above the best single aligner Hunalign. Ensembling increased the recall of BH by 8.94% compared to Hunalign, but also hurt precision severely (by 7.05%), due to the accumulation of incorrect alignments made by each constituent aligner. To mitigate this effect, we used the LASER[4] toolkit to filter out incorrect alignments. LASER, a cross-lingual sentence representation model, uses similarity scores between the embeddings of candidate sentences to perform as both aligner (Schwenk et al., 2019) and filter (Chaudhary et al., 2019). We used LASER as a filter on top of the ensembles, varied the similarity margin (Artetxe and Schwenk, 2019) between 0.90 to 1.10 with 0.01 increment, and plotted the performance metrics in Figure 2. We also reported the performance of LASER as a standalone aligner (referred to as L in the figure; +L indicates the application of LASER as a filter). The dashed lines indicate ensemble performance without the filter.

As Figure 2a indicates, ensembles achieve significant gain on precision with the addition of the LASER filter. While recall (Figure 2b) doesn't face a significant decline at first, it starts to take a deep plunge when margin exceeds 1.00. We balanced

---

[4] `https://github.com/facebookresearch/LASER`

between the two by considering the F_1 score (Figure 2c). Table 3 shows the performance metrics of LASER and all filtered ensembles for which their respective F_1 score is maximized.

Table 3 shows that despite being a good filter, LASER as an aligner does not show considerable performance compared to filtered ensembles. The best F_1 score is achieved by the BH ensemble with its margin set to 0.96. Its precision increased by 5.75% while trailing a mere 1.16% in recall behind its non-filtered counterpart. Compared to single Hunalign, its recall had a 7.78% gain, while lagging in precision by only 1.30%, with an overall F_1 score increase of 3.38%. Thus, in all future experiments, we used BH+L(0.96) as our default aligner with the mentioned filter margin.

4 Training Data and Batch Filtering

We categorize our training data into two sections: (1) Sentence-aligned corpora and (2) Document-aligned corpora.

4.1 Sentence-aligned Corpora

We used the corpora mentioned below which are aligned by sentences:

Open Subtitles 2018 corpus (Lison et al., 2018) from OPUS[5] (Tiedemann, 2012)

TED corpus (Cettolo et al., 2012)

SUPara corpus (Mumin et al., 2012)

Tatoeba corpus from `tatoeba.org`

Tanzil corpus from the Tanzil project[6]

AMARA corpus (Abdelali et al., 2014)

SIPC corpus (Post et al., 2012)

Glosbe[7] online dictionary example sentences

MediaWiki Content Translations[8]

Gnome, KDE, Ubuntu localization files

Dictionary entries from `bdword.com`

Miscellaneous examples from `english-bangla.com` and `onubadokderadda.com`

4.2 Document-aligned Corpora

The corpora below have document-level links from where we sentence-aligned them:

Globalvoices: Global Voices[9] publishes and translates articles on trending issues and stories from press, social media, blogs in more than 50 languages. Although OPUS provides sentence-aligned corpus from Global Voices, we re-extracted sentences using our segmenter and filtered ensemble, resulting in a larger amount of pairs compared to OPUS.

JW: Agić and Vulić (2019) introduced JW300, a parallel corpus of over 300 languages crawled from `jw.org`, which also includes Bengali-English. They used Polyglot (Al-Rfou' et al., 2013) for sentence segmentation and Yasa (Lamraoui and Langlais, 2013) for sentence alignment. We randomly sampled 100 sentences from their Bengali-English corpus and found only 23 alignments to be correct. So we crawled the website using their provided instructions and aligned using our segmenter and filtered ensemble. This yielded more than twice the data than theirs.

Banglapedia: "Banglapedia: the National Encyclopedia of Bangladesh" is the first Bangladeshi encyclopedia. Its online version[10] contains over 5,700 articles in both Bengali and English. We crawled the website to extract the article pairs and aligned sentences with our segmenter and filtered ensemble.

Bengali Translation of Books: We collected translations of more than 100 books available on the Internet with their genres ranging from classic literature to motivational speeches and aligned them using our segmenter and filtered ensemble.

Bangladesh Law Documents: The Legislative and Parliamentary Affairs Division of Bangladesh makes all laws available on their website.[11] Some older laws are also available under the "Heidelberg Bangladesh Law Translation Project".[12] Segmenting the laws was not feasible with the aligners in section 3.1 as most lines were bullet points terminating in semicolons, and treating

Table 4: Summary of the training corpus.

semicolons as terminals broke down valid sentences. Thus, we made a regex-based segmenter and aligner for these documents. Since most laws were exact translations with an equal number of bullet points under each section, the deterministic aligner yielded good alignment results.

HRW: Human Rights Watch[13] investigates and reports on abuses happening in all corners of the world on their website. We crawled the Bengali-English article pairs and aligned them using our segmenter and filtered ensemble.

Wiki Sections: Wikipedia is the largest multilingual resource available on the Internet. But most article pairs are not exact or near-exact translations of one another. However, such a large source of parallel texts cannot be discarded altogether. Wikimatrix (Schwenk et al., 2019) extracted bitexts from Wikipedia for 1620 language pairs, including Bengali-English. But we found them to have issues like foreign texts, incorrect sentence segmentations and alignments etc. As such, we resorted to the original source and only aligned from sections having high similarity. We translated the Bengali articles into English using an NMT model trained on the rest of our data and compared each section of an article against the sections of its English counterpart. We used SacreBLEU (Post, 2018) score as the similarity metric and only picked sections with score above 20. We then used our filtered ensemble on the resulting matches.

4.3 Batch Filtering

LASER uses cosine similarity between candidate sentences as the similarity metric and calculates margin by normalizing over the nearest neighbors of the candidates. Schwenk et al. (2019) suggested using a global space, i.e., the complete corpus for neighbor search while aligning, albeit without any indication of what neighborhood to use for filtering. In section 3.2, we used local neighborhood on document level and found satisfactory results. So we tested it with a single aligner, Hunalign,[14] on three large document sources, namely, Globalvoices (GV), JW, and Banglapedia (BP). But the local approach took over a day to filter from about 25k document pairs, the main bottleneck being the

---

[13] `https://www.hrw.org/`

[14] The optimal margin was found to be 0.95 for Hunalign.

loading time for each document. Even with several optimizations, running time did not improve much. The global approach suffered from another issue: memory usage. The datasets were too large to be fit into GPU as a whole.[15] Thus, we shifted the neighbor search to CPU, but that again took more than a day to complete. Also, the percentage of filtered pairs was quite higher than the local neighborhood approach, raising the issue of data scarcity again. So, we sought the following middle-ground between global and local approach: for each source, we merged all alignments into a single file, shuffled all pairs, split the file into 1k size batches, and then applied LASER locally on each batch, reducing running time to less than two hours.

Source	Document	1k Batch	Global
GV	**4.05**	4.60	8.03
JW	**6.22**	7.06	13.28
BP	**13.01**	14.96	25.65

Table 5: Filtered pairs (%) for different neighborhoods

In Table 5, we show the percentage of filtered out pairs from the sources for each neighborhood choice. The global approach lost about twice the data compared to the other two. The 1k batch neighborhood achieved comparable performance with respect to the more fine-grained document-level neighborhood while improving running time more than ten-folds. Upon further inspection, we found that more than 98.5% pairs from the document-level filter were present in the batched approach. So, in subsequent experiments, we used 'Batch Filtering' as standard. In addition to the document-aligned sources, we also used batch filtering on each sentence-aligned corpus in section 4.1 to remove noise from them. Table 4 summarizes our training corpus after the filtering.

5 Evaluation Data

A major challenge for low-resource languages is the unavailability of reliable evaluation benchmarks that are publicly available. After exhaustive searching, we found two decent test sets and developed one ourselves. They are mentioned below:

SIPC: Post et al. (2012) used crowdsourcing to build a collection of parallel corpora between English and six Indian languages, including Bengali. Although they are not translated by experts and have issues for many sentences (e.g., all capital letters on English side, erroneous translations, punctuation incoherence between Bn and En side, presence of foreign texts), they provide four English translations for each Bengali sentence, making it an ideal test-bed for evaluation using multiple references. We only evaluated the performance of Bn→En for this test set.

SUPara-benchmark (Mumin et al., 2018): Despite having many spelling errors, incorrect translations, too short (less than 50 characters) and too long sentences (more than 500 characters), due to its balanced nature having sentences from a variety of domains, we used it for our evaluation.

RisingNews: Since the two test sets mentioned above suffer from many issues, we created our own test set. Risingbd,[16] an online news portal in Bangladesh, publishes professional English translations for many of their articles. We collected about 200 such article pairs and had them aligned by an expert. We had them post-edited by another expert. We then removed, through automatic filtering, pairs that had (1) less than 50 or more than 250 characters on either side, (2) more than 33% transliterations or (3) more than 50% or more than 5 OOV words (Guzmán et al., 2019). This resulted in 600 validation and 1000 test pairs; we named this test set "**RisingNews**".

6 Experiments and Results

6.1 Pre-processing

Before feeding into the training pipeline, we performed the following pre-processing sequentially:

1. We normalized punctuations and characters that have multiple unicode representations to reduce data sparsity.
2. We removed foreign strings that appear on both sides of a pair, mostly phrases from which both sides of the pair have been translated.
3. We transliterated all dangling English letters and numerals on the Bn side into Bengali, mostly constituting bullet points.
4. Finally, we removed all evaluation pairs from the training data to prevent data leakage.

---

[15] We used an RTX 2070 GPU with 8GB VRAM for these experiments.

[16] `https://www.risingbd.com/`

At this point, a discussion with respect to language classification is in order. It is a standard practice to use a language classifier (e.g., Joulin et al., 2017) to filter out foreign texts. But when we used it, it classified a large number of valid English sentences as non-English, mostly because they contained named entities transliterated from Bengali side. Fearing that this filtering would hurt translation of named entities, we left language classification out altogether. Moreover, most of our sources are bilingual and we explicitly filtered out sentences with foreign characters, so foreign texts would be minimal.

As for the test sets, we performed minimal preprocessing: we applied character and punctuation normalization; and since SIPC had some sentences that were all capital letters, we lowercased those (and those only).

6.2 Comparison with Previous Results

We compared our results with Mumin et al. (2019b), Hasan et al. (2019), and Mumin et al. (2019a). The first work used SMT, while the latter two used NMT models. All of them evaluated on the SUPara-benchmark test set. We used the OpenNMT (Klein et al., 2017) implementation of big Transformer model (Vaswani et al., 2017) with 32k vocabulary on each side learnt by Unigram Language Model with subword regularization[17] (Kudo, 2018) and tokenized using SentencePiece (Kudo and Richardson, 2018). To maintain consistency with previous results, we used lowercased BLEU (Papineni et al., 2002) as the evaluation metric. Comparisons are shown in Table 6.

Model	**Bn→En**	**En→Bn**
Mumin et al. (2019b)	17.43	15.27
Hasan et al. (2019)	19.98	–
Mumin et al. (2019a)	22.68	16.26
Ours	**32.10**	**22.02**

Table 6: Comparison (BLEU) with previous works on SUPara-benchmark test set (Hasan et al., 2019 did not provide En→Bn scores)

Evident from the scores in Table 6, we outperformed all works by more than **9** BLEU points for Bn→En. Although for En→Bn the difference in improvement (**5.5+**) is not that much striking compared to Bn→EN, it is, nevertheless, commendable on the basis of Bengali being a morphologically rich language.

6.3 Comparison with Automatic Translators

We compared our models' SacreBLEU[18] (Post, 2018) scores with Google Translate and Bing Translator, two most widely used publicly available automatic translators. Results are shown in Table 7.

Model /Translator	**SUPara Bn→En**	**SUPara En→Bn**	**SIPC Bn→En**
Google	29.4	11.1	41.2
Bing	24.4	10.7	37.2
Ours	**30.7**	**22.0**	**42.7**

Table 7: Comparison (SacreBLEU) with automatic translators

From Table 7 we can see that our models have superior results on all test sets when compared to Google and Bing.

6.4 Evaluation on RisingNews

We performed evaluation on our own test set, **RisingNews**. We show our models' lowercased detokenized BLEU and mixedcased SacreBLEU scores in Table 8.

Metric	**Bn→En**	**En→Bn**
BLEU	39.04	27.73
SacreBLEU	36.1	27.7

Table 8: Evaluation on **RisingNews** corpus

We put great care in creating the test set by performing extensive manual and automatic quality control, and believe it is better in quality than most available evaluation sets for Bengali-English. We also hope that our performance on this test set will act as a baseline for future works on Bengali-English MT. In Figure 3, we show some example translations from the RisingNews test set.

6.5 Comparison with Human Performance

Remember that SIPC had four reference English translations for each Bengali sentence. We used the final translation as a baseline human translation and used the other three as ground truths (the fourth reference had the best score among all permutations). To make a fair comparison, we evaluated our model's score on the same three references

Figure 3: Sample translations from the RisingNews test set

instead of four. Human SacreBLEU score was 32.6, while our model scored 38.0, about **5.5** points above human judgement.

6.6 Ablation Study of Filtered Ensembles

To validate that our choice of ensemble and filter had direct impact on translation scores, we performed an ablation study. We chose four combinations based on their F_1 scores from section 3:

1. Best aligner: **Hunalign**
2. Best aligner with filter: **Hunalign+L(0.95)**
3. Best ensemble: **BH**
4. Best ensemble with filter: **BH+L(0.96)**

To ensure apples to apples comparison, we only used data from the parallel documents, i.e., Globalvoices, JW, Banglapedia, HRW, Books, and Wiki sections. Table 9 shows SacreBLEU scores along with the number of pairs for these combinations. We used the base Transformer model.

Aligner /Ensemble	**#Pairs (million)**	**SUPara Bn→En**	**SIPC Bn→En**
Hunalign	1.35	20.5	33.2
H+L(.95)	1.20	21.0	33.9
BH	**1.64**	21.0	34.0
BH+L(.96)	1.44	**22.1**	**35.7**

Table 9: SacreBLEU scores for ablation study

BH+L(.96) performed better than others by a noticeable margin, and the single Hunalign performed the poorest. While only having 73% pairs compared to BH, H+L(.95) stood almost on par. Despite the superiority in data count, BH could not perform well enough due to the accumulation of incorrect alignments from its constituent aligners. A clearer picture can be visualized through Figure 4. BH+L(.96) mitigated both data shortage and incorrect alignments and formed a clear envelope over the other three, giving clear evidence that the filter and the ensemble complemented one another.

7 Related Works

The first initiative towards machine translation for Bengali dates back to the 90s. Sinha et al. (1995) developed ANGLABHARTI, a rule-based transla-

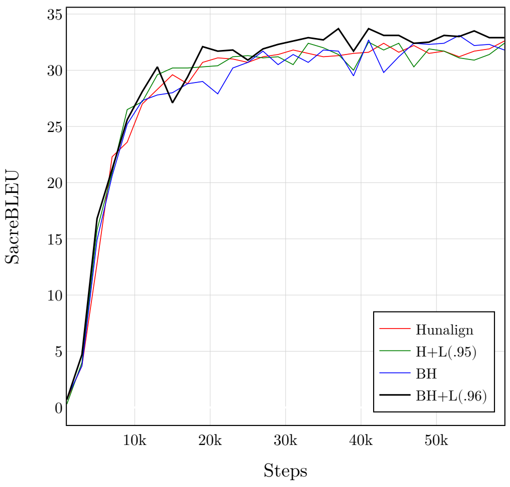

Figure 4: SacreBLEU vs Steps on SIPCdev set

tion system from English to multiple Indian languages, including Bengali. Asaduzzaman and Ali (2003); Dasgupta et al. (2004) conducted extensive syntactic analyses to write rules for constructing Bengali parse trees and designed algorithms to transfer between Bengali and English parse trees.

Subsequently, Saha and Bandyopadhyay (2005) reported an example-based machine translation approach for translating news headlines using a knowledge base. Naskar and Bandyopadhyay (2005) described a hybrid between rule-based and example-based translation approaches; here terminals would end at phrases that would then be looked up in the knowledge base.

The improved translation quality of phrase-based statistical machine translation (SMT) (Koehn et al., 2003) and the wide availability of toolkits thereof (Koehn et al., 2007) created an increased interest in SMT for Bangali-English. As SMT was more data-driven, specialized techniques were integrated to account for the low amount of parallel data for Bengali-English. Among many, Roy (2009) proposed several semi-supervised techniques; Haffari et al. (2009) used active learning to improve SMT; Islam et al. (2010) used an additional transliteration module to handle OOV words; Banerjee et al. (2018) introduced multilingual SMT for Indic languages, including Bengali.

Although NMT is currently being hailed as the state-of-the-art, very few works have been done on NMT for the Bengali-English pair. Dandapat and Lewis (2018) trained a deployable general domain NMT model for Bengali-English using sentences aligned from comparable corpora. They combated the inadequacy of training examples by data augmentation using back-translation (Sennrich et al., 2016). Hasan et al. (2019); Mumin et al. (2019a) also showed with limited parallel data available on the web that NMT provided improved translation for Bengali-English pair.

8 Conclusion and Future Works

In this work, we developed a custom sentence segmenter for Bengali, showed that aligner ensembling with batch filtering provides better performance than single sentence aligners, collected a total of 2.75 million high-quality parallel sentences for Bengali-English from multiple sources, trained NMT models that outperformed previous results, and prepared a new test set; thus elevating Bengali from its low-resource status. In future, we plan to design segmentation-agnostic aligners or aligners that can jointly segment and align sentences. We want to experiment more with the LASER toolkit: we used LASER out-of-the-box, we want to train it with our data, and modify the model architecture to improve it further. LASER fails to identify one-to-many/many-to-one sentence alignments, we want to address this. We would also like to experiment with BERT (Devlin et al., 2019) embeddings for similarity search. Furthermore, we wish to explore semi-supervised and unsupervised approaches to leverage monolingual data and explore multilingual machine translation for low-resource Indic languages.

Acknowledgements

We would like to thank the ICT Division, Government of the People's Republic of Bangladesh for funding the project and Intelligent Machines Limited for providing cloud support.

Abstract

This paper proposes a new pre-training method, called Code-Switching Pre-training (CSP for short) for Neural Machine Translation (NMT). Unlike traditional pre-training method which randomly masks some fragments of the input sentence, the proposed CSP randomly replaces some words in the source sentence with their translation words in the target language. Specifically, we firstly perform lexicon induction with unsupervised word embedding mapping between the source and target languages, and then randomly replace some words in the input sentence with their translation words according to the extracted translation lexicons. CSP adopts the encoder-decoder framework: its encoder takes the code-mixed sentence as input, and its decoder predicts the replaced fragment of the input sentence. In this way, CSP is able to pre-train the NMT model by explicitly making the most of the cross-lingual alignment information extracted from the source and target monolingual corpus. Additionally, we relieve the pretrain-finetune discrepancy caused by the artificial symbols like [mask]. To verify the effectiveness of the proposed method, we conduct extensive experiments on unsupervised and supervised NMT. Experimental results show that CSP achieves significant improvements over baselines without pre-training or with other pre-training methods.

1 Introduction

Neural machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015) which typically follows the encoder-decoder framework, directly applies a single neural network to transform the source sentence into the target sentence. With tens of millions of trainable parameters in the NMT model, translation tasks are usually data-hungry, and many of them are low-resource or even zero-resource in terms of training data. Following the idea of unsupervised and self-supervised pre-training methods in the NLP area (Peters et al., 2018; Radford et al., 2018, 2019; Devlin et al., 2019; Yang et al., 2019), some works are proposed to improve the NMT model with pre-training, by making full use of the widely available monolingual corpora (Lample and Conneau, 2019; Song et al., 2019b; Edunov et al., 2019; Huang et al., 2019; Wang et al., 2019; Rothe et al., 2019; Clinchant et al., 2019). Typically, two different branches of pre-training approaches are proposed for NMT: ***model-fusion*** and ***parameter-initialization***.

The ***model-fusion*** approaches seek to incorporate the sentence representation provided by the pre-trained model, such as BERT, into the NMT model (Yang et al., 2019b; Clinchant et al., 2019; Weng et al., 2019; Zhu et al., 2020; Lewis et al., 2019; Liu et al., 2020). These approaches are able to leverage the publicly available pre-trained checkpoints in the website but they need to change the NMT model to fuse the sentence embedding calculated by the pre-trained model. Large-scale parameters of the pre-trained model significantly increase the storage cost and inference time, which makes it hard for this branch of approaches to be directly used in production. As opposed to ***model-fusion*** approaches, the ***parameter-initialization*** approaches aim to directly pre-train the whole or part of the NMT model with tailored objectives, and then initialize the NMT model with pre-trained parameters (Lample and Conneau, 2019; Song et al., 2019b). These approaches are more production-ready since they keep the size and structure of the model same as standard NMT systems.

While achieving substantial improvements, these

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2624–2636,
November 16–20, 2020.

pre-training approaches have two main cons. Firstly, as pointed out by Yang et al. (2019), the artificial symbols like [mask] used by these approaches during pre-training are absent from real data at fine-tuning time, resulting in a pretrain-finetune discrepancy. Secondly, while each pre-training step only involves sentences from the same language, these approaches are unable to make use of the cross-lingual alignment information contained in the source and target monolingual corpus. We argue that, as a cross-lingual sequence generation task, NMT requires a tailored pre-training objective which is capable of making use of cross-lingual alignment signals explicitly, e.g., word-pair information extracted from the source and target monolingual corpus, to improve the performance.

To address the limitations mentioned above, we propose Code-Switching Pre-training (CSP) for NMT. We extract the word-pair alignment information from the source and target monolingual corpus automatically, and then apply the extracted alignment information to enhance the pre-training performance. The detailed training process of CSP can be presented in two steps: 1) perform lexicon induction to get translation lexicons by unsupervised word embedding mapping (Artetxe et al., 2018a; Conneau et al., 2018); 2) randomly replace some words in the input sentence with their translation words in the extracted translation lexicons and train the NMT model to predict the replaced words. CSP adopts the encoder-decoder framework: its encoder takes the code-mixed sentence as input, and its decoder predicts the replaced fragments based on the context calculated by the encoder. By predicting the sentence fragment which is replaced on the encoder side, CSP is able to either attend to the remaining words in the source language or to the translation words of the replaced fragment in the target language. Therefore, CSP trains the NMT model to: 1) learn how to build the sentence representation for the input sentence as the traditional pre-training methods do; 2) learn how to perform cross-lingual translation with extracted word-pair alignment information. In summary, we mainly make the following contributions:

- We propose the code-switching pre-training for NMT, which makes full use of the cross-lingual alignment information contained in source and target monolingual corpus to improve the pre-training for NMT.
- We conduct extensive experiments on supervised and unsupervised translation tasks. Experimental results show that the proposed approach consistently achieves substantial improvements.
- Last but not least, we find that CSP can successfully handle the code-switching inputs.

2 Related works

Several approaches have been proposed to improve NMT with pre-training. Edunov et al. (2019) proposed to feed the last layer of ELMo to the encoder of NMT and investigated several different ways to add pre-trained language model representations to the NMT model. Weng et al. (2019) proposed a bi-directional self-attention language model to get sentence representation and introduced two individual methods, namely weighted-fusion mechanism and knowledge transfer paradigm, to enhance the encoder and decoder. Yang et al. (2019b) proposed a concerted training framework to make the most use of BERT in NMT. Zhu et al. (2020) proposed to fuse the representations from BERT with each layer of the encoder and decoder of the NMT model through attention mechanisms. Large-scale parameters of the pre-trained model in these approaches discussed above significantly increase the storage cost and inference time, which makes these approaches a little far from production.[1] The other branch of approaches aims to keep the structure and size the same to the standard NMT system and designs some pre-training objectives tailored for NMT. Lample and Conneau (2019) proposed Cross-Lingual Language Model (XLM) objective and built a universal cross-lingual encoder. To improve the cross-lingual pre-training, they introduced supervised translation language modeling objective relying on the parallel data available. Song et al. (2019b) proposed the MASS objective to pre-train the whole NMT model instead of only pre-training the encoder by XLM. CSP builds on top of Lample and Conneau (2019) and Song et al. (2019b), and it explicitly makes full use of the alignment information extracted from the source and target monolingual corpus to enhance pre-training.

There have also been works on applying pre-specified translation lexicons to improve the performance of NMT. Hokamp and Liu (2017) and Post

---

[1] To be used in production easily, these models need to be distilled into a student model with the structure and size same as standard NMT systems.

and Vilar (2018) proposed an altered beam search algorithm, which took target-side pre-specified translations as lexical constraints during beam search. Song et al. (2019a) investigated a data augmentation method, making code-switched training data by replacing source phrases with their target translations according to the pre-specified translation lexicons. Recently, motivated by the success of unsupervised cross-lingual embeddings, Artetxe et al. (2018b), Lample et al. (2018a) and Yang et al. (2018) applied the pre-trained translation lexicons to initialize the word embeddings of the unsupervised NMT model. Sun et al. (2019) applied translation lexicons to unsupervised domain adaptation in NMT. In this paper, we apply the translation lexicons automatically extracted from the monolingual corpus to improve the pre-training of NMT.

3 CSP

In this section, we firstly describe how to build the shared vocabulary for the NMT model; then we present the way extracting the probabilistic translation lexicons; and we introduce the detailed training process of CSP finally.

3.1 Shared sub-word vocabulary

This paper processes the source and target languages with the same shared vocabulary created through the sub-word toolkits, such as SentencePiece (SP) and Byte-Pair Encoding (BPE) (Sennrich et al., 2016b). We learn the sub-word splits on the concatenation of the sentences equally sampled from the source and target corpus. The motivation behind is two-fold: Firstly, with processing the source and target languages by the shared vocabulary, the encoder of the NMT model is able to share the same vocabulary with the decoder. Sharing the vocabulary between the encoder and decoder makes it possible for CSP to replace the source words in the input sentence with their translation words in the target language. Secondly, as pointed out by Lample and Conneau (2019), the shared vocabulary greatly improves the alignment of embedding spaces.

3.2 Probabilistic translation lexicons

Recently, some works successfully learned translation equivalences between word pairs from two monolingual corpus and extracted translation lexicons (Artetxe et al., 2018a; Conneau et al., 2018). Following Artetxe et al. (2018a), we utilize unsupervised word embedding mapping to extract probabilistic translation lexicons with monolingual corpus only. The probabilistic translation lexicons in this paper are defined as one-to-many source-target word translations. Specifically, giving separate source and target word embeddings, i.e., X_e and Y_e trained on source and target monolingual corpus X and Y, unsupervised word embedding mapping utilizes self-learning or adversarial-training to learn a mapping function $f(X) = WX$, which transforms source and target word embeddings to a shared embedding space. With word embeddings in the same latent space, we measure the similarities between source and target words with the cosine distance of word embeddings. Then, we extract the probabilistic translation lexicons by selecting the top k nearest neighbors in the shared embedding space. Formally, considering the word x_i in the source language, its top k nearest neighbor words in the target language, denoted as $y^{'}_{i1}, y^{'}_{i2}, \ldots, y^{'}_{ik}$ are extracted as its translation words, and the corresponding normalized similarities $s^{'}_{i1}, s^{'}_{i2}, \ldots, s^{'}_{ik}$ are defined as the translation probabilities.

3.3 Training process of CSP

CSP only requires monolingual data to pre-train the NMT model. Given an unpaired source sentence $x \in X$, where $x = (x_1, x_2, \ldots, x_m)$ is the source sentence with m tokens, we denote $x_{[u:v]}$ as the sentence fragment of x from u to v where $0 < u < v < m$, and denote $x^{\backslash u:v}$ as modified version of x where its fragment from position u to v are replaced with their translation words according to the probabilistic translation lexicons. Formally, $x^{\backslash u:v}$ is represented as:

$$x^{\backslash u:v} = (x_1, \ldots, x_{u-1}, y^{'}_u, \ldots, y^{'}_v, x_{v+1} \ldots, x_m) \tag{1}$$

where $x^{\backslash u:v}_{[u:v]} = (y^{'}_u, \ldots, y^{'}_v)$ is sampled based on the extracted probabilistic translation lexicons presented on Section 3.2. Here, we take the replacing process from x_u to $y^{'}_u$ as an example. Considering the source word x_u, its top k translation words $y^{'}_{u1}, y^{'}_{u2}, \ldots, y^{'}_{uk}$ and the translation probabilities $s^{'}_{u1}, s^{'}_{u2}, \ldots, s^{'}_{uk}$, $y^{'}_u$ is calculated as:

$$y^{'}_u = y^{'}_{uj} (1 \leq j \leq k) \tag{2}$$

where $y^{'}_{uj}$ is decided by performing multinomial sampling on the distribution defined by translation probabilities $s^{'}_{u1}, s^{'}_{u2}, \ldots, s^{'}_{uk}$. With higher translation probability $s^{'}_{uj}$, the translation word $y^{'}_{uj}$ is more likely to be selected.

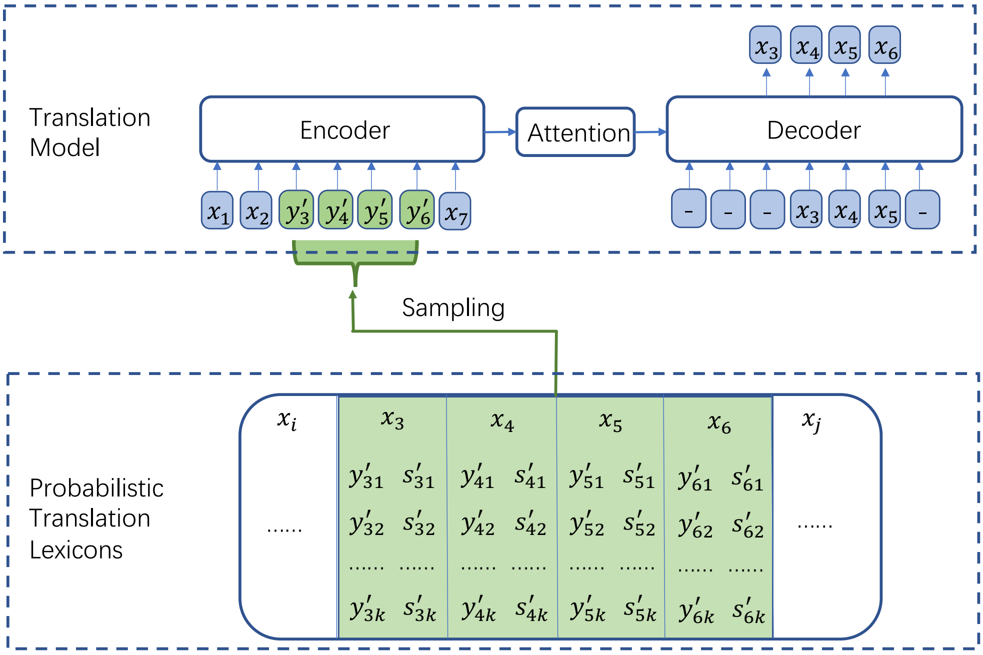

Figure 1: The training example of our proposed CSP which randomly replaces some words in the source input with their translation words based on the probabilistic translation lexicons. Identical to MAS, the token '-' represents the padding in the decoder. The attention module represents the attention between the encoder and decoder

Similar to Song et al. (2019b), CSP pre-trains a sequence to sequence model by predicting the sentence fragment $x_{[u:v]}$ with the modified sequence $x^{\backslash u:v}$ as input. With the log likelihood as the objective function, CSP trains the NMT model on the monolingual corpora X as:

$$
\begin{aligned}
L(\theta; X) &= \tfrac{1}{|X|} \textstyle\sum_{x \in X} logP(x_{[u:v]}|x^{\backslash u:v}; \theta) \\
&= \tfrac{1}{|X|} \textstyle\sum_{x \in X} log \prod_{t=u}^{v} P(x_t|x_{<t}, x^{\backslash u:v}; \theta)
\end{aligned}
\tag{3}
$$

Figure 1 shows an example for CSP training, where the original source sentence $(x_1, x_2, x_3, x_4, x_5, x_6, x_7)$ with the fragment (x_3, x_4, x_5, x_6) being replaced with their translation words, i.e., (y'_3, y'_4, y'_5, y'_6) sampled from the extracted probabilistic translation lexicons. The encoder takes the code-mixed source sentence as input, and the decoder only predicts the replaced fragment (x_3, x_4, x_5, x_6).

4 Experiments and Results

This section describes the experimental details about CSP pre-training and fine-tuning on the supervised and unsupervised NMT tasks. To test the effectiveness and generality of CSP, we conduct extensive experiments on English-German, English-French and Chinese-to-English translation tasks.

4.1 CSP pre-training

Model configuration We choose Transformer as the basic model structure. Following the base model in Vaswani et al. (2017), we set the dimension of word embedding as 512, dropout rate as 0.1 and the head number as 8. To be comparable with previous works, we set the model as 4-layer encoder and 4-layer decoder for unsupervised NMT, and 6-layer encoder and 6-layer decoder for supervised NMT. The encoder and decoder share the same word embeddings.

Datasets and pre-processing Following the work of Song et al. (2019b), we use the monolingual data sampled from WMT News Crawl datasets for English, German and French, with 50M sentences for each language.[2] For Chinese, we choose 10M sentences from the combination of LDC and WMT2018 corpora. For each translation task, the source and target languages are jointly tokenized into sub-word units with BPE (Sennrich et al., 2016b). The vocabulary is extracted from the tokenized corpora and shared by the source and target languages. For English-German and English-French translation tasks, we set the vocabulary size as 32k. For Chinese-English, the vocabulary size is set as 60k since few tokens are shared by Chinese

---

[2] In this paper, we lower-cased all of the case-sensitive languages by default, such as English, German and French.

Table 1: The translation performance of the fine-tuned unsupervised NMT models. To reproduce the results of Lample and Conneau (2019) and Song et al. (2019b), we directly run their released codes on the website.[3]

and English. To extract the probabilistic translation lexicons, we utilize the monolingual corpora described above to train the embeddings for each language independently by using word2vec (Mikolov et al., 2013) . We then apply the public implementation of the method proposed by Artetxe et al. (2017) to map the source and target word embeddings to a shared-latent space.[4]

Training details We replace the consecutive tokens in the source input with their translation words sampled from the probabilistic translation lexicons, with random start position u. Following Song et al. (2019b), the length of the replaced fragment is empirically set as roughly 50% of the total number of tokens in the sentence, and the replaced tokens in the encoder will be the translation tokens 80% of the time, a random token 10% of the time and an unchanged token 10% of the time. [5] In the extracted probabilistic translation lexicons, we only keep top three translation words for each source word and also investigate how the number of translation words produces an effect on the training process. All of the models are implemented on Py-Torch and trained on 8 P40 GPU cards.[6] We use Adam optimizer with a learning rate of 0.0005 for pre-training.

4.2 Fine-tuning on unsupervised NMT

In this section, we describe the experiments on the unsupervised NMT, where we only utilize monolingual data to fine-tune the NMT model based on the pre-trained model.

Experimental settings For the unsupervised English-German and English-French translation tasks, we take the similar experimental settings to Lample and Conneau (2019); Song et al. (2019b). Specifically, we randomly sample 5M monolingual sentences from the monolingual data used during pre-training and report BLEU scores on WMT14 English-French and WMT16 English-German. For fine-tuning on the unsupervised Chinese-to-English translation task, we also randomly sample 1.6M monolingual sentences for Chinese and English respectively similar to Yang et al. (2018). We take $NIST02$ as the development set and report the BLEU score averaged on the test sets $NIST03$, $NIST04$ and $NIST05$. To be consistent with the baseline systems, we apply the script *multi-bleu.pl* to evaluate the translation performance for all of the translation tasks.

Baseline systems We take the following four strong baseline systems. Lample et al. (2018b) achieved state-of-the-art (SOTA) translation performance on unsupervised English-German and English-French translation tasks, by utilizing cross-lingual vocabulary, denoising auto-encoding and back-translation. Yang et al. (2018) proposed the weight-sharing architecture for unsupervised NMT and achieved SOTA results on unsupervised Chinese-to-English translation task. Lample and Conneau (2019) and Song et al. (2019b) are among the first endeavors to apply pre-training to unsupervised NMT, and both of them achieved substantial improvements compared to the methods without utilizing pre-training.

Results Table 1 shows the experimental results on the unsupervised NMT. From Table 1, we can find that the proposed CSP outperforms all of the previous works on English-to-German, German-to-

CSP and fine-tuning (ours) / + BT	**28.9 / 30.0**	**38.8 / 39.9**	**43.2 / 44.6**

Table 2: The translation performance of supervised NMT on English-German, English-French and Chinese-to-English test sets. (+ BT: trains the model with back-translation method.)

English, English-to-French and Chinese-to-English unsupervised translation tasks, with as high as +0.7 BLEU points improvement in German-to-English translation task. In French-to-English translation direction, CSP also achieves comparable results with the SOTA baseline of Song et al. (2019b). In Chinese-to-English translation task, CSP even achieves +1.1 BLEU points improvement compared to the reproduced result of Song et al. (2019b). These results indicate that fine-tuning unsupervised NMT on the model pre-trained by CSP consistently outperforms the previous unsupervised NMT systems with or without pre-training.

4.3 Fine-tuning on supervised NMT

This section describes our experiments on supervised NMT where we fine-tune the pre-trained model with bilingual data.

Experimental settings For supervised NMT, we conduct experiments on the publicly available data sets, i.e., WMT14 English-French, WMT14 English-German and LDC Chinese-to-English corpora, which are used extensively as benchmarks for NMT systems. We use the full WMT14 English-German and WMT14 English-French corpus as our training sets, which contain 4.5M and 36M sentence pairs respectively. For Chinese-to-English translation task, our training data consists of 1.6M sentence pairs randomly extracted from LDC corpora.[7] All of the sentences are encoded with the same BPE codes utilized in pre-training.

Baseline systems For supervised NMT, we consider the following three baseline systems. [8] The first one is the work of Vaswani et al. (2017), which achieves SOTA results on WMT14 English-German and English-French translation tasks. The other two baseline systems are proposed by Lample and Conneau (2019) and Song et al. (2019b), both of which fine-tune the supervised NMT tasks on the pre-trained models. Furthermore, we compare with the back-translation method which has shown its great effectiveness on improving NMT model with monolingual data (Sennrich et al., 2016a). Specifically, for each baseline system, we translate the target monolingual data used during pre-training back to the source language by a reversely-trained model, and get the pseudo-parallel corpus by combining the translation with its original data. [9] At last, the training data which includes pseudo and parallel sentence pairs is shuffled and used to train the NMT system.

Results The experimental results on supervised NMT are presented at Table 2. We report the BLEU scores on English-to-German, English-to-French and Chinese-to-English translation directions. For each translation task, we report the BLEU scores for the standard NMT model and the model trained with back-translation respectively. As shown in Table 2, compared to the baseline system without pre-training (Vaswani et al., 2017), the proposed model achieves +1.6 and +0.7 BLEU points improvements on English-to-German and English-to-French translation directions respectively. Even compared to stronger baseline system with pre-training (Song et al., 2019b), we also achieve +0.5 and +0.4 BLEU points improvements respectively on these two translation directions. On Chinese-to-English translation task, the proposed model achieves +0.7 BLEU points improvement compared to the baseline system of Song et al. (2019b). With back-translation, the proposed model still outperforms all of the baseline systems. Experimental results above show that fine-tuning the supervised

---

[7] LDC2002L27,LDC2002T01,LDC2002E18,LDC2003E07, LDC2004T08,LDC2004E12,LDC2005T10

[8] Since ***model-fusion*** approaches incorporate too much extra parameters, it is not fair to take them as baselines here. We leave the comparison between CSP and ***mode-fusion*** approaches in the appendix C.

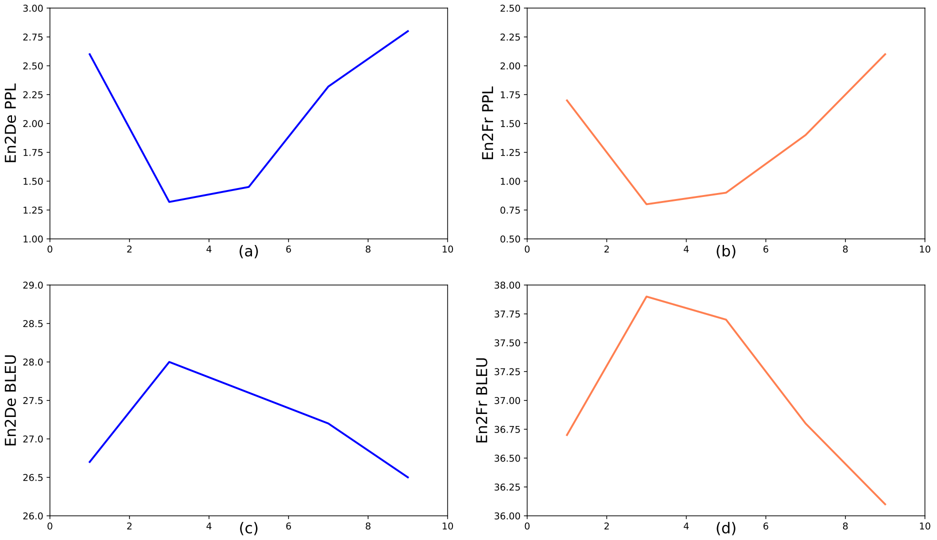

Figure 2: The performance of CSP with the probabilistic translation lexicons keeping different translation words for each source word, which includes: (a) the PPL score of the pre-trained English-to-German model; (b) the PPL score of the pre-trained English-to-French model; (c) the BLEU score of the fine-tuned unsupervised English-to-German NMT model; (d)the BLEU score of the fine-tuned unsupervised English-to-French NMT model.

NMT on the model pre-trained by CSP achieves substantial improvements over previous supervised NMT systems with or without pre-training. Additionally, it has been verified that CSP is able to work together with back-translation.

5 Analysis

5.1 Study the number of translation words

In CSP, the probabilistic translation lexicons only keep the top k translation words for each source word. For each word in the translation lexicons, the number of translation words k is viewed as an important hyper-parameter and can be set carefully during the process of pre-training. A natural question is that how much of translation words do we need to keep for each source word? Intuitively, if k is set as a small number, the model may lose its generality since each source word can be replaced with only a few translation words, which severely limits the diversity of the context. And if otherwise, the accuracy of the extracted probabilistic translation lexicons may get significantly diminished, which shall introduce too much noise for pre-training. Therefore, there is a trade-off between the generality and accuracy. We investigate this problem by studying the translation performance of unsupervised NMT with different k, where we vary k from 1 to 10 with the interval 2. We observe both the performance of CSP after pre-training and the translation performance after fine-tuning on the unsupervised NMT tasks, including the English-to-German and English-to-French translation directions. For each translation direction, we firstly present the perplexity (PPL) score of the pre-trained model averaged on the monolingual validation sets of the source and target languages.[10] And then we show the BLEU score of the fine-tuned model on the bilingual validation set. Figure 2 (a) and (c) illustrate the PPL score of the pre-trained model and BLEU score of the fine-tuned unsupervised NMT model respectively on English-to-German translation. Figure 2 (b) and (d) present the PPL and BLEU score respectively for English-to-French translation. From Figure 2, it can be seen that, when k is set around 3, the pre-trained model achieves the best validation PPL scores on both of the English-to-German and English-to-French translation directions. Similarly, CSP also achieves the best BLEU scores on the unsupervised translation tasks when k is set around 3.

5.2 Ablation study

To understand the importance of different components of the model pre-trained by CSP, we perform an ablation study by training multiple versions of

---

[9] We randomly select the target monolingual data with the same size to the bilingual data.

[10] For English-German translation, the monolingual validation set for English is built by including all English sentences in the bilingual English-German validation set, and the monolingual validation set for German is built in the same way.

the supervised NMT model with some components initialized randomly: the word embeddings, the encoder, the attention module between the encoder and decoder, and the decoder. Experiments are conducted on English-to-German and English-to-French translation tasks. All models are trained without back-translation and results are reported in Table 3. We can find that the two most critical components are the pre-trained encoder and attention module. It shows that CSP enhances NMT not only on the ability of building sentence representation for the input sentence, but also on the ability of aligning the source and target languages with the help of word-pair alignment information. Additionally, the experimental results indicate that the pre-trained decoder shows little effect on the translation performance. This is mainly because the decoder only predicts the source-side words during pre-training but predicts the target-side words during fine-tuning. This pretrain-finetune mismatch makes the pre-trained decoder less helpful for performance improvement.

System	en-de	en-fr
No pre-trained embeddings	28.4	38.5
No pre-trained encoder	27.9	38.2
No pre-trained attention module	28.1	38.3
No pre-trained decoder	28.8	38.8
Full model pre-trained by CSP	28.9	38.8

Table 3: Ablation study on English-German and English-French translation tasks. The embeddings include the source-side and target-side word embeddings.

5.3 Code-switching translation

Code-switching, which contains words from different languages in single input, has aroused more and more attention in NMT (Johnson et al., 2017; Menacer et al., 2019). In this section, we show that the proposed CSP is able to enhance the ability of the fine-tuned NMT model on handling the code-switching input. To present quantitative results, we build two test sets for the supervised Chinese-to-English translation task to evaluate the performance of the translation model on handling code-switching inputs. We randomly select 200 Chinese-English sentence pairs from $NIST02$, based on which we build two code-switching test sets. The first test set, referred to as test A, is built by randomly replacing some phrases in each Chinese sentence with their counterpart English phrases, where the English phrase is the translation result by feeding the corresponding Chinese phrase to the Google Chinese-to-English translator; The second test set, referred to as test B, is constructed by randomly replacing parts of the words in each Chinese sentence with their nearest target words in the shared latent embedding space (the same way used by CSP in Section 3.2). Table 4 shows the translation performance of NMT systems on the two code-switching test sets.[11] Besides the baseline systems mentioned in section 4.3, we also train a Chinese-English multi-lingual system (Johnson et al., 2017) based on Transformer, which has shown the ability of handling code-switching inputs. From Table 4, We can find that the proposed approach achieves significant improvements over previous works. Compared to multi-lingual system, we achieve +2.3 and +3.0 BLEU points improvements respectively on test A and test B. The case study can be found in appendix D.

System	test A	test B
Vaswani et al. (2017)	28.17	32.51
Lample and Conneau (2019)	28.82	32.90
Song et al. (2019b)	28.70	33.21
Multi-lingual system	30.51	35.10
CSP and fine-tuning	**32.84**	**38.17**

Table 4: The performance of Chinese-to-English translation on in-house code-switching test sets.

6 Conclusions and Future work

This work proposes a simple yet effective pre-training approach, i.e., CSP for NMT, which randomly replaces some words in the source sentence with their translation words in the probabilistic translation lexicons extracted from monolingual corpus only. To verify the effectiveness of CSP, we investigate two downstream tasks, supervised and unsupervised NMT, on English-German, English-French and Chinese-to-English translation tasks. Experimental results show that the proposed approach achieves substantial improvements over strong baselines consistently. Additionally, we show that CSP is able to enhance the ability of NMT on handling code-switching inputs. There are two promising directions for the future work. Firstly, we are interested in applying CSP to other

---

[11] The two in-house code-switching test sets can be found in the attached files.

related NLP areas for code-switching problems. Secondly, we plan to investigate the pre-training objectives which are more effective in utilizing the cross-lingual alignment information for NMT.

A The configurations for the open-source toolkit

A.1 Get word embeddings with word2vec

We train the word embedding use the following script:

```
word2vec −train text −output
    embedding.txt −cbow 0 −size
    512 −window 10 −negative 10 −
    hs 0 −sample 1e− −threads 50 −
    binary 0 −min−count 5 −iter 10
```

A.2 Word embedding mapping with Vecmap

After we get the embeddings for both the source and target languages, namely s_embedding.txt and t_embedding.txt, we use the open-source Vecmap to map these embeddings to a shared-latent space with the following scripts:[12]

```
python normalize_embeddings.py
    unit center −i s_embedding.txt
     −o s_embedding.normalized.txt
```

```
python normalize_embeddings.py
    unit center −i t_embedding.txt
     −o t_embedding.normalized.txt
```

```
python map_embeddings.py −
    orthogonal s_embedding.
    normalized.txt t_embedding.
    normalized.txt
s_embedding.mapped.txt
    t_embedding.mapped.txt −
    numerals −self_learning −v
```

B Study of different length of the replaced segment

The length of the replaced fragment is an hyperparameter which can be set by the user beforehand. We are curious to know how the length of the replaced fragment shows effect on CSP. In this section, we study the performance of CSP with different length of the replaced fragment, where we set the length of the replaced fragment from 10% to 90% percentage of the sentence length with a step size of 10%. Similar to section 5.1, we report both the performance of CSP after pre-training and the translation performance after fine-tuning on the unsupervised NMT tasks, including the English-to-German and English-to-French translation directions. For each translation direction, we firstly present the perplexity (PPL) score of the pre-trained model averaged on the monolingual validation sets of the source and target languages. And then we show the BLEU score of the fine-tuned model on the bilingual validation set. Figure 3 (a) and (c) illustrate the PPL score of the pre-trained model and BLEU score of fine-tuned unsupervised NMT model respectively on English-to-German translation direction. Figure 3 (b) and (d) present the PPL and BLEU score respectively for English-to-French translation direction. We can find that when the length of the replaced fragment is set nearly 50% of the sentence length, CSP achieves best performance not only on the pre-training task but also on the downstream unsupervised NMT task. Therefore, we set the length of the replaced fragment as 50% of the sentence length in our experiments.

Zhu et al. (2020)	29.2	39.1	43.8
+Knowledge Distillation	28.7	38.5	**43.4**
CSP and fine-tuning (ours)	**28.9**	**38.8**	43.2

Table 5: The comparison between CSP and ***model-fusion*** approaches. We get the translation result of Zhu et al. (2020) by directly running their released codes on the website.[13]

C Compared to *model-fusion* approaches

In this section, we compare the proposed CSP with ***model-fusion*** approaches. We conduct experiments on supervised NMT where we fine-tune the pre-trained model with bilingual data. Experimental settings are identical to the settings in section 4.3. We report the performance of English-to-German, English-to-French and Chinese-to-English translation tasks. Since Zhu et al. (2020) released their code which makes their results reproducible, we take their system as the baseline. To make the comparison more fair, we distill the model of Zhu et al. (2020) to a student model which has the same size and structure to standard NMT model. For knowledge distillation, we utilized the sequence-level knowledge distillation proposed by Kim and Rush (2016). [14] Experimental results are presented in Table 5. We can find that, compared to the distilled student model of Zhu et al. (2020), CSP achieves better translation performance on two of three translation tasks.

D Case study for code-switching

In this section, we compare the performance of different NMT systems by case study. We randomly select some examples of the code-switching inputs and get the outputs by feeding the code-switching inputs into different NMT systems. The results are presented in Table 6. We can find that, for the two code-switching input sentences in Table 6, the standard Transformer and the multi-lingual system are both easily to give insufficient translations with some semantic contents untranslated. We assume that this is mainly because these systems are weak in encoding the full context of the code-switching input. Compared to the baseline systems, our system gives more sufficient and fluent translations. This shows that CSP enhances the model's ability

Type B Reflexivization as an Unambiguous Testbed for Multilingual Multi-Task Gender Bias

Ana Valeria González[1], **Maria Barrett**[1,2], **Rasmus Hvingelby**[2], **Kellie Webster**[3], and **Anders Søgaard**[1,3]

`websterk@google.com`

Abstract

The one-sided focus on English in previous studies of gender bias in NLP misses out on opportunities in other languages: English challenge datasets such as GAP and WinoGender highlight model preferences that are ”hallucinatory”, e.g., disambiguating gender-ambiguous occurrences of ’doctor’ as male doctors. We show that for languages with type B reflexivization, e.g., Swedish and Russian, we can construct multi-task challenge datasets for detecting gender bias that lead to *unambiguously wrong* model predictions: In these languages, the direct translation of ’the doctor removed his mask’ is not ambiguous between a coreferential reading and a disjoint reading. Instead, the coreferential reading requires a non-gendered pronoun, and the gendered, possessive pronouns are *anti-reflexive*. We present a multilingual, multi-task challenge dataset, which spans four languages and four NLP tasks and focuses only on this phenomenon. We find evidence for gender bias across *all* task-language combinations and correlate model bias with national labor market statistics.

1 Introduction

A reflexive pronoun is an anaphor that requires a c-commanding antecedent within its binding domain (Chomsky, 1991).[1] In languages with *Type B* reflexivization (Heine, 2005), the referent of a reflexive possessive pronoun has to be the subject of the clause, while non-reflexive possessive pronouns (so-called *anti-reflexives*) trigger an interpretation where its referent is *not* the subject; see Table 1.

We focus on the subset of those languages in which *anti-reflexive possessive pronouns are gendered, but reflexives are not*. This includes Chinese, Russian, Danish, and Swedish, as well as other Scandinavian, Slavic, and Sino-Tibetan languages languages (Bílý, 1981; Battistella, 1989; Kiparsky, 2001).[2] Our motivation for highlighting this particular linguistic phenomenon is that the antecedents of reflexive and anti-reflexive pronouns are grammatically determined; if gender bias leads models (or humans) to predict alternative coreference chains, this violates hard grammatical rules and is thus a clear case of gender bias leading not only to ’hallucinations’,[3] but to errors. To see this, consider the following examples:

	TYPE A			TYPE B		
Person	1st	2nd	3rd	1st	2nd	3rd
REFL	✓	✓	✓	✓	✓	

Table 1: In Type B reflexivization (Heine, 2005), 3rd person pronouns cannot be used reflexively. We are interested in Type B languages with gendered pronouns, and where the non-gendered special (3rd person) reflexive marker has a possessive form.

(1) The surgeon$_1$ put a book on PRON.POSS.REFL.3RD$_1$ table. → The book is on the surgeon’s$_1$ table.

(2) The surgeon$_1$ put a book on PRON.POSS.3RD$_2$ table. $\not\rightarrow$ The book is on the surgeon’s$_1$ table.

Examples (1) and (2) should not be thought of as examples of English, but placeholders for sentences

---

[1] This means that the antecedent should be in the same sentence, be different from the pronoun and not command it, but any ancestor of the antecedent is an ancestor of the pronoun. This is why in *Lea*$_1$*’s sister*$_2$ *taught herself*$_{1*/2/3*}$ the pronoun refers to *sister*, not to *Lea* or a discourse referent.

[2] This rules out languages such as German and French, where the reflexive (e.g., *sich* and *se*) does not have a possessive form (Steinbach, 1998). We focus on the reflexive and anti-reflexive *possessive* forms rather than pure reflexives, since they occur more freely, i.e., not only in the context of reflexive verbs, and they are thus more likely to interact with implicit gender assumptions.

[3] We use the word *hallucination* to refer to gender bias leading models to infer gender without evidence; see Tian et al. (2020) for a similar use of the term in abstractive summarization.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2637–2648,
November 16–20, 2020. ©2020 Association for Computational Linguistics

in the languages above since this grammatical distinction is not possible in English: the possessive reflexive (PRON.POSS.REFL.3RD) and the possessive anti-reflexive (PRON.POSS.3RD) in these languages would be translated to the same pronoun in English. In Example (1), the reflexive possessive pronoun is co-referential with the grammatical subject (as indicated by subscripts), which leads to the conclusion that the book is now on a table that is associated with the subject, in other words, the *surgeon's* table. In Example (2), in contrast, when an anti-reflexive possessive pronoun is used, this reading is no longer possible. Instead, Example (2) unambiguously means that the book is on someone else's table. This distinction is not possible in English where the same pronoun (*his/her*) would be used in both Examples (1) and (2): *The surgeon put a book on his table*, which is therefore ambiguous between a disjoint and a coreferent reading.

Language users may be *more likely to prefer the ungrammatical reflexive reading if the gender of the anti-reflexive possessive pronoun matches their (possibly gender-stereotypical) expectations about the referent of the subject*, in this case, *the surgeon*. A masculine possessive pronoun aligns with a prevalent stereotype that surgeons are men; although in the US, in reality, only 62% are.[4] Such a reading is, however, clearly not intended, and this is an example of when gender bias prohibits effective communication. Introducing a new referent in a discourse, usually comes at a cognitive cost when processing the sentence if the referent is not already salient (Grosz et al., 1995). While Example (2) is grammatically unambiguous, language users may occasionally be willing to violate grammatical constraints to avoid the more costly non-coreferential reading, if the meaning of the grammatically correct disjoint reading does not align with their expectations about the world.[5]

The challenge dataset that we present here consists of examples such as the one above and is intended as a diagnostic of implicit gender assumptions in NLP models. It is applicable across four languages (Danish, Russian, Swedish, and Chinese) and four NLP tasks: natural language inference (NLI), machine translation (MT), coreference resolution, and language modeling (LM)). We will, for example, be interested in whether models are more likely to produce errors when the anti-reflexive pronouns – PRON.POSS.3RD in Example (2) – exhibit the gender that is implicitly associated with the entity in the subject position, i.e., *surgeon*. As should be clear by now, the challenge dataset is fundamentally different from previously introduced challenge datasets in that it focuses on a single linguistic phenomenon that exists across many languages (Lødrup et al., 2011; Honselaar, 1986; Cohen, 1973; Stoykova, 2012) and includes **four languages and four tasks**, and because it focuses on gender bias leading to prediction errors rather than 'hallucinations', i.e., unwarranted disambiguations. To the best of our knowledge, the dataset introduced below is in this way the first of its kind.

Contributions We present a multilingual, multitask challenge dataset focusing on a specific linguistic phenomenon found in some Scandinavian, Slavic, and Sino-Tibetan languages, namely *gendered possessive anti-reflexive pronouns* in combination with non-gendered possessive reflexive pronouns. We show, by designing multilingual example generation templates by hand, how this phenomenon can interact with gender assumptions in interesting ways. This results in a unique challenge dataset, which we use to detect and quantify gender biases in state-of-the-art and off-the-shelf models across several tasks, including machine translation, natural language inference, coreference resolution, and language modeling. Unlike all other previous challenge datasets focusing on gender bias, our examples quantify *to what extent gender bias in models leads to prediction errors*, rather than unwarranted disambiguation. Data and code is available at `https://github.com/anavaleriagonzalez/ABC-dataset`

2 The Anti-reflexive Bias Challenge

The ANTI-REFLEXIVE BIAS CHALLENGE (ABC) dataset is designed to force humans and models to align with either widespread gender assumptions or hard grammatical rules. Note, again, that this is in sharp contrast with other gender bias challenge datasets, where gender biases lead to biases in semantic disambiguation, but do not interact with grammatical constraints. Our approach is similar to previous work in other respects:

Similarly to Rudinger et al. (2018) and other recent challenge datasets, ABC relies on hand-

---

[4] `http://www.bls.gov/cps/cpsaat11.htm`

[5] Note that this is *not* a conflict between syntax and semantics, such as, for example, those studied in Kos et al. (2010), but a conflict between syntax, on the one hand, and belief bias and pragmatics.

written templates, which are used to generate examples in conjunction with lists of occupations. We make use of the 60 occupations listed in Caliskan et al. (2017) containing statistics about gender distributions across professions, taken from the U.S. Bureau of Labor Statistics. Specifically, we generate a base set of 4,560 sentences from 38 templates, two tenses (present and past), and 60 occupations. The 38 templates vary the position of the pronouns, e.g.:

(3) The OCCUPATION lost PRON.POSS.3RD wallet at the house.

(4) The OCCUPATION lost the wallet at PRON.POSS.3RD house.

where PRON.POSS.3RD, in this case, is a place holder for anti-reflexive and reflexive third-person pronouns. Our templates only include transitive verbs.

In our language modelling experiments, we predict the pronoun in question. For NLI and coreference, we introduce three variations of each datapoint (possessive masculine, possessive feminine (anti-reflexive) pronouns and the non-gendered reflexive pronoun). This leads to a total of 13,680 examples for each language. For NLI, we use these as premises and add possible entailments to our templates. See Examples (1) and (2). For machine translation, we use the English versions of Examples (3) and (4) as source sentences, with feminine and masculine third-person pronouns. This leads to 9,120 translation problems. Native speakers manually verified and corrected all templates and sample examples for all tasks. Appendix A shows examples from the four tasks in the four languages. We discuss each task in detail below.

NLI Examples (1) and (2) illustrate the entailment phenomenon that we are interested in. Reflexive possessive pronouns are coreferential with their subjects, which leads to the interpretation that the book is on the surgeon's table. Anti-reflexive pronouns, on the other hand, prevent this reading and leads to an interpretation that a new discourse entity – another person – exists and that the book is located on that person's table.

The general form of our inference examples is as follows:

(5) OCCUPATION.DEF$_1$ [VERB PHRASE] PRON.POSS.REFL.3RD$_1$ OBJECT PREP NOUN.DEF. → OCCUPATION.DEF.POSS$_1$ OBJECT [VERB PHRASE.PASSIVE] PREP NOUN.DEF.

(6) OCCUPATION.DEF$_1$ [VERB PHRASE] PRON.POSS.3RD$_2$ OBJECT PREP NOUN.DEF. ↛ OCCUPATION.DEF.POSS$_1$ OBJECT [VERB PHRASE.PASSIVE] PREP NOUN.DEF.

We will primarily be interested in the rate at which state-of-the-art NLI models (wrongly) predict examples of the form in Example (5) to be cases of entailment, and how this depends on whether the possessive pronoun PRON.POSS is masculine or feminine. To generate examples of this form, we translate one prototype example and then identify the variables in the output example. We also make sure to check that there are no morpho-syntactic dependencies, e.g., agreement, between these variables. We then generate all possible examples and have native speakers manually verify the correctness of samples of the generated examples.

Machine Translation For machine translation, we are interested in the way that gender assumptions play a role in the resolution of the gendered possessive pronoun in the source language. As an example, when translating the phrase *The doctor put the book on her table*, an English-Danish translation system would likely generate one of the following two options, a reflexive reading and an anti-reflexive one:

(7) Lægen lagde bogen på *sit* bord

doctor.DEF put book.DEF on PRON.POSS.REFL.3RD table

(8) Lægen lagde bogen på *hendes* bord

doctor.DEF put book.DEF on PRON.POSS.3RD table

While ABC focuses on translating *from English*, it holds that similarly, if we translate the Danish sentence *mekanikeren har brug for sine.*REFL *værktøjer til at arbejde*, which uses a gender-neutral reflexive possessive pronoun *sine*, into English, the model will have to choose between two possible, correct translations:

(9) The mechanic needs *his* tools to work

(10) The mechanic needs *her* tools to work

The machine translation section of the ABC dataset consists of translations from English sentences with gendered possessive pronouns into one of the four target languages (Danish, Russian, Swedish, and Chinese). For a single occupation on the list, this would correspond to two English sentences (masculine and feminine possessive pronoun) per template. We quantify to what extent models translate English source sentences with possessive masculine or feminine pronouns into target sentences with reflexive pronouns.[6]

Coreference Resolution For coreference resolution, we generate variants of our templates in the four target languages with each of the gendered anti-reflexives and the reflexive pronoun. That is , for a sentence such as:

(11) The firefighter placed *her/his* shoes in the closet

we generate the following examples for Danish:

(12) Brandmanden placerede *hendes* sko i skabet (FEM)

(13) Brandmanden placerede *hans* sko i skabet (MASC)

(14) Brandmanden placerede *sine* sko i skabet (REFL)

In Examples (12) and (13), the use of anti-reflexive pronouns *hans* or the femine anti-reflexive *hendes* means the shoes placed in the closet belong to someone other than the firefighter. In our coreference resolution experiments, we are thus interested in how often models wrongly link the anti-reflexive pronouns (*hans/hendes*) to the occupation. Such predictions violate grammatical constraints and are clear examples of gender assumptions overwriting morpho-syntactic evidence.

Language Modelling For language modeling, we are interested in how likely the models are to predict gendered anti-reflexive possessive pronoun when the original sentence contains a reflexive pronoun. In:

(15) Brandmanden placerede *sine* sko i skabet (REFL)

we compute the sentence perplexity replacing the reflexive pronoun *sine* with a feminine anti-reflexive (*hendes*) or masculine (*hans*) anti-reflexive pronoun. A difference in perplexity reveals a gender bias, and if the model prefers an anti-reflexive reading, this possibly leads to a grammatically incorrect sentence.[7]

3 Experiments

In this work, we are focused on highlighting a linguistic phenomenon that is useful for diagnosing gender bias, therefore we do not focus on an extensive comparison of model architectures; further work would be required to examine more models. We are interested in the gender associations that *existing* models make. Because of this, we take off-the-shelf translation models and language models. As there were not any state-of-the-art models already pre-trained for coreference in the languages of interest, we train a state-of-the-art architecture for coreference resolution on languages where we could obtain data. To be able to evaluate NLI models on the target languages, we fine-tune a pre-trained model for this task.

As previously found in (Rudinger et al., 2018), gender biases in models tended to correlate with labor statistics of the percentage of female in each occupation according to Bureau of Labor Statistics 2015 [8] released with Caliskan et al. (2017). We correlate our findings with these statistics as well as national statistics.

NLI NLI is originally a three-way classification task. Given two sentences; a premise and a hypothesis, the system classifies the relation between them as `entailment, contradiction`, or `neutral`. Since ABC is only intended for diagnosing gender bias in off-the-shelf models, and not for training models, we only consider the `entailment` relation. If the premise contains a reflexive pronoun, the true class is `entailment`, and if the premise contains a masculine or feminine pronoun it is not `entailment`.

XNLI (Conneau et al., 2018) is a manual translation of the English NLI data into 15 languages. Chinese and Russian are among them and we benchmark the model on the XNLI test set. Singh et al. (2019) extend the XNLI train set to a wider set of languages, including Danish and Swedish but there is not test set for benchmarking. We use

---

[6] In the context of examples such as Example (9) and (10), using an anti-reflexive pronoun in the target translation may seem more like a hallucination than violating grammatical constraints, and we acknowledge that in machine translation, as well as in language modeling, the difference concerning existing gender bias challenge datasets is less pronounced than with NLI and coreference resolution. Nevertheless, note that the model not only hallucinates a gender attribution, but also co-referentiality, making it relatively simple to construct semantically impossible examples, e.g., *The mechanic needs his tools, but not his own tools*. Furthermore, introducing a new referent without evidence also violates pragmatic economy principles (Grosz et al., 1995; Gardent and Webber, 2001). Google Translate incorrectly translates into a sentence with two reflexive pronouns (violating the semantic principle of bivalence).

[7] See also the footnote above on whether our machine translation examples diagnose model 'hallucinations' or unambiguous prediction errors.

[8] `http://www.bls.gov/cps/cpsaat11.htm`

cross-lingual language model pre-training (XLI) (Conneau and Lample, 2019), i.e., we fine-tune on English NLI training data. For Chinese and Russian, we use a publicly available implementation[9] of the XLM-15 model (Conneau and Lample, 2019) and fine-tune it using a batch size of 4 and a learning rate of 0.000005 for 35 epochs, which led to the best performance on the XNLI development set. For Danish and Swedish, we use the XLM-100 model, which we fine-tune for 28 epochs.

Machine Translation For machine translation, we evaluate models for English→ {Danish, Russian, Swedish, Chinese} *to assess how often they predict the non-gendered reflexive possessive pronouns when the source possessive pronoun is masculine versus feminine*. For all languages, we report the performance of Google Translate. Additionally, for the languages where an off-the-shelf, near-state-of-the-art system was publicly available, we also report performance. For Chinese, we use the pre-trained models provided by Sennrich et al. (2017) [10] (E-WMT). For Russian, we use the winner system of WMT19 (Ng et al., 2019), which is provided as part of the Fairseq toolkit (F-WMT).[11]

Coreference Resolution For coreference resolution, we are interested in whether the system violates grammatical rules by placing an anti-reflexive possesive pronoun in a cluster. We train coreference resolution models for Chinese and Russian using the model and code of Joshi et al. (2019). For Chinese, we use the Chinese version of Ontonotes as our training data, which is made up of about 1800 documents for training. For Russian, we use the RuCor corpus (Ju et al., 2014), which is small, containing only 181 documents total, but has been used to train coreference models for Russian before (Ju et al., 2014; Sysoev et al., 2017). The task consists of predicting the spans that make up a coreference cluster. We train the model using the hyperparameters specified in the source code [12]. We use a maximum segment length of 128. See Appendix §B for statistics of the coreference resolution datasets used for training. While we do not have coreference resolution systems we can evaluate for Danish and Swedish, we include challenge examples for these languages that can be used to detect bias in future systems for these languages.

Language Modeling For our language modeling experiments, we use the pre-trained BERT masked language modeling architecture (Devlin et al., 2019). We turn pronoun prediction into a Cloze task (Taylor, 1953) where the pronoun is masked and then the probabilities of each possible alternative taken to compute the sentence-level perplexity. We use Chinese BERT (for Chinese) and multilingual BERT for Russian, Danish, and Swedish.[13] The overall perplexities of these models on our challenge examples, are low; again, this is because of the simple vocabulary and constructions used in the examples. We nevertheless see strong gender bias in the language models, especially for Danish and Chinese.

4 Results

Our evaluation results are found in Table 2, with results on Danish (da), Russian (ru), Swedish (sv), and Chinese (zh), and for machine translation (MT), natural language inference (NLI), coreference resolution (COREF), and language modeling (LM). A system with a significant correlation between error Δ on sentences with feminine pronouns and the % of women in the corresponding occupations is shown by a check mark.

NLI For NLI, the XLM models generally overpredict entailment for anti-reflexive pronouns. The models perform well on benchmark data, e.g., 0.742 on the Chinese XNLI test set, but much worse (0.330) on our challenge examples. For Chinese and Danish, the models perform slightly better on sentences with masculine anti-reflexive pronouns, whereas they perform slightly better on sentences with feminine anti-reflexives in Russian and Swedish. For all four languages, we see significant negative correlations between relative error increase on sentences with feminine pronouns and the ratio of women in corresponding occupations; see §5 for a discussion of the statistics. This suggests that the very poor performance numbers on sentences with anti-reflexive pronouns is, in part, the result of gender bias.

Machine translation For machine translation, we also observe strong negative correlations, sug-

Table 2: Gender Bias Results. Performance on benchmarks and ABC. ✓: Pearson's ρ of error Δ on sentences with feminine pronouns and % of women in corresponding occupations significant ($p < 0.01$); see §5 for a discussion of the labor market statistics. †: Systems insensitive to variation in pronouns.

gesting gender bias. In the manual analysis of the output translations, we see a very clear pattern that English masculine possessive pronouns are more likely to translate into reflexive pronouns in the target languages, than feminine possessive pronouns. For Danish, 93.7% of masculine pronouns were translated into reflexives, whereas only 72.9% of feminine pronouns were. For Russian, the two systems were consistent in this respect and both translated 69.3% of masculine pronouns and 18.1% of feminine pronouns into reflexive pronouns. For Swedish, the numbers were 90.0% and 73.1%, respectively. For Chinese, where the reflexive pronoun is used less frequently,[14] the machine translation models only produced a few translations with reflexive pronouns (for masculine source pronouns).

These differences are not reflected in BLEU scores, and in our correlations we correlate the increase in pronoun translation errors for source sentences with feminine pronouns and the ratio of women in the corresponding occupations. In general, our models achieve high BLEU scores on our challenge examples, which are all syntactically simple and use simple, in-vocabulary words.

Coreference Resolution For coreference resolution, we observe clear performance differences between our Chinese and Russian models. This possibly reflects the fact that the Russian model was trained on a very small dataset and is less likely to generalize. For both models, we observe a clear bias towards clustering masculine anti-reflexive pronouns with their grammatical subjects, despite how this violates grammar. The Chinese model, which exhibits a strong gender bias, errs on 17% of sentences with masculine anti-reflexive pronouns, and on 14.6% of sentences with feminines anti-reflexives. For Russian, the differences are small, but note the model is trained on limited data, e.g., 140 documents. Out of around 13,000 examples, the model only predicts clusters for 475 pronouns, and 400 of those are in reflexive case. The remaining 75 are masculine (0 feminine). In other words: we see a similar tendency to Chinese, but since the overall performance is poor, and the model is in general rather insensitive to differences in pronouns, we do not include correlation results.

---

[14] The systems are trained on a combination of traditional and simplified Chinese; the latter variant does not include the reflexive pronoun.

Language Modeling Also for language modeling, we observe consistent bias when predicting a masculine pronoun in place of a reflexive for all languages. These differences are higher for Chinese and Russian. We are not interested in the model's ability to generate a particular pronoun, the more interesting observation is whether the perplexities for sentences containing masculine possessives are lower than for predicting feminine possessives when forcing the model to predict these in place of a reflexive. Our results show that perplexities are lower for masculine possessives in all languages with the biggest differences of 3.7 sentence perplexity for Russian.

5 Analysis: Biased statistics?

We used occupations from Caliskan et al. (2017) in creating our template data; this database also includes U.S. occupation statistics. In our results in Table 2, however, we rely on national statistics instead, but how much of a bias would it be to rely on the original American statistics? In this section, we explain how we collected the national statistics and show how they strongly correlate with the American statistics, but also that national statistics are slightly better at detecting gender bias:

Our Danish labor market statistics come from Larsen et al. (2016), as well as Statistics Denmark[15] and Bevægelsesregisteret,[16] which is a national database over authorised health staff. Some numbers (paramedic, scientist and receptionist) are based on graduation statistics. The Russian labor market statistics were mostly obtained from the Federal State Statistic Service.[17] For occupations not contained on this website we obtained the numbers from separate sources such as the Center of Fire Statistics (CFS) of International Association of Fire and Rescue Services (CTIF)[18] and the Organisation for Economic Cooperation and Development's statistics website[19]. We obtain most of our Swedish labor market statistics from Statistics Sweden (SCB).[20] We use the most recent statistic from 2017, which considers people aged 16-64 (Eriksson and Nguyen, 2019). For clerk and worker, we found labor market statistics in SCB (2018). For medical jobs, we used member statistics by Swedish Medical Association (SLF) from 2016.[21] Finally, we obtain statistics for China from National Bureau of Statistics (2004), which is based on census data from 2000.[22]

	Swedish	Danish	Russian	Chinese	US
Swedish	1.0	0.85	0.8	0.34	0.82
Danish	0.85	1.0	0.79	0.39	0.81
Russian	0.8	0.79	1.0	0.51	0.81
Chinese	0.34	0.39	0.51	1.0	0.38
US	0.82	0.81	0.81	0.38	1.0

Figure 1: Correlations between collected labor statistics. Numbers > 0.7 are significant ($p < 0.01$).

While labor statistics correlate strongly across countries (Table 1), U.S. statistics are not universal; e.g., almost all pathologist in the U.S. are women (97.5%), whereas the percentage for Denmark is 60%. In the U.S. and Sweden, the painter profession is very male-dominated, like mechanic and electrician (5.70% and 8% women, respectively), whereas in Russia, 57.0% of painters are women.

Correlation Results To assess the potential bias of using U.S. labor market statistics in multilingual experiments, we correlate the gender bias of models for language l with labor statistics from the U.S. and the country in which l is a national language, i.e., we correlate performance differences on Swedish ABC examples with both U.S. and Swedish labor statistics, Danish ABC examples with U.S. and Danish labor statistics, etc. We do so for the subset of occupations, where national gender statistics are available: **NLI** Correlations were stronger with national rather than U.S. statistics for Danish and Swedish (-0.35 vs. -0.28; -0.36 vs. -0.34). **Machine Translation**Correlations were

[19] `stats.oecd.org/`

[20] `www.scb.se/`

[21] `slf.se/app/uploads/2018/04/`

[22] We did not find reliable gender statistics for all occupations for all countries, but for 51 (Denmark), 50 (Sweden), 38 (Russia), and 10 (China) occupations. One reason was a mismatch between how gender statistics are reported in official reports, including how jobs are grouped. We release the numbers we were able to collect and will continuously work on obtaining more statistics.

stronger with national rather than U.S. statistics for Russian and Swedish (-0.31 vs. -0.20; -0.31 vs. -0.14). **Coreference Resolution** For coreference, we were able to correlate only the results for Chinese due to the fact that the coreference model for Russian only predicted clusters for sentences with male pronouns. The correlations with U.S. and Chinese labor market statistics were not significantly different because we only had statistics for 10 occupations. **Language Modeling** Correlations were stronger with national rather than U.S. statistics on average, but not significantly so.

6 Related Work

The ABC dataset is not first to focus on pronouns and gender bias. The UD English-Pronouns[23] (Munro, 2020), a manually constructed, gender-balanced benchmark of English sentences with pronouns, was motivated by the observation that the genitive pronoun *hers* only occurs three times in the English Universal Dependencies (Nivre et al., 2016). The gendered, ambiguous pronoun (GAP) dataset (Webster et al., 2018) is a coreference resolution dataset of human-annotated ambiguous pronoun-name examples from English Wikipedia. Prates et al. (2018) constructed a translation challenge dataset of simple sentences in gender-neutral languages such as Hungarian and Yoruba and English target sentences such as *he/she is an engineer* to estimate gender biases in machine translation. Both these challenge datasets focus on gender hallucinations, not unambiguous errors induced by gender bias. Some of our examples share similarities with the English WinoGender schema (Rudinger et al., 2018). Consider the following minimal pair of Winograd schema taken from their paper:

(16) The paramedic$_1$ performed CPR on the passenger$_2$ even though PRON$_1$ knew it was too late.

(17) The paramedic performed CPR on the passenger$_2$ even though PRON$_2$ was already dead.

In the Winograd schema, the context, i.e., the second clause, is supposed to disambiguate the pronoun on semantic grounds. In Example (16), the pronoun refers to the paramedic, because the patient is unlikely to know whether CPR is too late. In Example (17), the pronoun refers to the patient, because it is impossible to perform CPR if you are dead. Our examples, in contrast, do not disambiguate pronouns on semantic grounds and this is why we are interested in reflexive possessive pronouns: they always refer to the subject, and their anti-reflexive counterparts never do, so there is no grammatical ambiguity. The disadvantage with semantic disambiguation, we argue, is that it ultimately becomes a subjective competition of belief biases. It is generally impossible to perform CPR if you are dead, but special cases exist:

(18) Dr Jones$_1$ has turned into a zombie! He$_1$ performed CPR on the passenger even though he$_1$ was already dead.

The ABC dataset evaluates to what extent gender bias leads to unambiguous NLP errors not based on semantic grounds. Finally, Zhao et al. (2018) also include English examples with reflexive pronouns that can be resolved on syntactic grounds, such as:

(19) The secretary called the physician and told *him* about a new patient.

This construction, however, is less interesting than the reflexive possessive pronominal construction, since in this case, pronouns are always coreferential with the object position, regardless of the pronoun. In sum, the ABC challenge dataset is, to the best of our knowledge, the first dataset to focus on cases where gender bias leads to unambiguous errors; it is also the first multilingual, multi-task gender bias challenge dataset, and the first to focus on anti-reflexive pronouns.

7 Conclusion

In this work we have introduced the Anti-reflexive Bias Challenge (ABC) dataset for multilingual, multi-task gender bias detection, the first of its kind, including four languages and four tasks: machine translation, natural language inference, coreference resolution and masked language modeling. The ABC dataset focuses on a specific linguistic phenomenon that does not occur in English but is found in languages with *Type B reflexivization*: namely, anti-reflexive gendered pronouns. This phenomenon is shown to be useful for exposing unambiguous gender bias, because it quantifies to what extent gender bias leads to prediction *errors*, in contrast to just *unwarranted disambiguations* ('hallucinations'). The problem of anti-reflexive gendered pronouns has, to the best of our knowledge, not received attention before in the NLP literature, which tends to focus heavily on English (Bender and Friedman, 2018). Our evaluations of

---

[23] `universaldependencies.org/`

state-of-the-art models across the four tasks generally reveal significant gender biases leading to false predictions. Additionally, we find that for some tasks, these associations are more in line with national labor market gender statistics than with U.S. statistics, revealing another way that anglocentric biases can prohibit the detection of gender biases in our models.

A Example Data

We present example data for each task.

A.1 NLI

For each occupation, template and language in our NLI benchmark, we have three premise-hypothesis pairs. The hypotheses are identical. For the premises, we have three versions, one for each pronoun (the non-gendered reflexive possessive pronoun and and the two gendered, anti-reflexive possessive pronouns). Examples with reflexives are labeled `entailment`; examples with anti-reflexives are labeled `neutral`. An example datapoint for this task, with the label `entailment`, is shown in Table 3.

	NATURAL LANGUAGE INFERENCE

Table 3: Example data for NLI. For NLI, we only generate entailments and neutral statements. The English translation is shown for reference only.

A.2 Machine Translation

For machine translation, we have 4560 pairs of source sentences with masculine (*his*) and feminine possessive pronouns (*her*), respectively. We translate these into the target languages using off-the-shelf models and assess the tendency of these models to predict reflexive possessive pronouns in the target languages, instead of anti-reflexive possessive pronouns. An example of the data can be found in Table 4.

	MACHINE TRANSLATION
	SOURCE SENTENCE

zh	Gōngchéngshī cóng zhuōzi shàng zhāi xià *zìjǐ* de yǎnjìng

Table 4: Example data for machine translation.

A.3 Coreference Resolution

For coreference resolution, we are interested in whether the model is more likely to cluster a masculine possessive pronoun with the subject of the sentence than a feminine pronoun, even when this reading violates grammatical constraints. In Table 5, we list examples of how the task data would look. In brackets, we have mentions of an entity that can be clustered together by the system as belonging to the same coreference chain.

A.4 Language Modeling

For language modeling, we take a sentence containing a reflexive pronoun and swap the reflexive for the possessive masculine and feminine anti-reflexives; we then compute the perplexities of the original and perturbed sentences. Example of how this is framed can be found in Table 6.

B Coreference Dataset Statistics

In table 7 we show the number of documents used to train each system. For Chinese, the data is available with predefined train, development and test sets. For Russian, however, this is not specified, therefore we split the data 80-20-20.

Abstract

We investigate the following question for machine translation (MT): can we develop a single universal MT model to serve as the common seed and obtain derivative and improved models on arbitrary language pairs? We propose mRASP, an approach to pre-train a universal multilingual neural machine translation model. Our key idea in mRASP is its novel technique of random aligned substitution, which brings words and phrases with similar meanings across multiple languages closer in the representation space. We pre-train a mRASP model on 32 language pairs jointly with only public datasets. The model is then fine-tuned on downstream language pairs to obtain specialized MT models. We carry out extensive experiments on 42 translation directions across a diverse settings, including low, medium, rich resource, and as well as transferring to exotic language pairs. Experimental results demonstrate that mRASP achieves significant performance improvement compared to directly training on those target pairs. It is the first time to verify that multiple low-resource language pairs can be utilized to improve rich resource MT. Surprisingly, mRASP is even able to improve the translation quality on exotic languages that never occur in the pre-training corpus. Code, data, and pre-trained models are available at `https://github.com/linzehui/mRASP`.

1 Introduction

Pre-trained language models such as BERT have been highly effective for NLP tasks (Peters et al., 2018; Devlin et al., 2019; Radford et al., 2019; Conneau and Lample, 2019; Liu et al., 2019; Yang et al., 2019). Pre-training and fine-tuning has been a successful paradigm. It is intriguing to discover a "BERT" equivalent – a pre-trained model – for machine translation. In this paper, we study the following question: can we develop a single universal MT model and derive specialized models by fine-tuning on an arbitrary pair of languages?

While pre-training techniques are working very well for NLP task, there are still several limitations for machine translation tasks. First, pre-trained language models such as BERT are not easy to directly fine-tune unless using some sophisticated techniques (Yang et al., 2020). Second, there is a discrepancy between existing pre-training objective and down-stream ones in MT. Existing pre-training approaches such as MASS (Song et al., 2019) and mBART (Liu et al., 2020) rely on auto-encoding objectives to pre-train the models, which are different from translation. Therefore, their fine-tuned MT models still do not achieve adequate improvement. Third, existing MT pre-training approaches focus on using multilingual models to improve MT for low resource or medium resource languages. There has not been one pre-trained MT model that can improve for any pairs of languages, even for rich resource settings such as English-French.

In this paper, we propose multilingual Random Aligned Substitution Pre-training (mRASP), a method to pre-train a MT model for many languages, which can be used as a common initial model to fine-tune on arbitrary language pairs. mRASP will then improve the translation performance, comparing to the MT models directly trained on downstream parallel data. In our method, we ensure that the pre-training on many languages and the down-stream fine-tuning share the same model architecture and training objective. Therefore, this approach lead to large translation performance gain. Consider that many languages differ lexically but are closely related at the semantic level, we start by training a large-scale multilingual NMT model across different translation directions, then fine-tuning the model in a specific direction.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2649–2663,
November 16–20, 2020.

Further, to close the representation gap across different languages and make full use of multilingual knowledge, we explicitly introduce additional loss based on random and aligned substitution of the words in the source and target sentences. Substituted sentences are trained jointly with the same translation loss as the original multilingual parallel corpus. In this way, the model is able to bridge closer the representation space across different languages.

We carry out extensive experiments in different scenarios, including translation tasks with different dataset scales, as well as zero-shot translation tasks. For extremely low resource (<100k), mRASP obtains gains up to +29 BLEU points compared to directly trained models on the downstream language pairs. mRASP obtains consistent performance gains as the size of datasets increases. Remarkably, even for rich resource (>10M, e.g. English-French), mRASP still achieves big improvements. Surprisingly, even when mRASP is fine-tuned on two exotic languages that never occur in the pre-training corpus, the resulting MT model is still much better than the directly trained ones (+3.3 to +14.1 BLEU). We finally conduct extensive analytic experiments to examine the contributing factors inside the mRASP method for the performance gains.

We highlight our contributions as follows:

- We propose mRASP, an effective pre-training method that can be utilized to fine-tune on any language pairs in NMT. It is very efficient in the use of parallel data in multiple languages. While other pre-trained language models are obtained through hundreds of billions of monolingual or cross-lingual sentences, mRASP only introduces several hundred million bilingual pairs. We suggest that the consistent objectives of pre-training and fine-tuning lead to better model performance.

- We explicitly introduce a random aligned substitution technique into the pre-training strategy, and find that such a technique can bridge the semantic space between different languages and thus improve the final translation performance.

- We conduct extensive experiments 42 translation directions across different scenarios, demonstrating that mRASP can significantly boost the performance on various translation tasks. mRASP achieves 14.1 BLEU with only 12k pairs of Dutch and Portuguese sentences even though neither appears in the pre-training data. mRASP also achieves 44.3 BLEU on WMT14 English-French translation. Note that our pre-trained model only use parallel corpus in 32 languages, unlike other methods that also use much more monolingual raw corpus.

2 Methodology

In this section, we introduce our proposed mRASP and the training details.

2.1 mRASP

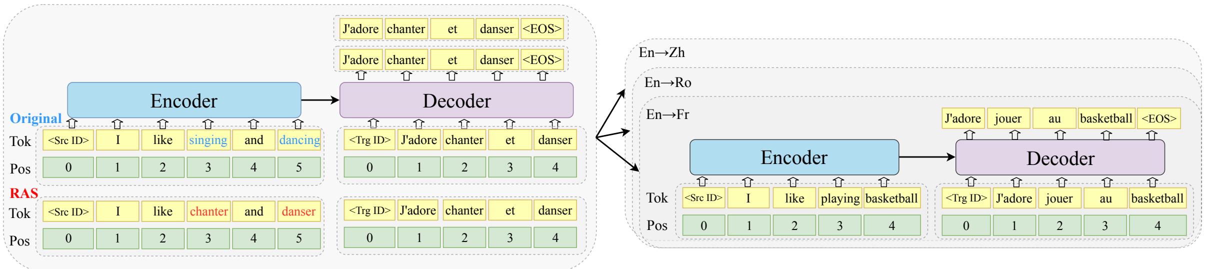
Architecture We adopt a standard Transformer-large architecture (Vaswani et al., 2017) with 6-layer encoder and 6-layer decoder. The model dimension is 1,024 on 16 heads. We replace ReLU with GeLU (Hendrycks and Gimpel, 2016) as activation function on feed forward network. We also use learned positional embeddings.

Methodology A multilingual neural machine translation model learns a many-to-many mapping function f to translate from one language to another. More formally, define $L = \{L_1, \ldots, L_M\}$ where L is a collection of languages involving in the pre-training phase. $\mathcal{D}_{i,j}$ denotes a parallel dataset of (L_i, L_j), and $\mathcal{E}$ denotes the set of parallel datasets $\{\mathcal{D}\}_{i=1}^{i=N}$, where N the numbers of the bilingual pair. The training loss is then defined as:

$$\mathcal{L}^{pre} = \sum_{i,j \in \mathcal{E}} \mathbb{E}_{(\mathbf{x}^i, \mathbf{x}^j) \sim \mathcal{D}_{i,j}} [-\log P_\theta(\mathbf{x}^i | C(\mathbf{x}^j))]. \tag{1}$$

where $\mathbf{x}^i$ represents a sentence in language L_i, and θ is the parameter of mRASP, and $C(\mathbf{x}^i)$ is our proposed alignment function, which randomly replaces the words in $\mathbf{x}^i$ with a different language. In the pre-training phase, the model jointly learns all the translation pairs.

Language Indicator Inspired by (Johnson et al., 2017; Ha et al., 2016), to distinguish from different translation pairs, we simply add two artificial language tokens to indicate languages at the source and target side. For instance, the following En→Fr sentence "`How are you? -> Comment vas tu?` " is transformed to "`<en> How are you? -> <fr> Comment vas tu?`"



Pre-training

Fine-tuning

Figure 1: The proposed mRASP method. "Tok" denotes token embedding while "Pos" denotes position embedding. During the pre-training phase, parallel sentence pairs in many languages are trained using translation loss, together with their substituted ones. We randomly substitute words with the same meanings in the source and target sides. During the fine-tuning phase, we further train the model on the downstream language pairs to obtain specialized MT models.

Multilingual Pre-training via RAS Recent work proves that cross-lingual language model pre-training could be a more effective way to representation learning (Conneau and Lample, 2019; Huang et al., 2019). However, the cross-lingual information is mostly obtained from shared subword vocabulary during pre-training, which is limited in several aspects:

- The vocabulary sharing space is sparse in most cases. Especially for dissimilar language pairs, such as English and Hindi, they share a fully different morphology.
- The same subword across different languages may not share the same semantic meanings.
- The parameter sharing approach lacks explicit supervision to guild the word with the same meaning from different languages shares the same semantic space.

Inspired by constructive learning, we propose to bridge the semantic gap among different languages through **Random Aligned Substitution (RAS)**. Given a parallel sentence $(\mathbf{x}^i, \mathbf{x}^j)$, we randomly replace a source word in $\mathbf{x}^i_t$ to a different random language L_k, where t is the word index. We adopt an unsupervised word alignment method MUSE(Lample et al., 2018b), which can translate $\mathbf{x}^i_t$ to $d_{i,k}(\mathbf{x}^i_t)$ in language L_k, where $d_{i,k}(\cdot)$ is the dictionary translating function. With the dictionary replacement, the original bilingual pair will construct a code-switched sentence pair $(C(\mathbf{x}^i), \mathbf{x}^j)$. As the benefits of random sampling, the translation set $\{d_{i,k}(\mathbf{x}^i_t)\}_{k=1}^{k=M}$ potentially appears in the same context. Since the word representation depends on the context, the word with similar meaning across different languages can share a similar representation. Figure 1 shows our alignment methodology.

2.2 Pre-training Data

We collect 32 English-centric language pairs, resulting in 64 directed translation pairs in total. English is served as an anchor language bridging all other languages. The parallel corpus are from various sources: *ted*[1], *wmt*[2], *europarl*[3], *paracrawl*[4], *open-subtitles*[5], *qed*[6]. We refer to our pre-training data as **PC32**(Parallel Corpus 32). **PC32** contains a total size of 197M pairs of sentences. Detailed descriptions and summary for the datasets can be found in Appendix.

For RAS, we utilize ground-truth En-X bilingual dictionaries[7], where X denotes languages involved in PC32. Since not all languages in PC32 have ground-truth dictionaries, we only use available dictionaries.

2.3 Pre-training Details

We use learned joint vocabulary. We learn shared BPE (Sennrich et al., 2016b) merge operations (with 32k merge ops) across all the training data and added monolingual data as a supplement (limit to 1M sentences). We do over-sampling in learning BPE to balance the vocabulary size of languages, whose resources are drastically different in size. We over-sampled the corpus of each language based on the volume of the largest language corpus. We

Table 1: Fine-tuning performance on *extremely low* / *low* / *medium* resource machine translation settings. The numbers in parentheses indicate the size of parallel corpus for fine-tuning. Pre-training with mRASP and then fine-tuning on downstream MT tasks consistently improves over MT models directly trained on bilingual parallel corpus.

keep tokens occurring more than 20, which results in a subword vocabulary of 64,808 tokens.

In pre-training phase, we train our model with the full pairs of the parallel corpus. Following the training setting in Transformer, we use Adam optimizer with $\epsilon = 1e-8, \beta_2 = 0.98$. A warm-up and linear decay scheduling with a warm-up step of 4000 is used. We pre-train the model for a total of 150000 steps.

For RAS, we use the top 1000 words in dictionaries and only substitute words in source sentences. Each word is replaced with a probability of 30% according to the En-X bilingual dictionaries. To address polysemy, we randomly select one substitution from all candidates.

3 Experiments

This section shows that mRASP obtains consistent performance gains in different scenarios. We also compare our method with existing pre-training methods and outperforms the baselines on En→Ro dataset. The performance further boosts by combining back-translation(Sennrich et al., 2016a) technique. Otherwise stated, for all experiments, we use the pre-trained model as initialization and fine-tune with the downstream target parallel corpus.

3.1 Experiment Settings

Datasets We collect 14 pairs of parallel corpus to simulate different scenarios. Most of the En-X parallel datasets are from the pre-training phase to avoid introducing new information. Most pairs for fine-tuning are from previous years of WMT and IWSLT. Specifically, we use WMT14 for En-De and En-Fr, WMT16 for En-Ro. For pairs like Nl(Dutch)-Pt(Portuguese) that are not available in WMT or IWSLT, we use news-commentary instead. For a detailed description, please refer to the Appendix.

---

[8] CTNMT only reports the Transformer-base setting.

Lang-Pairs Size	En→De 4.5M	Zh→En 20M	En→Fr 40M
Direct	29.3	24.1	43.2
CTNMT[8] (2020)	30.1	-	42.3
mBART (2020)	-	-	41.0
XLM (2019)	28.8	-	-
MASS (2019)	28.9	-	-
mBERT (2019)	28.6	-	-
mRASP	**30.3**	**24.7**	**44.3**

Table 2: Fine-tuning performance for popular *medium* and *rich* resource MT tasks. For fair comparison, we report detokenized BLEU on WMT newstest18 for Zh→En and tokenized BLEU on WMT newstest14 for En→Fr and En→De. Notice unlike previous methods (except CTNMT) which do not improve in the rich resource settings, mRASP is again able to consistently improve the downstream MT performance. It is the first time to verify that low-resource language pairs can be utilized to improve rich resource MT.

Based on the volume of parallel bi-texts, we divide the datasets into four categories: extremely low resource (<100K), low resource(>100k and <1M), medium resource (>1M and <10M), and rich resource (>10M).

For back translation, we include 2014-2018 newscrawl for the target side, En. The total size of the monolingual data is 3M.

Baseline To better quantify the effectiveness of the proposed pre-training models, we also build two baselines.

mRASP w/o RAS. To measure the effect of alignment information, we also pre-train a model on the same PC32. We do not include alignment information on this pre-training model.

Direct. We also train randomly initialized models directly on downstream bilingual parallel corpus as a comparison with pre-training models.

Fine-tuning We fine-tune our obtained mRASP model on the target language pairs. We apply a dropout rate of 0.3 for all pairs except for rich resource such as En-Zh and En-Fr with 0.1. We carefully tune the model, setting different learning rates and learning scheduler warm-up steps for different data scale. For inference, we use beam-search with beam size 5 for all directions. For most cases, We measure case-sensitive tokenized BLEU. We also report de-tokenized BLEU with SacreBLEU (Post, 2018) for a fair comparison with previous works.

3.2 Main Results

We first conduct experiments on the (extremely) low-resource and medium-resource datasets, where multilingual translation usually obtains significant improvements. As illustrated in Table 1, we obtain significant gains in all datasets. For extremely low resources setting such as En-Be (Belarusian) where the amount of datasets cannot train an NMT model properly, utilizing the pre-training model boosts performance.

We also obtain consistent improvements in low and medium resource datasets. Not surprisingly, We observe that with the scale of the dataset increasing, the gap between the randomly initialized baseline and pre-training model is becoming closer. It is worth noting that, for En→De benchmark, we obtain 1.0 BLEU points gains[9].

To verify mRASP can further boost performance on rich resource datasets, we also conduct experiments on En→Zh and En→Fr. We compare our results with two strong baselines reported by Ott et al. (2018); Li et al. (2019). As shown in Table 2, surprisingly, when large parallel datasets are provided, it still benefits from pre-training models. In En→Fr, we obtain 1.1 BLEU points gains.

Comparing to other Pre-training Approaches We compare our mRASP to recently proposed multilingual pre-training models. Following Liu et al. (2020), we conduct experiments on En-Ro, the only pairs with established results. To make a fair comparison, we report de-tokenized BLEU.

As illustrated in Table 4 , Our model reaches comparable performance on both En→Ro and Ro→En. We also combine Back Translation (Sennrich et al., 2016a) with our PNMT, observing performance boost up to 2 BLEU points, suggesting mRASP is complementary to BT. It should be noted that the competitors introduce much more pre-training data.

mBART contucted experiments on extensive language pairs. To illustrate the superiority of mRASP, we also compare our results with mBART. We use the same test sets as mBART. As illustrated in Table 5, mRASP outperforms mBART for most of language pairs by a large margin. Note that while mBART underperforms baseline for benchmarks En-De and En-Fr, mRASP obtains 4.3 and 2.9 BLEU gains compared to baseline.

---

[9] We report results of En→De on newstest14. The baseline result is reported in Ott et al. (2018)

MASS (2019)	-	-	**39.1**
BART (2020)	-	-	38.0
XLM-R (2020)	35.6	35.8	-
mBART (2020)	**37.7**	**37.8**	38.8
mRASP	37.6	36.9	38.9

Table 4: Comparison with previous Pre-training models on WMT16 En-Ro. Following (Liu et al., 2020), We report detokenized BLEU. We reaches comparable results on both En→Ro and Ro→En. By combining back translation, the performance further boost for 2 BLEU points on Ro→En.

3.3 Generalization to Exotic Corpus

To illustrate the generalization of mRASP, we also conduct experiments on exotic corpus, which is not included in our pre-training phase. Here we divide exotic corpus into four categories with respect to the source and target side.

- **Exotic Pair** Both source and target languages are individually pre-trained while they have not been seen as bilingual pairs.
- **Exotic Source** Only target language is pre-trained, but source language is not.
- **Exotic Target** Only source language is pre-trained, but the target language is not.
- **Exotic Full** Neither source nor target language is pre-trained.

For each category, we select language pairs of different scales. The results are shown in Table 3. As is shown, mRASP obtains significant gains for each category for different scales of datasets, indicating that even trained with exotic languages, with pre-training initialization, the model still works reasonably well.

Note that in the most challenging case, Exotic Full, where the model does not have any knowledge of both sides, with only 11K parallel pairs for Nl(Dutch)-Pt(Portuguese), the pre-training model still reaches reasonable performance, while the baseline fails to train appropriately. It suggests the pre-train model does learn language-universal knowledge and can transfer to exotic languages easily.

4 Analysis

In this section, we conduct a set of analytical experiments to better understand what contributes to performance gains. Three aspects are studied. First, we study whether the main contribution comes from pre-training or fine-tuning by comparing the performance of fine-tuning and no-fine-tuning. The results suggest that the performance mainly comes from pre-training, while fine-tuning further boosts

Table 5: Comprehensive comparison with mBART. mRASP outperforms mBART on MT for all but two language pairs.

the performance. Second, we thoroughly analyze the difference between incorporating RAS at the pre-training phase and pre-training without RAS. The finding shows that incorporating alignment information helps bridge different languages and obtains additional gains. Lastly, we study the effect of data volume in the fine-tuning phase.

The effects with fine-tuning .

In the pre-training phase, the model jointly learns from different language pairs. To verify whether the gains come from pre-training or fine-tuning, we directly measure the performance without any fine-tuning, which is, in essence, zero-shot translation task.

We select datasets covering different scales. Specifically, En-Af (41k) from extremely low resource, En-Ro (600k) from low resource, En-De (4.5M) from medium resource, and En-Fr (40M) from rich resource are selected.

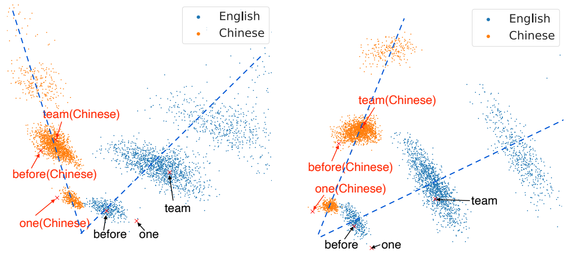
As shown in Table 6 , we find that model without fine-tuning works surprisingly well on all datasets, especially in low resource where we observe model without fine-tuning outperforms randomly initialized baseline model. It suggests that the model already learns well on the pre-training phase, and fine-tuning further obtains additional gains. We suspect that the model mainly tunes the embedding of specific language at the fine-tuning phase while keeping the other model parameters mostly unchanged. Further analytical experiments can be conducted to verify our hypothesis.

Note that we also report pre-trained model without RAS (NA-mRASP). For comparison, we do not apply fine-tuning on NA-mRASP. mRASP consistently obtains better performance that NA-mRASP, implying that injecting information at the pre-training phase do improve the performance.

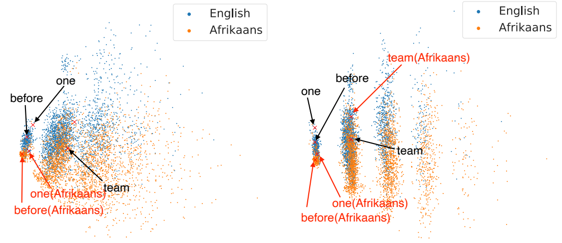
The effectiveness of RAS technique .

In the pre-training phase, we explicitly incorporate RAS. To verify the effectiveness of RAS, we first compare the performance of mRASP and mRASP without RAS.

As illustrated in Table 7, We find that utilizing RAS in the pre-training phase consistently helps improve the performance in datasets with different scales, obtaining gains up to 2.5+ BLEU points.



(a) en-zh w/o RAS (b) en-zh w/ RAS



(c) en-af w/o RAS (d) en-af w/ RAS

Figure 2: Visualization of Word Embedding from mRASP w/o RAS vs mRASP w/ RAS. For both similar language pairs and dissimilar language pairs that have no lexical overlap, the word embedding distribution becomes closer after RAS.

To verify whether the semantic space of different languages draws closer after adding alignment information quantitatively, we calculate the average cosine similarity of words with the same meaning in different languages. We choose the top frequent 1000 words according to MUSE dictionary. Since words are split into subwords through BPE, we

Lang-Pairs	En-Af		En-Ro		En-De		En-Fr	
Size	41K		600k		4.5M		40M	
Direction	→	←	→	←	→	←	→	←
Direct	8.3	7.2	30.5	29.2	29.3	30.8	43.2	39.8
mRASP *w/o RAS & ft*	16.1	23.2	24.4	33.9	22.5	30.9	38.6	37.3
mRASP *w/o ft*	18.5	23.9	25.2	34.7	24.2	31.2	39.6	37.6
mRASP	31.1	27.0	39.0	37.4	30.3	34.4	44.3	45.4

Table 6: MT performance of mRASP with and without the RAS technique and fine-tuning strategy. mRASP includes both the RAS technique and fine-tuning strategy. "*w/o ft*" denotes "without fine-tuning". We also report mRASP without fine-tuning and NAS to compare with mRASP without fine-tuning. Both RAS and fine-tuning proves effective and essential for mRASP.

Lang-Pairs	En-Af		En-Ro		En-De	
Direction	→	←	→	←	→	←
. w/o RAS	30.6	25.4	36.3	36.4	27.7	33.2
mRASP	31.1	27.0	39.0	37.4	30.3	34.4

Table 7: The MT performance of three language pairs with and without alignment information (mRASP w/o RAS) at pre-training phase. We see consistent performance gains for mRASP with RAS.

simply add all subwords constituting the word. As illustrated in Figure 3, we find that for all pairs in the Figure, the average cosine similarity increases by a large margin after adding RAS, suggesting the efficacy of alignment information in bridging different languages. It is worth mentioning that the increase does not only happen on similar pairs like En-De, but also on dissimilar pairs like En-Zh.

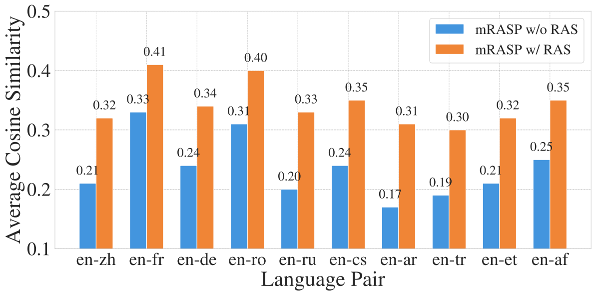


Figure 3: Average cosine similarity No-Alignment (mRASP w/o RAS) vs Alignment (mRASP w/ RAS). The similarity increases after applying the RAS technique, which explains the effectiveness of RAS.

To further illustrate the effect of RAS on semantic space more clearly, we use PCA (Principal Component Analysis) to visualize the word embedding space. We plot En-Zh as the representative for dissimilar pairs and En-Af for similar pairs. More figures can be found in the Appendix.

As illustrated in Figure 2, we find that for both similar pair and dissimilar pair, the overall word embedding distribution becomes closer after RAS. For En-Zh, as the dashed lines illustrate, the angle of the two word embedding spaces becomes smaller after RAS. And for En-Af, we observe that the overlap between two space becomes larger. We also randomly plot the position of three pairs of words, with each pair has the same meaning in different languages.

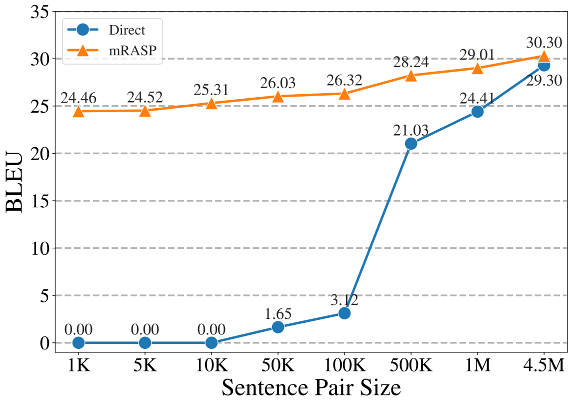

Figure 4: Performance curves for En→De along with the size of parallel pairs. With mRASP pre-trained model, the fine-tuned down-stream MT model is able to obtain descent translation performance even when there is very small corpus to train.

Fine-tuning Volume To study the effect of data volume in the fine-tuning phase, we randomly sample 1K, 5K, 10K, 50K, 100K, 500K, 1M datasets from the full En-De corpus (4.5M). We fine-tune the model with the sampled datasets, respectively. Figure 4 illustrates the trend of BLEU with the increase of data volume. With only 1K parallel pairs, the pre-trained model works surprisingly well, reaching 24.46. As a comparison, the model with random initialization fails on this extremely low resource. With only 1M pairs, mRASP reaches comparable results with baseline trained on 4.5M pairs.

With the size of dataset increases, the performance of the pre-training model consistently increases. While the baseline does not see any improvement until the volume of the dataset reaches 50K. The results confirm the remarkable boosting of mRASP on low resource dataset.

5 Related Works

Multilingual NMT aims at taking advantage of multilingual data to improve NMT for all languages involved, which has been extensively studied in a number of papers such as Dong et al. (2015); Johnson et al. (2017); Lu et al. (2018); Rahimi et al. (2019); Tan et al. (2019). The most related work to mRASP is Rahimi et al. (2019), which performs extensive experiments in training massively multilingual NMT models. They show that multilingual many-to-many models are effective in low resource settings. Inspired by their work, we believe that the translation quality of low-resource language pairs may improve when trained together with rich-resource ones. However, we are different in at least two aspects: *a)* Our goal is to find the best practice of a single language pair with multilingual pre-training. Multilingual NMT usually achieves inferior accuracy compared with its counterpart, which trains an individual model for each language pair when there are dozens of language pairs. *b)* Different from multilingual NMT, mRASP can obtain improvements with rich-resource language pairs, such as English-Frence.

Unsupervised Pretraining has significantly improved the state of the art in natural language understanding from word embedding (Mikolov et al., 2013b; Pennington et al., 2014), pretrained contextualized representations (Peters et al., 2018; Radford et al., 2019; Devlin et al., 2019) and sequence to sequence pretraining (Song et al., 2019). It is widely accepted that one of the most important factors for the success of unsupervised pre-training is the scale of the data. The most successful efforts, such as RoBERTa, GPT, and BERT, highlight the importance of scaling the amount of data. Following their spirit, we show that with massively multilingual pre-training, more than 110 million sentence pairs, mRASP can significantly boost the performance of the downstream NMT tasks.

On parallel, there is a bulk of work on unsupervised cross-lingual representation. Most traditional studies show that cross-lingual representations can be used to improve the quality of monolingual representations. Mikolov et al. (2013a) first introduces dictionaries to align word representations from different languages. A series of follow-up studies focus on aligning the word representation across languages (Xing et al., 2015; Ammar et al., 2016; Smith et al., 2017; Lample et al., 2018b). Inspired by the success of BERT, Conneau and Lample (2019) introduced XLM - masked language models trained on multiple languages, as a way to leverage parallel data and obtain impressive empirical results on the cross-lingual natural language inference (XNLI) benchmark and unsupervised NMT(Sennrich et al., 2016a; Lample et al., 2018a; Garcia et al., 2020). Huang et al. (2019) extended XLM with multi-task learning and proposed a universal language encoder.

Different from these works, *a)* mRASP is actually a multilingual sequence to sequence model which is more desirable for NMT pre-training; *b)* mRASP introduces alignment regularization to bridge the sentence representation across languages.

6 Conclusion

In this paper, we propose a multilingual neural machine translation pre-training model (mRASP). To bridge the semantic space between different languages, we incorporate word alignment into the pre-training model. Extensive experiments are conducted on different scenarios, including low/medium/rich resource and exotic corpus, demonstrating the efficacy of mRASP. We also conduct a set of analytical experiments to quantify the model, showing that the alignment information does bridge the gap between languages as well as boost the performance. We leave different alignment approaches to be explored in the future. In future work, we will pre-train on larger corpus to further boost the performance.

Acknowledgments

We would like to thank the anonymous reviewers for their valuable comments. We would also like to thank Liwei Wu, Huadong Chen, Qianqian Dong, Zewei Sun, and Weiying Ma for their useful suggestion and help with experiments.

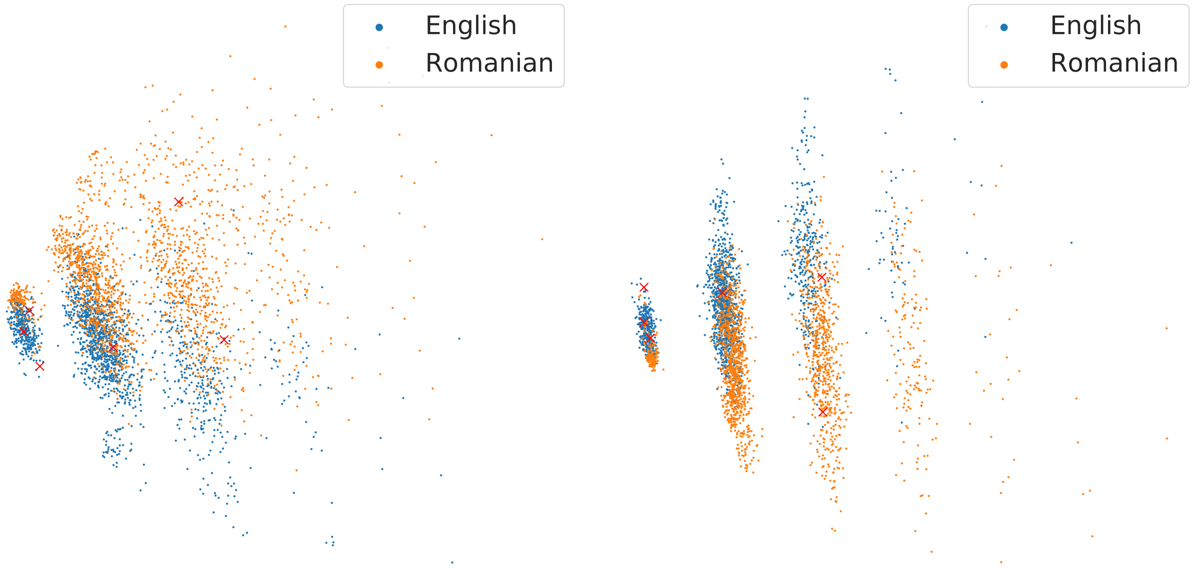
A Appendices

A.1 Visualization of Word Embedding

In addition to visualization of En-Zh and En-Af presented in main body of paper, we also plot visualization of En-Ro, En-Ar, En-Tr and En-De. As shown in Figure 5,6,7,8, the overall word embedding distribution becomes closer after RAS.

A.2 Data Description

As listed in Table 8, we collect 32 English-centric language pairs, resulting in a total pairs of 110M. The parallel corpus are from various source, ted, wmt, europarl, paracrawl, opensubtitles and qed.



(a) en-ro w/o RAS (b) en-ro w/ RAS

Losing Heads in the Lottery:
Pruning Transformer Attention in Neural Machine Translation

Abstract

The attention mechanism is the crucial component of the transformer architecture. Recent research shows that most attention heads are not confident in their decisions and can be pruned after training. However, removing them before training a model results in lower quality. In this paper, we apply the lottery ticket hypothesis to prune heads in the early stages of training, instead of doing so on a fully converged model. Our experiments on machine translation show that it is possible to remove up to three-quarters of all attention heads from a transformer-big model with an average -0.1 change in BLEU for Turkish→English. The pruned model is 1.5 times as fast at inference, albeit at the cost of longer training. The method is complementary to other approaches, such as teacher-student, with our English→German student losing 0.2 BLEU at 75% encoder attention sparsity.

1 Introduction

The transformer model (Vaswani et al., 2017) performs well for a variety of tasks, including neural machine translation (Dong et al., 2018; Grundkiewicz and Junczys-Dowmunt, 2019; Junczys-Dowmunt, 2018). However, like many neural networks, it is overparametrised, and inference is costly. Attention heads are the headline feature of the transformer model, essential to learning relationships between words as well as complex structural representations. Voita et al. (2019) showed that many of these heads could be pruned in a fully trained model, but removing the same heads before training yielded lower quality. We investigate a third way: pruning heads in early training. Empirically our method enables even more pruning, which is useful for faster machine translation.

Reinitialising a model with the same pruned structure underperformed in Voita et al. (2019), which is consistent with the lottery ticket hypothesis (Frankle and Carbin, 2019). According to the lottery ticket hypothesis, randomly initialising a model is akin to buying lottery tickets and a smaller network, such as a pruned model, buys fewer tickets. Prior lottery ticket research prunes individual parameters to form a sparse network; we show that this logic extends to entire transformer heads. We follow lottery ticket training strategies (Frankle et al., 2019) to prune in early training, achieving a better trade-off between pruning and quality than pruning after training (Voita et al., 2019).

Our main goal is faster inference speed for machine translation deployment with minimal impact on quality. Pruning heads means they can be removed from the model entirely (with other heads shifted down), resulting in a layer configured to have fewer heads. Unlike most work on pruning (Zhu and Gupta, 2017; Gale et al., 2019), there is no need for sparse matrices, block-sparse matrix operators, or additional masking. In particular, we go further than Voita et al. (2019) by removing rather than masking.

In this paper we combine findings of both Voita et al. (2019) ("what") and Frankle and Carbin (2019) ("how") to prune attention heads. First, we define a training scheme based on an iterative approach that does not require full convergence of a model each time partial pruning takes place. To analyse the impact of pruning in a variety of settings, we experiment with a stock and highly optimised system across two language pairs: Turkish→English and English→German. We present and analyse our results in Sections 7 and 8.

Our key findings show that:

1. The lottery ticket hypothesis can be applied to prune whole blocks of parameters, instead of removing them separately.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2664–2674,
November 16–20, 2020.

2. Most attention heads can be removed early into training without significant damage to quality. The most aggressive attention pruning loses about 1 BLEU point with 80-90% block sparsity.
3. The lottery ticket approach achieves better results than a model trained from scratch with the same structure.
4. Pruned models exhibit patterns in regards to a number of heads in layers. For example, context attention gets more important as layers go on. The decoder requires self-attention only in the first layer — the rest is redundant, thus removable.

2 Related work

Magnitude pruning is one of the simplest algorithms, in which the smallest weights are removed. Successfully applied to NMT (See et al., 2016), this method works on a coefficient level and often requires retraining to recover the damage done by pruning. Further research shows that training a model from scratch with the same structure as the pruned one yields subpar results. Finishing training is a necessary step to reduce the size of a model (Gale et al., 2019) without too much damage. However, the sparsity of singular weights is generally too low to be efficiently exploited by a CPU or GPU. Block sparsity (Narang et al., 2017) is more hardware friendly because masked blocks can be skipped entirely. In this paper, we concentrate on a specific case of block sparsity that removes entire attention heads from a model without masking.

Brix et al. (2020) applied the lottery ticket hypothesis and other techniques to prune individual coefficients from a transformer for machine translation. In their experiments, a stabilised version of lottery ticket pruning damages translation quality by 2 BLEU points while removing 80% of all parameters. They improve upon that further by proposing a mix of lottery ticket and magnitude pruning. In their work, all layers are pruned the same amount, whereas our work prunes globally to reveal which layers can be pruned more aggressively. They aimed to compress the model and did not report any speed results, subsequently clarifying after their presentation that they did not achieve a speed improvement. Here, we aim for speed and only marginal improvements to size. Rather than prune individual coefficients, we pruned entire heads which can then be removed from the model entirely without even calling a sparse matrix routine.

Pruning is usually done at the end of training and then requires either retraining or tuning. There is an ongoing research field on integrating pruning into training For example, Golub et al. (2018) pruned weights that have accumulated the lowest total gradients and reduces the memory footprint to allow training much larger models than possible on available hardware. Our lottery ticket method does not require to modify a training algorithm and can be easily scripted to work “out of the box” with existing toolkits.

Xiao et al. (2019) observed that numerous computations in the attention mechanism are redundant with many layers sharing similar distributions. They proposed reusing attention output within adjacent layers in a model, which requires a model to learn which layers should be allowed to share outputs. This reuse of parameters could be understood as a pruning method that concentrates on removing vertical redundancy, in contrast to our research, which is more horizontal.

Since the attention mechanism is expensive to use in a decoder — with $O(n^2)$ complexity looping when generating translations — the better option would be to replace it with less expensive equivalent. In our teacher-student experiments, Simpler Simple Recurrent Unit (SSRU) (Kim et al., 2019) replaces the decoder self-attention mechanism. Still, this approach leaves an encoder and context between them unchanged. The lottery ticket pruning is complementary and can remove encoder and context heads on the top of it.

Looking into an impact of attention on output, Serrano and Smith (2019) analysed a text classification task whether “high attention weights correlate with greater impact on model predictions”. They argued that, in contrast to a simple classification, “for tasks with a much larger output space (such as language modelling or machine translation) . . . almost anything may flip the decision”. However, according to our experiments, careful head removal based on their importance does not damage quality.

3 Background

The usual approach to pruning assumes that a model is converged first and pruned second, optionally with continued training. Frankle et al.

(2019) have shown that iteratively pruning a model uncovers smaller and better quality subnetworks in comparison to pruning just once at the end. Still, training a model until convergence at every pruning iteration is too expensive to utilise for most architectures. For this reason, Frankle et al. (2019) introduced *late resetting* and *early turnaround*. Both of these methods combined shorten training time of each step in the iterative lottery scheme. Late resetting reverts parameters after pruning back to a checkpoint from early stages of training, not to the starting initialisation. Early turnaround means a model does not need to be fully trained to make a pruning decision but can approximate that by doing short training loops.

Lottery ticket pruning has been applied to natural language processing (NLP) tasks, including NMT (Yu et al., 2020). The winning ticket for that task was "remarkably robust to pruning" of singular weights if embeddings were spared from pruning. However, Yu et al. (2020) noted a linear drop in BLEU with sparsit.

Voita et al. (2019) analysed the attention mechanism and noticed that the majority of heads are useless: they either do not have linguistically interpretable roles or cannot make reliable choices when making alignments. Those heads were pruned by tuning a model with a L_0 regulariser that progressively switched off less essential heads. The L_0 regulariser needs a model to be fully trained first and then pruned while tuned. In contrast, our paper focuses on pruning heads as early as possible in training so that a model can converge with them removed. Using their selection heuristic, empirically we can safely prune more heads overall.

4 Methodology

In this section, we describe the lottery ticket approach as well as the decision heuristic based on attention importance (Voita et al., 2019) to remove heads in our models.

4.1 Lottery ticket

We apply an iterative pruning strategy based on Frankle and Carbin (2019), which introduced the lottery ticket hypothesis:

> *A randomly-initialized, dense neural network contains a subnetwork that is initialized such that – when trained in isolation – it can match the test accuracy of the original network after training for at most the same number of iterations.*

In other words, some parts of the network were luckily initialized and perform most of the work.

One could train a complete model, identify unlucky heads with a pruning heuristic, and retrain the pruned model starting with the same initialization.[1] This approach is expensive because the model is trained twice. Frankle et al. (2019) pointed out that unlucky parameters can be identified earlier in convergence, so it is not necessary to fully train a complete model first. We follow their work by partially training a model to make a pruning decision.

Frankle and Carbin (2019) reported that pruning iteratively yields smaller higher-quality networks that converge faster than those pruned in a single round. Removing most of the attention heads in one go seems too drastic using a simple heuristic, since other heads in layers may adapt to having fewer parameters and the roles of pruned heads may even transfer to those that are still active. For all these reasons, we apply a loop that iteratively prunes attention heads guided by partial training (Section 2). The training scheme is presented in Figure 1.

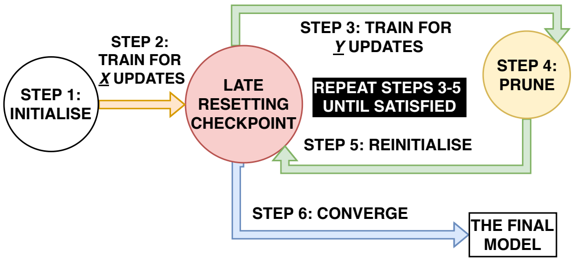

Figure 1: Iterative lottery ticket pruning.

First, we train a model for a set number of updates and keep it as a late resetting checkpoint. Then the pruning phase starts — the model trains for a while, and selected heads are removed to have other parameters reinitialised to the checkpoint mentioned earlier at the end. That loop repeats until we are satisfied with how many parameters were removed. Finally, the pruned model can be converged.

---

[1] The order of data fed into a model is also retained among experiments.

4.2 Attention confidence

The lottery ticket hypothesis explains how pruning should progress, but the question remains: which heads should be removed in each pruning iteration? Inspired by Voita et al. (2019), we are mostly interested in heads that are *confident* in their decisions, which Voita et al. (2019) has shown to correlate with major identifiable roles attention heads performs. In their analysis, an attention head is defined as confident when it assigns a large weight to one of the words within a sentence That head should routinely make strong alignments to be considered a candidate to remain in a model.

When a head appears, its softmax layer computes a probability distribution over the words it attends to. We record the maximum of this probability distribution as confidence. For example, a context head attends over source words s.

$$\text{confidence} = \max_{s} \text{attention}(s)$$

These confidence values are averaged over all times the head appears while translating a development corpus. For example, a context head appears once per word in the output, so its confidence is averaged over all words in the output.

5 Baseline approaches

5.1 Just fewer attention heads

Do we even need to prune attention heads at all? Can we train a model that has fewer heads from the beginning? The typical transformer implementation described by Vaswani et al. (2017) initialises attention matrices based on the embedding dimension and those matrices are split into separate heads. That means the fewer heads there are set to be in a model, the larger they are. To compare models with different number of heads fairly, we fix their size to a constant instead.

We use all the parallel data allowed by the constrained condition of the WMT17 news task (Bojar et al., 2017) for English→German ($4.56M$ sentences) following a standard preprocessing: normalisation, tokenisation, truecasing using Moses scripts, and BPE segmentation (Sennrich et al., 2016) with 36000 subwords. We tried training a model with 32 heads but could not due to memory constraints. For that reason, we start with a typical transformer-big (Vaswani et al., 2017) architecture using recommended hyperparameters. It has 16 heads of size 64 ($64 \times 16 = 1024$). Then, we train the same model but with 8, 4 and 2 heads of the same size. The results are below in Table 1.

Model	Heads	wmt14	wmt15	wmt16	Avg.
Transformer-big	16	26.7	29.8	33.9	30.1
Transformer-big-8	8	27.2	29.7	34.2	30.4
Transformer-big-4	4	26.1	29.0	34.2	29.8
Transformer-big-2	2	26.0	29.0	33.6	29.5

Table 1: A transformer-big with different number of heads for English→German.

When it comes to quality, the model needs a reasonable number of attention heads to perform well. The more this number is reduced, the worse the quality. However, more heads does not necessarily equal better translation quality. We concur that 8 heads per layer strikes a perfect balance between memory consumption and quality degradation.

5.2 Voita et al. (2019) pruning

Using the same language pair and dataset, we tried a pruning method presented by Voita et al. (2019). We used their Tensorflow implementation[2] with their training scripts, in which they set up a transformer-base architecture that it to be pruned globally. The pruning scheme requires a baseline model to fully converge first and then tuned with a regulariser that masks the heads. The attention sparsity is controlled by a λ hyperparameter.

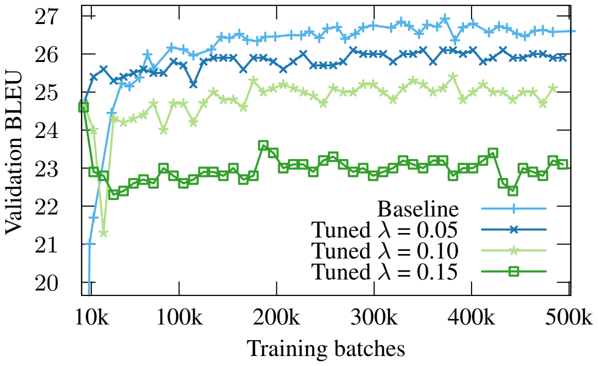

Figure 2: Validation BLEU for English→German transformer-base baseline and pruned with Voita et al. (2019) models.

The main focus of Voita et al. (2019) was attention analysis and its behaviour, rather than pruning and efficiency. Even though we used the authors'

$\lambda = 0.15$	67%	23.5	25.8	28.8	26.0	-4.30

Table 2: Evaluation BLEU of English→German transformer-base models pruned with Voita et al. (2019)

implementation and the baseline achieved a reasonable score, pruning degraded its quality. Looking at Figure 2, the more sparsity was enforced with regularisation, the lower the translation quality. Even though we tuned for as long as the baseline training, the models do not recover. We tried experimenting with various hyperparameters settings such as learning rate and its scheduling, but to no further success.

5.3 Michel et al. (2019) pruning

Michel et al. (2019) experiment with pruning during and after training using a different heuristic: they introduce a mask variable for each head then define importance as the gradient of loss with respect to the mask variable. Their results are quite poor: pruning 40% of the total heads results in "staying within 85–90% of the original BLEU score". Results of pruning after training are worse: about 3 BLEU points lost with 40% sparsity and 10 BLEU points lost with 60% sparsity.[3] In our experiments, we see no loss in average BLEU at 67% sparsity.

We attribute our superior performance to adopting best practices for pruning during training (Frankle et al., 2019) and the choice of heuristic following Voita et al. (2019) instead.

Michel et al. (2019) reported that important heads emerge at the beginning of training. This supports our hypothesis that pruning during training will outperform pruning after training.

6 Setup

In order to investigate how effectively pruning works, we concentrate on two language pairs: Turkish→English and English→German. The first one is considered a low-resource, even with additional back-translated data. In contrast, English→German is a high-resource language pair with English not being a target language. We trained and decoded our models using the Marian machine translation toolkit (Junczys-Dowmunt et al., 2018a).

Turkish→English We use all the parallel data allowed by the constrained condition of the WMT18 (Bojar et al., 2018). The corpus consists of ~200 000 parallel sentences plus an additional 800 000 sampled from News Crawl and back-translated using a shallow NMT model trained on the existing small bilingual corpora (Haddow et al., 2018). We use the development and test sets provided in 2016. We also evaluate on the 2017 and 2018 testsets.

The preprocessing follows the steps of normalisation, tokenisation, truecasing using Moses scripts, and BPE segmentation (Sennrich et al., 2016). The vocabulary is shared and contains 36000 words. The architecture is transformer-big (Vaswani et al., 2017), trained using default recommended settings for such a model in Marian toolkit.[4] The models trained until cross-entropy has stopped improving for 10 consecutive validations, and select model checkpoints with highest BLEU scores.

English→German To measure impact on the speed of a highly optimized system, we follow the Workshop on Neural Generation and Translation 2020 Efficiency Shared task.[5] The shared task specified English→German translation under the WMT 2019 data condition (Barrault et al., 2019). As is standard for efficient translation, we applied teacher-student training (Kim and Rush, 2016) using the sentence-level system submitted by Microsoft to the WMT 2019 News Translation Task (Junczys-Dowmunt, 2019). The student models have a standard 6-layers transformer encoder (Vaswani et al., 2017) but the decoder is a faster two-layer Simpler Simple Recurrent Unit (SSRU) (Kim et al., 2019). The embedding dimension is 256, feed-forward network size is 1536. The models use shared vocabulary of 32,000 subword units created with SentencePiece (Kudo and Richardson, 2018).

All student models were trained on 13M sentences of available parallel data, using the concatenated English-German WMT testsets from 2016-2018 as a validation set.[6] The models were trained

---

[3] Comparisons are based on their reported numbers, which use non-standard tokenized BLEU (Post, 2018).

[6] The validation sentences were not teacher-translated.

until BLEU stopped improving for 20 consecutive validations to overfit the teacher, and the checkpoint with highest BLEU scores was selected. Since a student model should mimic the teacher as closely as possible, we did not use regularization like dropout and label smoothing. Other training hyperparameters were Marian defaults for training a Transformer Base model.[7] Student models have sharp probability distributions so we translate using beam size 1. Thanks to those settings, the baseline translates about 2335 words per second on a single CPU core.

7 Experiments

The goal is to prune as many heads as possible without damaging translation quality. The pruning procedure has some hyperparameters: the late resetting point, how long to train before making a pruning decision and how many heads to prune each iteration. Exploring this space is expensive; we arbitrarily set these to 5–6 saving checkpoints (25k batches for en–de, 12k for tr–en) Each pruning iteration have run for 3-4 checkpoints (15k batches for en–de, 8k for tr–en) after which selected attention heads are removed. The number of heads removed is roughly a total number of layers containing attention divided by 2. Removing less than that makes pruning slow and removing more in one go results in a unified distribution of attention heads (it usually picks one head per layer) and may be too aggressive in some cases. In each iteration, we change a seed value to make a model see data in different order.

We focus on results roughly within 50% to 85% heads removed. This range covers the interesting part from minor to noticeable degradation in translation quality. To evaluate an iteration, heads are pruned as usual then we reset the model back to the late resetting checkpoint and continue training to completion.

7.1 Transformer-big (Turkish→English)

Since we have shown that there is no need for having 16 heads per layer in transformer-big architecture (Section 5.1), we halve our attention matrices to start pruning from 8 heads per layer to save time. Thus, the model has 144 attention heads in total: 48 (6 layers with 8 heads each) self-attention heads in the encoder, 48 self-attention heads in the decoder, and 48 context heads in the decoder that attend to the encoder. The model was pretrained for 12k batches. Then, we train in a loop for 8k updates, remove 8 heads, revert and repeat until satisfied. The convergence progression is presented in Figure 3.

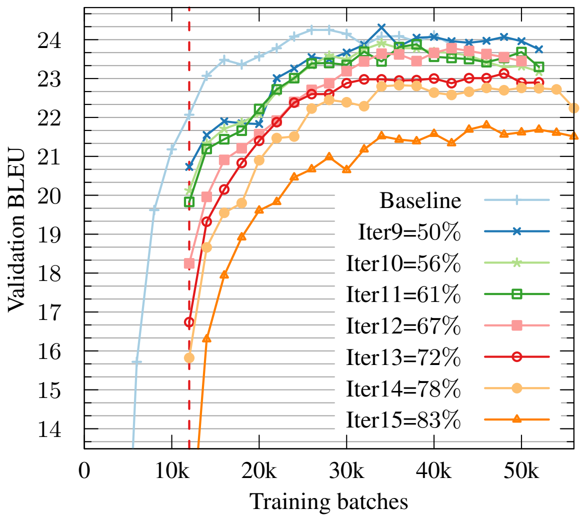

Figure 3: Convergence of Turkish→English models after removing a given percentage of all attention heads.

The baseline reaches the top BLEU scores quicker, but many pruned models still achieve competitive results later in training. The dashed vertical line shows the late resetting checkpoint. Pruning up to 61–67% (Iter. 11–12 in Figure 3) of the heads leads to longer convergence times, but nearly the same BLEU results on the development set. There is a breaking point of considerable damage at about 83% heads removed.

In Table 3, we perform evaluation and calculate the average difference in BLEU between the unpruned and pruned models. Similarily to training validation, pruning up to 72% of heads mostly maintains quality, then degrades progressively beyond that point.

7.2 Tiny student (English→German)

In this model, the decoder is already reduced to two tied layers. Since in self-attention is replaced with an SSRU anyway and context is not prioritised by our algorithm, we focus on pruning only the encoder.

We pretrained the model for 25k batches, with each pruning iteration lasting 15k updates and removing 3 heads from the encoder. The results are presented in Table 4. The models follow the trend set by our Turkish→English experiments — 75% of encoder heads can be removed with slight (-0.2)

damage to the quality. Pruning more than that is a trade-off between sparsity and quality.

In conclusion, the lottery ticket approach successfully pruned attention heads in both large transformer model and a tiny student architecture based on a simple heuristic; we leave the general case of block-sparse pruning to future work.

8 Analysis

In this section, we further analyse our pruning results in terms of pruning progress and head distribution. We reinitialise our pruned English→German models to demonstrate that the advantage of pruning comes from lucky initialisation, not the architecture itself.

Head distribution In both Table 3 and 4, we present attention distribution as it changes throughout pruning iterations. Each attention prioritised heads differently depending on layer depth and which attention type it is. Looking at Turkish→English results, the decoder attention is pruned more eagerly with more and more heads removed in each layer. The first layer seems to be crucial, others almost not at all. This seems to explain the trend of student models having 1–2 decoder layers and still performing well. The context attention interlocks with the decoder self-attention with each consecutive layer gaining more importance than the previous one. When it comes to the encoder in both language pairs, the middle layers do not hold the same significance as the first and last ones.

Architecture or initialisation? To check if the lottery ticket hypothesis is right in the context of our paper, we reinitialise our pruned models while keeping their structure. We compare average BLEU difference between pruned (Table 4) and trained from scratch (Table 5) models.

There is a consistent quality gap between pruned and reinitialised models that widens with sparsity. It confirms the assumptions made by the lottery ticket hypothesis: starting with a larger model and then deliberately selecting attention heads reveals which are the “winning tickets” in the initialisation lottery.

9 Speed

The main objective of our research is to remove heads from a transformer to make inference faster. For this reason, we make a trade-off between a total training time and inference speed, which is particularly useful in an industry production environment. In Table 6, we compare how long it takes to prune and train a model in comparison to the baseline approach. In practice, if a model trains for 2–3 days, an additional day is needed for a pruning procedure.

To compare translation speed, we select the

Model	Params	Sparsity	Enc. heads	wmt16	wmt17	wmt18	wmt19	Avg.	Δ
Baseline	15,7M	0%	8 8 8 8 8 8	36.4	29.3	43.2	39.9	37.2	-
Reinit i9	14,8M	56.25%	5 1 3 1 5 6	36.5	28.9	43.1	40.0	37.1	-0.1
Reinit i10	14,7M	62.50%	4 1 2 1 4 6	36.4	28.9	43.0	39.6	37.0	-0.2

Table 7: Translation speed comparison between baseline and the best pruned models (converged at 13th and 12th pruning iterations in the respective models).

models with the best Pareto trade-off between quality and sparsity. The speed comparison is presented in Table 7.

Despite attention heads being just a small fraction of all parameters (~5% fewer parameters with about 10% size reduction), pruning them lessens the burden on inference significantly. Since all three attention types were pruned in transformer-big experiments, the speed-up is considerable — the model is 1.5 times faster with 0.3 BLEU loss.

In their paper among many reported models, Junczys-Dowmunt et al. (2018b) achieved 8.57× speed-up with −0.8 BLEU loss on GPU when scaling down from transformer-big teacher to transformer-base student. In another experiment, they gained 1.31× speed-up with −0.6 BLEU when using int8 quantisation on CPU. Our method is complementary to those as lottery ticket pruning can always remove heads on the top of existing solutions.

Continuing that line of thought, our small student model translates about 10% faster when pruned. However, it is important to remember that decoder is the key reason why the transformer is slow and it has already been optimized with an SSRU. This means there is a smaller margin of improvement in this type of a model. Again, attention pruning in this case is complementary and pushes the state-of-the-art even further. Just for comparison, we also include the baseline models trained with half (4) and one (1) attention head in each layer (including context attention). The model with just one head everywhere is slightly faster than our pruned model but at the cost of 2 BLEU points. This clearly shows again that careful pruning gives much better results than just training a smaller model from the start.

To compare our work with the state-of-the-art in machine translation speed, we submitted English→German student models to the WNGT2020 efficiency shared task (Bogoychev et al., 2020). These submissions were converged on a larger amount of data to maximize quality. Since our method usually selects one head to remove per layer, we experimented with more aggressive and lenient pruning by removing 3 and 6 heads per iteration respectively. These submissions were on the Pareto frontier for speed and quality, meaning that no other submission was simultaneously faster and higher quality.

The speed-up is about 10% on CPU with 75% encoder heads removed (Tab. 8). In terms of on GPU, our best pruned model gains 15% speed-up w.r.t. words per second (WPS) losing 0.1 BLEU in comparison to an unpruned model (Tab. 9). These results show that even when tested on a

Model	Enc. heads	Params.	Size	BLEU WMT19	 WMT1*	WPS
Tiny	8 8 8 8 8 8	15.7M	61MB	41.5	32.9	2050

Tiny.Pushy.i6	2 2 2 2 2 2	14.5M	56MB	41.0	32.4	9508

Table 9: Quality and inference speed of our WNGT2020 models with pruned attention on GPU. Words per second (WPS) measured on an AWS *g4dn.xlarge* instance with one NVidia T4 GPU.

larger scale, the pruned models achieve comparable quality with faster translation.

10 Future work

In this paper, we applied block-wise pruning to the transformer and its attention mechanism in particular. The natural progress of this research would be to prune other parts of the network — with the lottery ticket approach or not — to see how far block pruning can go without too much impact on quality. Furthermore, the heuristic algorithm we chose that decides which heads are not to be removed can definitely be improved on and extended to other types of block-sparsity cases.

11 Conclusions

This paper investigated block-wise pruning of attention heads in the transformer by applying the lottery ticket hypothesis to the problem. We used an iterative approach with pruning done in early stages training. Our experiments on NMT have proved that it is possible to remove a significant percentage of all heads (50–72%) in a large transformer with no significant damage to translation quality. Since attention mechanism is expensive, especially during inference, reducing the number of heads in a model led to 1.5× speed-up and more if one is willing to sacrifice quality for speed. In the teacher-student regime, the student model with a reduced decoder can be pruned of 75% encoder heads with 0.1–0.2 BLEU loss and 10–15% faster translation speed. This shows that lottery ticket pruning is complementary to other methods that reduce inference workload. No matter how a model is trained like, attention heads can be easily removed from it.

We hope our paper will inspire further work on attention-sparse architectures. In our paper, we have only shown one example of a heuristic approach — there may be yet to be identified more efficient algorithms better suited to specific tasks, which will result in no need to train overly parametrised models.

Abstract

Neural machine translation (NMT) has achieved great success due to the ability to generate high-quality sentences. Compared with human translations, one of the drawbacks of current NMT is that translations are not usually faithful to the input, e.g., omitting information or generating unrelated fragments, which inevitably decreases the overall quality, especially for human readers. In this paper, we propose a novel training strategy with a multi-task learning paradigm to build a faithfulness enhanced NMT model (named FENMT). During the NMT training process, we sample a subset from the training set and translate them to get fragments that have been mistranslated. Afterward, the proposed multi-task learning paradigm is employed on both encoder and decoder to guide NMT to correctly translate these fragments. Both automatic and human evaluations verify that our FENMT could improve translation quality by effectively reducing unfaithful translations.

1 Introduction

Neural machine translation (NMT) based on the *encoder-decoder framework* (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014; Luong et al., 2015b) has obtained state-of-the-art performance on many language pairs (Wu et al., 2019; Wei et al., 2020). Various neural architectures have been explored for modeling NMT under this framework, such as recurrent neural network (RNN) (Bahdanau et al., 2014; Luong et al., 2015b, RNNSearch), convolutional neural network (CNN) (Gehring et al., 2016, Conv-S2S) and self-attention network (Vaswani et al., 2017, Transformer). Compared with human translations or traditional statistical machine translation (SMT) (Koehn et al., 2007b; Chiang, 2007), NMT can generate high-quality sentences that are very close to natural language. However, it usually appears some parts (e.g., phrase) from input sentences cannot be correctly translated, leading to that the translation is inadequate for direct using in some scenarios. This phenomenon appeals that enhancing the faithfulness of translations is an important aspect for further improving NMT.

We summarize three possible causes for the unfaithfulness problem based on the encoder-decoder framework: 1). *Some parts from input sentences are hard to encode, and thus cannot be translated correctly.* 2). *The decoder cannot fetch the correct contextual representation from the encoder.* 3).*The dominant language model of NMT prompts the decoder generates common words to make sure outputs are fluent.* Several recent studies are proposed following one of the above perspectives and have achieved considerable effects. Zheng et al. (2019) proposed to divide the encoder output into past and future parts to fine-grained modeling contextual representation. Feng et al. (2020) proposed a faithfulness part to optimize the contextual representation before feeding into the decoder. Kong et al. (2019) proposed to use a coverage difference ratio metric as a reward to train NMT.

In this paper, we propose a novel training strategy with a multi-task learning paradigm, taking into account the use of real translations for building a faithfulness enhanced NMT (named FENMT). Firstly, we align source and target sentences in the training set. Then, at each training epoch, we sample a subset from the training set and translate source sentences by the NMT in the this set. For convenience, we simply define a mistranslated fragment is a continues segment from a target sentence which does not appear in the translation. So, we can collect mistranslated fragments by comparing the translation and reference, and get the corresponding source words by the alignment relationship.

November 16–20, 2020.

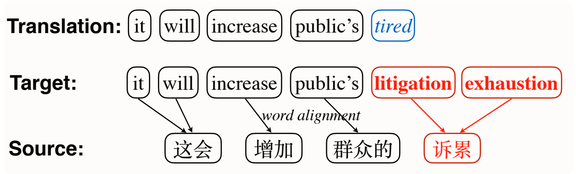

Figure 1: The case of collecting mistranslated fragments. "litigation exhaustion" is the mistranslated fragment and "累诉" is the corresponding source word.

After that, our multi-task learning paradigm (MTL) is incorporated into the training process to learn to correctly translate these mistranslated fragments. To make the most of the collected mistranslated fragments, the proposed MTL method considers all sides of the above hypotheses.

Specifically, we employ a *masked language model task* (Devlin et al., 2018) on the encoder side to infer the input words didn't be correctly translated. This task can enhance the ability of modeling the whole input sentence and give the decoder accurate and complete representations. On the decoder side, we use a *word alignment task* to improve the alignment accuracy of the *encoder-decoder attention* (or *cross-attention*) to help the decoder to capture correct contextual representation. Furthermore, along with the NMT objective, an auxiliary *max-margin objective* based on contrastive learning is introduced in all decoding timesteps. The goal of this task is to avert the tendency of translating frequent but unrelated words.

We implement the proposed approach based on Transformer (Vaswani et al., 2017) and evaluate it on WMT14 English to German (En→De), WMT17 Chinese to English (Zh→En) and WMT16 English to Romania (En→Ro) machine translation tasks. Both automatic and human evaluations show that the proposed FENMT could substantially improve the overall quality and faithfulness of translations.

2 The Proposed Approach

We will introduce the whole procedure of the proposed FENMT model based on the advanced Transformer (Vaswani et al., 2017). We firstly show the details of how to collect mistranslated fragments and the multi-task learning paradigm at section 2.1 and 2.2, respectively. Then, the overall training strategy of our approach is represented at section 2.3.

2.1 Collecting Mistranslated Fragments

Given a parallel training set $\mathcal{B}$, we achieve the alignment matrix set $\mathcal{A}$ through a word alignment model trained by the parallel training set, and get the phrase table $\mathcal{P}$ according to the word alignment (Koehn et al., 2003).

At the tth training epoch of NMT, we sample a subset $\mathcal{B}_t^{\mathrm{S}}$ from the $\mathcal{B}$. Given a sentence pair $\{\mathbf{x}, \mathbf{y}\}$ from the $\mathcal{B}_t^{\mathrm{S}}$, where $\mathbf{x}$ is the source sequence $(x_1, \cdots, x_i, \cdots, x_I)$ and $\mathbf{y}$ is the target sequence $(y_1, \cdots, y_j, \cdots, y_J)$, I and J are the length of $\mathbf{x}$ and $\mathbf{y}$, respectively. The alignment matrix $\mathbf{A} \in \mathbb{R}^{J \times I}$ of $\{\mathbf{x}, \mathbf{y}\}$ can be obtained from $\mathcal{A}$, in which $a_{j,i} = 1$ means y_j aligns x_i. We then translate the source sentence by $\hat{\mathbf{y}} = f_{\theta_{t-1}}(\mathbf{x})$, where $f_{\theta_{t-1}}(\cdot)$ is the NMT model, which parameters are θ and has been trained after $t-1$ epochs. $\hat{\mathbf{y}}$ is composed of $(\hat{y}_1, \cdots, \hat{y}_k, \cdots, \hat{y}_K)$, K is the sentence length.

We define that a fragment in $\mathbf{y}$ is mistranslated when it does not appear in $\hat{\mathbf{y}}$ but is contained in $\mathcal{P}$. Subsequently, we randomly sample consecutive parts from $\mathbf{y}$ included in $\mathcal{P}$ and compare them with $\hat{\mathbf{y}}$ to achieve mistranslated fragments. We denote a subsequence $\mathbf{y}^T$ of $\mathbf{y}$ containing all words mistranslated, $y_{t,j}$ is the tth word of $\mathbf{y}^T$ whose position in the $\mathbf{y}$ is j. Afterward, we can get the aligned source words of $\mathbf{y}^T$ by using the alignment relationship. For a word $y_{t,j}$, we collect source words when $a_{j,\cdot} = 1$. We denote the sequence having all aligned source words as $\mathbf{x}^M$, in which $x_{m,i}$ is the mth word of $\mathbf{x}^M$ whose position in the $\mathbf{x}$ is i. A shortly case is shown in Figure 1.

2.2 Multi-task Learning Paradigm

Masked language model task for the encoder. The first hypothesis mentioned above is that *the encoder cannot model mistranslated parts well*, which leads to the subsequent module cannot translate them correctly. Here, we introduce a *masked language model task* (MLM) to further model these source words. Specifically, before feeding into the decoder, we ask for the source representation predicts mistranslated words which are masked at the input sentence (see Figure 2).[1]

Formally, given the input sentence $\mathbf{x}$ from $\mathcal{B}_t^{\mathrm{S}}$ and the mistranslated subsequence $\mathbf{x}^M$. We define a sequence $\mathbf{x}^R$, which likes $\mathbf{x}$ but the words in the $\mathbf{x}^M$ will be replaced as a special <MASK> token with the probability of 80%, and as a random word

---

[1] We also implement the MLM task though randomly sampling tokens in sentences, but it doesn't work well.

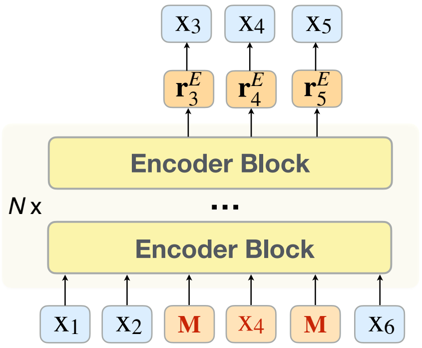

Figure 2: The overview of the masked language model task. M means the masked source word.

or keep unchanged with the probability of 10% individually. This procedure is the same as Devlin et al. (2018). The encoder with the MLM task maximizes the conditional probability defined as:

$$P(x_{m,i}|\mathbf{x}^R) = \text{softmax}(\text{FFN}(\mathbf{r}_i^E)), \quad (1)$$

$$\mathbf{R}^E = \text{Encoder}(\mathbf{x}^R), \quad (2)$$

where $\mathbf{R}^E \in \mathbb{R}^{l_{\text{input}} \times d_{\text{model}}}$ is the output hidden states of the encoder, and $\mathbf{r}_i^E \in \mathbb{R}^{d_{\text{model}}}$ is ith hidden state of $\mathbf{R}^E$. l_{input} is the length of the input sentence and d_{model} is the dimension of hidden state. Finally, the objective of the masked language model is

$$\mathcal{L}_{\text{M}} = -\mathbb{E}_{\mathbf{x}^R \in \mathcal{B}_t^{\text{S}}}[\mathbb{E}_{x_{m,i} \in \mathbf{x}^M}[\log P(x_{m,i}|\mathbf{x}^R)]]. \quad (3)$$

Word alignment task for the cross attention. After getting a better source contextual representation, i.e., the $\mathbf{R}^E$, *whether the decoder can get the correct representation for each output word* is another factor determining translation faithfulness. The cross-attention is the single connection between the encoder and decoder. A natural intuition is that improving the accuracy of cross-attention is helpful for getting faithful translations. Thus, we introduce a word alignment task for the cross-attention here (see Figure 3).

Specifically, given the target sentence $\mathbf{y}$, we define the cross-attention weight matrix as $\mathbf{C} \in \mathbb{R}^{J \times I}$, the vector $\mathbf{c}_j$ from $\mathbf{C}$ is the weight of jth decoder hidden state to the encoder representation. We then define the alignment label as $\mathbf{B} \in \mathbb{R}^{J \times I}$. Given the word y_j in the $\mathbf{y}^T$, the corresponding alignment label vector $\mathbf{b}_j$ is computed by:

$$\mathbf{b}_j = \text{softmax}(\mathbf{a}_j), \quad (4)$$

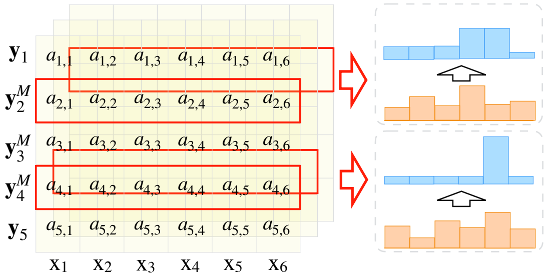

Figure 3: The overview of the word alignment objective. The word has superscript M is mistranslated.

where $\mathbf{a}_j$ is from the alignment matrix $\mathbf{A}$. Note that when using subword (Sennrich et al., 2015; Devlin et al., 2018) as input, alignment probability will be divided into the corresponding tokens equally (e.g., if a word is divided into two tokens, the probability for each token is 0.5).

Generally, the decoder has N block and the cross attention from each block has H heads (Vaswani et al., 2017). We randomly choose two heads at each blocks to employ the word alignment objective. We define the selected attention weight matrix set as $\mathcal{C} = \{\mathbf{C}_1, \cdots, \mathbf{C}_k, \cdots, \mathbf{C}_K\}$, where $K = 2 * N$. Then, the word alignment objective is

$$\mathcal{L}_{\text{A}} = -\mathbb{E}_{\mathbf{C}_k \in \mathcal{C}}[\mathbb{E}_{\mathbf{b}_j \in \mathbf{B}, \mathbf{c}_j \in \mathbf{C}_k}[\mathbf{b}_j \log \mathbf{c}_j]]. \quad (5)$$

This objective is used to guide the cross-attention to capture correct contextual information rather than only learn the word alignment information. So we only employing it on parts of attention head to avoid "*overfitting*" to the alignment task.

Max-margin task for the decoder. Empirically, the language model in current NMT is more stronger than the translation model, so the NMT model tends to translate common words even unrelated to the source sentence (Kong et al., 2019). Only using cross-entropy objective isn't enough to keep translations faithful. Here, we introduce a *max-margin objective* based on contrastive learning to suppress the tendency of NMT to generate common but unfaithful words.

Specifically, given the target sentence $\mathbf{y}$ and the translation $\hat{\mathbf{y}}$, the max-margin loss is defined as $\mathcal{L}_{\text{C}} = \sum_{j=1}^{J} \mathcal{L}_j$, where $\mathcal{L}_j$ is computed by

$$\mathcal{L}_j = \begin{cases} \max(0, mg - P(y_j|y_{1:j}, \mathbf{x}) \\ \quad + P(\hat{y}_j)|\hat{y}_{1:j}, \mathbf{x})) & , y_{t,j} \in \mathbf{y}^T \\ 0 & , y_{t,j} \notin \mathbf{y}^T \end{cases}$$

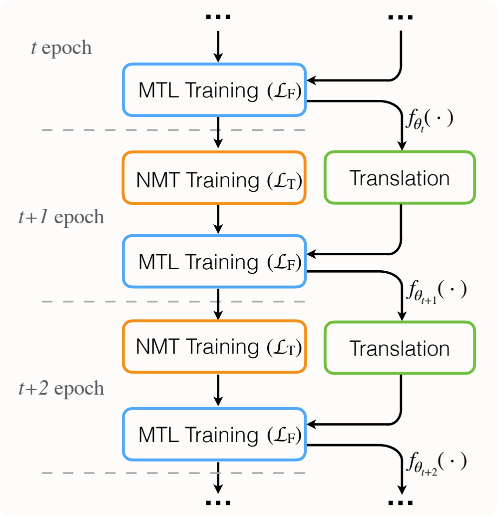

Figure 4: Overview of the training strategy of the proposed FENMT. MTL: multi-task learning.

where the mg is the margin, we empirically set to 0.2. The cross-entropy objective with this objective can prompt the decoder to translate fluent and faithful sentences.

2.3 The Overall Training Strategy

The standard NMT training objective is to minimize the negative log-likelihood by:

$$\mathcal{L}_{\mathrm{T}} = -\mathbb{E}_{\{\mathbf{x},\mathbf{y}\}\in\mathcal{B}} \log P(\mathbf{y}|\mathbf{x}). \tag{6}$$

And the final training objective of our proposed approach is:

$$\mathcal{L}_{\mathrm{F}} = \mathcal{L}_{\mathrm{T}} + \alpha \cdot \mathcal{L}_{\mathrm{M}} + \beta \cdot \mathcal{L}_{\mathrm{A}} + \gamma \cdot \mathcal{L}_{\mathrm{C}}, \tag{7}$$

where α, β and γ are used to balance the preference among the external losses, which are empirically set to 0.3 individually. Note that due to the different inputs, $\mathcal{L}_{\mathrm{M}}$ should be computed separately.

The training strategy as follows: at the tth NMT training epoch, we are going to sample part of the sentences from the training set, the sampling ratio is computed by:

$$ratio = \max(d^{(t-1)} * 20\%, 5\%), \tag{8}$$

where d is the decay rate, we set as 0.9 here. To avoid decreasing training efficiency, the sampled data will be translated by $f_{\theta_t}(\cdot)$ at the tth epoch and used at the $t+1$th epoch. And the first epoch will not use this method as a warm-up.

The overview of the training strategy is shown in Figure 4 The NMT will begin to translate sampled sentences at the end of the tth epoch, which is synchronous with the training process. Then, when both of the training process and translation process are finished, the multi-task learning paradigm will be employed to continue train the NMT model.

3 Experiment

3.1 Implementation Detail

We conduct experiments on the WMT data-sets[2], including WMT17 Chinese to English CWMT part (Zh→En), WMT 14 English to German (En→De) and English to Romanian (En→Ro). On the Zh→En, our training set has about 7.5M sentence pairs. We use `newsdev2017` as dev set which has 2002 sentence pairs, and `newstest2017` as test set which has 2001 sentence pairs. On the En→De, our training set has about 4.5M sentence pairs. We use `newstest2013` as dev set which has 3000 sentence pairs, and `newstest2014` as test set, which has 3003 sentence pairs. On the En→Ro, our training set has about 0.6M sentence pairs. We use `newstest2015` as dev set which has 2000 sentence pairs, and `newstest2016` as test set which has 2000 sentence pairs. We apply the byte pair encoding (BPE) (Sennrich et al., 2015) to all language pairs and limit the vocabulary to 32K. All out-of-vocabulary words were mapped to the *UNK* token. The same training sets were used to train a word alignment model using fast_align[3]. Then, the bilingual phrase table is extracted by Koehn et al. (2003, 2007a). We limit the length of phrase is 2-4, and finally 6.7M, 3.4M and 0.2M phrases are extracted from Zh→En, En→De and En→Ro.

Following Transformer-Base and Transformer-Big settings, we set the dimension of the input and output of all layers as 512/768, and that of the feed-forward layer to 2048/3072. We employ 8/12 parallel attention heads. The number of layers for the encoder and decoder are 6. Sentence pairs are batched together by approximate sentence length. Each batch has approximately 25000 source and 25000 target tokens. We use label smoothing with value 0.1 and dropout with a rate of 0.1. We use the Adam (Kingma and Ba, 2014) with the learning rate of 1e-3, $\beta_1 = 0.9, \beta_2 = 0.98$, and it was varied under the warm-up with 4000 steps. Other settings of Transformer follow Vaswani et al. (2017).

We use beam search for heuristic decoding, and the size is set to 4. We use the *sacreBLEU*[4] to calcu-

Table 1: The comparison of our FENMT, Transformer baselines and related work on the WMT17 Chinese to English (Zh→En), WMT14 English to German (En→De), and WMT16 English to Romania (En→Ro) tasks (* indicates the results came from their paper, †/‡ indicate significantly better than the baseline ($p < 0.05/0.01$)).

late *case-sensitive* BLEU (Papineni et al., 2002) as the automatic metric. We implement the proposed approach with the implementation of Transformer derived from the *tensor2tensor*[5].

3.2 Automatic Evaluation

Translation quality. The results are summarized in Table 1. We implement the Transformer-Base and Transformer-Big as our baselines. Several Transformer systems with the same settings (Vaswani et al., 2017; Hassan et al., 2018; Gu et al., 2017) are reported as a comparison (line 1-6). Then, several related researches about improve faithfulness of NMT (Kong et al., 2019; Zheng et al., 2019; Chen et al., 2019; Feng et al., 2020) or exploiting translations for improving NMT (Xia et al., 2017; Wang et al., 2019) also be reported (line 7-12). We implement three comparable approaches on our Transformer baseline, including: 1). self-supervised learning: we use the translations of training data as a self-supervision signal to fine tune the NMT model; 2). minimum risk training (MRT): we implement the MRT following Shen et al. (2016); 3). Knowledge Distillation: we adopt the KL divergence to distill knowledge from Transformer-Big to Transformer-Base (line 13-15).

The results on the ZH→EN task are shown in the third column of Table 1. The improvement of our model (FENMT) could be up to 1.03 based on the Transformer-Base baseline (line 16 vs. line 1), and 1.44 base on the Transformer-Big baseline (line 17 vs. line 2). Then, the results on the En→De task are shown in the fourth column. On this task, the proposed model with base and big settings could attain 28.25 BLEU (+0.88) and 29.36 BLEU (+0.89), which outperforms all previous studies. We also experiment our method on low resource language pair of the En→Ro. Results are shown in the last column. The improvement is 1.20 BLEU on the base setting, which is a material improvement in low resource scenario.

Experimental results on three machine translation tasks show that the proposed approach can improve translation quality which is not limited by the language or size of training data. Moreover, our method is more effect on Zh→En than De→En, which may appeal the unfaithful problem is more serious on the language pair which have a larger difference in morphology.

Model size and efficiency. The number of parameters is shown in Table 1, our work only adds 3M/4M parameters on the Base/Big settings. The training efficiency of our FENMT based on the base

Model	Degree	Addition	Omission	Grammar	Style	Others	Total
Baseline	Minor	0	0	50	15	3	68
	Major	6	54	3	0	0	63
	Critical	0	5	0	0	1	6
FENMT	Minor	0	0	41	12	8	61(-10.3%)
	Major	1	43	4	0	0	48(-23.8%)
	Critical	0	3	0	0	0	3(-50.0%)

Table 2: Human evaluation on 100 sentences sampled from Zh→En test set. We divide mistranslations into several types: **Addition** includes repetitive and useless translation, **Omission** means a consecutive part is not be translated correctly (miss or wrong), **Grammar** includes word order, word form, function word, etc. **Critical**, **Major** and **Minor** mean the degree of errors. We invite a professional translator to label errors in the sampled sentences.

Quality	Baseline	FENMT
Incomprehensible (1)	0	0
Bad (2)	7	3(-57.1%)
Understandable (3)	43	29(-32.6%)
Good (4)	42	54(+28.6%)
Excellent (5)	8	14(+75.0%)
Overall score	3.51	3.79

Table 3: Human evaluation on 100 sentences sampled from Zh→En test set. We divide translation quality into 5 levels and give score 1 to 5 (larger is better). We ask a professional translator to score them. The overall score is the weighted average of above categories.

Model	BLEU	Δ
Baseline	27.37	–
FENMT-Base	28.25	+0.88
w/o $\mathcal{L}_A$ w/o $\mathcal{L}_C$	28.00	+0.63
w/o $\mathcal{L}_M$ w/o $\mathcal{L}_C$	27.70	+0.33
w/o $\mathcal{L}_M$ w/o $\mathcal{L}_A$	27.89	+0.42
w/o $\mathcal{L}_C$	28.14	+0.77
w/o $\mathcal{L}_A$	28.10	+0.73
w/o $\mathcal{L}_M$	27.86	+0.49

Table 4: Ablation study on the En→De task.

setting is 0.86x compared with Transformer-Base, and based on the big setting is 0.94x compared with Transformer-Big.[6] Our approach only influence the training process of NMT, so the inference efficiency will not be affected.

3.3 Human Evaluation

The automatic metric, i.e., BLEU, sometimes can't accurately evaluate translation quality. For example, the sentence missing content words has decrease more on faithfulness than missing function words, but the BLEU scores may be equal. So, we make detailed human evaluations to see the variations of translation quality in the real environment.

Number of mistranslations. We divide mistranslations into several types and each type has three degrees. We sample 100 sentences from the Zh→En test set, and invite a professional translator to label errors contained in these translations.

The results are reported in Table 2. Our method can reduce the number of mistranslations at the most of categories. Typically, our approach significantly reduce the number of the **Omission**, which means a continue part from the input doesn't be translated correctly. At the **Addition** category, our approach also achieves remarkable improvement even it's not a main error type in current NMT. Omission and Addition are two serious error types greatly hurting the faithfulness of translations. The reduction of these errors will improve the faithfulness of translations obviously.

Translation quality ranking. Besides evaluating the error types in the sampled sentences, we also evaluate the overall quality for each sentence. Here, the translation quality is divided into 5 levels and give score 1 to 5 (larger is better) and a professional translator is invited to score them.

The results are shown in Table 3, the overall score of the proposed method is better than baseline (3.79 > 3.51). Specifically, the good (4) and excellent(5) translations from our approach are more than baseline (+75.0% and + 28.6%) by revising the errors from the bad (2) and understandable (3) translations (-57.1% and -32.6%). This results show that the reduction of mistranslations really improve the overall quality for human readers.

Reference	8082	–
Baseline	5676	70.2%
FENMT	6453	79.8%

Table 5: The accuracy of phrase translation on the En→De task.

Model	Sampling Rate	BLEU
FENMT	5%	27.79
	20%	28.27
	100%	28.39
	ours (20%→5%)	28.25

Table 6: The effectiveness of different sampling rates on the En→De task. *ours*: computed by Eq. 8.

3.4 Analysis

Ablation study. To further show the function of each task in our approach, we make ablation study in this section. Specifically, we investigate how the *masked language model objective*, *word alignment objective*, and *max-margin objective* affect the translation performance.

The results are shown in Table 4. Firstly, we analysis the effect of each task. The model achieves 0.63, 0.33 and 0.42 gains when only using masked language model ($\mathcal{L}_{\mathrm{M}}$), word alignment ($\mathcal{L}_{\mathrm{A}}$) and max-margin ($\mathcal{L}_{\mathrm{C}}$) individually. Then, the results of combining two of three tasks are shown in the second part. The masked language model combines word alignment or max-margin can get improvements of 0.77 and 0.73, which are close to the best performance. While the combination of word alignment and max-margin is not work well (+0.49).

The above experimental results show that each task could get a decent improvement. But compared with improving the ability of the decoder, the high quality contextual representation learned from the masked language model is more important.

Accuracy of phrase translation. We compute the accuracy of phrase translation on the En→De task to evaluate the proposed multi-task objective in a fine-grained aspect. The result are shown in Table 5. The total number of phrases in the references is 8082. Our approach successfully translate the 6453 (79.8%) and the baseline correctly translate the 5676 (70.2%). The accuracy of our approach largely improves 9.6% compared with the baseline.

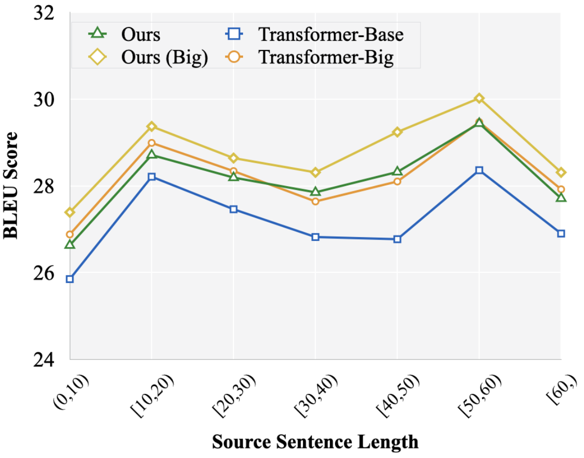

Figure 5: Performance of translations with different lengths of source sentences on the En→De task. "Ours" means the proposed FENMT.

Analysis of different sampling rate. The results of the FENMT with different sampling rate are shown in Table 6. When the sampling rate is 5%, the performance decreases 0.46 compared with the rate computed by Eq. 8. When the sampling rate is larger than 20%, the performance does not change significantly. But the dynamical sampling rate will reduce the number of sentences needed to be translated, which can avoid dropping training efficiency.

Analysis of sentence length. We group the En→De test set by the length of source sentences, and then re-evaluate the BLEU score of each group. The test set is divided into 7 subsets. Figure 5 shows the results. We find that our model outperforms the baseline in all categories in both base and big setting. The proposed model performs better on long sentences (e.g., [30,60]). Because long sentences are usually complex and difficult to translate which causes the number of mistranslations in them is more than short sentences. Our approach can avoid these mistranslations compared with baselines.

Case study. We show two cases from the Zh→En task to see the difference between baseline and our approach, which are shown in Table 7.

Our approach could learn how to translate the difficult fragments in the input which are easier to be mistranslated. For example, the idiom "*turn the table*" in case 1 is translated to *loss* by the baseline, which only observe the word "败" in the input. In case 2, the baseline makes a serious mistake at the beginning of the sentence. The translation of "私

Input	不论他是从前面，还是后面靠近你，它都会教你如何反败为胜。
Refer.	whether you’re approached from in front or behind, it will show you how to turn the tables on your mugger.
Baseline	whether he comes from the front, or from the *front*, it will teach you how to *lose*.
FENMT	whether you’re approached from in **front or back**, it will show you how to **turn the tables**.
Input	私募股权基金等领域风险事件的爆发, 资产托管机制是一个重要原因。
Refer.	asset custody mechanism is a major reason to explain the outbreak of risk events in private equity funds and other sectors .
Baseline	*trust* is an important reason for the outbreak of risk events in private equity fund .
FENMT	**asset custody mechanism** is an important reason for the outbreak of risk events in private equity funds and **other sectors** .

Table 7: Translation cases from Transformer and FENMT on the Zh→En task. Words with **Bold** and blue fonts are correct translations revised by our model. Words with *Italic* and red fonts are mistranslations from baseline. Words with underline are the corresponding parts in the reference.

募股权基金” is omitted. Our FENMT avoids this kind of mistakes by specialized modeling mistranslated parts in the NMT model.

4 Related Work

Enhancing faithfulness for NMT. Faithfulness and Fluency are two fundamental factors of translation quality. NMT has been able to generate fluent sentences. While translating faithful sentences is an urgent problem to be solved. In the RNN-based NMT, Tu et al. (2016) and Mi et al. (2016) proposed a coverage mechanism to improve the accuracy of translation outputs. Following this intuition, Zheng et al. (2018) divided source representation into past and future parts to fine-grained control translation process. These studies focus on using source representation effectively. On the other hand, improving the ability of the decoder is another way. Tu et al. (2017) proposed to introduce a reconstruction loss to make translation can reconstruct the input sentence. Weng et al. (2017) proposed a bag-of-words loss to constrain decoding process. These methods are similar to multi-task learning, but the motivation of them are different.

Recent studies found that Transformer also suffer this problem even its translation quality is far better than RNN model. Kong et al. (2019) proposed a coverage difference ratio metric as a reward to train the Transformer model. Weng et al. (2020) proposed to model global representation in the source side to improve the source representation. Zheng et al. (2019) proposed a capsule based module to control the source representation dynamically in the decoding process. Zhang et al. (2019), Feng et al. (2020) and Garg et al. (2019) proposed to introduce word alignment information in Transformer to improve translation accuracy. However, they only focus on one side causing this problem while don’t have an overall solution. Our study is the first work to pay attention to using mistranslations guides NMT model to avoid making these mistakes again.

Multi-task learning in NMT. Multi-task learning has been widely used in NMT. Dong et al. (2015) proposed to share an encoder between different translation tasks to exploit multi lingual knowledge. Luong et al. (2015a) proposed to jointly learn the translation task for different languages, the parsing task and the image captioning task, with a shared encoder or decoder. Zhang and Zong (2016) and Domhan and Hieber (2017) proposed to use multi-task learning for incorporating source/target side monolingual data in NMT. Zhou et al. (2019) introduced noisy data with multi-task learning to improve the robustness of NMT. Different from these attempts, our approach wants to improve the faithfulness of current NMT model, while learning extra knowledge from other tasks.

5 Conclusion

In this paper, we address the problem that current NMT can’t generate faithful translations which will observably decrease translation quality. We propose a FENMT to learn the faithful translation from mistranslated parts. We implement the proposed method based on the Transformer model and evaluate it on three translation tasks. Both the automatic and human evaluations show that our approach can effectively improve the faithfulness of translations. Our work can employ on different text generation tasks, e.g., text summarization and dialogue, to enhance the key phrases (or terms) generation. In the future, we will continue investigate the learning method for effectively utilizing self-generated samples and expand to other text generation tasks.

Abstract

We present COMET, a neural framework for training multilingual machine translation evaluation models which obtains new state-of-the-art levels of correlation with human judgements. Our framework leverages recent breakthroughs in cross-lingual pretrained language modeling resulting in highly multilingual and adaptable MT evaluation models that exploit information from both the source input and a target-language reference translation in order to more accurately predict MT quality. To showcase our framework, we train three models with different types of human judgements: *Direct Assessments*, *Human-mediated Translation Edit Rate* and *Multidimensional Quality Metrics*. Our models achieve new state-of-the-art performance on the WMT 2019 Metrics shared task and demonstrate robustness to high-performing systems.

1 Introduction

Historically, metrics for evaluating the quality of machine translation (MT) have relied on assessing the similarity between an MT-generated hypothesis and a human-generated reference translation in the target language. Traditional metrics have focused on basic, lexical-level features such as counting the number of matching n-grams between the MT hypothesis and the reference translation. Metrics such as BLEU (Papineni et al., 2002) and METEOR (Lavie and Denkowski, 2009) remain popular as a means of evaluating MT systems due to their light-weight and fast computation.

Modern neural approaches to MT result in much higher quality of translation that often deviates from monotonic lexical transfer between languages. For this reason, it has become increasingly evident that we can no longer rely on metrics such as BLEU to provide an accurate estimate of the quality of MT (Barrault et al., 2019).

While an increased research interest in neural methods for training MT models and systems has resulted in a recent, dramatic improvement in MT quality, MT evaluation has fallen behind. The MT research community still relies largely on outdated metrics and no new, widely-adopted standard has emerged. In 2019, the WMT News Translation Shared Task received a total of 153 MT system submissions (Barrault et al., 2019). The Metrics Shared Task of the same year saw only 24 submissions, almost half of which were entrants to the Quality Estimation Shared Task, adapted as metrics (Ma et al., 2019).

The findings of the above-mentioned task highlight two major challenges to MT evaluation which we seek to address herein (Ma et al., 2019). Namely, that current metrics **struggle to accurately correlate with human judgement at segment level** and **fail to adequately differentiate the highest performing MT systems**.

In this paper, we present COMET[1], a PyTorch-based framework for training highly multilingual and adaptable MT evaluation models that can function as metrics. Our framework takes advantage of recent breakthroughs in cross-lingual language modeling (Artetxe and Schwenk, 2019; Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2019) to generate prediction estimates of human judgments such as *Direct Assessments* (DA) (Graham et al., 2013), *Human-mediated Translation Edit Rate* (HTER) (Snover et al., 2006) and metrics compliant with the *Multidimensional Quality Metric* framework (Lommel et al., 2014).

Inspired by recent work on Quality Estimation (QE) that demonstrated that it is possible to achieve high levels of correlation with human judgements even without a reference translation (Fonseca et al., 2019), we propose a novel approach for incorporat-

ing the source-language input into our MT evaluation models. Traditionally only QE models have made use of the source input, whereas MT evaluation metrics rely instead on the reference translation. As in (Takahashi et al., 2020), we show that using a multilingual embedding space allows us to leverage information from all three inputs and demonstrate the value added by the source as input to our MT evaluation models.

To illustrate the effectiveness and flexibility of the COMET framework, we train three models that estimate different types of human judgements and show promising progress towards both better correlation at segment level and robustness to high-quality MT.

We will release both the COMET framework and the trained MT evaluation models described in this paper to the research community upon publication.

2 Model Architectures

Human judgements of MT quality usually come in the form of segment-level scores, such as DA, MQM and HTER. For DA, it is common practice to convert scores into relative rankings (DARR) when the number of annotations per segment is limited (Bojar et al., 2017b; Ma et al., 2018, 2019). This means that, for two MT hypotheses h_i and h_j of the same source s, if the DA score assigned to h_i is higher than the score assigned to h_j, h_i is regarded as a "better" hypothesis.[2] To encompass these differences, our framework supports two distinct architectures: The **Estimator model** and the **Translation Ranking model**. The fundamental difference between them is the training objective. While the Estimator is trained to regress directly on a quality score, the Translation Ranking model is trained to minimize the distance between a "better" hypothesis and both its corresponding reference and its original source. Both models are composed of a cross-lingual encoder and a pooling layer.

2.1 Cross-lingual Encoder

The primary building block of all the models in our framework is a pretrained, cross-lingual model such as multilingual BERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019) or XLM-RoBERTa (Conneau et al., 2019). These models contain several transformer encoder layers that are trained to reconstruct masked tokens by uncovering the relationship between those tokens and the surrounding ones. When trained with data from multiple languages this pretrained objective has been found to be highly effective in cross-lingual tasks such as document classification and natural language inference (Conneau et al., 2019), generalizing well to unseen languages and scripts (Pires et al., 2019). For the experiments in this paper, we rely on XLM-RoBERTa (base) as our encoder model.

Given an input sequence $x = [x_0, x_1, ..., x_n]$, the encoder produces an embedding $\boldsymbol{e}_j^{(\ell)}$ for each token x_j and each layer $\ell \in \{0, 1, ..., k\}$. In our framework, we apply this process to the source, MT hypothesis, and reference in order to map them into a shared feature space.

2.2 Pooling Layer

The embeddings generated by the last layer of the pretrained encoders are usually used for fine-tuning models to new tasks. However, (Tenney et al., 2019) showed that different layers within the network can capture linguistic information that is relevant for different downstream tasks. In the case of MT evaluation, (Zhang et al., 2020) showed that different layers can achieve different levels of correlation and that utilizing only the last layer often results in inferior performance. In this work, we used the approach described in Peters et al. (2018) and pool information from the most important encoder layers into a single embedding for each token, $\boldsymbol{e}_j$, by using a layer-wise attention mechanism. This embedding is then computed as:

$$\boldsymbol{e}_{x_j} = \mu E_{x_j}^{\top} \boldsymbol{\alpha} \tag{1}$$

where μ is a trainable weight coefficient, $\boldsymbol{E}_j = [\boldsymbol{e}_j^{(0)}, \boldsymbol{e}_j^{(1)}, \ldots \boldsymbol{e}_j^{(k)}]$ corresponds to the vector of layer embeddings for token x_j, and $\boldsymbol{\alpha} = \text{softmax}([\alpha^{(1)}, \alpha^{(2)}, \ldots, \alpha^{(k)}])$ is a vector corresponding to the layer-wise trainable weights. In order to avoid overfitting to the information contained in any single layer, we used layer dropout (Kondratyuk and Straka, 2019), in which with a probability p the weight $\alpha^{(i)}$ is set to $-\infty$.

Finally, as in (Reimers and Gurevych, 2019), we apply average pooling to the resulting word embeddings to derive a sentence embedding for each segment.

---

[2] In the WMT Metrics Shared Task, if the difference between the DA scores is not higher than 25 points, those segments are excluded from the DARR data.

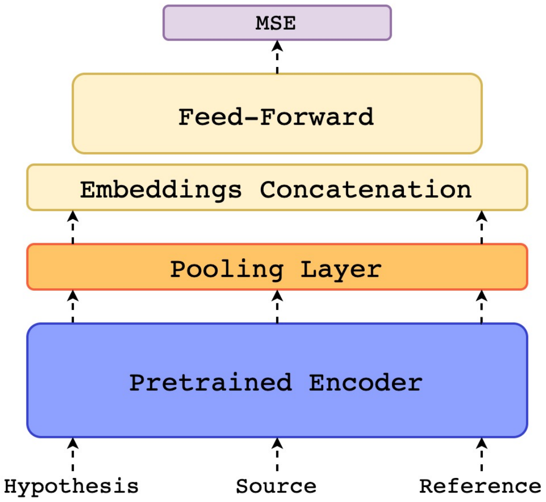

Figure 1: Estimator model architecture. The source, hypothesis and reference are independently encoded using a pretrained cross-lingual encoder. The resulting word embeddings are then passed through a pooling layer to create a sentence embedding for each segment. Finally, the resulting sentence embeddings are combined and concatenated into one single vector that is passed to a feed-forward regressor. The entire model is trained by minimizing the Mean Squared Error (MSE).

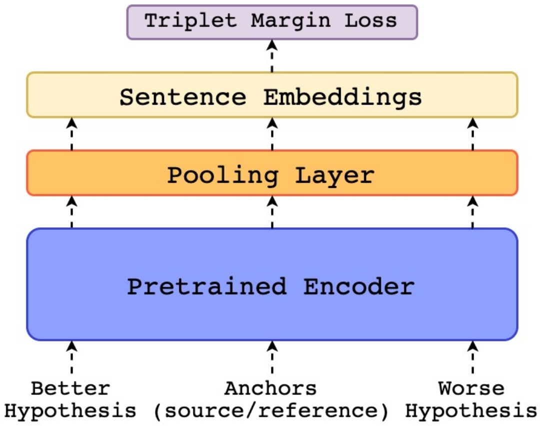

Figure 2: Translation Ranking model architecture. This architecture receives 4 segments: the source, the reference, a "better" hypothesis, and a "worse" one. These segments are independently encoded using a pretrained cross-lingual encoder and a pooling layer on top. Finally, using the triplet margin loss (Schroff et al., 2015) we optimize the resulting embedding space to minimize the distance between the "better" hypothesis and the "anchors" (source and reference).

2.3 Estimator Model

Given a d-dimensional sentence embedding for the source, the hypothesis, and the reference, we adopt the approach proposed in RUSE (Shimanaka et al., 2018) and extract the following combined features:

- Element-wise source product: $\boldsymbol{h} \odot \boldsymbol{s}$
- Element-wise reference product: $\boldsymbol{h} \odot \boldsymbol{r}$
- Absolute element-wise source difference: $|\boldsymbol{h} - \boldsymbol{s}|$
- Absolute element-wise reference difference: $|\boldsymbol{h} - \boldsymbol{r}|$

These combined features are then concatenated to the reference embedding $\boldsymbol{r}$ and hypothesis embedding $\boldsymbol{h}$ into a single vector $\boldsymbol{x} = [\boldsymbol{h}; \boldsymbol{r}; \boldsymbol{h} \odot \boldsymbol{s}; \boldsymbol{h} \odot \boldsymbol{r}; |\boldsymbol{h} - \boldsymbol{s}|; |\boldsymbol{h} - \boldsymbol{r}|]$ that serves as input to a feed-forward regressor. The strength of these features is in highlighting the differences between embeddings in the semantic feature space.

The model is then trained to minimize the mean squared error between the predicted scores and quality assessments (DA, HTER or MQM). Figure 1 illustrates the proposed architecture.

Note that we chose not to include the raw source embedding ($\boldsymbol{s}$) in our concatenated input. Early experimentation revealed that the value added by the source embedding as extra input features to our regressor was negligible at best. A variation on our HTER estimator model trained with the vector $\boldsymbol{x} = [\boldsymbol{h}; \boldsymbol{s}; \boldsymbol{r}; \boldsymbol{h} \odot \boldsymbol{s}; \boldsymbol{h} \odot \boldsymbol{r}; |\boldsymbol{h} - \boldsymbol{s}|; |\boldsymbol{h} - \boldsymbol{r}|]$ as input to the feed-forward only succeed in boosting segment-level performance in 8 of the 18 language pairs outlined in section 5 below and the average improvement in Kendall's Tau in those settings was +0.0009. As noted in Zhao et al. (2020), while cross-lingual pretrained models are adaptive to multiple languages, the feature space between languages is poorly aligned. On this basis we decided in favor of excluding the source embedding on the intuition that the most important information comes from the reference embedding and reducing the feature space would allow the model to focus more on relevant information. This does not however negate the general value of the source to our model; where we include combination features such as $\boldsymbol{h} \odot \boldsymbol{s}$ and $|\boldsymbol{h} - \boldsymbol{s}|$ we do note gains in correlation as explored further in section 5.5 below.

2.4 Translation Ranking Model

Our Translation Ranking model (Figure 2) receives as input a tuple $\chi = (s, h^+, h^-, r)$ where h^+ denotes an hypothesis that was ranked higher than another hypothesis h^-. We then pass χ through our cross-lingual encoder and pooling layer to obtain a sentence embedding for each segment in the χ. Finally, using the embeddings $\{\boldsymbol{s}, \boldsymbol{h}^+, \boldsymbol{h}^-, \boldsymbol{r}\}$, we compute the triplet margin loss (Schroff et al., 2015) in relation to the source and reference:

$$L(\chi) = L(\boldsymbol{s}, \boldsymbol{h}^+, \boldsymbol{h}^-) + L(\boldsymbol{r}, \boldsymbol{h}^+, \boldsymbol{h}^-) \quad (2)$$

where:

$$\begin{aligned} L(\boldsymbol{s}, \boldsymbol{h}^+, \boldsymbol{h}^-) = \\ \max\{0, d(\boldsymbol{s}, \boldsymbol{h}^+) \ - d(\boldsymbol{s}, \boldsymbol{h}^-) + \epsilon\} \end{aligned} \quad (3)$$

$$\begin{aligned} L(\boldsymbol{r}, \boldsymbol{h}^+, \boldsymbol{h}^-) = \\ \max\{0, d(\boldsymbol{r}, \boldsymbol{h}^+) \ - d(\boldsymbol{r}, \boldsymbol{h}^-) + \epsilon\} \end{aligned} \quad (4)$$

$d(\boldsymbol{u}, \boldsymbol{v})$ denotes the euclidean distance between $\boldsymbol{u}$ and $\boldsymbol{v}$ and ϵ is a margin. Thus, during training the model optimizes the embedding space so the distance between the anchors ($\boldsymbol{s}$ and $\boldsymbol{r}$) and the "worse" hypothesis $\boldsymbol{h}^-$ is greater by at least ϵ than the distance between the anchors and "better" hypothesis $\boldsymbol{h}^+$.

During inference, the described model receives a triplet $(s, \hat{h}, r)$ with only one hypothesis. The quality score assigned to $\hat{h}$ is the harmonic mean between the distance to the source $d(\boldsymbol{s}, \hat{\boldsymbol{h}})$ and the distance to the reference $d(\boldsymbol{r}, \hat{\boldsymbol{h}})$:

$$f(s, \hat{h}, r) = \frac{2 \times d(\boldsymbol{r}, \hat{\boldsymbol{h}}) \times d(\boldsymbol{s}, \hat{\boldsymbol{h}})}{d(\boldsymbol{r}, \hat{\boldsymbol{h}}) + d(\boldsymbol{s}, \hat{\boldsymbol{h}})} \quad (5)$$

Finally, we convert the resulting distance into a similarity score bounded between 0 and 1 as follows:

$$\hat{f}(s, \hat{h}, r) = \frac{1}{1 + f(s, \hat{h}, r)} \quad (6)$$

3 Corpora

To demonstrate the effectiveness of our described model architectures (section 2), we train three MT evaluation models where each model targets a different type of human judgment. To train these models, we use data from three different corpora: the QT21 corpus, the DARR from the WMT Metrics shared task (2017 to 2019) and a proprietary MQM annotated corpus.

3.1 The QT21 corpus

The QT21 corpus is a publicly available[3] dataset containing industry generated sentences from either an information technology or life sciences domains (Specia et al., 2017). This corpus contains a total of 173K tuples with source sentence, respective human-generated reference, MT hypothesis (either from a phrase-based statistical MT or from a neural MT), and post-edited MT (PE). The language pairs represented in this corpus are: English to German (en-de), Latvian (en-lt) and Czech (en-cs), and German to English (de-en).

The HTER score is obtained by computing the translation edit rate (TER) (Snover et al., 2006) between the MT hypothesis and the corresponding PE. Finally, after computing the HTER for each MT, we built a training dataset $D = \{s_i, h_i, r_i, y_i\}_{n=1}^N$, where s_i denotes the source text, h_i denotes the MT hypothesis, r_i the reference translation, and y_i the HTER score for the hypothesis h_i. In this manner we seek to learn a regression $f(s, h, r) \to y$ that predicts the human-effort required to correct the hypothesis by looking at the source, hypothesis, and reference (but not the post-edited hypothesis).

3.2 The WMT DARR corpus

Since 2017, the organizers of the WMT News Translation Shared Task (Barrault et al., 2019) have collected human judgements in the form of adequacy DAs (Graham et al., 2013, 2014, 2017). These DAs are then mapped into relative rankings (DARR) (Ma et al., 2019). The resulting data for each year (2017-19) form a dataset $D = \{s_i, h_i^+, h_i^-, r_i\}_{n=1}^N$ where h_i^+ denotes a "better" hypothesis and h_i^- denotes a "worse" one. Here we seek to learn a function $r(s, h, r)$ such that the score assigned to h_i^+ is strictly higher than the score assigned to h_i^- $(r(s_i, h_i^+, r_i) > r(s_i, h_i^-, r_i))$. This data[4] contains a total of 24 high and low-resource language pairs such as Chinese to English (zh-en) and English to Gujarati (en-gu).

3.3 The MQM corpus

The MQM corpus is a proprietary internal database of MT-generated translations of customer support

---

[3] QT21 data: `https://lindat.mff.cuni.cz/repository/xmlui/handle/11372/LRT-2390`

[4] The raw data for each year of the WMT Metrics shared task is publicly available in the results page (2019 example: `http://www.statmt.org/wmt19/results.html`). Note, however, that in the `README` files it is highlighted that this data is not well documented and the scripts occasionally require custom utilities that are not available.

chat messages that were annotated according to the guidelines set out in Burchardt and Lommel (2014). This data contains a total of 12K tuples, covering 12 language pairs from English to: German (en-de), Spanish (en-es), Latin-American Spanish (en-es-latam), French (en-fr), Italian (en-it), Japanese (en-ja), Dutch (en-nl), Portuguese (en-pt), Brazilian Portuguese (en-pt-br), Russian (en-ru), Swedish (en-sv), and Turkish (en-tr). Note that in this corpus English is always seen as the source language, but never as the target language. Each tuple consists of a source sentence, a human-generated reference, a MT hypothesis, and its MQM score, derived from error annotations by one (or more) trained annotators. The MQM metric referred to throughout this paper is an internal metric defined in accordance with the MQM framework (Lommel et al., 2014) (MQM). Errors are annotated under an internal typology defined under three main error types; 'Style', 'Fluency' and 'Accuracy'. Our MQM scores range from $-\infty$ to 100 and are defined as:

$$\text{MQM} = 100 - \frac{I_{\text{Minor}} + 5 \times I_{\text{Major}} + 10 \times I_{\text{Crit.}}}{\text{Sentence Length} \times 100} \tag{7}$$

where I_{Minor} denotes the number of minor errors, I_{Major} the number of major errors and $I_{\text{Crit.}}$ the number of critical errors.

Our MQM metric takes into account the severity of the errors identified in the MT hypothesis, leading to a more fine-grained metric than HTER or DA. When used in our experiments, these values were divided by 100 and truncated at 0. As in section 3.1, we constructed a training dataset $D = \{s_i, h_i, r_i, y_i\}_{n=1}^{N}$, where s_i denotes the source text, h_i denotes the MT hypothesis, r_i the reference translation, and y_i the MQM score for the hypothesis h_i.

4 Experiments

We train two versions of the Estimator model described in section 2.3: one that regresses on HTER (COMET-HTER) trained with the QT21 corpus, and another that regresses on our proprietary implementation of MQM (COMET-MQM) trained with our internal MQM corpus. For the Translation Ranking model, described in section 2.4, we train with the WMT DARR corpus from 2017 and 2018 (COMET-RANK). In this section, we introduce the training setup for these models and corresponding evaluation setup.

4.1 Training Setup

The two versions of the Estimators (COMET-HTER/MQM) share the same training setup and hyper-parameters (details are included in the Appendices). For training, we load the pretrained encoder and initialize both the pooling layer and the feed-forward regressor. Whereas the layer-wise scalars $\boldsymbol{\alpha}$ from the pooling layer are initially set to zero, the weights from the feed-forward are initialized randomly. During training, we divide the model parameters into two groups: the encoder parameters, that include the encoder model and the scalars from $\boldsymbol{\alpha}$; and the regressor parameters, that include the parameters from the top feed-forward network. We apply gradual unfreezing and discriminative learning rates (Howard and Ruder, 2018), meaning that the encoder model is frozen for one epoch while the feed-forward is optimized with a learning rate of $3\mathrm{e}{-5}$. After the first epoch, the entire model is fine-tuned but the learning rate for the encoder parameters is set to $1\mathrm{e}{-5}$ in order to avoid catastrophic forgetting.

In contrast with the two Estimators, for the COMET-RANK model we fine-tune from the outset. Furthermore, since this model does not add any new parameters on top of XLM-RoBERTa (base) other than the layer scalars $\boldsymbol{\alpha}$, we use one single learning rate of $1\mathrm{e}{-5}$ for the entire model.

4.2 Evaluation Setup

We use the test data and setup of the WMT 2019 Metrics Shared Task (Ma et al., 2019) in order to compare the COMET models with the top performing submissions of the shared task and other recent state-of-the-art metrics such as BERTSCORE and BLEURT.[5] The evaluation method used is the official Kendall's Tau-like formulation, τ, from the WMT 2019 Metrics Shared Task (Ma et al., 2019) defined as:

$$\tau = \frac{\textit{Concordant} - \textit{Discordant}}{\textit{Concordant} + \textit{Discordant}} \tag{8}$$

where *Concordant* is the number of times a metric assigns a higher score to the "better" hypothesis h^+ and *Discordant* is the number of times a metric assigns a higher score to the "worse" hypothesis

---

[5] To ease future research we will also provide, within our framework, detailed instructions and scripts to run other metrics such as CHRF, BLEU, BERTSCORE, and BLEURT

Table 1: Kendall's Tau (τ) correlations on language pairs with English as source for the WMT19 Metrics DARR corpus. For BERTSCORE we report results with the default encoder model for a complete comparison, but also with XLM-RoBERTa (base) for fairness with our models. The values reported for YiSi-1 are taken directly from the shared task paper (Ma et al., 2019).

Metric	**en-cs**	**en-de**	**en-fi**	**en-gu**	**en-kk**	**en-lt**	**en-ru**	**en-zh**
BLEU	0.364	0.248	0.395	0.463	0.363	0.333	0.469	0.235
CHRF	0.444	0.321	0.518	0.548	0.510	0.438	0.548	0.241
YISI-1	0.475	0.351	0.537	0.551	0.546	0.470	0.585	0.355
BERTSCORE (default)	0.500	0.363	0.527	0.568	0.540	0.464	0.585	0.356
BERTSCORE (xlmr-base)	0.503	0.369	0.553	0.584	0.536	0.514	0.599	0.317

COMET-MQM	0.537	0.398	0.567	0.564	0.534	0.574	**0.615**	0.378
COMET-RANK	**0.603**	**0.427**	**0.664**	**0.611**	**0.693**	**0.665**	0.580	**0.449**

h^- or the scores assigned to both hypotheses is the same.

As mentioned in the findings of (Ma et al., 2019), segment-level correlations of all submitted metrics were frustratingly low. Furthermore, all submitted metrics exhibited a dramatic lack of ability to correctly rank strong MT systems. To evaluate whether our new MT evaluation models better address this issue, we followed the described evaluation setup used in the analysis presented in (Ma et al., 2019), where correlation levels are examined for portions of the DARR data that include only the top 10, 8, 6 and 4 MT systems.

5 Results

5.1 From English into X

Table 1 shows results for all eight language pairs with English as source. We contrast our three COMET models against baseline metrics such as BLEU and CHRF, the 2019 task winning metric YISI-1, as well as the more recent BERTSCORE. We observe that across the board our three models trained with the COMET framework outperform, often by significant margins, all other metrics. Our DARR Ranker model outperforms the two Estimators in seven out of eight language pairs. Also, even though the MQM Estimator is trained on only 12K annotated segments, it performs roughly on par with the HTER Estimator for most language-pairs, and outperforms all the other metrics in en-ru.

5.2 From X into English

Table 2 shows results for the seven to-English language pairs. Again, we contrast our three COMET models against baseline metrics such as BLEU and CHRF, the 2019 task winning metric YISI-1, as well as the recently published metrics BERTSCORE and BLEURT. As in Table 1 the DARR model shows strong correlations with human judgements outperforming the recently proposed English-specific BLEURT metric in five out of seven language pairs. Again, the MQM Estimator shows surprising strong results despite the fact that this model was trained with data that did not include English as a target. Although the encoder used in our trained models is highly multilingual, we hypothesise that this powerful "zero-shot" result is due to the inclusion of the source in our models.

5.3 Language pairs not involving English

All three of our COMET models were trained on data involving English (either as a source or as a target). Nevertheless, to demonstrate that our metrics generalize well we test them on the three WMT 2019 language pairs that do not include English in either source or target. As can be seen in Table 3, our results are consistent with observations in Tables 1 and 2.

5.4 Robustness to High-Quality MT

For analysis, we use the DARR corpus from the 2019 Shared Task and evaluate on the subset of the data from the top performing MT systems for each language pair. We included language pairs for which we could retrieve data for at least ten different MT systems (i.e. all but kk-en and gu-en). We contrast against the strong recently proposed BERTSCORE and BLEURT, with BLEU as a baseline. Results are presented in Figure 3. For language pairs where English is the target, our three models are either better or competitive with all others; where English is the source we note that in general our metrics exceed the performance of oth-

Table 2: Kendall's Tau (τ) correlations on language pairs with English as a target for the WMT19 Metrics DARR corpus. As for BERTSCORE, for BLEURT we report results for two models: the base model, which is comparable in size with the encoder we used and the large model that is twice the size.

ers. Even the MQM Estimator, trained with only 12K segments, is competitive, which highlights the power of our proposed framework.

5.5 The Importance of the Source

To shed some light on the actual value and contribution of the source language input in our models' ability to learn accurate predictions, we trained two versions of our DARR Ranker model: one that uses only the reference, and another that uses both reference and source. Both models were trained using the WMT 2017 corpus that only includes language pairs from English (en-de, en-cs, en-fi, en-tr). In other words, while English was never observed as a target language during training for both variants of the model, the training of the second variant includes English source embeddings. We then tested these two model variants on the WMT 2018 corpus for these language pairs and for the reversed directions (with the exception of en-cs because cs-en does not exist for WMT 2018). The results in Table 4 clearly show that for the translation ranking architecture, including the source improves the overall correlation with human judgments. Furthermore, the inclusion of the source exposed the second variant of the model to English embeddings which is

Table 4: Comparison between COMET-RANK (section 2.4) and a reference-only version thereof on WMT18 data. Both models were trained with WMT17 which means that the reference-only model is never exposed to English during training.

Metric	**en-cs**	**en-de**	**en-fi**	**en-tr**	**cs-en**	**de-en**	**fi-en**	**tr-en**
COMET-RANK (ref. only)	0.660	0.764	0.630	0.539	0.249	0.390	0.159	0.128
COMET-RANK	0.711	0.799	0.671	0.563	0.356	0.542	0.278	0.260
$\Delta\tau$	0.051	0.035	0.041	0.024	**0.107**	**0.155**	**0.119**	**0.132**

reflected in a higher $\Delta\tau$ for the language pairs with English as a target.

6 Reproducibility

We will release both the code-base of the COMET framework and the trained MT evaluation models described in this paper to the research community upon publication, along with the detailed scripts required in order to run all reported baselines.[6] All the models reported in this paper were trained on a single Tesla T4 (16GB) GPU. Moreover, our framework builds on top of PyTorch Lightning (Falcon, 2019), a lightweight PyTorch wrapper, that was created for maximal flexibility and reproducibility.

7 Related Work

Classic MT evaluation metrics are commonly characterized as n-**gram matching metrics** because, using hand-crafted features, they estimate MT quality by counting the number and fraction of n-grams that appear simultaneous in a candidate translation hypothesis and one or more human-references. Metrics such as BLEU (Papineni et al., 2002), METEOR (Lavie and Denkowski, 2009), and CHRF (Popović, 2015) have been widely studied and improved (Koehn et al., 2007; Popović, 2017; Denkowski and Lavie, 2011; Guo and Hu, 2019), but, by design, they usually fail to recognize and capture semantic similarity beyond the lexical level.

In recent years, word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Peters et al., 2018; Devlin et al., 2019) have emerged as a commonly used alternative to n-gram matching for capturing word semantics similarity. **Embedding-based metrics** like METEOR-VECTOR (Servan et al., 2016), BLEU2VEC (Tättar and Fishel, 2017), YISI-1 (Lo, 2019), MOVERSCORE (Zhao et al., 2019), and BERTSCORE (Zhang et al., 2020) create soft-alignments between reference and hypothesis in an embedding space and then compute a score that reflects the semantic similarity between those segments. However, human judgements such as DA and MQM, capture much more than just semantic similarity, resulting in a correlation upper-bound between human judgements and the scores produced by such metrics.

Learnable metrics (Shimanaka et al., 2018; Mathur et al., 2019; Shimanaka et al., 2019) attempt to directly optimize the correlation with human judgments, and have recently shown promising results. BLEURT (Sellam et al., 2020), a learnable metric based on BERT (Devlin et al., 2019), claims state-of-the-art performance for the last 3 years of the WMT Metrics Shared task. Because BLEURT builds on top of English-BERT (Devlin et al., 2019), it can only be used when English is the target language which limits its applicability. Also, to the best of our knowledge, all the previously proposed learnable metrics have focused on optimizing DA which, due to a scarcity of annotators, can prove inherently noisy (Ma et al., 2019).

Reference-less MT evaluation, also known as Quality Estimation (QE), has historically often regressed on HTER for segment-level evaluation (Bojar et al., 2013, 2014, 2015, 2016, 2017a). More recently, MQM has been used for document-level evaluation (Specia et al., 2018; Fonseca et al., 2019). By leveraging highly multilingual pretrained encoders such as multilingual BERT (Devlin et al., 2019) and XLM (Conneau and Lample, 2019), QE systems have been showing auspicious correlations with human judgements (Kepler et al., 2019a). Concurrently, the OpenKiwi framework (Kepler et al., 2019b) has made it easier for researchers to push the field forward and build stronger QE models.

8 Conclusions and Future Work

In this paper we present COMET, a novel neural framework for training MT evaluation models that can serve as automatic metrics and easily be

---

[6] These will be hosted at: `https://github.com/Unbabel/COMET`

adapted and optimized to different types of human judgements of MT quality.

To showcase the effectiveness of our framework, we sought to address the challenges reported in the 2019 WMT Metrics Shared Task (Ma et al., 2019). We trained three distinct models which achieve new state-of-the-art results for segment-level correlation with human judgments, and show promising ability to better differentiate high-performing systems.

One of the challenges of leveraging the power of pretrained models is the burdensome weight of parameters and inference time. A primary avenue for future work on COMET will look at the impact of more compact solutions such as DistilBERT (Sanh et al., 2019).

Additionally, whilst we outline the potential importance of the source text above, we note that our COMET-RANK model weighs source and reference differently during inference but equally in its training loss function. Future work will investigate the optimality of this formulation and further examine the interdependence of the different inputs.

Acknowledgments

We are grateful to André Martins, Austin Matthews, Fabio Kepler, Daan Van Stigt, Miguel Vera, and the reviewers, for their valuable feedback and discussions. This work was supported in part by the P2020 Program through projects MAIA and Unbabel4EU, supervised by ANI under contract numbers 045909 and 042671, respectively.

A Appendices

In Table 5 we list the hyper-parameters used to train our models. Before initializing these models a random seed was set to 3 in all libraries that perform "random" operations (`torch`, `numpy`, `random` and `cuda`).

Table 5: Hyper-parameters used in our COMET framework to train the presented models.

Hyper-parameter	COMET**(Est-HTER/MQM)**	COMET-RANK
Encoder Model	XLM-RoBERTa (base)	XLM-RoBERTa (base)
Optimizer	Adam (default parameters)	Adam (default parameters)
n frozen epochs	1	0
Learning rate	3e-05 and 1e-05	1e-05
Batch size	16	16
Loss function	MSE	Triplet Margin ($\epsilon = 1.0$)
Layer-wise dropout	0.1	0.1
FP precision	32	32
Feed-Forward hidden units	2304,1152	–
Feed-Forward activations	Tanh	–
Feed-Forward dropout	0.1	–

Abstract

Using a language model (LM) pretrained on two languages with large monolingual data in order to initialize an unsupervised neural machine translation (UNMT) system yields state-of-the-art results. When limited data is available for one language, however, this method leads to poor translations. We present an effective approach that reuses an LM that is pretrained only on a high-resource language. The monolingual LM is fine-tuned on both languages and is then used to initialize a UNMT model. To reuse the pretrained LM, we have to modify its predefined vocabulary, to account for the new language. We therefore propose a novel vocabulary extension method. Our approach, RE-LM, outperforms a competitive cross-lingual pretraining model (XLM) in English-Macedonian (En-Mk) and English-Albanian (En-Sq), yielding more than $+8.3$ BLEU points for all four translation directions.

1 Introduction

Neural machine translation (NMT) has recently achieved remarkable results (Bahdanau et al., 2015; Vaswani et al., 2017), based on the exploitation of large parallel training corpora. Such corpora are only available for a limited number of languages. UNMT has attempted to address this limitation by training NMT systems using monolingual data *only* (Artetxe et al., 2018; Lample et al., 2018). Top performance is achieved using a bilingual masked language model (Devlin et al., 2019) to initialize a UNMT encoder-decoder system (Lample and Conneau, 2019). The model is then trained using denoising auto-encoding (Vincent et al., 2008) and back-translation (Sennrich et al., 2016a). The approach was mainly evaluated by translating between high-resource languages.

Translating between a high-resource and a low-resource language is a more challenging task. In this setting, the UNMT model can be initialized with a pretrained cross-lingual LM. However, training this UNMT model has been shown to be ineffective when the two languages are not related (Guzmán et al., 2019). Moreover, in order to use a pretrained cross-lingual LM to initialize a UNMT model, the two models must have a shared vocabulary. Thus, a bilingual LM needs to be trained from scratch for each language pair, before being transferred to the UNMT model (e.g. En-De LM for En-De UNMT).

Motivated by these issues, we focus on the question: *how can we accurately and efficiently translate between a high-monolingual-resource (***HMR***) and a low-monolingual-resource (***LMR***) language*? To address this question, we adapt a monolingual LM, pretrained on an HMR language to an LMR language, in order to initialize a UNMT system.

We make the following contributions: (1) We propose REused-LM[1] (**RE-LM**), an effective transfer learning method for UNMT. Our method reuses a pretrained LM on an HMR language, by fine-tuning it on both LMR and HMR languages. The fine-tuned LM is used to initialize a UNMT system that translates the LMR to the HMR language (and vice versa). (2) We introduce a novel vocabulary extension method, which allows fine-tuning a pretrained LM to an unseen language. (3) We show that RE-LM outperforms a competitive transfer learning method (XLM) for UNMT on three language pairs: English-German (En-De) on a synthetic setup, En-Mk and En-Sq. (4) We show that RE-LM is effective in low-resource supervised NMT. (5) We conduct an analysis of fine-tuning schemes for RE-LM and find that including adapters (Houlsby et al., 2019) in the training procedure yields almost the same UNMT results as RE-LM at a lower computational price. We also run experiments to identify the contribution of the vocabulary extension method.

2 Related Work

Transfer learning for UNMT. The field of UNMT has recently experienced tremendous progress. Artetxe et al. (2018); Lample et al. (2018) train UNMT models with monolingual data only, using denoising auto-encoding (Vincent et al., 2008) and online back-translation (Sennrich et al., 2016a) as training objectives. This approach is successful for languages with high-quality, large, comparable data. When these conditions are not met, though, UNMT provides near-zero scores (Neubig and Hu, 2018). UNMT is further improved when initialized with a cross-lingual pretrained model, trained on large corpora (Lample and Conneau, 2019; Song et al., 2019). However, many languages have only limited monolingual data available, a setting where UNMT is not effective (Guzmán et al., 2019). Sun et al. (2020), whose work is close to our work in motivation, train a UNMT model for an HMR-LMR language pair. Iteratively, every subset (e.g. 10%) of HMR and all LMR data is backtranslated and the pseudo-parallel corpus is added to the training process. Just like XLM, this training procedure needs to run from scratch for every new language pair. By contrast, our method fine-tunes a monolingual pretrained LM for UNMT, so it is computationally faster and simpler.

Vocabulary. Transferring a pretrained model (*source*) to a new model (*target*) requires the use of a shared vocabulary (Nguyen and Chiang, 2017). Kim et al. (2019) propose a linear alignment of the source and target model embeddings using an unsupervised dictionary. However, when the embeddings of the two models do not have enough overlapping strings, dictionary induction might fail (Søgaard et al., 2018). Lakew et al. (2018) transfer a source NMT model to a target NMT model (e.g. De-En to Nl-En). To enable transfer, they overwrite the source vocabulary with the target vocabulary. By contrast, we keep the union of the two vocabularies. We fine-tune a pretrained monolingual LM to an LMR language, to initialize an NMT model. Thus, we need the vocabularies of both languages.

Adapters. Residual adapters (Houlsby et al., 2019) are feed-forward networks, added to each of to the original model's layers. During fine-tuning, the model parameters are frozen and only the adapters are fine-tuned. This can prevent catastrophic forgetting (Goodfellow et al., 2014; Bapna and Firat, 2019). Adapters show promising results in domain adaptation (Bapna and Firat, 2019) and cross-lingual classification (Artetxe et al., 2020). Motivated by this, we study the use of adapters during LM fine-tuning in our analysis.

3 Proposed Approach

We describe our method for translation between a high-resource (HMR) and a low-resource language (LMR) using monolingual data in this section.

3.1 RE-LM

Our proposed approach consists of three steps, as shown in Figure 1:

(A) We train a monolingual masked LM on the HMR language, using all available HMR corpora. This step needs to be performed only *once* for the HMR language. Note that a publicly available pretrained model could also be used.

(B) To fine-tune the pretrained LM on the LMR language, we first need to overcome the vocabulary mismatch problem. Fine-tuning without extending the vocabulary is detrimental, as we will show later in the analysis. We therefore extend the vocabulary of the pretrained model using our proposed method, described in §3.2.

(C) Finally, we initialize an encoder-decoder UNMT system with the fine-tuned LM. The UNMT model is trained using denoising auto-encoding and online back-translation for the HMR-LMR language pair.

BPE$_{HMR}$	Pro_gram_et e fes_ti_val_it p_ë_r_f_shi_j_n_ë nj_ë rang t_ë g_jer_ë v_ep_rim_tar_ish
BPEjoint	Progra_met e fe_s_ti_val_it përfshijnë një rang të gjerë veprimtari_sh

Figure 2: Segmentations of Albanian (Sq). We observe that splitting Sq using En BPEs (BPE$_{HMR}$) results in heavily segmented tokens. This problem is alleviated using BPE$_{joint}$ tokens, learned on both languages.

3.2 Vocabulary Extension

We propose a novel method that enables adapting a pretrained monolingual LM to an unseen language. We consider the case of an LM pretrained on an HMR language. The training data is split using Byte-Pair-Encoding (BPE) (Sennrich et al., 2016b). We denote these BPE tokens as BPE$_{HMR}$ and the resulting vocabulary as V_{HMR}. We aim to fine-tune the trained LM to an unseen LMR language. Splitting the LMR language with BPE$_{HMR}$ tokens would result in heavy segmentation of LMR words (Figure 2). To counter this, we learn BPEs on the joint LMR and HMR corpus (BPE$_{joint}$). We then use BPE$_{joint}$ tokens to split the LMR data, resulting in a vocabulary V_{LMR}. This technique increases the number of shared tokens and enables cross-lingual transfer of the pretrained LM. The final vocabulary is the union of the V_{HMR} and V_{LMR} vocabularies. We extend the input and output embedding layer to account for the new vocabulary items. The new parameters are then learned during fine-tuning.

4 Experimental Setup

Datasets. We experiment with two setups. In the first *synthetic* setup we use En-De. We sample 8M En sentences from NewsCrawl. To simulate an LMR language, we gradually sample 0.05M, 0.5M and 1M De sentences. We use the WMT dev/test sets (Bojar et al., 2016). The second, *real-world setup* is En-Mk, En-Sq. We use 68M En sentences from NewsCrawl. For Mk and Sq, we use 2.4M Mk and 4M Sq, obtained from OSCAR[2] (Ortiz Suárez et al., 2019) and Wikipedia. We randomly select 3K sentences from SETIMES[3] as dev and 3K as test set. We tokenize data with standard Moses (Koehn et al., 2006) scripts. For the low-resource supervised case, we sample 10K, 100K, and 200K parallel sentences from SETIMES for Mk and Sq.

Preprocessing. We train a standard XLM model (Lample and Conneau, 2019) as a baseline using 32K BPE merge operations, learned on the concatenation of sentences sampled randomly from the corpora of each language pair with $\alpha = 0.5$. For RE-LM, we learn 32K BPEs on the HMR corpus and extract the initial vocabulary (V_{HMR}). Then, we learn 32K BPEs on the joint LMR and HMR corpus (BPE$_{joint}$). We extend the initial V$_{HMR}$ vocabulary by the amount of LMR vocabulary items that are not already present in V$_{HMR}$. To identify whether a smaller number of BPE merges would be useful for splitting the LMR language, we conduct experiments varying their number in the analysis.

Model Configuration. RE-LM is built using the XLM codebase[4]. Each masked LM has a Transformer architecture with 1024 hidden units, 6 layers and 8 attention heads. Each NMT model is a 6-layer encoder-decoder Transformer with 1024 hidden units and 8 heads. Each LM is trained using Adam (Kingma and Ba, 2015) with learning rate 10^{-4} and masking follows Devlin et al. (2019). During UNMT and supervised NMT training, Adam with inverse square root scheduling and a learning rate of 10^{-4} is used. We evaluate NMT models on the dev set every 3000 updates using greedy decoding. The En LM and each XLM are trained on 8 NVIDIA GTX 11 GB GPUs for 1 week, with a per-GPU batch size of 32. LM fine-tuning and NMT training models are computationally efficient, using just 1 GPU and 32 batch size. We assume that by fine-tuning the LM on 8 GPUs, we could get even better results. Final translations are generated using beam search of size 5. We report de-tokenized BLEU using SacreBLEU (Post, 2018)[5].

Experiments. For unsupervised translation, we train a randomly initialized UNMT model for each language pair as a first baseline. As a transfer learning baseline, we use XLM (Lample and Conneau, 2019), trained on the two languages and transferred to a UNMT model. The UNMT models are trained using monolingual data. For supervised translation, NMT training is performed using only parallel corpora, without offline back-translation of monolingual data. The first baseline is a randomly initialized NMT system. The second baseline is an NMT model initialized with XLM. We compare them to our proposed approach, RE-LM. Both XLM and RE-LM are trained on the monolingual corpora of both languages of interest. In the analysis, we add adapters (Rebuffi et al., 2018) of hidden size 256 after each self-attention and each feed-forward layer of the pretrained monolingual LM. We freeze the parameters of the pretrained LM and fine-tune only the adapters and the embedding layer.

5 Results and Analysis

5.1 Unsupervised Translation

Table 1 presents our UNMT results, comparing random initialization, XLM and RE-LM.

RE-LM	**10.7**	**7.5**	**22.6**	**19.0**	**24.3**	**21.9**	**22.0**	**21.1**	**27.6**	**28.1**

Table 1: UNMT BLEU scores. The first column indicates the pretraining method used. Left arrow (←) refers to translation from the LMR language to En, while right arrow (→) refers to translation from En to the LMR language.

Synthetic setup. We observe that RE-LM consistently outperforms XLM. Using 50K De sentences, RE-LM has small gains over XLM (+1.1 BLEU in En→De). However, when we scale to slightly more data (500K), the performance of RE-LM is clearly better than the one of XLM, with +3 En→De BLEU gains. With 1M De data, our model surpasses the XLM by more than 2.6 BLEU in both directions.

Real-world setup. Our approach surpasses XLM in both language pairs. We observe that RE-LM achieves at least +8.3 BLEU over XLM for En-Mk. Our model was first pretrained on En and then fine-tuned on both En and Mk. Therefore, it has processed *all* En and Mk sentences, obtaining a good cross-lingual representation. However, XLM is jointly trained on En and Mk. As a result, it overfits Mk before processing all En data. RE-LM is similarly effective for En-Sq, achieving an improvement of at least +9.3 BLEU over XLM.

Synthetic vs Real-world setup. The effectiveness of RE-LM is pronounced in the real-world setup. We identify two potential reasons. First, for En-De, 8M En is used for LM pretraining, while for En-Mk and En-Sq, 68M En is used. When XLM is trained on imbalanced HMR-LMR data, it overfits the LMR language. This is more evident for the En-Mk (or En-Sq) than for the En-De XLM, perhaps due to the larger data imbalance. Second, in En-De, we use high-quality corpora for both languages (NewsCrawl), whereas Mk and Sq are trained on low-quality CommonCrawl data. The fact that RE-MLM outperforms XLM for Mk and Sq shows that it is more robust to noisy data than the XLM.

5.2 Low-Resource Supervised Translation

We sample 10K, 100K and 200K of En-Mk and En-Sq bi-text and train supervised NMT systems. We compare XLM, RE-LM and *random*, an NMT model trained from scratch. We observe (Table 2) that RE-LM consistently outperforms the baselines when trained on 100K or less for En-Mk and En-Sq. Using 200K, though, RE-LM yields the same results as XLM. We hypothesize that this happens because SETIMES is a homogeneous domain. Thus, training an NMT model with 200K is sufficient for competitive results, so both pretraining models provide similar improvements over *random*.

parallel	languages direction	En-Mk ←	 →	En-Sq ←	 →
10K	random	23.4	23.7	25.5	18.9
	XLM	38.7	38.7	44.7	41.4
	RE-LM	**40.1**	38.9	**45.7**	**42.8**
100K	random	48.4	48.2	51.8	37.4
	XLM	53.7	53.2	57.1	52.0
	RE-LM	**54.8**	53.4	**58.1**	**52.9**
200K	random	51.3	51.2	55.6	51.4
	XLM	55.0	55.5	60.9	55.1
	RE-LM	55.2	55.3	61.1	54.8

Table 2: BLEU scores on the dev set using increasing amounts of parallel data. We show in bold the models that achieve at least +1 BLEU compared to XLM.

5.3 Analysis

We experiment with different fine-tuning schemes and show results in Table 3. Then, we vary the number of BPE merges used to split the LMR language using the vocabulary extension method and also show experiments where this method is not used at all. The results are presented in Table 4.

RE-LM. In Table 3, we compare fine-tuning an LM *only* on the LMR language to fine-tuning it on *both* the HMR and LMR language (rows 1 and 2). Fine-tuning only on the LMR language provides worse BLEU scores because of catastrophic forgetting. The negative effect is clear for Mk and Sq, where fine-tuning only on the LMR results in worse BLEU scores than random initialization, shown in Table 1. For De, the effect is smaller, perhaps because En and De are very similar languages.

Adapters. We insert adapters to the pretrained LM and fine-tune only the adapter and embedding layer. We use the fine-tuned LM to initialize a UNMT system. Adapters are used for both translation directions during UNMT training. Results are presented in Table 3. Fine-tuning the LM only on the LMR language yields at least +3.9 BLEU for En-Sq com-

	HMR-LMR language pair	En-De		En-De		En-De		En-Mk		En-Sq	
	size of LMR language	**0.05M**		**0.5M**		**1M**		**2.4M**		**4M**	
		←	→	←	→	←	→	←	→	←	→
LM	ft on LMR	9.4	7.3	20.4	16.8	20.6	17.8	2.7	2.4	4.7	4.7
	ft on LMR & HMR (**RE-LM**)	**10.7**	**7.5**	**22.6**	**19.0**	**24.3**	**21.9**	**22.0**	**21.1**	27.6	28.1
	+ adapters ft on LMR (**adapter RE-LM**)	9.8	**7.5**	21.3	18.3	23.7	20.0	21.6	19.0	**30.2**	**29.4**
	+ adapters ft on LMR & HMR	9.2	7.1	20.6	18.0	23.4	19.9	21.6	20.3	24.6	25.5

Table 3: Comparison of UNMT BLEU scores obtained using different fine-tuning schemes of the pretrained monolingual LM. *LM* refers to the pretrained LM (on HMR data), while *ft* refers to fine-tuning.

pared to fine-tuning on both (rows 3, 4). En and Sq are not similar languages and their embeddings also differ. Thus, fine-tuning on both is not helpful. By contrast, fine-tuning only on Sq preserves the pretrained model's knowledge, while adapters are trained to encode Sq. For En-De and En-Mk, both approaches provide similar results. En and Mk do not share an alphabet, so their embeddings do not overlap and both fine-tuning methods are equally effective. In En-De, fine-tuning only on De is marginally better than fine-tuning on both. We highlight that adapters allow parameter-efficient fine-tuning. Adapter RE-LM reaches almost the same results as RE-LM, using just a fraction of the RE-LM parameters while fine-tuning. Details can be found in the appendix.

BPE_{joint} merges	En-De		En-Mk		En-Sq	
	0.5M		**2.4M**		**4M**	
	→	←	→	←	→	←
-	8.1	8.0	6.1	6.4	7.2	7.6
8K	8.3	10.2	14.3	17.3	18.1	16.4
16K	8.7	14.6	14.9	20.2	27.1	25.5
32K	22.6	19.0	22.0	21.1	27.6	28.1

Table 4: UNMT BLEU scores obtained with RE-LM, **with** (rows 2-4) and **without** (row 1) extending the vocabulary of the pretrained LM (V_{HMR}). When extending the vocabulary, we vary the number of BPE_{joint} merges used to split the LMR data. We note that 32K BPEs are used to split the HMR data (BPE_{HMR}).

BPE_{joint}	new vocabulary items		
merges	Mk	Sq	De
8K	5K	5K	0.6K
16K	10K	10K	2K
32K	19K	20K	19K

Table 5: Statistics of the vocabulary extension method. We split the LMR corpus using 8K, 16K, or 32K BPE merges and report the number of new vocabulary items.

Vocabulary Extension. In order to use RE-LM, we extend the vocabulary of each language, as described in §3.2. The intuition is that, since the pretrained monolingual LM uses BPEs learned exclusively on the HMR language, these BPEs would not split the LMR corpus in a meaningful way. We conduct experiments to clarify the contribution of the vocabulary extension, presented in Table 4. In Table 5, we present the amount of vocabulary items added for each of our experimental setups.

Without vocabulary extension, the results are poor. This is expected, as in the case of Mk for example, the HMR language (En) uses Latin alphabet, whereas Mk uses Cyrillic. If the vocabulary of Mk is not taken into account, the UNMT model cannot provide accurate results. The same applies for Sq and De. We hypothesize that, even though these languages use Latin script, a lot of their words do not appear in En, therefore extending the initial vocabulary to include them is crucial. Using vocabulary extension, we experiment with learning 8K, 16K or 32K BPEs on the joint corpus. We then use them to split the LMR data. We observe in Table 4 that even using only 8K BPEs, there is a large improvement in Mk and Sq (more than +8 BLEU). For En-De, the improvement is negligible. This might be the case because, as Table 5 shows, using 8K merges, only 600 items are added to the initial vocabulary, which are not sufficient for representing De language. This setup for En-De is in fact very similar to not employing vocabulary extension. We notice that adding more vocabulary items (using more BPE merge operations) is helpful for all language pairs, providing improved BLEU scores.

6 Conclusions

Training competitive unsupervised NMT models for HMR-LMR scenarios is important for many real low-resource languages. We proposed RE-LM, a novel approach that fine-tunes a high-resource LM on a low-resource language and initializes an NMT model. RE-LM outperformed a strong baseline in UNMT, while also improving translations on a low-resource supervised setup. In future work, we will apply our method to languages with corpora from diverse domains and also to other languages.

A Appendix

A.1 Vocabulary Extension

We provide more examples of different segmentations of Sq, De and Mk using either the BPE_{HMR} or the BPE_{joint} tokens in Figure 3. We observe that, as expected, the Mk sentence is split to the character level, as it uses a different alphabet (Cyrillic) than the one that the BPE_{HMR} tokens were learned on (Latin).

Figure 3: Segmentation of Sq, De and Mk using BPE_{HMR} or BPE_{joint} tokens. Using BPE_{HMR} tokens results in heavily split words.

A.2 Datasets

We report that we remove sentences longer than 100 words after BPE splitting. We split the data using the fastBPE codebase[6].

A.3 Model Configuration

We tie the embedding and output (projection) layers of both LM and NMT models (Press and Wolf, 2017). We use a dropout rate of 0.1 and GELU activations (Hendrycks and Gimpel, 2017). We use the default parameters of Lample and Conneau (2019) in order to train our models unless otherwise specified. We do not tune the hyperparameters. The code was built with PyTorch (Paszke et al., 2019) on top of the XLM implementation[7]. This code was used for LM pretraining, LM fine-tuning, UNMT training, and NMT training.

LM configuration and training details. RE-LM approach pretrains a **monolingual** language model whereas the XLM approach pretrains a **bilingual** language model. We obtain a checkpoint every 200K sentences processed by the model. We train each LM using as criterion the validation perplexity on the LMR language, with a patience of 10.

The training details of the two *pretraining* methods are presented here:

- The monolingual LM pretraining required 1 week, 8 GPUs and had 137M parameters.
- The XLM pretraining required 1 week, in 8 GPUs. The total number of trainable parameters is 138M.

Our approach also requires an *LM fine-tuning* step. The runtimes, parameters and GPU details are shown in Table 6 under RE-LM *ft* column. The runtimes mentioned refer to the En-Mk language pair. We note that the *LM fine-tuning* step is a lot faster than performing *XLM pretraining* for each language pair (note that pretraining ran on 8 GPUs, whereas fine-tuning on a single GPU).

NMT configuration and training details. The parameters and runtimes of the UNMT models we used are shown in Table 6 under UNMT columns. Likewise, the details of supervised NMT models are shown under sup NMT columns. We get a checkpoint every 50K sentences processed by the model. Regarding the adapter RE-LM training procedure, we note that, different from Houlsby et al. (2019); Bapna and Firat (2019), we also freeze the layer normalization (Ba et al., 2016) parameters, without introducing new ones.

A.4 Validation Scores of Results

In Tables 7 and 8 we show the dev scores of the main results of our proposed approach (RE-LM) compared to the baselines. These Tables extend Table 1 of the main paper.

In Tables 9 and 10, we show the dev scores of the extra fine-tuning experiments we did for the analysis. The Tables correspond to Table 3 of the main paper.

We note that the dev scores are obtained using greedy decoding, while the test scores are obtained with beam search of size 5. We clarify that we train each NMT model using as training criterion the validation BLEU score of the LMR→HMR direction, with a patience of 10. We specifically use `multi-bleu.perl` script from Moses.

[†]Salesforce Research
`{mohi0004, bari0001, srjoty}@ntu.edu.sg`

Abstract

Most of the successful and predominant methods for Bilingual Lexicon Induction (BLI) are mapping-based, where a linear mapping function is learned with the assumption that the word embedding spaces of different languages exhibit similar geometric structures (*i.e.,* approximately *isomorphic*). However, several recent studies have criticized this simplified assumption showing that it does not hold in general even for closely related languages. In this work, we propose a novel semi-supervised method to learn cross-lingual word embeddings for BLI. Our model is independent of the isomorphic assumption and uses non-linear mapping in the latent space of two independently pre-trained autoencoders. Through extensive experiments on fifteen (15) different language pairs (in both directions) comprising resource-rich and low-resource languages from two different datasets, we demonstrate that our method outperforms existing models by a good margin. Ablation studies show the importance of different model components and the necessity of non-linear mapping.

1 Introduction

In recent years, a plethora of methods have been proposed to learn cross-lingual word embeddings (or CLWE for short) from monolingual word embeddings. Here words with similar meanings in different languages are represented by similar vectors, regardless of their actual language. CLWE enable us to compare the meaning of words across languages, which is key to most multi-lingual applications such as bilingual lexicon induction (Heyman et al., 2017), machine translation (Lample et al., 2018; Artetxe et al., 2018c), or multi-lingual information retrieval (Vulić and Moens, 2015). They also play a crucial role in cross-lingual knowledge transfer between languages (*e.g.,* from resource-rich to low-resource languages) by providing a common representation space (Ruder et al., 2019).

Mikolov et al. (2013a), in their pioneering work, learn a *linear* mapping function to transform the source embedding space to the target language by minimizing the squared Euclidean distance between the translation pairs of a seed dictionary. They assume that the similarity of geometric arrangements in the embedding spaces is the key reason for their method to succeed as they found linear mapping superior to non-linear mappings with multi-layer neural networks. Subsequent studies propose to improve the model by normalizing the embeddings, imposing an orthogonality constraint on the linear mapper, modifying the objective function, and reducing the seed dictionary size (Artetxe et al., 2016, 2017, 2018a; Smith et al., 2017).

A more recent line of research attempts to eliminate the seed dictionary totally and learn the mapping in a purely unsupervised way (Barone, 2016; Zhang et al., 2017; Conneau et al., 2018; Artetxe et al., 2018b; Xu et al., 2018; Hoshen and Wolf, 2018; Alvarez-Melis and Jaakkola, 2018; Mohiuddin and Joty, 2019, 2020). While not requiring any cross-lingual supervision makes these methods attractive, Vulić et al. (2019) recently show that even the most robust unsupervised method (Artetxe et al., 2018b) fails for a large number of language pairs. They suggest to rethink the main motivations behind fully unsupervised methods showing that with a small seed dictionary (500-1K pairs) their semi-supervised method always outperforms the unsupervised method and does not fail for any language pair. Other concurrent work (Ormazabal et al., 2019; Doval et al., 2019) also advocates for weak supervision in CLWE methods.

Almost all mapping-based CLWE methods, supervised and unsupervised alike, solve the *Procrustes* problem in the final step or during self-learning (Ruder et al., 2019). This restricts the transformation to be orthogonal linear mappings.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2712–2723,
November 16–20, 2020.

However, learning an orthogonal linear mapping inherently assumes that the embedding spaces of different languages exhibit similar geometric structures (*i.e.,* approximately *isomorphic*). Several recent studies have questioned this strong assumption and empirically showed that the isomorphic assumption does not hold in general even for two closely related languages like English and German (Søgaard et al., 2018; Patra et al., 2019).

In this work, we propose LNMAP (**L**atent space **N**on-linear **Map**ping), a novel semi-supervised approach that uses *non-linear* mapping in the latent space to learn CLWE. It uses minimal supervision from a seed dictionary, while leveraging semantic information from the monolingual word embeddings. As shown in Figure 1, LNMAP comprises two *autoencoders*, one for each language. The auto-encoders are first trained independently in a self-supervised way to induce the latent code space of the respective languages. Then, we use a small seed dictionary to learn the non-linear mappings between the two code spaces. To guide our mapping in the latent space, we include two additional constraints: back-translation and original embedding reconstruction. Crucially, our method does not enforce any strong prior constraints like the orthogonality (or isomorphic), rather it gives the model the flexibility to induce the required latent structures such that it is easier for the non-linear mappers to align them in the code space.

In order to demonstrate the effectiveness and robustness of LNMAP, we conduct extensive experiments on bilingual lexicon induction (BLI) with fifteen (15) different language pairs (in both directions) comprising high- and low-resource languages from two different datasets for different sizes of the seed dictionary. Our results show significant improvements for LNMAP over the state-of-the-art in most of the tested scenarios. It is particularly very effective for low-resource languages; for example, using 1K seed dictionary, LNMAP yields about 18% absolute improvements on average over a state-of-the-art supervised method (Joulin et al., 2018). It also outperforms the most robust unsupervised system of Artetxe et al. (2018b) in most of the translation tasks. Interestingly, for resource-rich language pairs, linear autoencoder performs better than non-linear ones. Our ablation study reveals the collaborative nature of LNMAP's different components and efficacy of its non-linear mappings in the code space. We open-source our framework at https://ntunlpsg.github.io/project/lnmap/.

2 Background

Limitations of Isomorphic Assumption. Almost all CLWE methods inherently assume that embedding spaces of different languages are approximately *isomorphic* (i.e., similar in geometric structure). However, recently researchers have questioned this simplified assumption and attributed the performance degradation of existing CLWE methods to the strong mismatches in embedding spaces caused by the linguistic and domain divergences (Søgaard et al., 2019; Ormazabal et al., 2019). Søgaard et al. (2018) empirically show that even closely related languages are far from being isomorphic. Nakashole and Flauger (2018) argue that mapping between embedding spaces of different languages can be approximately linear only at small local regions, but must be non-linear globally. Patra et al. (2019) also recently show that etymologically distant language pairs cannot be aligned properly using orthogonal transformations.

Towards Semi-supervised Methods. A number of recent studies have questioned the robustness of existing unsupervised CLWE methods (Ruder et al., 2019). Vulić et al. (2019) show that even the most robust unsupervised method (Artetxe et al., 2018b) fails for a large number of language pairs; it gives zero (or near zero) BLI performance for 87 out of 210 language pairs. With a seed dictionary of only 500 - 1000 word pairs, their supervised method outperforms unsupervised methods by a wide margin in most language pairs. Other recent work also suggested using semi-supervised methods (Patra et al., 2019; Ormazabal et al., 2019).

Mapping in Latent Space. Mohiuddin and Joty (2019) propose adversarial autoencoder for *unsupervised* word translation. They use *linear* autoencoders in their model, and the mappers are also linear. They emphasize the benefit of using latent space over the original embedding space. Although their method is more robust than other existing adversarial models, still it suffers from training instability for distant language pairs.

Our Contributions. Our proposed LNMAP is independent of the isomorphic assumption. It uses weak supervision from a small seed dictionary, while leveraging rich structural information from monolingual embeddings. Unlike Mohiuddin and Joty (2019), the autoencoders in LNMAP are

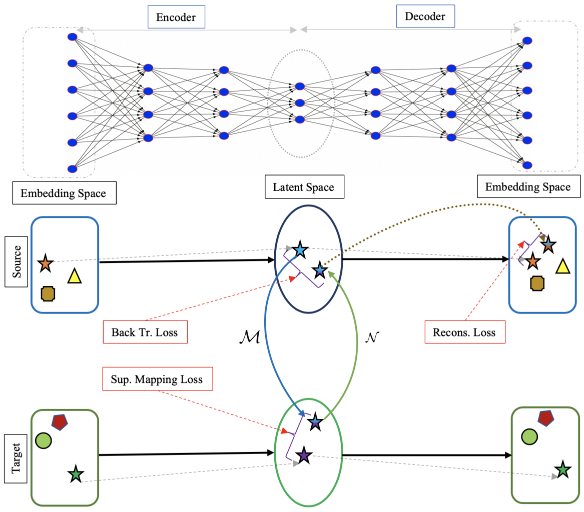

Figure 1: LNMAP: Our proposed semi-supervised framework. Identical shapes with different colors denote the similar meaning words in different spaces (e.g., source/target embedding space or latent space).

not limited to only linearity. More importantly, it uses *non-linear* mappers. These two factors contribute to its robust performance even for very low-resource languages (§5). To the best of our knowledge, we are the first to showcase such robust and improved performance with non-linear methods.[1]

3 LNMAP Semi-supervised Framework

Let $\mathcal{V}_{\ell_x}=\{v_{x_1},...,v_{x_{n_x}}\}$ and $\mathcal{V}_{\ell_y}=\{v_{y_1},...,v_{y_{n_y}}\}$ be two sets of vocabulary consisting of n_x and n_y words for a source (ℓ_x) and a target (ℓ_y) language, respectively. Each word v_{x_i} (resp. v_{y_j}) has an embedding $x_i \in \mathbb{R}^d$ (resp. $y_j \in \mathbb{R}^d$), trained with any word embedding models, *e.g.*, `FastText` (Bojanowski et al., 2017). Let $\mathcal{E}_{\ell_x} \in \mathbb{R}^{n_x \times d}$ and $\mathcal{E}_{\ell_y} \in \mathbb{R}^{n_y \times d}$ be the word embedding matrices for the source and target languages, respectively. We are also given with a seed dictionary $\mathcal{D}$ $=\{(x_1,y_1),...,(x_k,y_k)\}$ with k word pairs. Our objective is to learn a transformation function $\mathcal{M}$ such that for any $v_{x_i} \in \mathcal{V}_{\ell_x}$, $\mathcal{M}(x_i)$ corresponds to its translation y_j, where $v_{y_j} \in \mathcal{V}_{\ell_y}$. Our approach LNMAP (Figure 1) follows two sequential steps:

(i) Unsupervised latent space induction using monolingual autoencoders (§3.1), and

(ii) Supervised non-linear transformation learning with back-translation and source embedding reconstruction constraints (§3.2).

3.1 Unsupervised Latent Space Induction

We use two autoencoders, one for each language. Each autoencoder comprises an encoder E_{ℓ_x} (resp. E_{ℓ_y}) and a decoder D_{ℓ_x} (resp. D_{ℓ_y}). Unless otherwise stated, the autoencoders are *non-linear*, where each of the encoder and decoder is a three-layer feed-forward neural network with two non-linear hidden layers. More formally, the encoding-decoding operations of the source autoencoder ($\texttt{autoenc}_{\ell_x}$) are defined as:

$$h_1^{E_{\ell_x}} = \phi(\theta_1^{E_{\ell_x}} x_i) \quad (1) \qquad h_1^{D_{\ell_x}} = \phi(\theta_3^{D_{\ell_x}} z_{x_i}) \quad (4)$$

$$h_2^{E_{\ell_x}} = \phi(\theta_2^{E_{\ell_x}} h_1^{E_{\ell_x}}) \quad (2) \qquad h_2^{D_{\ell_x}} = \phi(\theta_2^{D_{\ell_x}} h_1^{D_{\ell_x}}) \quad (5)$$

$$z_{x_i} = \theta_3^{E_{\ell_x}} h_2^{\ell_x} \quad (3) \qquad \hat{x}_i = \phi(\theta_1^{D_{\ell_x}} h_2^{D_{\ell_x}}) \quad (6)$$

where $\theta_i^{E_{\ell_x}} \in \mathbb{R}^{c_i \times d_i}$ and $\theta_i^{D_{\ell_x}} \in \mathbb{R}^{d_i \times c_i}$ are the parameters of the layers in the encoder and decoder respectively, and ϕ is a non-linear activation function; we use Parametric Rectified Linear Unit (`PReLU`) in all the hidden layers and `tanh` in the final layer of the decoder (Eq. 6). We use linear activations in the output layer of the encoder (Eq. 3). We train $\texttt{autoenc}_{\ell_x}$ with l_2 reconstruction loss as:

$$\mathcal{L}_{\text{autoenc}_{\ell_x}}(\Theta_{E_{\ell_x}}, \Theta_{D_{\ell_x}}) = \frac{1}{n_x}\sum_{i=1}^{n_x} \|x_i - \hat{x}_i\|^2 \quad (7)$$

where $\Theta_{E_{\ell_x}} = \{\theta_1^{E_{\ell_x}}, \theta_2^{E_{\ell_x}}, \theta_3^{E_{\ell_x}}\}$ and $\Theta_{D_{\ell_x}} = \{\theta_1^{D_{\ell_x}}, \theta_2^{D_{\ell_x}}, \theta_3^{D_{\ell_x}}\}$ are the parameters of the encoder and the decoder of $\texttt{autoenc}_{\ell_x}$.

The encoder, decoder and the reconstruction loss for the target autoencoder ($\texttt{autoenc}_{\ell_y}$) are similarly defined.

3.2 Supervised Non-linear Transformation

Let $q(z_x|x)$ and $q(z_y|y)$ be the distributions of latent codes in $\texttt{autoenc}_{\ell_x}$ and $\texttt{autoenc}_{\ell_y}$, respectively. We have two non-linear mappers: $\mathcal{M}$ that translates a source code into a target code, and $\mathcal{N}$ that translates a target code into a source code (Figure 1). Both mappers are implemented as a feed-forward neural network with a single hidden layer and `tanh` activations, and they are trained using the provided seed dictionary $\mathcal{D}$.

Non-linear Mapping Loss. Let $\Theta_{\mathcal{M}}$ and $\Theta_{\mathcal{N}}$ denote the parameters of the two mappers $\mathcal{M}$ and $\mathcal{N}$, respectively. While mapping from $q(z_x|x)$ to $q(z_y|y)$, we jointly train the mapper $\mathcal{M}$ and the source encoder E_{ℓ_x} with the following l_2 loss.

---

[1] Our experiments with (unsupervised) adversarial training showed very unstable results with the non-linear mappers.

$$\mathcal{L}_{\text{MAP}}(\Theta_{\mathcal{M}}, \Theta_{E_{\ell_x}}) = \frac{1}{k}\sum_{i=1}^{k} \|z_{y_i} - \mathcal{M}(z_{x_i})\|^2 \quad (8)$$

The mapping loss for $\mathcal{N}$ and E_{ℓ_y} is similarity defined. To learn a better transformation function, we enforce two additional constraints to our objective – back-translation and reconstruction.

Back-Translation Loss. To ensure that a source code $z_{x_i} \in q(z_x|x)$ translated to the target language latent space $q(z_y|y)$, and then translated back to the original latent space remain unchanged, we enforce the back-translation constraint, that is, $z_{x_i} \rightarrow \mathcal{M}(z_{x_i}) \rightarrow \mathcal{N}(\mathcal{M}(z_{x_i})) \approx z_{x_i}$. The back-translation (BT) loss from $q(z_y|y)$ to $q(z_x|x)$ is

$$\mathcal{L}_{\text{BT}}(\Theta_{\mathcal{M}}, \Theta_{\mathcal{N}}) = \frac{1}{k}\sum_{i=1}^{k} \|z_{x_i} - \mathcal{N}(\mathcal{M}(z_{x_i}))\|^2 \quad (9)$$

The BT loss in the other direction $(z_{y_j} \rightarrow \mathcal{N}(z_{y_j}) \rightarrow \mathcal{M}(\mathcal{N}(z_{y_j})) \approx z_{y_j})$ is similarly defined.

Reconstruction Loss. In addition to back-translation, we include another constraint to guide the mapping further. In particular, we ask the decoder D_{ℓ_x} of $\texttt{autoenc}_{\ell_x}$ to reconstruct the original embedding x_i from the back-translated code $\mathcal{N}(\mathcal{M}(z_{x_i}))$. We compute this original embedding reconstruction loss for $\texttt{autoenc}_{\ell_x}$ as:

$$\mathcal{L}_{\text{REC}}(\theta_{E_{\ell_x}}, \theta_{D_{\ell_x}}, \Theta_{\mathcal{M}}, \Theta_{\mathcal{N}}) = \frac{1}{k}\sum_{i=1}^{k} \|x_i - D_{\ell_x}(\mathcal{N}(\mathcal{M} z_{x_i}))\|^2 \quad (10)$$

The reconstruction loss for $\texttt{autoenc}_{\ell_y}$ is defined similarly. Both back-translation and reconstruction lead to more *stable training* in our experiments. In our ablation study (§5.4), we empirically show the efficacy of the addition of these two constraints.

Total Loss. The total loss for mapping a batch of word embeddings from source to target is:

$$\mathcal{L}_{\ell_x \rightarrow \ell_y} = \mathcal{L}_{\text{MAP}} + \lambda_1 \mathcal{L}_{\text{BT}} + \lambda_2 \mathcal{L}_{\text{REC}} \quad (11)$$

where λ_1 and λ_2 control the relative importance of the loss components. Similarly we define the total loss for mapping in the opposite direction $\mathcal{L}_{\ell_y \rightarrow \ell_x}$.

Remark. Note that our approach is fundamentally different from existing methods in two ways. First, most of the existing methods directly map the distribution of the source embeddings $p(x)$ to the distribution of the target embeddings $p(y)$. Second, they learn a linear mapping function assuming that the two languages' embedding spaces are nearly isomorphic, which does not hold in general (Søgaard et al., 2018; Patra et al., 2019).

Mapping the representations in the code space using non-linear transformations gives our model the flexibility to induce the required semantic structures in its latent space that could potentially yield more accurate cross-lingual mappings (§5).

3.3 Training Procedure

We present the training method of LNMAP in Algorithm 1. In the first step, we pre-train $\texttt{autoenc}_{\ell_x}$ and $\texttt{autoenc}_{\ell_y}$ separately on the respective monolingual word embeddings. In this unsupervised step, we use the first 200K embeddings. This pre-training induce word semantics (and relations) in the code space (Mohiuddin and Joty, 2019).

The next step is the self-training process, where we train the mappers along with the autoencoders using the seed dictionary in an iterative manner. We keep a copy of the original dictionary $\mathcal{D}$; let us call it $\mathcal{D}_{\text{orig}}$. We first update the mapper $\mathcal{M}$ and the source encoder E_{ℓ_x} on the mapping loss (Eq. 8). The mappers (both $\mathcal{M}$ and $\mathcal{N}$) then go through two more updates, one for back-translation (Eq. 9) and the other for reconstruction of the source embedding (Eq. 10). The entire source autoencoder $\texttt{autoenc}_{\ell_x}$ (both E_{ℓ_x} and D_{ℓ_x}) in this stage gets updated only on the reconstruction loss.

After each iteration of training (step *i.* in Alg. 1), we induce a new dictionary $\mathcal{D}_{\text{new}}$ using the learned encoders and mappers. To find the nearest target word (y_j) of a source word (x_i) in the target latent space, we use the Cross-domain Similarity Local Scaling (CSLS) measure which works better than simple cosine similarity in mitigating the *hubness* problem (Conneau et al., 2018). It penalizes the words that are close to many other words in the target latent space. To induce the dictionary, we compute CSLS for K most frequent source and target words and select the translation pairs that are nearest neighbors of each other according to CSLS.

For the next iteration of training, we construct the dictionary $\mathcal{D}$ by merging $\mathcal{D}_{\text{orig}}$ with the l most similar (based on CSLS) word pairs from $\mathcal{D}_{\text{new}}$.

Algorithm 1: Training LNMAP

```
Input  : Word embedding matrices: $\mathcal{E}_{\ell_x}$, $\mathcal{E}_{\ell_y}$, seed dictionary: $\mathcal{D}$, and increment count $C$
// Unsup.  latent space induction
1. Train autoenc$_{\ell_x}$ and autoenc$_{\ell_y}$ separately for some epochs on monolingual word
   embeddings
// Sup.  non-linear transformation
2. $iter = 0$; $\mathcal{D}_{\text{orig}} = \mathcal{D}$
3. do
    $iter = iter + 1$
    i. for $n\_epochs$ do
        ($a$) Sample a mini-batch from $\mathcal{D}$
        ($b$) Update mapper $\mathcal{M}$ and $E_{\ell_x}$ on the non-linear mapping loss
        ($c$) Update mappers $\mathcal{M}$ and $\mathcal{N}$ on the back-translation loss
        ($d$) Update mappers ($\mathcal{M}, \mathcal{N}$) and autoenc$_{\ell_x}$ on the reconstruction loss
      end
    ii. Induce a new dictionary $\mathcal{D}_{\text{new}}$ of size: $iter \times C$
    iii. Create a new dictionary, $\mathcal{D} = \mathcal{D}_{\text{orig}} \bigcup \mathcal{D}_{\text{new}}$
while not converge;
```

We set l as $l = iter \times C$, where $iter$ is the current iteration number and C is a hyperparameter. This means we incrementally update the dictionary size. This is because the induced dictionary at the initial iterations is likely to be noisy. As the training progresses, the model becomes more mature, and the induced dictionary pairs become better. For convergence, we use the criterion: if the difference between the average similarity scores of two successive iteration steps is less than a threshold (we use $1e^{-6}$), then stop the training process.

4 Experimental Settings

We evaluate our approach on bilingual lexicon induction, also known as *word translation*.

4.1 Datasets

To demonstrate the effectiveness of our method, we evaluate our models against baselines on two popularly used datasets: MUSE (Conneau et al., 2018) and VecMap (Dinu et al., 2015).

The MUSE dataset consists of FastText monolingual embeddings of 300 dimensions (Bojanowski et al., 2017) trained on Wikipedia monolingual corpus and gold dictionaries for 110 language pairs.[2] To show the generality of different methods, we consider 15 different language pairs with $15 \times 2 = 30$ different translation tasks encompassing resource-rich and low-resource languages from different language families. In particular, we evaluate on English (En) from/to Spanish (Es), German (De), Italian (It), Russian (Ru), Arabic (Ar), Malay (Ms), Finnish (Fi), Estonian (Et), Turkish (Tr), Greek (El), Persian (Fa), Hebrew (He), Tamil (Ta), Bengali (Bn), and Hindi (Hi). We differentiate between high- and low-resource languages by the availability of NLP-resources in general.

The VecMap dataset (Dinu et al., 2015; Artetxe et al., 2018a) is a more challenging dataset and contains monolingual embeddings for English, Spanish, German, Italian, and Finnish.[3] According to Artetxe et al. (2018b), existing unsupervised methods often fail to produce meaningful results on this dataset. English, Italian, and German embeddings were trained on WacKy crawling corpora using CBOW (Mikolov et al., 2013b), while Spanish and Finnish embeddings were trained on WMT News Crawl and Common Crawl, respectively.

4.2 Baseline Methods

We compare our proposed LNMAP with several existing methods comprising supervised, semi-supervised, and unsupervised models. For each baseline model, we conduct experiments with the publicly available code. In the following, we give a brief description of the baseline models.

Supervised & Semi-supervised Methods.

(*a*) Artetxe et al. (2017) propose a *self-learning framework* that performs two steps iteratively until

---

[2] https://github.com/facebookresearch/MUSE

[3] https://github.com/artetxem/vecmap/

convergence. In the first step, they use the dictionary (starting with the seed dictionary) to learn a linear mapping, which is then used in the second step to induce a new dictionary.

(*b*) Artetxe et al. (2018a) propose a *multi-step framework* that generalizes previous studies. Their framework consists of several steps: whitening, orthogonal mapping, re-weighting, de-whitening, and dimensionality reduction.

(*c*) Conneau et al. (2018) compare their unsupervised model with a supervised baseline that learns an orthogonal mapping between the embedding spaces by iterative Procrustes refinement. They also propose CSLS for nearest neighbour search.

(*d*) Joulin et al. (2018) show that minimizing a convex relaxation of the CSLS loss significantly improves the quality of bilingual word vector alignment. Their method achieves state-of-the-art results for many languages (Patra et al., 2019).

(*e*) Jawanpuria et al. (2019) propose a geometric approach where they decouple CLWE learning into two steps: (i) learning rotations for language-specific embeddings to align them to a common space, and (ii) learning a similarity metric in the common space to model similarities between the embeddings of the two languages.

(*f*) Patra et al. (2019) propose a semi-supervised technique that relaxes the isomorphic assumption while leveraging both seed dictionary pairs and a larger set of unaligned word embeddings.

Unsupervised Methods.

(*a*) Conneau et al. (2018) are the first to show impressive results for unsupervised word translation by pairing adversarial training with effective refinement methods. Given two monolingual word embeddings, their adversarial training plays a *two-player game*, where a linear mapper (generator) plays against a discriminator. They also impose the orthogonality constraint on the mapper. After adversarial training, they use the iterative Procrustes solution similar to their supervised approach.

(*b*) Artetxe et al. (2018b) learn an initial dictionary by exploiting the structural similarity of the embeddings in an unsupervised way. They propose a robust self-learning to improve it iteratively. This model is by far the most robust and best performing unsupervised model (Vulić et al., 2019).

(*c*) Mohiuddin and Joty (2019) use adversarial autoencoder for unsupervised word translation. They use linear autoencoders in their model, and the mappers are also linear.

4.3 Model Variants and Settings

We experiment with two variants of our model: the default LNMAP that uses non-linear autoencoders and LNMAP (LIN. AE) that uses linear autoencoders. In both the variants, the mappers are non-linear. We train our models using stochastic gradient descent (SGD) with a batch size of 128, a learning rate of $1e^{-4}$, and a step learning rate decay schedule. During the dictionary induction process in each iteration, we consider $K = 15000$ most frequent words from the source and target languages. For dictionary update, we set $C = 2000$.

5 Results and Analysis

We present our results on low-resource and resource-rich languages from MUSE dataset in Tables 1 and 2, respectively, and the results on VecMap dataset in Table 3. We present the results in *precision@1*, which means how many times one of the correct translations of a source word is predicted as the top choice. For each of the cases, we show results on seed dictionary of three different sizes including 1-to-1 and 1-to-many mappings; **"1K Unique"** and **"5K Unique"** contain 1-to-1 mappings of 1000 and 5000 source-target pairs respectively, while **"5K All"** contains 1-to-many mappings of all 5000 source and target words, that is, for each source word there can be multiple target words. Through experiments and analysis, our goal is to assess the following questions.

(i) Does LNMAP improve over the best existing methods in terms of mapping accuracy on low-resource languages (§5.1)?

(ii) How well does LNMAP perform on resource-rich languages (§5.2)?

(iii) What is the effect of non-linearity in the autoencoders? (§5.3)

(iv) Which components of LNMAP attribute to improvements (§5.4)?

5.1 Performance on Low-resource Languages

Most of the unsupervised models fail in the majority of the low-resource languages (Vulić et al., 2019). On the other hand, the performance of supervised models on low-resource languages was not satisfactory, especially with small seed dictionary.

Table 1: Word translation accuracy (P@1) on **low-resource** languages on **MUSE dataset** using fastText.

Hence, we first compare LNMAP's performance on these languages. From Table 1, we see that on average LNMAP outperforms every baseline by a good margin (1.1% - 5.2% from the best baselines).

For "1K Unique" dictionary, LNMAP exhibits impressive performance. In all the 20 translation tasks, it outperforms all the (semi-)supervised baselines by a wide margin. If we compare with Joulin et al. (2018), a state-of-the-art supervised model, LNMAP's average improvement is ∼18%, which is remarkable. Compared to other baselines, the average margin of improvement is also quite high – $9.9\%, 14.6\%, 5.2\%, 9.7\%$, and 8.0% gains over Artetxe et al. (2017), Artetxe et al. (2018a), Conneau et al. (2018), Jawanpuria et al. (2019), and Patra et al. (2019), respectively. We see that among the supervised baselines, Conneau et al. (2018)'s model performs better than others.

If we increase the dictionary size, we can still see the dominance of LNMAP over the baselines. For "5K Unique" seed dictionary, it performs better than the baselines on 14/20 translation tasks, while for "5K All" seed dictionary, the best performance by LNMAP is on 13/20 translation tasks.

One interesting thing to observe is that, under resource-constrained setup LNMAP's performance is impressive, making it suitable for very low-resource languages like En-Ta, En-Bn, and En-Hi.

Now if we look at the performance of unsupervised baselines on low-resource languages, we see that Conneau et al. (2018)'s model fails to converge on the majority of the translation tasks (12/20), while the model of Mohiuddin and Joty (2019) fails to converge on En↔Ta, En↔Bn, and En↔Hi. Although the most robust unsupervised method of Artetxe et al. (2018b) performs better than the other unsupervised approaches, it still fails to converge on En↔Ta tasks. If we compare its performance with LNMAP, we see that our model outperforms the best unsupervised model of Artetxe et al. (2018b) on 18/20 low-resource translation tasks.

5.2 Results on Resource-rich Languages

Table 2 shows the results for 5 resource-rich language pairs (10 translation tasks) from the MUSE dataset. We notice that our model achieves the highest accuracy in all the tasks for "1K Unique", 4 tasks for "5K Unique", 3 for "5K All".

We show the results on the VecMap dataset in Table 3, where there are 3 resource-rich language

Table 2: Word translation accuracy (P@1) on **resource-rich** languages on **MUSE dataset** using fastText.

pairs, and one low-resource pair (En-Fi) with a total of 8 translation tasks. Overall, we have similar observations as in MUSE – our model outperforms other models on 7 tasks for “1K Unique”, 4 tasks for “5K Unique”, and 4 for “5K All”.

5.3 Effect of Non-linearity in Autoencoders

The comparative results between our model variants in Tables 1 - 3 reveal that LNMAP (with non-linear autoencoders) works better for low-resource languages, whereas LNMAP (LIN. AE) works better for resource-rich languages. This can be explained by the geometric similarity between the embedding spaces of the two languages.

In particular, we measure the geometric similarity of the language pairs using the **Gromov-Hausdorff (GH)** distance (Patra et al., 2019), which is recently proposed to quantitatively estimate isometry between two embedding spaces.[4] From the measurements (Tables 1-2), we see that etymologically close language pairs have lower GH distance compared to etymologically distant and low-resource language pairs.[5] Low-resource language pairs' high GH distance measure implies that English and those languages embedding spaces are far from isomorphism. Hence, we need strong non-linearity for those distant languages.

5.4 Dissecting LNMAP

We further analyze our model by dissecting it and measuring the contribution of its different components. Specifically, our goal is to assess the contribution of back-translation, reconstruction, non-linearity in the mapper, and non-linearity in the autoencoder. We present the ablation results in Table 4 on 8 translation tasks from 4 language pairs consisting of 2 resource-rich and 2 low-resource languages. We use MUSE dataset for this purpose.

---

[4] https://github.com/joelmoniz/BLISS

[5] We could not compute GH distances for the VecMap dataset; the metric gives ‘inf’ in the BLISS framework.

	En-Es		En-It		En-Ta		En-Bn	
	→	←	→	←	→	←	→	←
LNMAP	80.1	80.2	77.1	75.3	17.6	21.2	18.4	27.2
⊖ Recon. loss	79.6	75.4	75.7	69.4	14.8	14.9	16.2	20.7
⊖ Back-tran. loss	79.8	79.1	76.6	74.4	16.7	20.3	16.5	26.7
⊕ Linear mapper	78.8	78.9	76.3	74.7	16.6	20.2	18.0	26.3
⊕ Procrustes sol.	75.9	73.9	72.0	72.2	11.1	12.1	12.2	14.8
⊕ Linear autoenc.	83.2	85.5	79.2	79.6	14.5	20.3	16.5	26.1

Table 4: Ablation study of LNMAP with “1K Unique” dictionary. ⊖ indicates the component is removed from the full model, and ‘⊕’ indicates the component is added by replacing the corresponding component.

All the experiments for the ablation study are done using “1K Unique” seed dictionary.

⊖ **Reconstruction loss:** For removing the reconstruction loss from the full model, on average high-resource language pairs lose accuracy by 0.9% and 5.3% for from and to English, respectively. The losses are even higher for low-resource language pairs, on average 2.5% and 6.4% in accuracy.

⊖ **Back-translation (BT) loss:** Removing the BT loss also has a negative impact, but not as high as the reconstruction. This is because the reconstruction loss (Eq. 10) also covers the BT signal.

⊕ **Linear mapper:** If we replace the non-linear mapper with a linear one in the full model, we see that the effect is not that severe. The reason can be explained by the fact that the autoencoders are still non-linear, and the non-linear signal passes through back-translation and reconstruction.

⊕ **Procrustes solution:** To assess the proper effect of the non-linear mapper, we need to replace it with a linear mapper through which no non-linear signal passes by during training. This can be achieved by replacing the non-linear mapper with the Procrustes solution. The results show an adverse effect on removing non-linearity in the mapper in all the language pairs. However, low-resource pairs' performance drops quite significantly.

⊕ **Linear autoencoder:** For high-resource language pairs, linear autoencoder works better than the non-linear one. However, it is the opposite for the low-resource pairs, where the performance drops significantly for the linear autoencoder.

6 Conclusions

We have presented a novel semi-supervised framework LNMAP to learn the cross-lingual mapping between two monolingual word embeddings. Apart from exploiting weak supervision from a small (1K) seed dictionary, our LNMAP leverages the information from monolingual word embeddings. In contrast to the existing methods that directly map word embeddings using the isomorphic assumption, our framework is independent of any such strong prior assumptions. LNMAP first learns to transform the embeddings into a latent space and then uses a non-linear transformation to learn the mapping. To guide the non-linear mapping further, we include constraints for back-translation and original embedding reconstruction.

Extensive experiments with fifteen different language pairs comprising high- and low-resource languages show the efficacy of non-linear transformations, especially for low-resource and distant languages. Comparison with existing supervised, semi-supervised, and unsupervised baselines show that LNMAP learns a better mapping. With an in-depth ablation study, we show that different components of LNMAP works in a collaborative nature.

Abstract

As a sequence-to-sequence generation task, neural machine translation (NMT) naturally contains *intrinsic uncertainty*, where a single sentence in one language has multiple valid counterparts in the other. However, the dominant methods for NMT only observe one of them from the parallel corpora for the model training but have to deal with adequate variations under the same meaning at inference. This leads to a discrepancy of the data distribution between the training and the inference phases. To address this problem, we propose *uncertainty-aware semantic augmentation*, which explicitly captures the universal semantic information among multiple semantically-equivalent source sentences and enhances the hidden representations with this information for better translations. Extensive experiments on various translation tasks reveal that our approach significantly outperforms the strong baselines and the existing methods.

1 Introduction

In recent years neural machine translation (NMT) has demonstrated state-of-the-art performance on many language pairs with advanced architectures and large scale data (Bahdanau et al., 2015; Wu et al., 2016; Vaswani et al., 2017). At training time the parallel data only contains one source sentence as the input and the rest reasonable ones are ignored, while at inference the resulting model has to deal with adequate variations under the same meaning. This discrepancy of the data distribution poses a formidable learning challenge of the inherent uncertainty in machine translation. Since typically there are several semantically-equivalent source sentences that can be translated to the same target sentence, but the model only observes one at training time. Thus it is natural to enable an NMT model trained with the token-level cross-entropy (CE) to capture such a rich distribution, which exactly motivates our work.

Intuitively, the NMT model should be trained under the guidance of the same latent semantics that it will access at inference time. In their seminal work, the variational models (Blunsom et al., 2008; Zhang et al., 2016; Shah and Barber, 2018) introduce a continuous latent variable to serve as a global semantic signal to guide the generation of target translations. Wei et al. (2019) consider an universal topic representation for each sentence pair as global semantics for enhancing representations learnt by NMT models. Yang et al. (2019) minimize the difference between the representation of source and target sentences. Although their methods yield notable results, they are still limited to one-to-one parallel sentence pairs.

To address these problems, we present a novel *uncertainty-aware semantic augmentation* method, which takes account of the intrinsic uncertainty sourced from the one-to-many nature of machine translation (Ott et al., 2018). Specifically, we first synthesize multiple reasonable source sentences to play the role of inherent uncertainty[1] for each target sentence. To achieve this, we introduce a *controllable sampling* strategy to cover adequate variations for inputs, by quantifying the sharpness of the word distribution in each decoding step and taking the proper word (the one with the maximum probability if sharp enough or determined by multinomial sampling) as the output. Then a *semantic constrained network* (SCN) is developed to summarize multiple source sentences that share the same meaning into a *closed semantic region*, augmented

[1] In our scenario, we mainly study the uncertainty in source-side, as it is problematic if the synthetic targets that inevitably contain noise and errors are used to supervise the training of models. We leave further study on this to future work.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2724–2735,

by which the model generates translations finally. By integrating such *soft* correspondences into the translation process, the model can intuitively work well when fed with an unfamiliar literal expression that can be supported by its underlying semantics. In addition, given the effectiveness of leveraging monolingual data in improving translation quality (Sennrich et al., 2016a), we further propose to combine the strength of both semantic augmentation and massive monolingual data distributed in the target language.

We conduct extensive experiments in both a supervised setup with bilingual data only, and a semi-supervised setup where both bilingual and target monolingual data are available. We evaluate the proposed approach on the widely used WMT14 English→French, WMT16 English→German, NIST Chinese→English and WMT18 Chinese→English benchmarks. Experimental results show that the proposed approach consistently improves translation performance on multiple language pairs. As another bonus, by adding monolingual data in German, our approach yields an additional gain of +1.5∼+3.3 BLEU points on WMT16 English→German task. Extensive analyses reveal that:

- Our approach demonstrates strong capability on learning semantic representations.
- The proposed controllable sampling strategy introduces reasonable uncertainties into the training data and generates sentences are of both high diverse and high quality.
- Our approach motivates the models to be consistent when processing equivalent source inputs with various lteral expressions.

2 Preliminary

Neural Machine Translation (Bahdanau et al., 2015) directly models the translation probability of a target sentence $\mathbf{y} = y_1, ..., y_{T_\mathrm{y}}$ given its corresponding source sentence $\mathbf{x} = x_1, ..., x_{T_\mathrm{x}}$:

$$P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \prod_{i=1}^{T_\mathrm{y}} P(y_i|\mathbf{y}_{<i},\mathbf{x};\boldsymbol{\theta}), \qquad (1)$$

where $\boldsymbol{\theta}$ is a set of model parameters and $\mathbf{y}_{<i}$ is a partial translation. The word-level translation probability is formulated as: $P(y_i|\mathbf{y}_{<i},\mathbf{x};\boldsymbol{\theta}) \propto \exp\{g(y_{i-1}, s_i, c_i;\boldsymbol{\theta})\}$, in which $g(\cdot)$ denotes a non-linear function to predict the i-th target word y_i from the decoder state s_i and the context vector c_i summarized from a sequence of representations of the encoder with an attention module. For training, given a parallel corpus $\{(\mathbf{x}^n, \mathbf{y}^n)\}_{n=1}^{\mathcal{N}}$, the objective is to maximize $\log P(\mathbf{y}^n|\mathbf{x}^n;\boldsymbol{\theta})$ over the entire training set.

Related Work on Data augmentation. DA has been used to improve the diversity of training signals for NMT models, like randomly shuffle (swap) or drop some words in a sentence (Iyyer et al., 2015; Artetxe et al., 2018; Lample et al., 2018), randomly replace one word in the original sentences with another word (Fadaee et al., 2017; Xie et al., 2017; Kobayashi, 2018; Wang et al., 2018; Cheng et al., 2018; Gao et al., 2019), syntax-aware methods (Duan et al., 2020), as well as using target monolingual data (Sennrich et al., 2016a; Cheng et al., 2016; He et al., 2016; Zhang et al., 2018; Wu et al., 2018; Hoang et al., 2018; Niu et al., 2018; Edunov et al., 2018; Imamura et al., 2018; Xia et al., 2019). More recently, Fadaee and Monz (2018) introduce several variations of sampling strategies targeting difficult-to-predict words. Li et al. (2019) have studied that what benefits from data augmentation across different methods and tasks. Cheng et al. (2019) propose to improve the robustness of NMT models towards perturbations and minor errors by introducing adversarial inputs into training process. In contrast, we aim at bridging the discrepancy of the data distribution between the training and the inference phases, through augmenting each training instance with multiple semantically-equivalent source inputs.

Related Work on Uncertainty in NMT. Recently, there are increasing number of studies investigating the effects of quantifying uncertainties in different applications (Kendall et al., 2017; Kendall and Gal, 2017; Xiao and Wang, 2018; Zhang et al., 2019b,a; Shen et al., 2019). However, most work in NMT has focused on improving accuracy without much consideration for the intrinsic uncertainty of the translation task itself. In their seminal work, the latent variable models (Blunsom et al., 2008; Zhang et al., 2016) introduce a (set of) continuous latent variable(s) to model underlying semantics of source sentences and to guide the generation of target translations. Zaremoodi and Haffari (2018) propose a forest-to-sequence NMT model to make use of exponentially many parse trees of the source

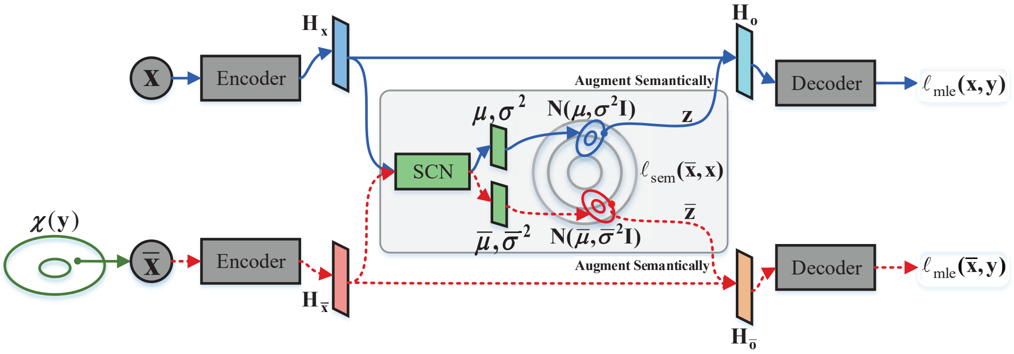

Figure 1: Uncertainty-Aware Semantic Augmentation for NMT. $\mathcal{X}(\mathbf{y})$ indicates a set of semantically-equivalent source sentences for $\mathbf{y}$. The blue-solid and red-dashed lines represent the forward-pass information flow for $\mathbf{x}$ and $\bar{\mathbf{x}}$, respectively. Note that our method involves a *shared encoder* as well as a *shared decoder* for both $\mathbf{x}$ and $\bar{\mathbf{x}}$.

sentence. Ott et al. (2018) have focused on analyzing the uncertainty in NMT that demonstrate how uncertainty is captured by the model distribution and how it affects search strategies. (Wang et al., 2019) propose to quantify the confidence of NMT model predictions based on model uncertainty. Our work significantly differs from theirs. We model the inherent uncertainty by representing multiple source sentences into a closed semantic region, and use this semantic information to enhance NMT models where diverse literal expressions intuitively be supported by their underlying semantics.

3 Uncertainty-Aware Semantic Augmentation for NMT

Here, we present the *uncertainty-aware semantic augmentation* (as shown in Figure 1), which takes account of the intrinsic uncertainty of machine translation and enhances the latent representation semantically. For each sentence-pair $(\mathbf{x}, \mathbf{y})$, supposing $\mathcal{X}(\mathbf{y})$ is a set of correct source sentences for $\mathbf{y}$, in which each sentence $\bar{\mathbf{x}}$ is assumed to have the same meaning as $\mathbf{x}$. Given a training corpus $\mathcal{D}$, we introduce the objective function as:

$$\begin{aligned}
&\mathcal{J}(\boldsymbol{\theta}) \\
&= \sum_{(\mathbf{x},\mathbf{y})\in\mathcal{D}} \Big\{ \lambda_1 \mathbb{E}_{\mathcal{P}_\phi(\mathbf{z}|\mathbf{x})} \big[\underbrace{\log P(\mathbf{y}|\mathbf{z},\mathbf{x};\boldsymbol{\theta})}_{\ell_{\text{mle}}(\mathbf{x},\mathbf{y};\mathbf{z})}\big] \\
&\quad - \gamma \mathbb{E}_{\bar{\mathbf{x}}\sim\mathcal{X}(\mathbf{y})} \big[\underbrace{\mathbf{KL}\big(\mathcal{P}_\phi(\bar{\mathbf{z}}|\bar{\mathbf{x}})||\mathcal{P}_\phi(\mathbf{z}|\mathbf{x})\big)}_{\ell_{\text{sem}}(\bar{\mathbf{x}},\mathbf{x})}\big] \\
&\quad + \lambda_2 \mathbb{E}_{\bar{\mathbf{x}}\sim\mathcal{X}(\mathbf{y})} \big[\mathbb{E}_{\mathcal{P}_\phi(\bar{\mathbf{z}}|\bar{\mathbf{x}})} \big[\underbrace{\log P(\mathbf{y}|\bar{\mathbf{z}},\bar{\mathbf{x}};\boldsymbol{\theta})}_{\ell_{\text{mle}}(\bar{\mathbf{x}},\mathbf{y};\bar{\mathbf{z}})}\big]\big] \Big\},
\end{aligned} \tag{2}$$

where

- $\ell_{\text{sem}}(\bar{\mathbf{x}}, \mathbf{x})$ to encourage the SCN to extract the core semantics ($\bar{\mathbf{z}}$ and $\mathbf{z}$) for $\bar{\mathbf{x}}$ and $\mathbf{x}$ respectively, while constraining them into a closed semantic region. It is formulated as the negative Kullback-Leibler (**KL**) divergence between the semantic distributions $\mathcal{P}_\phi(\bar{\mathbf{z}}|\bar{\mathbf{x}})$ and $\mathcal{P}_\phi(\mathbf{z}|\mathbf{x})$, where ϕ denotes the combined parameters of the encoder and the SCN.

- $\ell_{\text{mle}}(\mathbf{x}, \mathbf{y}; \mathbf{z})$ and $\ell_{\text{mle}}(\bar{\mathbf{x}}, \mathbf{y}; \bar{\mathbf{z}})$ to guide the decoder to generate the output $\mathbf{y}$ with the assist of input-invariant semantics given diverse inputs $\mathbf{x}$ and $\bar{\mathbf{x}}$.

- λ_1 and λ_2 control the balance between the original source sentence $\mathbf{x}$ and its reasonable counterparts $\mathcal{X}(\mathbf{y})$. In experiments, we set $\lambda_1 + \lambda_2 = 1.0$, which means a target sentence occurs once in total. γ controls the impact of the semantic agreement training to be described in Section 3.3.

Intuitively, our new objective is exactly a regularized version of the widely used maximum likelihood estimation (MLE) in conventional NMT. The models are trained to optimize both the translation loss and the semantic agreement between $\mathbf{x}$ and $\bar{\mathbf{x}}$.

In the following sections, we will first describe how to summarize multiple source sentences into a closed semantic region by developing a *semantic constrained network* (SCN) in Section 3.1. And then introduce the proposed *controllable sampling* strategy in Section 3.2 to construct adequate and reasonable variations for source inputs.

3.1 Semantic Constrained Network

Network Architecture. One core component of our approach is the proposed SCN, which aims to learn the global semantics and make them no difference between multiple source sentences ($\mathbf{x}$ and $\bar{\mathbf{x}}$). We adopt the CNN to address the variable-length problem of a sequence of hidden representations $\mathbf{H}_{\mathbf{x}}$ (which is the output of the top encoder layer given $\mathbf{x}$) of the encoder stack. Formally, given an encoded representation $\mathbf{H}_{\mathbf{x}} = \mathbf{H}_{x_1}, \mathbf{H}_{x_2}, ..., \mathbf{H}_{x_{T_{\mathrm{x}}}}$, the SCN first represents it as:

$$\xi_{1:T_{\mathrm{x}}} = \mathbf{H}_{x_1} \oplus \mathbf{H}_{x_2} \oplus ... \oplus \mathbf{H}_{x_{T_{\mathrm{x}}}}, \tag{3}$$

where $\oplus$ is the concatenation operator to build the matrix $\xi_{1:T_{\mathrm{x}}}$. Then a convolution operation involves a kernel $\mathbf{W}_c$ is applied to a window of l words to produce a new feature:

$$c_i = \mathrm{Relu}(\mathbf{W}_c \otimes \xi_{i:i+l-1} + \mathbf{b}), \tag{4}$$

where $\otimes$ operator is the summation of element-wise production, $\mathbf{b}$ is a bias term. Finally we apply a max-over-time pooling operation over the feature map $\mathbf{c} = \max\{c_1, c_2, .., c_{T_{\mathrm{x}}-l+1}\}$ to capture the most important feature, that is, one with the highest value. We can use various numbers of kernels with different window sizes to repeat the above process, and extract different features to form the semantic representation, denoted as $\mathbf{H}_{\mathbf{c}}$ for $\mathbf{x}$ (and $\mathbf{H}_{\bar{\mathbf{c}}}$ for $\bar{\mathbf{x}}$ in a symmetric way).

Semantic Agreement Training. Given the semantic distributions $\mathcal{P}_\phi(\mathbf{z}|\mathbf{x})$ of $\mathbf{x}$ and $\mathcal{P}_\phi(\bar{\mathbf{z}}|\bar{\mathbf{x}})$ of $\bar{\mathbf{x}}$, we formulate $\ell_{\mathrm{sem}}(\bar{\mathbf{x}}, \mathbf{x})$ as the negative **KL** divergence between them:

$$\ell_{\mathrm{sem}}(\bar{\mathbf{x}}, \mathbf{x}) = -\mathbf{KL}\big(\mathcal{P}_\phi(\bar{\mathbf{z}}|\bar{\mathbf{x}}) || \mathcal{P}_\phi(\mathbf{z}|\mathbf{x})\big). \tag{5}$$

We assume $\mathcal{P}_\phi(\mathbf{z}|\mathbf{x})$ and $\mathcal{P}_\phi(\bar{\mathbf{z}}|\bar{\mathbf{x}})$ have the following forms:

$$\mathcal{P}_\phi(\mathbf{z}|\mathbf{x}) \sim \mathcal{N}(\mu, \sigma^2\mathbf{I}),\ \mathcal{P}_\phi(\bar{\mathbf{z}}|\bar{\mathbf{x}}) \sim \mathcal{N}(\bar{\mu}, \bar{\sigma}^2\mathbf{I}). \tag{6}$$

The mean μ ($\bar{\mu}$) and s.d. σ ($\bar{\sigma}$) are the outputs of neural networks based on the observation $\mathbf{H}_{\mathbf{c}}$ (or $\mathbf{H}_{\bar{\mathbf{c}}}$), as

$$\begin{aligned} \mu &= \mathbf{H}_{\mathbf{c}} \cdot \mathbf{W}_\mu + \mathbf{b}_\mu, \\ \log \sigma^2 &= \mathbf{H}_{\mathbf{c}} \cdot \mathbf{W}_\sigma + \mathbf{b}_\sigma, \end{aligned} \tag{7}$$

or

$$\begin{aligned} \bar{\mu} &= \mathbf{H}_{\bar{\mathbf{c}}} \cdot \mathbf{W}_\mu + \mathbf{b}_\mu, \\ \log \bar{\sigma}^2 &= \mathbf{H}_{\bar{\mathbf{c}}} \cdot \mathbf{W}_\sigma + \mathbf{b}_\sigma, \end{aligned} \tag{8}$$

where $\mathbf{W}_\mu$, $\mathbf{b}_\mu$, $\mathbf{W}_\sigma$ and $\mathbf{b}_\sigma$ are trainable parameters. To obtain a representation for latent semantic distributions, we employ reparameterization technique as in (Kingma et al., 2014; Zhang et al., 2016). Formally,

Threshold	Method
$\hbar = 0$	Multinomial sampling
$\hbar = +\infty$	Greedy search
$\hbar \in (0, +\infty)$	Controllable sampling

Table 1: Multinomial sampling and greedy search, as special cases covered in controllable sampling.

$$\mathbf{z} = \mu + \sigma \odot \epsilon,\ \bar{\mathbf{z}} = \bar{\mu} + \bar{\sigma} \odot \epsilon, \tag{9}$$

where $\epsilon \sim \mathcal{N}(0, \mathbf{I})$ plays a role of introducing noises, and $\odot$ denotes an element-wise product. There can be other proper strategies to unify semantics of diverse inputs, we just present one example. Actually, the Gaussian form adopted here has several advantages, such as analytical evaluation of the KL divergence and ease of reparametrization for efficient gradient computation.

Augment Semantically. Given the encoder output $\mathbf{H}_{\mathbf{x}}$ of $\mathbf{x}$, we augment it semantically with the captured semantics $\mathbf{z}$ by combining them with a gate $g = \mathrm{sigmoid}(\mathbf{z} \cdot \mathbf{W}_{gz} + \mathbf{H}_{x_t} \cdot \mathbf{W}_{gx})$,

$$\mathbf{H}_{\mathbf{o}_t} = \mathrm{LayerNorm}(g \cdot \mathbf{z} + (1-g) \cdot \mathbf{H}_{x_t}). \tag{10}$$

Identically, $\mathbf{H}_{\bar{\mathbf{o}}}$ can be formulated given $\bar{\mathbf{z}}$ and $\mathbf{H}_{\bar{\mathbf{x}}}$. Finally, the augmented source representation $\mathbf{H}_{\mathbf{o}}$ (or $\mathbf{H}_{\bar{\mathbf{o}}}$) is fed to the decoder to generate the final translation $\mathbf{y}$ conditioned on $\mathbf{x}$ (or $\bar{\mathbf{x}}$). In this strategy, our model can intuitively work well when meeting infrequent literal expressions as that can be pivoted by their corresponding semantic regions.

3.2 Controllable Sampling

For each target sentence $\mathbf{y}$, we need a set of reasonable source sentences $\mathcal{X}(\mathbf{y})$ to play the role of the inherent uncertainty. Unfortunately, it is extremely cost to annotate multiple source sentences manually for tens of million target sentences. To this end, we automatically construct $\mathcal{X}(\mathbf{y})$ using a well-trained ***target-to-source*** model $\overleftarrow{\boldsymbol{\theta}}$ by sampling from the predicted word distributions:

$$\bar{\mathbf{x}}_t \sim P(\cdot|\bar{\mathbf{x}}_{<t}, \mathbf{y}; \overleftarrow{\boldsymbol{\theta}}). \tag{11}$$

However, it is problematic to force the generation of a certain number of source sentences indiscriminately for each target sentence using beam search or multinomial sampling. The reason is that both of them synthesize sentences are either of less diverse or of less quality. Therefore, we propose a controllable sampling strategy to generate reasonable source sentences: at each decoding step, if the word distribution is sharp then we take the word with the maximum probability, otherwise the sampling method formulated in Eq. (11) is applied. Formally,

$$\begin{cases} \bar{\mathbf{x}}_t \sim P(\cdot|\bar{\mathbf{x}}_{<t}, \mathbf{y}; \overleftarrow{\boldsymbol{\theta}}), \text{if } \varepsilon \geq \hbar \\ \bar{\mathbf{x}}_t = \text{argmax}\big(P(\cdot|\bar{\mathbf{x}}_{<t}, \mathbf{y}; \overleftarrow{\boldsymbol{\theta}})\big), \text{else} \end{cases} \tag{12}$$

where ε is exactly the information entropy respect to $P(\cdot|\bar{\mathbf{x}}_{<t}, \mathbf{y}; \overleftarrow{\boldsymbol{\theta}})$:

$$\varepsilon = -\sum\nolimits_j \big[P(x^j|\bar{\mathbf{x}}_{<t}, \mathbf{y}; \overleftarrow{\boldsymbol{\theta}}) \times \log P(x^j|\bar{\mathbf{x}}_{<t}, \mathbf{y}; \overleftarrow{\boldsymbol{\theta}})\big], \tag{13}$$

where $P(x^j|\bar{\mathbf{x}}_{<t}, \mathbf{y}; \overleftarrow{\boldsymbol{\theta}})$ denotes the conditional probability of the j-th word in the vocabulary appearing after the sequence $\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_{t-1}$. Actually, the widely used multinomial sampling and greedy search strategies can be served as special cases of the controllable sampling. $\hbar$ is a hyperparameter that indicates the sharpness threshold of the predicted word distributions and relates our method with the special cases as shown in Table 1. In practice, we repeat the above process N times to generate multiple source sentences to form $\mathcal{X}(\mathbf{y})$.

3.3 Training

Our framework initializes the model based on the parameters trained by the standard maximum likelihood estimation (MLE) (Eq. (1)). As shown in Eq. (2), the training objective of our approach is differentiable, which can be optimized using standard mini-batch stochastic gradient ascent techniques. To avoid the KL collapse (Bowman et al., 2016; Zhao et al., 2017), we use a simple scheduling strategy that sets $\gamma = 0$ at the beginning of training and gradually increases γ until $\gamma = 1$ is reached.

4 Experiments

We examine our method upon advanced TRANSFORMER (Vaswani et al., 2017) and conduct experiments on four widely used translation tasks, including WMT14 English→French (En→Fr), WMT16 English→German (En→De), NIST Chinese→English (Zh→En) and WMT18 Chinese→English.

4.1 Experimental Setting

Dataset For En→De, we used the WMT16[2] corpus containing 4.5M sentence pairs with 118M English words and 111M German words. The validation set is the concatenation of newstest2012 and newstest2013, and the results are reported on newstest2014 (test14), newstest2015 (test15) as well as newstest2016 (test16). For En→Fr, we used the significantly larger WMT 2014 English-French dataset consisting of 36M sentences. The validation set is the concatenation of newstest2012 and newstest2013, and the results are reported on newstest2014 (test14). For NIST Zh→En, we used the LDC[3] corpus consisting of 1.25M sentence pairs with 27.9M Chinese words and 34.5M English words respectively. We selected the best model using the NIST 2002 as the validation set for model selection and hyperparameters tuning. The NIST 2004 (MT04), 2005 (MT05), 2006 (MT06), and 2008 (MT08) datasets are used as test sets. For WMT18 Zh→En, we used a subset of WMT18 corpus containing 8M sentence pairs. We used newsdev 2017 as the validation set and reported results on newstest 2017 as well as newtest 2018.

We used the Stanford segmenter (Tseng et al., 2005) for Chinese word segmentation and applied the script `tokenizer.pl` of Moses (Koehn et al., 2007) for English, French and German tokenization. For En→De and En→Fr, all data had been jointly byte pair encoded (BPE) (Sennrich et al., 2016b) with 32k merge operations, which results in a shared source-target vocabulary. For NIST Zh→En, we created shared BPE codes with 60K operations that induce two vocabularies with 47K Chinese sub-words and 30K English sub-words. For WMT18 Zh→En, we used byte-pair-encoding to preprocess the source and target sentences, forming source- and target-side dictionaries with 32K types, respectively.

Model We adopt the `transformer_base` setting for Zh→En translations, while both `base` and `big` settings are adopted in En→De and En→Fr translations. For SCN, the filter windows are set to 2, 3, 4, 5 with 128 feature maps each. We set $\hbar = 2.5$, $N = 3$ for balancing the translation performance and the computation complexity. During training, we set $\lambda_1 = \lambda_2 = 0.5$, roughly 4,096 source and target to-

Table 2: BLEU [%] on Zh→En tasks. † denotes replicated results using tensor2tensor (T2T) toolkit. Both the training time and the number of parameters are related to the NIST Zh→En task. ‡The time spent in synthesizing pseudo data was included. §Both the time spent in generating synthetic data and training models were included.

kens are paired in one mini-batch. We employ the Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.998$, and $\epsilon = 10^{-9}$. Additionally, the same warmup and decay strategy for learning rate as Vaswani et al. (2017) is also used, with 8,000 warmup steps. For evaluation, we use beam search with a beam size of 4/5 and length penalty of 0.6/1.0 for En→{De,Fr}/Zh→En tasks respectively. We measure case-sensitive/insensitive tokenized BLEU[4] by `multi-bleu.pl`/`mteval-v11b.pl` for En→De/NIST Zh→En, while case-sensitive detokenized BLEU is reported by the official evaluation script `mteval-v13a.pl` for WMT18 Zh→En. Unless noted otherwise we run each experiment on up to four Tesla M40 GPUs and accumulate the gradients for 4 updates. For En→De/NIST Zh→En, each model was repeatedly run 4 times and we reported the average BLEU, while each model was trained only once on the larger WMT18 Zh→En dataset. For a strictly consistent comparison, we involve two strong baselines:

- **TRANSFORMER**, which is trained on the real parallel data only.
- **TRANSFORMER$_{\text{syn}}$**, which *is trained on the same data as ours* that consists of the real parallel data and the *back-translated* corpora. The latter contains N semantically-equivalent source sentences for each target sentence. These synthetic corpora are generated by a well-trained reverse NMT model using the proposed *controllable sampling* (see 3.2).

4.2 Comparison and Results

Table 2 shows the results on Zh→En tasks. For NIST Zh→En, we first compare our approach with the TRANSFORMER model on which our model is built. As we can see, our method can bring substantial improvements, which achieves notable gain of +2.36 BLEU points on average. In addition, our best model also achieves superior results across test sets to existing systems. For a more challenging task, we also report the results on WMT18 Zh→En task in Table 2. Compared with strong baseline systems, we observe that our method consistently improves translation performance on both newstest2017 and newstest2018. These results indicate that the effectiveness of our approach cannot be affected by the size of datasets.

Table 3: BLEU [%] on En→De and En→Fr translation tasks. ‡denotes our replicated results.

Table 3 shows the results on WMT16 En→De and WMT14 En→Fr translations. For En→De, when investigating semantic augmentation into NMT models, significant improvements over two baselines (up to +0.91 and +0.62 BLEU points on average respectively) can be observed. We also take existing NMT systems as comparison which use almost the same English-German corpus. Our best system outperforms the standard Transformer (Vaswani et al., 2017) with +1.27 BLEU on newstest2014. It worth mentioning that our method outperforms the advanced robust NMT systems (Cheng et al., 2018, 2019), which aim to construct anti-noise NMT models, with at least +0.23 BLEU and up to +0.48 BLEU improvements. On En→Fr, our method outperforms both the previous

Table 4: Effect of various numbers of synthetic source sentences on validation sets.

models and the in-house baselines. To further verify our approach, we study it with respect to `big` models and compare it with two related methods (Cheng et al., 2019; Gao et al., 2019). We can observe that the proposed approach achieves the best results among all methods for the same number of hidden units.

4.3 Analysis

Effect of N. To determine the number of synthetic source sentences N in our system beforehand, we conduct experiments on Zh→En and En→De translation tasks to test how it affects the translation performance. We vary the value of N from 1 to 9 with 2 as step size and the results are reported on validation sets (Table 4). We can find that the translation performance achieves substantial improvement with N increasing from 1 to 3. However, with N set larger than 3, we get little improvement. To make a trade-off between the translation performance and the computation complexity, we set N as 3 in our experiments.

Effect of $\hbar$. The introduction of the hyperparameter $\hbar$ aims at acquiring the proper quantity of synthetic data. To investigate the effect of it, we quantify: (1) the diversity using the edit distance among the synthetic source sentences and (2) the quality using BLEU scores of synthetic source sentences, with respect to various values of $\hbar$.

For each target sentence in validation sets, we generate $N = 3$ synthetic source sentences using *controllable sampling*. Table 5 shows the results. The BLEU scores were computed regarding the multiple synthetic sentences as a document. As in (Imamura et al., 2018), the edit distances are computed for two cases: (1) SYN vs. REAL, the average distance between a synthetic source sentence (SYN) and the real source sentence (REAL). (2) SYN vs. SYN, the average distance among synthetic source sentences of a target sentence ($C_3^2 = 3$ combinations per target sentence). We can find that when $\hbar$ tends to 0 our controlled sampling method achieves lowest BLEU scores but highest edit distances. However, if we increase $\hbar$ gradually, it can be quickly simplified to greedy search. Among all values of $\hbar$ in Table 5, $\hbar = 2.5$ is a proper setting as it demonstrates relatively higher BLEU scores and lower word error rates (SYN vs. REAL) as well as more of diversity (SYN vs. SYN) in corpora. Therefore, we set $\hbar$ as 2.5 in all of our experiments. In addition, we can observe that the controllable sampling achieves the goal of generating sentences are of both high diverse and high quality.

7.0	29.25	7.29	2.71

Table 5: Effect of $\hbar$ on validation sets with respect to BLEU scores as well as edit distances among synthetic and real source sentences. "*BS-3*" indicates that synthetic sentences are generated by beam search with a beam size of 3.

$\ell_{\text{mle}}(\mathbf{x}, \mathbf{y})$	ℓ_{sem}	$\ell_{\text{mle}}(\bar{\mathbf{x}}, \mathbf{y})$	BLEU
✓			22.59
✓		✓	23.37
✓	✓		23.68
✓	✓	✓	24.10

Table 6: Ablation study on WMT18 Zh→En validation set. "✓" means the loss function is included in the training objective.

Ablation Study. We perform an ablation study of our training objective formulated in Eq. (2) that contains three loss items. As shown in Table 6, the translation performance decreases by

Ours Method	N	BLEU
w/ beam search	3	23.41
w/ Multinomial sampling	3	23.74
w/ Controllable sampling	3	24.10

Table 7: Effect of different methods to generate multiple synthetic data. Experiments are conducted on WMT18 Zh→En validation set.

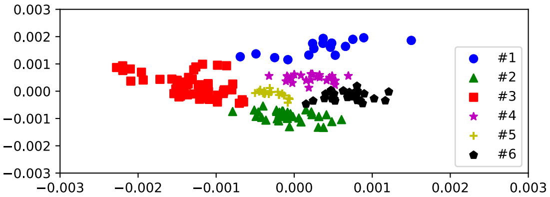

Figure 2: The figure shows a 2-dimensional PCA projection of the semantic representations ($\mathbf{z}$ in Eq. (9)) for six examples in the training corpus.

Input #1	我认为我们可以重新启动这些品牌，而且现在时间正合适。
TRANS$_{\text{syn}}$	I think we can restart these brands, and the time is right.
Ours	I think we can relaunch these brands, and now is the right time.
Input #2	我想现在是时候重新发布这些品牌了。
TRANS$_{\text{syn}}$	I think it is time to reissue these brands.
Ours	I think it's time to relaunch these brands.
Input #3	我认为我们可以重新上新这些品牌，而且现在时间正合适。
TRANS$_{\text{syn}}$	I think we can renew these brands, and now is the right time.
Ours	I think we can re-launch these brands, and the time is right now.

Table 8: Translation examples of TRANSFORMER$_{\text{syn}}$ (TRANS$_{\text{syn}}$ for short) and our method on various inputs under the same meaning on WMT18 Zh→En.

0.42 BLEU points when removing $\ell_{\text{mle}}(\bar{\mathbf{x}}, \mathbf{y})$ while that increases to 0.73 BLEU points when ℓ_{sem} is excluded. In addition, only adding ℓ_{sem} is able to achieve an improvement of +1.09 BLEU points.

Effect of Controllable Sampling The widely used multinomial sampling and beam (greedy) search can be viewed as two special cases of the newly introduced controllable sampling. As in Table 7, our controllable sampling method achieves the best result among them on the validation set. We think that reasonable uncertainties can be mined via our controllable sampling strategy.

Visualization of Latent Space. We would like to verify whether our approach can capture semantics. Fortunately, there are such cases in the training set: a target sentence appears several times with different source sentences. We take some of them as examples, in which there are at least 17 unique source sentences for each target sentence. We visualize the semantic representations captured by the SCN of these examples in Figure 2. We observe that the representations are clearly clustered into 6 groups as expected, although demonstrating some noises, which reveal the strong capability of our approach to capture semantic representations.

Case Study. Table 8 shows an example translation (more examples are shown in the Appendix C). In this example, input #1, #2 and #3 have the same meaning. For input #1 and #3, "启动" and "上新" both mean "launch new products" here. The input #2 presents a different literal expression. Compared to TRANSFORMER$_{\text{syn}}$, our approach motivates the models to be consistent when processing equivalent source inputs with various lteral expressions.

4.4 Semi-supervised Setting

Given the effectiveness of leveraging monolingual data in improving translation quality (Sennrich et al., 2016a), we further propose to improve our proposed model using target monolingual data on WMT16 En→De translation. Specifically, we augment the original parallel data of WMT16 corpus containing 4.5M sentence pairs by 24M[5] unique sentences randomly extracted from German monolingual newscrawl data. All of them are no longer than 100 words after tokenizing and BPE processing. We synthesize multiple source sentences for each monolingual sentence via controllable sampling (Section 3.2), and the one with the highest probability is served as the *real* source sentence (i.e., $\mathbf{x}$). We upsample the parallel data with a rate of 5 so that we observe every bitext sentence 5 times more often than each monolingual sentence. The resulted data is finally used to re-train our models and perform 300K updates on 8 P100 GPUs. Due to resource constraints, we adopt the smaller `transformer_base` setting here.

Table 9 summarizes our results and compares to other work in the literature. After incorporating monolingual data, our method yields an additional gain of +1.5∼+3.3 BLEU points. For comparison,

---

[5] Due to resource constraints, we use a subset with randomly selected 24M sentences of German monolingual newscrawl data distributed with WMT18, instead of the whole corpora (scale to 226M) used in (Edunov et al., 2018).

Method	test14	test15	test16
Wang et al. (2019), `big`	31.00	32.01	N/A
Edunov et al. (2018), `big`	**35.00**	34.87	37.89
TRANSFORMER, `base`	27.67	32.04	36.18
+ Monolingual Data	30.14	34.17	37.28
Ours, `base`	28.57	32.95	37.11
+ Monolingual Data	31.87	**35.19**	**38.65**

Table 9: BLEU scores [%] on WMT16 En→De test sets (newstest2014∼2016) with monolingual data. Wang et al. (2019) used 2M extra back-translated data and Edunov et al. (2018) used 226M German monolingual sentences during back-translation.

Wang et al. (2019) quantify the prediction confidence using model uncertainty to alleviate the noisy back-translated parallel data and achieve 31 BLEU on newstest2014. Edunov et al. (2018) achieve as high as 35.0 BLEU on newstest2014 by adopting the `transformer_big` setting and relying on massive (scale to 226M) monolingual data. For comparison, our models fall behind Edunov et al. (2018)'s method on newstest2014 but achieve superior results on other two test sets. This reveals that the proposed method is surprisingly effective and complements existing non-semantic data augmentation techniques quite well.

5 Conclusion and Future Work

We present an uncertainty-aware semantic augmentation method to bridge the discrepancy of the data distribution between the training and the inference phases for dominant NMT models. In particular, we first synthesize a proper number of source sentences to play the role of intrinsic uncertainties via the controllable sampling for each target sentence. Then, we develop a semantic constrained network to summarize multiple source inputs into a closed semantic region which is then utilized to augment latent representations. Experiments on WMT14 English→French, WMT16 English→German, NIST Chinese→English and WMT18 Chinese→English translation tasks show that the proposed method can achieve consistent improvements across different language pairs.

While we showed that uncertainty-aware semantic augmentation with Gaussian priors is effective, more work is required to investigate if such an approach will also be successful for more sophisticated priors. In addition, learning universal representations among semantically-equivalent source and target sentences (Wei et al., 2020) can complete the proposed method.

Abstract

Automatic post-editing (APE) aims to improve machine translations, thereby reducing human post-editing effort. APE has had notable success when used with statistical machine translation (SMT) systems but has not been as successful over neural machine translation (NMT) systems. This has raised questions on the relevance of APE task in the current scenario. However, the training of APE models has been heavily reliant on large-scale artificial corpora combined with only limited human post-edited data. We hypothesize that APE models have been underperforming in improving NMT translations due to the lack of adequate supervision. To ascertain our hypothesis, we compile a larger corpus of human post-edits of English to German NMT. We empirically show that a state-of-art neural APE model trained on this corpus can significantly improve a strong in-domain NMT system, challenging the current understanding in the field. We further investigate the effects of varying training data sizes, using artificial training data, and domain specificity for the APE task. We release this new corpus under CC BY-NC-SA 4.0 license at `https://github.com/shamilcm/pedra`.

1 Introduction

Automatic Post-Editing (APE) aims to reduce manual post-editing effort by automatically fixing errors in the machine-translated output. Knight and Chander (1994) first proposed APE to cope with systematic errors in selecting appropriate articles for Japanese to English translation. Earlier application of statistical phrase-based models for APE treated it as a monolingual re-writing task without considering the source sentence (Simard et al., 2007; Béchara et al., 2011). Modern APE models take the source text and machine-translated text as input and output the post-edited text in the target language (see Figure 1).

Source text (English):
Will he send the gifts to the house?

Machine translated text (German):
Die Geschenke in mein Haus schicken?
(The gifts) (to my) (house) (send)

Post-edited text (German):
Wird er die Geschenke ins Haus schicken?
(Will he) (the gifts) (to the) (house) (send)

Figure 1: An example of post-editing given the source text in English and the translated text in German.

APE models are usually trained and evaluated in a *black-box* scenario where the underlying MT model and the decoding process are inaccessible making it difficult to improve the MT system directly. APE can be effective in this case to improve the MT output or to adapt its style or domain.

Recent advancement of APE has shown remarkable success on statistical machine translation (SMT) outputs (Junczys-Dowmunt and Grundkiewicz, 2018; Correia and Martins, 2019) even when trained with limited number of post-edited training instances (generally "triplets" consisting of *source*, *translated*, and *post-edited* segments), with or without additional large-scale artificial data (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018). Substantial improvements have been reported especially on English-German (EN-DE) WMT APE shared tasks on SMT (Bojar et al., 2017; Chatterjee et al., 2018), when models were trained with fewer than 25,000 human post-edited triplets. However, on NMT, strong APE models have failed to show any notable improvement (Chatterjee et al., 2018, 2019; Ive et al., 2020) when trained on similar-sized human post-edited data. This has led to questions regarding the usefulness of APE with current NMT systems that produce improved trans-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2736–2746,
November 16–20, 2020.

lations compared to SMT. Junczys-Dowmunt and Grundkiewicz (2018) concluded that the results of the WMT'18 APE (NMT) task "might constitute the end of neural automatic post-editing for strong neural in-domain systems" and that "neural-on-neural APE might not actually be useful". Contrary to this belief, we hypothesize that a competitive neural APE model still has potential to further improve strong state-of-the-art in-domain NMT systems when trained on adequate human post-edited data.

We compile a new large post-edited corpus, *SubEdits*, which consists of actual human post-edits of translations of drama and movie subtitles produced by a strong in-domain proprietary NMT system. We use this corpus to train a state-of-the-art neural APE model (Correia and Martins, 2019), with the goal of answering the following three research questions to better assess the relevance of APE going forward:

- Can APE substantially improve in-domain NMT with adequate data size?
- How much does artificial APE data help?
- How significant is domain shift for APE?

Spoilers: Through automatic and human evaluation, we confirm our hypothesis that, in order to notably improve over the original NMT output ("do-nothing" baseline), state-of-the-art APE models need to be trained on a larger number of human post-edits, unlike the case with SMT. Training on datasets of sizes in the scale of those from the WMT APE tasks, even with large-scale in-domain artificial APE corpora, leads to underperformance. Our experimental results also highlight that APE models are highly sensitive to domain differences. To effectively exploit out-of-domain post-edited corpora such as SubEdits in other domains, it has to be carefully mixed with available in-domain data.

2 SubEdits Corpus

Human post-edited corpora of NMT outputs from previous WMT APE shared tasks usually consist of fewer than 25,000 instances. Large-scale artificial corpora such as eSCAPE (Negri et al., 2018), do not adequately cater to the primary APE objective of correcting systematic errors of the MT outputs since the pseudo "post-edits" are independent human-translated references often differing greatly from the MT output. Table 1 lists the real and artificial APE corpora on NMT outputs. Due to the paucity of larger human post-edited corpora on NMT outputs, a study of APE performance under sufficient supervised training data conditions was not possible previously. To enable such a study, we introduce the SubEdits EN-DE post-editing corpus with over 161K triplets of source sentences, NMT translations, and human post-edits of NMT translations.

	Lang.	Size	Domain
Human post-edited corpora			
QT21 (Specia et al., 2017)	EN-LV	21K	Life Sciences

Table 1: APE corpora on NMT outputs and their sizes in terms of number of post-edited triplets.

2.1 Corpus Collection

SubEdits corpus is collected from a database of subtitles of a popular video streaming platform, Rakuten Viki (https://www.viki.com/) Every subtitle segment had been originally manually transcribed and translated to English before translating it to German using a proprietary NMT system employed by the platform and specialized at translating subtitles. Viki community[1] members who volunteer as subtitle translators would then post-edit the machine-translated subtitles to further improve it, if necessary.

2.2 Corpus Filtering

We use an adaptation of Gale-Church filtering (Tan and Pal, 2014) used for machine translation for filtering the triplets. The global character mean ratio r_c is computed as the ratio between the number of characters in the source and machine translated portions of the entire corpus. We remove triplets (*src*, *mt*, *pe*) from the corpus where the ratio between the number of characters of source (*src*) and

---

[1] https://contribute.viki.com/

	No. of triplets	No. of tokens		
		src	mt	pe
Train	141,413	1,432,247	1,395,211	1,423,257
Dev	10,000	101,330	98,581	100,795
Test	10,000	101,709	99,032	101,112

Table 2: Statistics of the SubEdits corpus

post-edit (*pe*) does not lie within a threshold range of $(1-t)r_c$ and $(1+t)r_c$ with $t = 0.2$. We normalize punctuation[2] and remove duplicate triplets. Among the triplets that share the same *src* and *mt* segments, we choose only the one with the longest *pe*. Finally, we remove triplets that are not correctly identified with the respective source and target language using a language identification tool[3] (Lui and Baldwin, 2012). We set aside 10,000 triplets as development set and 10,000 triplets as test set. The final statistics are shown in Table 2.

3 BERT Encoder-Decoder APE Model

BERT Encoder-Decoder APE (Correia and Martins, 2019) is a state-of-the-art neural APE model based on a Transformer model (Vaswani et al., 2017) with the encoder and decoder initialized with pre-trained multilingual BERT (Devlin et al., 2019) weights and fine-tuned on post-editing data.

A single encoder is used to encode both the source text and the machine-translated text by concatenating them with the separator token `[SEP]`. The encoder component of the model is identical to the original Transformer encoder initialized with pre-trained weights from the multilingual BERT. For the decoder, Correia and Martins (2019) initialized the context attention weights with the corresponding BERT self-attention weights. Also, the weights of the self-attention layers of the encoder and decoder are tied. All other weights are initialized with corresponding weights from the same multilingual BERT model as well.

BERT Encoder-Decoder APE was shown to outperform other state-of-the-art APE models (Tebbifakhr et al., 2018; Junczys-Dowmunt and Grundkiewicz, 2018) on SMT outputs even in the absence of additional large-scale artificial data that competing models have used. An improved variant of this model with additional in-domain artificial data, despite being the winning submission of the recent WMT'19 APE EN-DE (NMT) task (Lopes et al., 2019), only performed marginally better than the baseline NMT output. For the purpose of this study, we base our experiments on the BERT Encoder-Decoder APE architecture (Correia and Martins, 2019).

4 Experimental Setup

4.1 Model Hyperparameters

For the BERT Encoder-Decoder model (**BERT Enc-Dec**), we use the implementation[4] and model hyperparameters used by Correia and Martins (2019) and initialize the encoder and decoder with cased multilingual BERT (base) from Transformers[5] library (Wolf et al., 2019). The encoder and decoder follow the architecture of BERT (base) with 12 layers and 12 attention heads, an embedding size of 768, and a feed-forward layer size of 3072. We set the effective batch size to 4096 tokens for parameter updates. We train BERT Enc-Dec on a single NVIDIA Quadro RTX6000 GPU. Training on our SubEdits corpus took approximately 5 hours to converge. We validate and save checkpoints at every 2000 steps and use early-stopping (patience of 4 checkpoints) to select the model based on best perplexity. We use a decoding beam size of 5.

As a control measure, we compare BERT Enc-Dec against two vanilla Transformer APE models using automatic metrics. The Transformer APE models use BERT vocabularies and tokenization, and employ a single encoder to encode the concatenation src and mt, but they are not initialized with pre-trained weights. The following are the descriptions of the two Transformer APE baselines:

TF (base) A Transformer (base) (Vaswani et al., 2017) model with 6 hidden layers implemented in OpenNMT-py.[6] The embedding size is 512 with 2048 feed-forward units. We use default learning parameters in OpenNMT-py: Adam optimizer with a learning rate of 2 and Noam scheduler.

TF (BERT size.) A bigger Transformer with the same number of layers, attention heads, embedding dimensions, hidden, and feed-forward dimensions as BERT Enc-Dec, but without any pretraining and tying of self-attention layers. All learning hyperparameters follow that of TF (base) model.

4.2 Pre-processing and Post-processing

SubEdits corpus contains HTML tags such as line breaks (`<br>`) and italic tags (`<i>`), and symbols denoting musical notes (♫, ♪) and segments often begin with hyphens (-). We applied several processing steps to make the data as close as possible to natural sentences on which BERT has been pre-trained on. The triplets with multi-line src, mt, and pe containing `<br>` tags are split into separate training instances[7] and we remove italics and other HTML tags, musical note symbols, and leading hyphens. Thereafter, the input is tokenized with the BERT tokenization and word-piece segmentation in the Transformers library. During test time, we keep track of the changes made to input such as deletion of leading hyphens, music symbols, and italics tags, and splitting at `<br>` tags. After decoding, the outputs are detokenized and post-processed to re-introduce the tracked changes and evaluated.

4.3 Evaluation

We evaluate the models using three different automatic metrics: BLEU (Papineni et al., 2002), ChrF (Popović, 2015), and TER (Snover et al., 2006). For our evaluation on SubEdits test set, differing from WMT APE task evaluation, we post-process and detokenize the outputs and use SacreBLEU[8] (Post, 2018) to evaluate BLEU and ChrF, and TER-COM[9] to compute TER with normalization. Significance test is done by bootstrap re-sampling on BLEU with 1000 samples (Koehn, 2004). Additionally, we conduct human evaluation to ascertain the improvement of the BERT Enc-Dec APE model and to determine the human upper-bound performance for the SubEdits benchmark (see Section 5.3).

We also compare the APE model on the canonical WMT APE dataset (Section 5.6 and Table 7). We follow their evaluation method and use the released tokenized post-edited reference to compute BLEU, ChrF, and TER on the tokenized output.

5 Results and Discussion

5.1 Proprietary In-domain NMT

We first assess the quality of an proprietary in-domain NMT system that is used for compiling the SubEdits corpus. We use it as a black-box system and use the evaluation results from Table 3 to demonstrate that it is a strong baseline for studying APE performance on NMT outputs.

	BLEU↑	**ChrF↑**	**TER↓**
Proprietary NMT	46.83	63.81	37.20
Google Translate	40.96	59.20	41.91
Microsoft Translator	38.78	57.68	43.72
SYSTRAN	38.06	56.74	44.37

Table 3: Comparison of the proprietary NMT to leading commercial MT systems on an in-domain test set.

We compare the proprietary NMT system to three leading commercial EN-DE NMT systems: Google Translate, Microsoft Translator, and SYSTRAN, on a separate in-domain EN-DE test set of 5,136 subtitle segments with independent reference translations (i.e., not post-edits of any system) fetched from the same video streaming platform as the SubEdits corpus. The results (as of May 2020) are summarized in Table 3. Unsurprisingly, the proprietary NMT system specialized at translating drama subtitles substantially outperforms other general MT systems.

5.2 APE Performance on SubEdits

Table 4 reports the performance of vanilla transformer and BERT Enc-Dec APE models and compares it the *do-nothing* NMT baseline (the output produced by the proprietary in-domain NMT system). TF (base) APE improves over the *do-nothing* NMT baseline output ($p < 0.05$), particularly on TER scores. However, TF (BERT size) APE shows a smaller improvement on ChrF and TER scores and a drop in BLEU. Even with the SubEdits corpus, large networks such as TF (BERT size) tends to overfit. However, with pre-trained BERT initialization, BERT Enc-Dec APE shows substantial improvement across all metrics. Unlike previous studies that report marginal improvements (Chatterjee et al., 2018, 2019), our results show that a strong APE model trained on large human post-edits can significantly outperform ($p < 0.001$) a strong in-domain NMT system.

5.3 Human Evaluation

To validate the improvement in automatic evaluation scores and to estimate the human upper-bound performance on SubEdits, we conducted human evaluation. We hired five German native freelance translators who are also proficient in English and

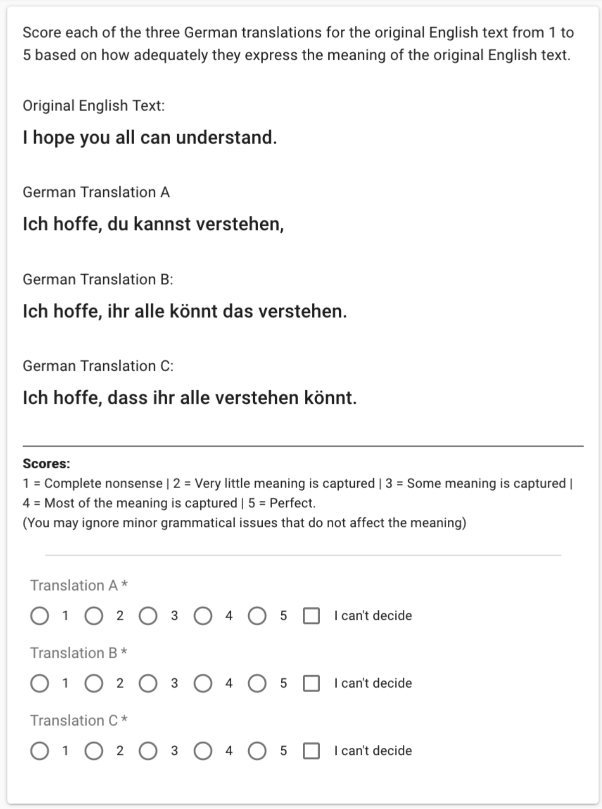
Table 4: Performance of APE models on the SubEdits test set.



Score each of the three German translations for the original English text from 1 to 5 based on how adequately they express the meaning of the original English text.

Original English Text:

I hope you all can understand.

German Translation A

Ich hoffe, du kannst verstehen,

German Translation B:

Ich hoffe, ihr alle könnt das verstehen.

German Translation C:

Ich hoffe, dass ihr alle verstehen könnt.

Scores:
1 = Complete nonsense | 2 = Very little meaning is captured | 3 = Some meaning is captured | 4 = Most of the meaning is captured | 5 = Perfect.
(You may ignore minor grammatical issues that do not affect the meaning)

Translation A *

○ 1 ○ 2 ○ 3 ○ 4 ○ 5 ☐ I can't decide

Translation B *

○ 1 ○ 2 ○ 3 ○ 4 ○ 5 ☐ I can't decide

Translation C *

○ 1 ○ 2 ○ 3 ○ 4 ○ 5 ☐ I can't decide

Figure 2: Interface used to rate the translations.

had prior experience with English/German translation.

Given the original English text, the annotators were asked to rate the adequacy (from 1 to 5) for three German translations: (1) the *do-nothing* baseline output (NMT), (2) BERT Enc-Dec APE output (APE), and (3) the human post-edited text (Human). Figure 2 shows the interface presented to the annotators for rating the translations. The three translations are presented on the same screen in random order and the annotators are unaware of their origin.

Following recent WMT APE tasks (Bojar et al., 2017; Chatterjee et al., 2018, 2019), our human evaluation is also based solely on adequacy assessments. Previous studies reported a high correlation of fluency judgments with adequacy (Callison-Burch et al., 2007) making the fluency annotations superfluous (Przybocki et al., 2009). Unlike the recent WMT APE tasks, we did not opt for direct assessments (Graham et al., 2013) since we wanted to evaluate the degradation or improvement in the quality of the NMT output due to APE and human post-edits on the same English source segments.

Annotator	NMT	APE	Human	# Eval.
A	3.7	4.2	4.5	593 / 603
B	3.5	4.0	4.4	594 / 603
C	3.7	4.3	4.4	603 / 603
D	2.8	3.4	3.8	587 / 603
E	3.3	3.8	4.3	602 / 603
A-E	3.4	3.9	4.3	2979 / 3015

Table 5: Average adequacy scores (1-5) rated by annotators (A to E). Overall average is shown in the last row (A-E).

We elicit judgments for all test set instances where the APE model modified the NMT output beyond simple edits on punctuation, HTML tags, spacing, or casing. 2,815 out of the 10,000 instances in our test set contains non-simple edits. A set of 50 instances out of 2,815 was evaluated by all annotators to compute inter-annotator agreement.[10]

After evaluation, we filtered out the instances where the annotator was unable to decide a score for any of the three translations. The average scores by each annotator (A to E) and the overall average scores are shown in Table 5. The numerator of the "# Eval." column indicates the number of evaluations used for the average score computation after filtering out the "*I can't decide*" annotations. The results of our human evaluation (Table 5) show that all five annotators rate the APE output better than baseline NMT output by at least +0.5 on average, reaching an overall score of 3.9. All the five annotators rated the human post-edited output substantially better than the NMT output and the APE output, which indicates that quality of the post-edits in the SubEdits corpus is high. Human post-edits received an overall average score of 4.3.

---

[10] Each annotator scored 603 test instances.

Using the repeated set of 46 instances,[11] we compute inter-annotator agreement using average pairwise Cohen's Kappa κ (Cohen, 1960) to be 0.27 which is considered to be fair (Landis and Koch, 1977) and similar to that observed for adequacy judgments in WMT tasks (Callison-Burch et al., 2007). However, the ranges of scores used by the annotators differ considerably (especially, annotator 'D'). Hence, measures such as a weighted Kappa κ_w (Cohen, 1968), which assigns partial credit to smaller disagreements and works better with ordinal data (such as our adequacy judgments), is more suitable. We compute the average pairwise quadratically weighted Kappa κ_w to be 0.50, and consider their agreement to be moderate.

5.4 Can APE substantially improve in-domain NMT with adequate data size?

To analyze the effect of training data size with respect to APE performance, we train BERT Enc-Dec APE with varying sizes of training data from the SubEdits corpus and evaluated the models on the SubEdits development set. For each training data size, ranging from 6,250 to 125,000, we train three models on three random samples of the respective size from the SubEdits training set. Each point in Figure 3 denotes the *mean* score of the three models (the vertical error bars at each point denote the *minimum* and *maximum* scores). The *do-nothing* NMT baseline score is represented by a *horizontal* dotted line. As a reference, we mark the size equivalent to that of WMT'18 APE EN-DE (NMT) training set (13,441 triplets) with the *vertical* dotted line. The rightmost point on each graph represents the score if the full training corpus is used.

Although the sizes of WMT APE dataset and the SubEdits corpus are not directly comparable, we see that size does matter for better APE performance. When the APE model was trained on a subset of SubEdits corpus that is of the same size as the WMT'18 APE training data, it performs worse than the baseline in terms of BLEU score and only marginally improves in ChrF and TER scores (see intersection points of the vertical and horizontal lines in Figure 3).

Interestingly, doubling the amount of training data from 12,500 to 25,000 provides slight BLEU gains above the *do-nothing* baseline and increasing the data size to 50,000 training instances improves the model further by $+1$ BLEU. The curves continue to show an increasing trend. After 100,000 training instances, the data size effect on score improvement slows down. This experiment shows the possibility that previous work on APE for NMT outputs might have reached a plateau simply due to the lack of human post-edited data rather than the limited usefulness of APE models.

5.5 How much does artificial APE data help?

Previous work using strong neural APE models (Junczys-Dowmunt and Grundkiewicz, 2018; Tebbifakhr et al., 2018) relied predominantly on artificial corpora such as that released by Junczys-Dowmunt and Grundkiewicz (2016) and the eSCAPE corpora (Negri et al., 2018). However, artificial post-edits are either generated from monolingual corpora or independent reference translations and they do not directly address the errors made by the MT system that is to be fixed by APE.

We compare the APE model performance when trained on large-scale in-domain and out-of-domain artificial data (in the order of millions of triplets) to training on the human post-edited SubEdits corpus (over 141K human post-edits). As out-of-domain artificial data, we use the eSCAPE EN-DE NMT corpus and filter sentences that have between 0 and 200 characters resulting in 5.3 million triplets. As in-domain artificial data, we generated an artificial APE corpus using the same approach used to create the eSCAPE corpus by decoding the source sentences from the OpenSubtitles2016 parallel corpus (Lison and Tiedemann, 2016), which is also from the subtitle domain [12] using the same proprietary NMT system we use to create the SubEdits corpus; the corresponding references translations become the artificial post-edits. We use the same filtering criteria and pre-processing methods for SubEdits (Section 2.2 and 4.2) resulting in 5.6 million artificial triplets. We set aside 10,000 triplets from each artificial corpus and use it as a development set when training solely on the corresponding corpus. We refer to this artificial corpus as SubEscape.

We compare the performance of the BERT Enc-Dec APE trained on SubEdits corpus to that when

---

[11] We removed 4 instances out of the 50, where one or more annotators chose the "I can't decide" option.

[12] Although both SubEdits and SubEscape are from the subtitle domain, the translations in SubEscape are from www.opensubtitles.org/ whereas the SubEdits post-edits are compiled from Rakuten Viki.

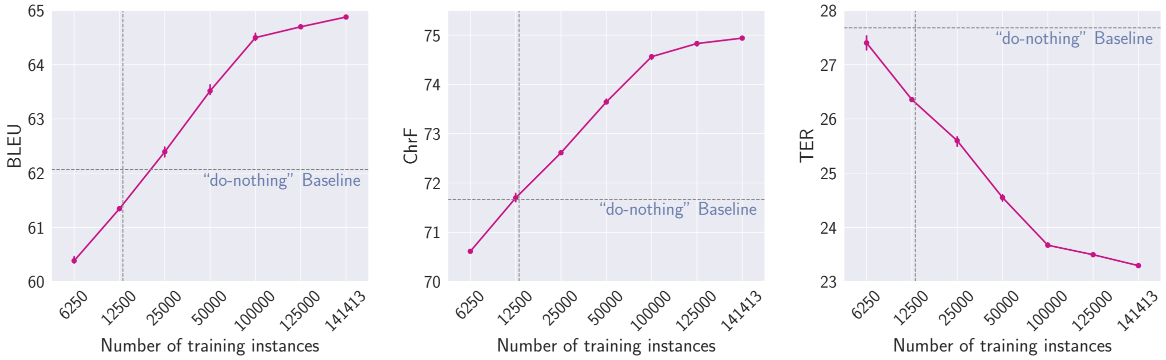


Figure 3: Performance of BERT Enc-Dec APE model with varying training data size in terms of BLEU, ChrF, and TER metrics on the SubEdits dev set. The vertical dotted line in each figure shows the data size used for WMT APE EN-DE (NMT) task (13,441 triplets) and the horizontal dotted line shows the NMT Baseline results.

	BLEU↑	**ChrF↑**	**TER↓**
do-nothing NMT	61.88	71.33	28.06
w/ BERT Enc-Dec APE trained on:			
SubEdits (R)	64.53	74.71	23.72
eSCAPE (A)	52.35	65.65	31.95
SubEscape (A)	50.51	65.89	32.78
+ SubEdits 10× (A+R)	**64.59**	**75.09**	**23.41**

Table 6: APE performance on SubEdits test set when trained with real (R) and artificial (A) training corpora.

	BLEU↑	**ChrF↑**	**TER↓**
do-nothing NMT	74.73	85.89	16.84
w/ BERT Enc-Dec APE trained on:			
WMT'18 APE (I)	75.08	85.81	16.88
SubEdits (O)	49.05	69.48	39.30
+WMT'18 APE (O+I)	74.93	85.90	16.92
+WMT'18 APE 10× (O+I)	**75.27**	**86.08**	**16.62**

Table 7: APE performance with in (I) and out-of-domain (O) training data on WMT APE NMT test set.

trained on the artificial corpora in Table 6. We find that training on artificial corpora alone, irrespective of their domain, cannot improve over the *do-nothing* baseline and in fact, degrades the performance substantially. However, when we combine SubEscape with up-sampled (10×) SubEdits corpus, we get a small improvement, particularly in terms of ChrF and TER.

5.6 How significant is domain shift for APE?

While NMT performance has been known to be particularly domain-dependant (Chu and Wang, 2018), domain shift between NMT and APE training has not been investigated previously. To assess this, we evaluate BERT Enc-Dec APE on the canonical WMT'18 APE EN-DE (NMT) dataset.[13]. The baseline NMT system and datasets used for the WMT'18 task is from the Information Technology (IT) domain and is notably different from the domain of SubEdits. We experiment with different methods of combining SubEdits (out-domain) with the WMT APE training data (in-domain). For all experiments, we use 1,000 instances held out from the WMT'18 APE training data as the validation set. The results are reported in Table 7. When trained on SubEdits alone, despite its size, we see that there is a drastic drop in performance compared to training the much smaller WMT APE data alone. When we combine SubEdits with 10× upsampled WMT APE training data, we observe some improvement, particularly in terms of BLEU ($p < 0.05$), over training with WMT APE data alone. These results show that in-domain training data is crucial to training APE models to improve in-domain NMT.

6 Analysis

6.1 Impact of APE with varying NMT quality

To study the impact of APE with varying quality of NMT output, we conduct analysis on subsets of our development set with varying translation qualities (Figure 4). We split the SubEdits development set into 10 subsets by aggregating those triplets with the NMT output scoring > 90 TER (lowest quality), $90 - 81$ TER, ..., $20 - 11$ TER, and ≤ 10 (highest quality). They are ordered from left to right in the x-axis in Figure 4 according to increasing MT quality. y-axis denotes the difference (Δ) between the TER score of APE output and NMT output for each subset.

---

[13] WMT'19 APE task also used the same dataset for benchmarking EN-DE APE systems

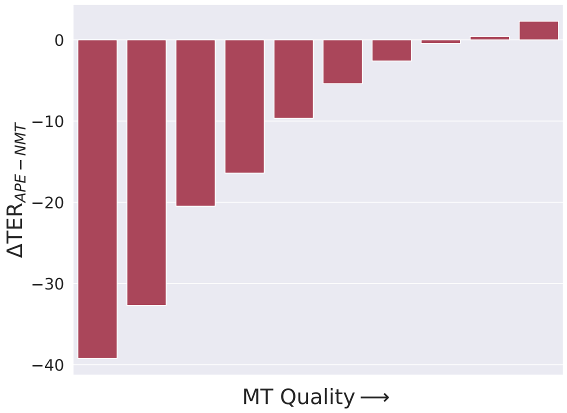

Figure 4: Translation quality difference due to APE (y-axis) shown by the $\Delta\text{TER}_{APE-NMT}$ with increasing MT quality (x-axis). Negative ΔTER indicates improvement in performance.

The more negative ΔTER indicates a larger improvement due to APE. We find that on the lower quality subsets, APE improves over NMT substantially. This improvement margin reduces with improving NMT quality and can deteriorate the NMT output when NMT quality is at the highest. This experiment shows that APE contributes to improving overall NMT performance by predominantly fixing poorer quality NMT outputs. The APE model's error will dominate and APE can become counter-productive when NMT output is nearly perfect (i.e., when there are very few or no post-edits done on them as indicated by sentence-level TER scores of < 10). APE task remains relevant until NMT systems achieve this state, which is still not the case even for strong in-domain NMT systems as indicated by our experiments.

6.2 Qualitative Analysis

We qualitatively analyze the output produced by APE on the SubEdits development set to better understand the improvements and errors made by the APE model. Table 8 shows three example outputs produced by the APE model along with the original English text (SRC), the *do-nothing* baseline output (NMT), and the human post-edits (Human).

APE is able to fix incorrect named-entity translations made by the NMT system. Example 1 demonstrates an example ("Zhongyuan Palast"→"Palast Zhongcui") where the incorrect entity is corrected by the APE model to match the human post-edits.

Example 1: Incorrect named entities	
SRC	Go to **Zhongcui Palace**!
NMT	Geh zum **Zhongyuan Palast**!
APE	Geh zum **Palast Zhongcui**!
Human	Geht zum **Palast Zhongcui**!
Example 2: Missing phrases	
SRC	Let's go back **to the resort** and we'll talk it out.
NMT	Geh zurck und wir werden reden.
APE	Geh zurck **zum Resort** und wir werden reden.
Human	Lass uns zurck **zum Resort** gehen und darber reden.
Example 3: Requires more context	
SRC	Before coming, City Master negotiated with me.
NMT	Bevor **er** gekommen ist, hat der Stadtmeister ml cit mir verhandelt.
APE	Bevor **wir** kommen, hat die Stadtmeisterin mit mir verhandelt.
Human	Bevor **ich** kam, hat die Stadtmeisterin mit mir verhandelt.

Table 8: Examples where the APE model proposes changes to the NMT output on the SubEdits test set. The original sentence in English (SRC) and the human post-edit (Human) is also shown.

NMT often under-translates and misses phrases and the APE models usually can patch these under-translations, e.g. Example 2 where the prepositional phrase "to the resort"→"zum Resort" was missing in the MT outputs and the APE model was able to mend the translation.

As much as sentence-level APE works well empirically, the lack of context results in erroneous translation by the NMT system where it tries to infer a wrong pronoun and the APE model attempts to assume yet another wrong pronoun, e.g. translating a pronoun-dropped source text in Example 3. Often, the prior or future context from video, audio, or other subtitle instances is necessary to fill these contextual gaps. Sentence-level APE cannot address these issues robustly, which calls for further research on multimodal (Deena et al., 2017; Caglayan et al., 2019) and document-level (Hardmeier et al., 2015; Voita et al., 2019) translation and post-editing, especially for subtitles.

7 Related Work

Until 2018, APE models were benchmarked on SMT outputs through various WMT APE tasks (Bojar et al., 2015, 2016, 2017). The scale of post-edited data provided by these tasks was in the order of 10,000 to 25,000 triplets. The largest collection of human post-edits, released by Zhechev (2012), however, was on SMT and consisted of 30,000 to 410,000 triplets across 12 language pairs. On SMT output, participating systems showed impressive gains even with small training datasets from WMT APE tasks (Junczys-Dowmunt and Junczys-Dowmunt, 2017; Tebbifakhr et al., 2018). The results of subsequent APE (NMT) tasks were not as promising with only marginal improvements on English-German and no improvement on English-Russian (Chatterjee et al., 2019).

Previously, there was no study to assess the necessity of larger human post-edited training data on APE performance on NMT outputs which we address in this paper. APE models were predominantly trained on large-scale artificial data combined with a few thousand human post-edits. Junczys-Dowmunt and Grundkiewicz (2016) proposed generation of large-scale artificial APE training data via round-trip translation approach inspired from *back-translation* (Sennrich et al., 2016). They combined artificial training data with real data provided by WMT APE tasks to train their model. Using a similar approach of generating artificial APE data, Freitag et al. (2019) trained a monolingual re-writing APE model trained on the generated artificial training data alone. Contrary to the round-trip translation approach, large-scale artificial APE data was generated by simply translating source sentences using NMT and SMT systems and using the reference translations as the "pseudo" post-edits to create eSCAPE corpus (Negri et al., 2018). Using the eSCAPE English-Italian APE corpus, Negri et al. (2017) assessed the performance of an online APE model in a simulated environment where the APE model is updated at test time with new user inputs. They found that their online APE models trained on eSCAPE found it difficult to improve specialized in-domain NMT systems.

Such an analysis by training on artificial corpora may not adequately assess the actual potential of APE since these corpora do not fully cater to the task and can be noisy. The "synthetic" post-edits are independent or loosely coupled with the MT outputs, and are often drastically different from the MT output. This makes analyzing APE performance over competitive NMT systems on actual post-edited data an important step in understanding the potential of APE research. Contrary to previous conclusions, our analysis shows that a competitive in-domain NMT system can be markedly improved by a strong neural APE model when trained on sufficient human post-edited training data.

8 Conclusion

APE has been an effective option to fix systematic MT errors and improve translations from black-box MT services. However, on NMT outputs, APE has shown hardly any improvement since training has been done on limited human post-edited data. The newly collected SubEdits corpus is the largest corpus of NMT human post-edits collected so far. We reassessed the usefulness of APE on NMT using this corpus.

We showed that with a larger human post-edited corpus, a strong neural APE model can substantially improve a strong in-domain NMT system. While artificial APE corpora help, we showed that the APE model performs better when trained on adequate human post-edited data (SubEdits) compared to large-scale artificial corpora. Finally, our experiments comparing in and out-domain APE show that domain-specificity of training affects APE performance drastically and a combination of in and out-of-domain data with certain upscaling alleviates the domain-shift problem for APE. We find that APE mostly contributes to improving NMT performance by fixing the poorer-quality outputs that still exist with strong in-domain NMT systems. We release the post-editing datasets used in this paper (SubEscape and SubEdits) along with pre/post-processing scipts at PEDRa GitHub repository (`https://github.com/shamilcm/pedra`)

Acknowledgements

We thank the anonymous reviewers for their useful comments. We also thank Rakuten Viki community members who had contributed subtitle post-edits that helped building the SubEdits dataset.

Abstract

A gapping construction consists of a coordinated structure where redundant elements are elided from all but one conjuncts. This paper proposes a method of parsing sentences with gapping to recover elided elements. The proposed method is based on constituent trees annotated with grammatical and semantic roles that are useful for identifying elided elements. Our method outperforms the previous method in terms of F-measure and recall.

1 Introduction

A gapping construction consists of a coordinated structure where redundant elements are elided from all but one conjuncts. For example, we can elide the second redundant verb "ate" from the sentence "John ate bread, and Mary ate rice." We need to recover elided elements to interpret sentences with gapping; however, little work has focused on developing such methods.

This paper proposes a method of parsing sentences with gapping. Our proposed method uses constituent trees annotated with grammatical and semantic tags and a special tag indicating gapped conjuncts. The method parses a sentence to obtain a tag-annotated constituent tree and analyzes gapping constructions using the resulting tree when it includes gapped conjuncts. The analysis is based on a sequence alignment algorithm using grammatical and semantic tags. An experiment shows that our method outperforms the previous method in terms of F-measure and recall.

2 Gapping Construction

This section first explains gapping constructions in the Penn Treebank (PTB, Marcus et al., 1993), on which our proposed method is based, and summarizes the previous work on analyzing sentences with gapping.

2.1 Gapping Constructions in the PTB

A gapping construction consists of a coordinated structure where redundant elements are elided from all but one conjuncts. The constituents remaining in a gapped conjunct are called *remnants*. The remnants have a corresponding constituent, called a *correlate*, in the ungapped conjunct.[1] We can obtain the ungapped version of the conjunct by replacing each correlate with its corresponding remnant.

In the PTB, the correspondences between remnants and correlates are annotated. Figure 1 shows an example of a PTB constituent tree, which includes a gapping construction. The nodes marked with "-" hyphen indices are the correlates, while those marked with "=" equal indices are the remnants. A gapped conjunct is flattened, that is, all remnants are children of the conjunct node. The number assigned to a correlate and a remnant indicates a correspondence relation. For example, `NP-SBJ-1` and `NP-SBJ=1` in this tree are a correlate and a remnant, respectively, and correspond to each other. We can obtain the constituent tree for "the six-month bills will still mature on May 3, 1990" by replacing `NP-SBJ-1` with the tree whose root is `NP-SBJ=1` and `NP-TMP-2` with that whose root is `PP-TMP=2`. In other words, "will still mature" is elided from the second conjunct.

2.2 Previous Work

This section gives an overview of previous approaches to analyzing sentences with gapping.

Ficler and Goldberg (2016) proposed a new representation for argument-cluster coordination, which is one kind of gapping constructions. They converted PTB trees by coordinating correlates and remnants. This conversion can be applied only when the correlates and the remnants are all to-

---

[1] In English, the first conjunct is ungapped.

November 16–20, 2020.

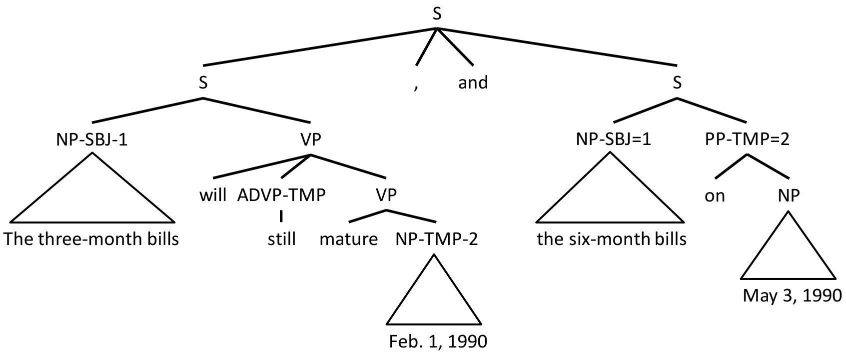

Figure 1: Gapping construction in the PTB.

gether on the right. Therefore, it cannot handle the tree shown in Figure 1.

Kummerfeld and Klein (2017) developed a parser that adopts a graph representation for syntactic structure. They discussed how to represent a correspondence between a remnant and a correlate with an arc in their graph representation. However, the parser struggled to generate such arcs, and the recall was very low.[2]

Schuster et al. (2018) proposed two methods based on dependency structure. One represents gapping constructions using complex relation labels (Seeker et al., 2012), and the other adopts a sequence alignment algorithm to assign remnant words to correlate words. The latter is similar to ours. We will discuss the differences between the latter method and ours in the later section.

Another approach is the one that does not depend on syntactic representation. In the Automatic Gapping Resolution Shared Task for Russian (AGRR-2019) (Ponomareva et al., 2019), the prepared dataset marked each element comprising gapping constructions. Most participants treated this task as a sequence labeling problem.

3 Proposed Method

This section describes our proposed method, which parses gapping constructions. Our method enables existing PTB-based parsers to identify correspondences between correlates and remnants. Elided elements can be recovered by such correspondences as described in Section 2.1.

One difficulty in parsing gapping constructions is insufficient data for modeling such phenomena because their occurrence is rare. To mitigate this problem, our method learns not directly from correspondences between correlates and remnants, but from the following tags easily obtained from the PTB:

- a special tag indicating gapped conjuncts
- grammatical and semantic role tags

Correspondences between correlates and remnants are identified by a sequence alignment algorithm using the tag-annotated constituent tree. We first explain our tag annotation and describe the sequence alignment algorithm.

3.1 Annotation

Our method uses a special tag to identify gapped conjuncts in constituency parsing. Specifically, we assign the `GAP` tag to a node n, if n satisfies the following condition:

- n has a child marked with "=" index.

In the coordinated structure shown in Figure 1, the `GAP` tag is assigned to the second `S` conjunct node.

Next, we explain grammatical and semantic tags. In general, each remnant and its corresponding correlate play an identical grammatical or semantic role. For example, in Figure 1, the constituents co-indexed with `1` are subjects (`SBJ`), while those co-indexed with `2` are temporal adjuncts (`TMP`). This fact suggests that correspondences between correlates and remnants can be identified using grammatical and semantic roles. Our method directly uses the PTB grammatical and semantic role tags shown in Table 1.[3]

An important point herein is that our method has an advantage from the viewpoint of training data. The PTB includes a massive amount of

---

[2] Note that the main purpose of the parser is to analyze traces, such as wh-movement, and not gapping constructions.

[3] The grammatical tag `PRD` can be used together with a semantic tag. We only used the `PRD` tag in this case.

grammatical		semantic	
DTV	Dative	BNF	Benefactive

SBJ	Surface subject	MNR	Manner
		PRP	Purpose
		TMP	Temporal

Table 1: Grammatical and semantic role tags.

grammatical and semantic tag information; thus, we can learn a model that identifies the tags by simply retaining them in the treebank (Gabbard et al., 2006).

3.2 How to identify correspondences between correlates and remnants

This section explains how to identify correspondences between correlates and remnants using the tag-annotated constituent trees described in the previous section. The procedure consists of the following two steps:

1. Extract remnant candidates R and correlate candidates C when gapped conjuncts exist.
2. Align nodes in R to nodes in C.

The first step is invoked if a node $n_{\mathtt{g}}$ annotated with the GAP tag exists. A set R of remnant candidates is defined as a set of $n_{\mathtt{g}}$'s children. To extract the correlate candidates C, the method seeks the ungapped conjunct $n_{\mathtt{u}}$ that satisfies the following condition:

$$\begin{aligned}&n_{\mathtt{u}} \in \mathtt{L}(n_{\mathtt{g}})\\ &\wedge \mathtt{ct}(n_{\mathtt{u}}) = \mathtt{ct}(n_{\mathtt{g}})\\ &\wedge \neg\exists n \in \mathtt{L}(n_{\mathtt{u}})\big(\mathtt{ct}(n) = \mathtt{ct}(n_{\mathtt{u}})\big)\end{aligned}$$

where, $\mathtt{L}(n)$ and $\mathtt{ct}(n)$ are the set of left siblings of n and the category of n, respectively. A set C of correlate candidates is defined as a set of $n_{\mathtt{u}}$'s proper descendants.

The second step aligns nodes in R to nodes in C. Here we impose a constraint that $r \in R$ plays an identical role to $c \in C$. More precisely, we can align r to c if the following condition holds:

$$\begin{aligned}&\mathtt{match}(c, r) \overset{def}{=}\\ &\quad\big(\mathtt{rl}(c) = \mathtt{rl}(r) \neq \mathtt{null}\big)\\ &\quad\vee \big(\mathtt{ct}(c) = \mathtt{ct}(r) = \mathrm{PP} \wedge \mathtt{hd}(c) = \mathtt{hd}(r)\big)\\ &\quad\vee \big(\mathtt{rl}(c) = \mathtt{rl}(r) = \mathtt{null} \wedge \mathtt{ct}(c) = \mathtt{ct}(r)\big)\end{aligned}$$

where, $\mathtt{rl}(x)$ stands for the role tag of x. If x has no role tag, $\mathtt{rl}(x) = \mathtt{null}$. $\mathtt{hd}(x)$ is the head preposition of x. Furthermore, we impose the following structural constraints to follow the PTB annotation scheme:

Uniqueness of remnant If $(c, r) \in A$ and $(c, r') \in A$, then $r = r'$.

Uniqueness of correlate If $(c, r) \in A$ and $(c', r) \in A$, then $c = c'$.

Order-Preserving For all $(c, r), (c', r') \in A$, if $\mathtt{e}(r) \leq \mathtt{s}(r')$, then $\mathtt{e}(c) \leq \mathtt{s}(c')$.

Non-overlapping For all $(c, r), (c', r') \in A(c \neq c')$, then $\mathtt{e}(c) \leq \mathtt{s}(c')$ or $\mathtt{e}(c') \leq \mathtt{s}(c)$.

Here, $A \subseteq C \times R$ is a set representing an alignment of correlates to remnants. $(c, r) \in A$ means that a correlate c is aligned to a remnant r. $\mathtt{s}(n)$ and $\mathtt{e}(n)$ stand for the start and end positions of node n, respectively.

3.3 DP-based sequence alignment

To realize the second step described in Section 3.2, we modify the sequence alignment algorithm proposed by Needleman and Wunsch (1970). Our algorithm is shown in Algorithm 1. $\mathtt{T}[i, j]$ keeps the highest scoring alignment of $c_i \cdots c_m$ to $r_j \cdots r_n$ and its score. The difference between our modified version and the original one can be seen in line 10. While the original version considers the next element c_{i+1}, ours skips all the descendants of c_i. That is, $\mathtt{skip\text{-}des}[i]$ is the index such that $c_{\mathtt{skip\text{-}des}[i]}$ is the first non-descendant of c_i in $c_{i+1} \cdots c_m$. This modification is required to satisfy the order-preserving and non-overlapping constraints.[4] The function $\mathtt{score}$ is defined as follows:[5]

$$\mathtt{score}(c, r) = \begin{cases}1 & (\mathtt{match}(c, r) = \mathtt{true})\\ -\infty & (\mathtt{match}(c, r) = \mathtt{false})\end{cases}$$

---

[4] C is sorted in a preorder traversal order, hence, all $c_k(i < k < \mathtt{skip\text{-}des}[i])$ are c_i's descendants, and all $c_l(\mathtt{skip\text{-}des}[i] \leq l \leq m)$ satisfy the equation $\mathtt{e}(c_i) \leq \mathtt{s}(c_l)$. That is, any c_k violates the constraints, and any c_l satisfies them.

[5] When two alignments obtain the same score, we prefer the one whose correlates cover more words.

Algorithm 1 Sequence alignment algorithm

3.4 Discussion

Our method is similar to that of Schuster et al. (2018) in that both rely on sequence alignment. The following differences, however, exist:

- The previous method converts Universal Dependencies (UD) v2 representations (Nivre et al., 2017) to enhanced UD representations (Schuster and Manning, 2016), which provides an analysis of gapping constructions. It cannot use grammatical and semantic roles unlike ours, because remnants cannot have such information in the UD v2 framework.[6]
- Our proposed sequence alignment algorithm is a novel one that can impose the order-preserving and non-overlapping constraints on the resulting alignment. This feature is required to deal with gapping constructions in PTB constituent trees.

4 Experiment

We conducted an experiment using the PTB to evaluate the performance of our proposed method.[7] We used the standard PTB training, development, and test data split (i.e., sections 02–21, 22, and 23, respectively) and the Kitaev and Klein parser (Kitaev and Klein, 2018)[8] that can use BERT (Devlin et al., 2019). We trained the parsing model by simply replacing the training and development data with those annotated by our annotation scheme. The hyperparameters were identical to those of Kitaev et al. (2019). The test data were parsed by the trained model to obtain tag-annotated trees. The correspondences between the correlates and the remnants were identified by our proposed alignment algorithm. The alignment accuracy was evaluated by the metric of Kummerfeld and Klein (2017). That is, we represent a correspondence between a correlate c and a remnant r as a tuple $(\mathtt{ct}(r), \mathtt{s}(r), \mathtt{e}(r), \mathtt{ct}(c), \mathtt{s}(c), e(c))$, and measure the precision and recall using tuples.

Table 2 shows the alignment performance of our method and the previous one. The previous method struggled to generate arcs between correlates and remnants and had a very low recall. In contrast, our method achieved high recall and F-measure. It outperformed the previous method even without BERT.

The last row in Table 2 shows the performance when using gold tag-annotated trees, indicating that our sequence alignment algorithm works well and that tag identification directly affects the overall performance. We evaluated the tag identification accuracy using a tuple $(\mathtt{rl}(n), \mathtt{s}(n), \mathtt{e}(n))$. Table 3 presents the tag identification accuracy. The performance of identifying grammatical and semantic tags did not differ much between using BERT and not using BERT. On the other hand, the performance of identifying the `GAP` tag without BERT is rather low compared to that with

---

[6] In the UD v2 framework, one remnant is treated as a head, and the others are attached to it with the special `orphan` dependency.

[7] The code is available at `https://github.com/yosihide/ptb2cf`.

Table 4: Comparison for constituency parsing performance on the test data.

BERT. Therefore, the main reason for the low performance of the alignment without BERT is the degraded performance of identifying the `GAP` tag.

Finally, we report the constituency parsing performance. Table 4 shows the accuracy of the Kitaev and Klein parser with and without our tag annotation. The result implies that our tag annotation to constituent trees has a tiny negative impact on the constituency parsing performance.

5 Conclusion

This paper has proposed a method of parsing gapping constructions based on tag-annotated constituent trees. Our proposed method is simple but effective. We believe that it will serve as a strong baseline for the task of parsing gapping constructions. In the future work, we will extend our method by replacing the simple role matching score with grammatical or semantic similarity-based measures to improve the alignment accuracy.

Span-based discontinuous constituency parsing: a family of exact chart-based algorithms with time complexities from $\mathcal{O}(n^6)$ down to $\mathcal{O}(n^3)$

Abstract

We introduce a novel chart-based algorithm for span-based parsing of discontinuous constituency trees of block degree two, including ill-nested structures. In particular, we show that we can build variants of our parser with smaller search spaces and time complexities ranging from $\mathcal{O}(n^6)$ down to $\mathcal{O}(n^3)$. The cubic time variant covers 98% of constituents observed in linguistic treebanks while having the same complexity as continuous constituency parsers. We evaluate our approach on German and English treebanks (Negra, Tiger, and DPTB) and report state-of-the-art results in the fully supervised setting. We also experiment with pre-trained word embeddings and Bert-based neural networks.

1 Introduction

Syntactic parsing aims to recover the latent syntactic relations between words in a sentence, expressed in a given syntactic formalism. In this paper, we focus on constituency trees where the syntactic structure is described by the means of a hierarchical structure composed of nodes: words are leaf nodes whereas internal nodes represent labeled constituents or phrases, see Figure 1. Constituency trees can broadly be classified into two categories. On the one hand, in a *continuous* constituent tree, each node must dominate a contiguous sequence of words.[1] On the other hand, in a *discontinuous* constituent tree, a node can dominate a non-contiguous sequence of words. It has been argued that modeling discontinuity is unavoidable, see for example McCawley (1982) and Bunt et al. (1987) for English and Müller (2004) for German.

Phrase-structure grammars have been proposed to parse and generate constituency trees. For example, Context-Free Grammars (CFG) are able to process continuous constituent trees whereas Multiple Context Free Grammars (Seki et al., 1991, MCFG) and Linear Context-Free Rewriting System (Vijay-Shanker et al., 1987, LCFRS) are able to process discontinuous constituent trees. CFGs have been widely studied for practical parsing due to the availability of time-efficient *chart-based* parsing algorithms based on dynamic programming: parsing a sentence of length n is a $\mathcal{O}(gn^3)$ problem where g is a grammar related constant (Kasami, 1966; Younger, 1967; Cocke, 1969). However, parsing algorithms for MCFGs and LCFRSs are deemed to be impractical despite their polynomial-time complexity (see Section 2). Therefore, most of the experimental work in this field has been limited to parsing short sentences, e.g. sentences that contain less than 40 words (Kallmeyer and Maier, 2010; Evang and Kallmeyer, 2011; Maier et al., 2012; Kuhlmann and Nivre, 2006).

Advances in machine learning led to the development of constituency parsers that are no longer based on phrase-structure grammars. Instead, the prediction step only ensures the well-formedness of the resulting structure and does not enforce compliance of the syntactic content represented by the structure. For example, a verbal phrase is not constrained to contain a verb. As such, they can be assimilated to the mainstream approach to bi-lexical dependency parsing where one considers candidate outputs only in a restricted class of graphs: non-projective (McDonald et al., 2005), projective (Eisner, 1997) or bounded block degree and well-nested spanning aborescences (Gómez-Rodríguez et al., 2009, 2011; Corro et al., 2016), among others (Kuhlmann and Nivre, 2006; Satta and Kuhlmann, 2013; Pitler et al., 2012). These approaches assume that intricate relations in the syntactic content can be implicitly learned by the scoring function.

Span-based parsing is a grammarless approach

to constituency parsing that decomposes the score of a tree solely into the score of its constituents, originally proposed for continuous constituency parsing (Hall et al., 2014; Stern et al., 2017; Cross and Huang, 2016).[2] Recovering the highest scoring tree can be done exactly using a slightly updated CYK algorithm or using inexact[3] methods like top-down or transition based algorithms. This approach has obtained state-of-the art results for continuous constituency parsing (Stern et al., 2017; Kitaev and Klein, 2018; Kitaev et al., 2019). In this work, we propose the first span-based parser with an exact decoding algorithm for discontinuous constituent parsing. To this end, we introduce a novel exact chart-based algorithm based on the parsing-as-deduction formalism (Pereira and Warren, 1983) that can parse constituent trees with a block degree of two, including ill-nested structures (see Section 3), which have been argued to be unavoidable to model natural languages (Chen-Main and Joshi, 2010). Therefore, our constituency parser is closely related to the dependency parser of Gómez-Rodríguez et al. (2009, 2011). Despite its $\mathcal{O}(n^6)$ time-complexity, where n is the length of the input sentence, our algorithm is reasonably fast: in our experiments, all treebanks can be parsed without removing long sentences. Moreover, we observe that several deduction rules are of little use to retrieve trees present in treebanks. Therefore, we experiment with variants of the algorithm where we remove specific deduction rules. This leads to parsing algorithms with lower asymptotic complexity that experimentally produce accurate parses. Importantly, we show that a specific form of discontinuity can be parsed in $\mathcal{O}(n^3)$, that is with the same asymptotic complexity as continuous constituency parsing.

Our main contributions can be summarized as follows:

- we propose a new span-based algorithm for parsing discontinuous constituency trees of block degree two with exact decoding and reasonable average execution time;
- we propose a cubic-time algorithm that can parse a significant portion of discontinuous constituents in various corpora while having the same theoretical complexity as continuous constituency parsers, without requiring any preprocessing or post-processing steps contrary to the approaches of van Cranenburgh et al. (2016) and Boyd (2007);
- we report state-of-the-art parsing results on these treebanks in a fully supervised setting and experiment with pre-trained word embeddings, including Bert based models.

We release the C++/Python implementation of the parser.[4]

2 Related Work

Phrase-structure grammars: The LCRFS formalism has been widely used in the context of discontinuous constituency parsing, although MCFG and Simple Range Concatenation Grammars (Boullier, 1998) have been shown to be equivalent, see Seki et al. (1991) and Boullier (2004). Kallmeyer and Maier (2010) introduced the first practical chart-based LCFRS parser for German, which was subsequently applied to English (Evang and Kallmeyer, 2011). However, they restrict their data to sentences that contain less than 25 words. To improve parsing time, Maier et al. (2012) proposed an experimentally faster parser based on the A^* search algorithm together with a block degree two restriction. However, they still limit the sentence size to a maximum of 40 words. A single sentence of 40 words takes around 3 minutes to be parsed, an impressive improvement over the parser of Kallmeyer and Maier (2010) that needs several hours, but still prohibitively slow for large scale parsing. Concurrently to this work, Stanojević and Steedman (2020) proposed a span based grammar-less LCFRS parser. They also explored the well-nested variants.

Graph based parsing: A different line of work proposed to explore constituency parsing as a dependency parsing problem.[5] In other words, even if it is straightforward to represent constituency trees as hierarchical phrase structures, the same syntactic content can be represented with different mathematical objects (Rambow, 2010), including directed graphs commonly used for de-

---

[2] In contrast, for example, to several transition systems that can incorporate scores related to actions that where executed during derivation, or to split point decision and left-right span scores in the parser of Stern et al. (2017).

[3] The term inexact refers to the fact that these methods are not guaranteed to recover the highest scoring structure.

[4] `https://github.com/FilippoC/disc-span-parser-release`

[5] Note that opposite line of work also exists, that is reducing dependency parsing to constituency parsing, see for example Maier and Kallmeyer (2010).

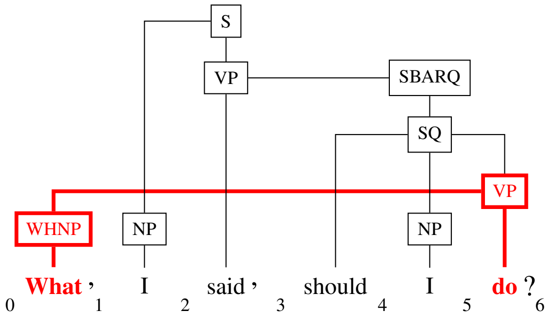

Figure 1: Example of a discontinuous constituency tree. The bold red VP node dominates two sequences of words: "What" and "do". All other nodes are continuous. Numbers below the sentence are interstice indices used in the algorithm description.

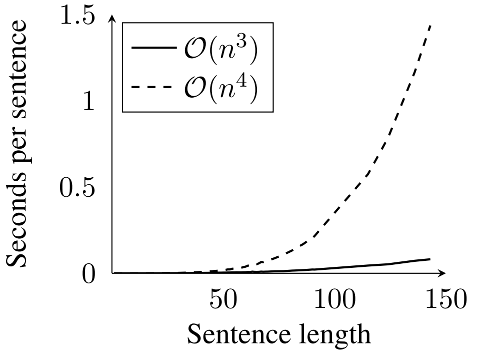

Figure 2: Execution time per sentence length of the chart-based algorithm for the $O(n^3)$ (solid line) and $O(n^4)$ (dashed lines) variants.

pendency parsing. Fernández-González and Martins (2015) reduced the (lexicalized) constituency parsing task to dependency parsing where the constituency structure is encoded into arc labels. Then, discontinuous constituency parsing is reduced to the labeled *Spanning Arborescence* problem which can be solved in quadratic time. The same reduction has also been used in a sequence-to-sequence framework (Fernández-González and Gómez-Rodríguez, 2020). Corro et al. (2017) proposed a joint supertagging and dependency parsing reduction where vertices represent supertags[6] and labeled arcs encode combination operations (substitution and adjunction). The problem is then reduced to the labeled *Generalized Spanning Arborescence* problem which is known to be NP-hard (Myung et al., 1995). One benefit of these approaches is that they do not assume any restriction on the constituency structure: they can parse ill-nested structures and have no block degree restriction. However, they cannot impose such constraints, which may be beneficial or required and they factor the score of a tree into dependency, supertag and/or label scores, which means that the learning objective is not directly related to the evaluation metric which focuses on constituents. Moreover, the factorization relies on possibly erroneous heuristics (head-percolation tables) to lexicalize the original structure if the information is not present in the treebank. On the contrary, in this work, we directly score parts of the syntactic content (i.e. labeled constituents). Therefore, at training time we can optimize an objective directly related to the end-goal evaluation.

Transition systems: Lastly, transition-based parsers have been proposed, based on the idea of the SWAP transition for non-projective dependency parsing (Nivre, 2009), see Versley (2014) and following work based on shift-reduce strategy (Maier, 2015; Maier and Lichte, 2016; Stanojević and Alhama, 2017a). These systems rely on the fact that a discontinuous tree can be transformed into a continuous one by changing word order in the input sentence. They do not require strong independence assumption on the scoring model which can be useful to encode richer information, especially for long-distance relationships. However, the number of transitions required to parse discontinuities can impact prediction accuracy. To alleviate this problem, two different approaches have been explored: Coavoux and Crabbé (2017) introduced a two-stack system coupled with a GAP transition and Maier and Lichte (2016) proposed the SHIFT-I transition to access non-local elements directly, therefore reducing the number of transitions. In exchange for a rich parameterization, transition systems lose optimality guarantees with respect to the scoring model and rely on greedy or beam-search decoding. These approaches achieve state-of-the-art results while being fast at test time (Coavoux and Cohen, 2019; Coavoux et al., 2019). On the contrary, our approach is exact with respect to the scoring model, i.e. it will always return the highest scoring structure.

Search space restriction: Previous work in constituency and dependency parsing proposed to restrict the search space to improve time complexity while at the same time ensuring a good coverage of data. Satta and Schuler (1998) proposed an al-

---

[6] A supertag is an elementary tree that encodes the sequence of lexicalized constituents for which a given word is the head, see Bangalore and Joshi (1999)

gorithm that parses a subclass of Tree Adjoining Grammar in $\mathcal{O}(n^5)$ instead of $\mathcal{O}(n^6)$. Our parsing algorithm is highly related to the dependency parser of Gómez-Rodríguez et al. (2011) and the restricted variant of the latter introduce by Pitler et al. (2012).

3 Parsing Algorithm

We describe our algorithm using the *parsing-as-deduction* framework (Pereira and Warren, 1983). As such, our description is independent of the value one wants to compute, whether it be the (k-)best derivation(s), the partition function or span marginals (Goodman, 1999).[7] However, we will focus on argmax decoding.

We are interested in constituency trees of block degree two, including ill-nested trees. The block degree two constraint is satisfied if each node dominate at most two disjoint sequences of words. Let $w_1 ... w_n$ be a sentence. A constituency tree for this sentence is ill-nested if it contains two nodes dominating disjoint sets of words $W^{(1)}$ and $W^{(2)}$ such that there exists $w_i, w_j \in W^{(1)}$ and $w_k, w_l \in W^{(2)}$ such that $i < k < j < l$ or $k < i < l < j$.

Filtering: Contrary to CFGs and LCFRS CKY-style parsers, there is no side-condition constraining allowed derivations in span-based parsers. The label of a constituent is independent of the label of its children.

Binarization: Interestingly, span-based parsers do not require explicit binarization of the constituency structure. Although grammar based parsers require binarization of the grammar production rules and therefore of the constituency structure to ensure tractable complexity, span-based parsers can take care of binarization *implicitly* by introducing a supplementary constituency label with a fixed null score.

Unary rules: We follow Stern et al. (2017) and merge unary chains into a single constituent with a new label, e.g. the chain `SBARQ` → `SQ` will result in a single constituent labeled `SBARQ_SQ`.

3.1 Items

Let $\mathcal{N}$ be the set of non-terminals (labels) and n the length of the input sentence. We define spans with interstice indices instead of word indices, see Figure 1. Items manipulated by our deduction rules are 5-tuples $[A, i, k, l, j]$ where $A \in \mathcal{N} \cup \{\varnothing\}$ is the constituent label with value $\varnothing$ indicating a null label used for implicit binarization. Given that each item represents a constituent, we will use the same notation to refer to the chart item and to the linguistic structure interchangeably. Indices $i, j \in \mathbb{N}, k, l \in \mathbb{N} \cup \{-\}$ define the constituent span:

- if the constituent is continuous, then $k = l = -$ and $0 \leq i < j \leq n$;
- otherwise, the constituent is discontinuous (with a single gap) and $0 \leq i < k$ and $l < j \leq n$, with $k < l$, define its left and right spans, respectively.

For example, the tree in Figure 1 contains the discontinuous constituent $[\text{VP}, 0, 1, 5, 6]$.

3.2 Axioms and goal

Axiom items are word level constituents, i.e. items of the form $[A, i, -, -, i + 1]$ with $0 \leq i < n$ and $A \in \mathcal{N} \cup \{\varnothing\}$. In our experiments, axioms can have a null label, i.e. $A = \varnothing$, because we do not include part-of-speech tags as leaves of the constituency tree.

The goal item is defined as $[A, 0, -, -, n]$ with $A \in \mathcal{N} \cup \{\varnothing\}$. The goal can have a null label, so we can parse empty trees and disconnected structures occurring in treebanks without further pre/post-processing steps.

3.3 Deduction rules

The deduction rules used to derive the goal from axioms are listed on Figure 3. Each rule takes exactly two premises. Note that rule **(a)** is the only rule needed for continuous constituency parsing.

Rule **(b)** creates a discontinuous constituent from two continuous constituents. The set of rules **(e)**-**(f)**-**(g)**-**(h)** (resp. **(c)**) allow to combine one discontinuous and one continuous constituent to produce a discontinuous one (resp. a continuous one).

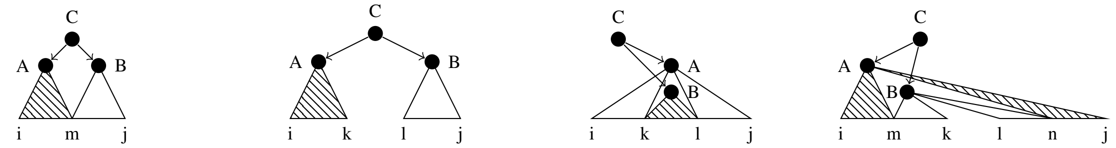
Finally, there are rules that combine two discontinuous antecedents. Rule **(d)** is the only such rule that is allowed for building well-nested trees. The other four rules **(i)**-**(j)**-**(k)**-**(l)** are used for the construction of ill-nested trees. As such, it is easy to control whether ill-nested structures are permitted or not by including or excluding them.

3.4 Soundness and completness

The algorithm is sound by definition because items cannot represent constituents with a gap degree

---

[7] Note that parsing without grammatical constraints results in all sentences having a non-empty parse forest, therefore the recognition problem is ill-defined.



$$\frac{[A,i,-,-,m]\,[B,m,-,-,j]}{[C,i,-,-,j]}$$

(a) Combine

$$\frac{[A,i,-,-,k]\,[B,l,-,-,j]}{[C,i,k,l,j]}$$

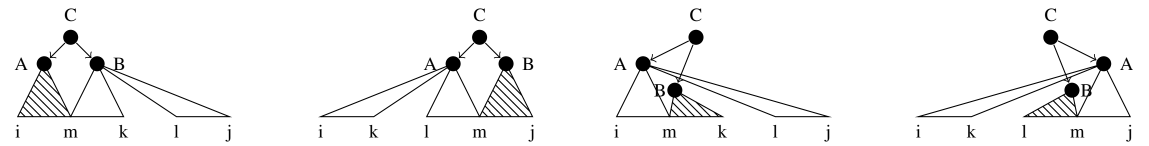
(b) Create gap

$$\frac{[A,i,k,l,j]\,[B,k,-,-,l]}{[C,i,-,-,j]}$$

(c) Fill gap

$$\frac{[A,i,m,n,j]\,[B,m,k,l,n]}{[C,i,k,l,j]}$$

(d) Wrapped combine



$$\frac{[A,i,-,-,m]\,[B,m,k,l,j]}{[C,i,k,l,j]}$$

(l) Ill-nested combine gap left

Figure 3: Deduction rules of our algorithm.

strictly greater than two and every rule deduces an item representing a constituent spanning a greater number of words, therefore they cannot construct invalid trees where a parent constituent spans fewer words than one of its children.

Completeness can be proved by observing that every possible binary parent-children combination can be produced by one of the rules. For the non-binary case, completeness follows from the fact that a constituent with 3 or more children can be built by first deriving intermediary constituents with label $\varnothing$.

3.5 Complexity

The space and time complexity can be inferred from item structures and deduction rules: the space complexity is $\mathcal{O}(|\mathcal{N}|n^4)$ and time complexity is $\mathcal{O}(|\mathcal{N}|^3 n^6)$. In practice, we decompose the score of a tree into the sum of the score of its constituents only and there are no constraints between antecedents and consequent labels. Therefore, we can build intermediary unlabeled items of the form $[i,k,l,j]$ which replace antecedents in every rule in Figure 3. With this update, the time complexity is linear in the number of labels, that is, $\mathcal{O}(|\mathcal{N}|n^6)$.

We instantiate variants of the algorithm than cannot parse the full family of block degree two trees but that can still fit most actual linguistic structures present in treebanks, with a lower time complexity. By using only rules **(a)**, **(b)** and **(c)** we can build a parser with a $\mathcal{O}(n^4)$ time complexity. In the next section, we show that this specific variant can be optimized into a $\mathcal{O}(n^3)$ time parser. By adding rules **(e)**, **(f)**, **(g)**, **(h)** and **(i)** we build a $\mathcal{O}(n^5)$ parser. Finally, we construct $\mathcal{O}(n^5)$ and $\mathcal{O}(n^6)$ well-nested parsers by excluding rules **(i)**, **(j)**, **(k)** and **(l)**.

3.6 Cubic time discontinuous constituency parser

A specific variant uses only deduction rules **(a)**, **(b)** and **(c)** from Figure 3, leading to a $\mathcal{O}(n^4)$ space and time complexity. In this setting, there is no way to combine two items representing discontinuous constituents or to have a discontinuous constituent that has a discontinuous child in the resulting parse tree. In this section, we prove that the family of trees induced by this variant of the parser can actually be parsed with a $\mathcal{O}(n^3)$ time complexity, that is equivalent to continuous constituency parsers.

The intuition goes as follows. We could replace rules (**b**) and (**c**) with the single rule (**m**) in Figure 4 where the right hand side condition $D \in \mathcal{N}$ implies the existence of a discontinuous constituent with label D,[8] with left part spanning words i to k and right part spanning words l to j. However, observe that this new rule performs two tests that could be done independently:

1. the right span boundary of the first antecedent must match the left span boundary of the second one;
2. the right span boundary of the second antecedent must match the left span boundary of the third antecedent.

Therefore, we can break the deduction into two sequential deductions, first testing the "k" boundary then the "l" boundary.[9]

To this end, we build a parser based on 4-tuple items $[A, \tau, i, j]$ where $\tau \in \{\top, \bot\}$ indicates whether the item represents a continuous constituent ($\tau = \top$) or an incomplete discontinuous constituent ($\tau = \bot$). More precisely, an item $[A, \bot, i, j]$ represents a partial discontinuous constituent who would be represented as $[A, i, ?, j, ?]$ in the previous formalization. The right boundary of its two spans are unknown: the one of the left span has been "forgotten" and the one on the right span is yet to be determined. The deduction rules of this new parser are listed on Figure 4, with axioms $[A, \tau, i, i+1]$, $0 \leq i < n$, and goal $[A, \tau, 0, n]$.

We report the running time per sentence length for the $\mathcal{O}(n^4)$ and $\mathcal{O}(n^3)$ parsers in Figure 2. As expected, the running time of the cubic time parser is way lower for long sentences.

4 Experiments

We experiment on the Discontinuous Penn Treebank (Marcus et al., 1993; Evang and Kallmeyer, 2011, DPTB) with standard split, the Tiger treebank (Brants et al., 2002) with the SPMRL 2014 shared task split (Seddah et al., 2014) and the Negra treebank (Skut et al., 1997) with the split proposed by Dubey and Keller (2003).

4.1 Data coverage

One important question is whether our parser has a good coverage of the dataset as we can only retrieve constituents of block degree one and two. We report the maximum recall that our parser can achieve in its different variants in Table 1.

First, we observe that our cubic time parser can recover 98% of all constituents in the three treebanks, or around 80% of constituents of block degree of exactly two. Second, the $\mathcal{O}(n^5)$ variant of the parser can recover more than 99% of all treebanks, and, interestingly, there is almost no coverage change when moving to the full deduction system. If we consider the parsers with well-nested restriction, the $\mathcal{O}(n^5)$ and $\mathcal{O}(n^6)$ variants have the same coverage in German datasets and the latter can only recover 2 additional constituents in the English treebanks. If we include ill-nested construction, the difference is either 2 (DPTB and Negra) or 8 (Tiger) constituents. In practice, we observed that both $\mathcal{O}(n^5)$ and $\mathcal{O}(n^6)$ variants predict the same analysis.

4.2 Neural parameterization

We use a neural architecture based on bidirectional LSTMs detailed in Appendix A.

Constituent scores Even with the block degree two restriction, there is a larger number (quartic!) of constituent scores to compute. In early experiments, we observed that weighting such a number of constituents without further decomposition blow up the neural network memory usage and was prohibitively slow. Therefore, we introduce a score decomposition that results in a quadratic number of scores to compute.

We decompose the score of a constituent $[A, i, k, l, j]$ as the sum of a score associated with its outer boundaries (i.e. indices i and j) and one with its gap boundaries (i.e. indices k and l). The score of the constituent is defined as:[10]

$$W_{A,i,k,l,j} = \begin{cases} S^{\text{(c. label)}}_{A,i+1,j} + S^{\text{(c. span)}}_{i+1,j} & \text{if } k = l = -, \\ \\ S^{\text{(o. label)}}_{A,i+1,j} + S^{\text{(o. span)}}_{i+1,j} & \text{otherwise.} \\ +S^{\text{(g. label)}}_{A,k+1,l} + S^{\text{(g. span)}}_{k+1,l} & \end{cases}$$

where tensors $\mathbf{S}^{\text{(c. label)}}$, $\mathbf{S}^{\text{(o. label)}}$, $\mathbf{S}^{\text{(g. label)}} \in \mathbb{R}^{|\mathcal{N} \cup \{\emptyset\}| \times n \times n}$ and matrices

---

[8] Without loss of generality, we assume the label D is not null. Although it could be without changing the overall idea, we would just add an extra way to do implicit binarization that can already be handled with rule (**a**).

[9] This idea of breaking up simultaneous tests in a deduction rule has been previously proposed for improving time complexity of lexicalized grammar parsers (Eisner and Satta, 1999, 2000)

[10] The +1 in tensor indices result of the fact that we use interstice indices for constituents but that the neural network layers focus on word indices.

Table 4: Total time in seconds to parse the full test sets: the nn column corresponds to the time taken by the forward pass of the neural network (max 5000 words per batch on a NVIDIA Tesla V100), each supplementary column is the time taken by each variant of the chart-based algorithm (without any parallelization).

$\boldsymbol{S}^{(\text{c. span})}$, $\boldsymbol{S}^{(\text{o. span})}$, $\boldsymbol{S}^{(\text{g. span})} \in \mathbb{R}^{n\times n}$ are computed using the deep biaffine attention mechanism (Dozat and Manning, 2016). The tensor $\mathbf{W}$ is never explicitly built: during the dynamic program execution we lazily compute requested constituent scores.

Training loss Span-based continuous constituency parsers are usually trained using a decomposable margin-based objective (Stern et al., 2017; Kitaev and Klein, 2018; Kitaev et al., 2019). This approach requires to repeatedly perform loss-augmented inference during training (Taskar et al., 2005), which can be prohibitively slow. A current trend in dependency parsing is to ignore the global structure and rely on negative log-likelihood for head selection independently for each modifier word (Dozat and Manning, 2016; Zhang et al., 2017). We rely on a similar approach and use as training objective the negative log-likelihood loss independently for each span (continuous, outer and gap), adding a null label with a fixed 0 weight as label for spans that do not appear in the gold annotation.

4.3 Evaluation

We evaluate our parser on the test sets of the three treebanks. We report F-measure and discontinuous F-measure as computed using the disco-dop tool[11] with standard parameters in Table 2.

First, we observe that the $\mathcal{O}(n^5)$ and $\mathcal{O}(n^6)$ variants of our parsers produced exactly the same results in all settings. This may be expected as their cover of the original treebanks are almost similar. Second, surprisingly, the $\mathcal{O}(n^3)$ parser produced better results in terms of F-measure than other variants in all cases. We report labeled discontinuous constituent recall and precision measures for the fully supervised model in Table 3. We observe that while the $\mathcal{O}(n^5)$ and $\mathcal{O}(n^6)$ have an better recall than the $\mathcal{O}(n^3)$ parser, their precision is drastically lower. This highlights a benefit of restricting the search space: the parser can retrieve less erroneous constituents leading to an improved overall precision.

Finally, in almost all cases, we achieve a novel state-of-the-art for the task in terms of labeled F-measure. However, we are slightly lower when evaluating discontinuous constituents only. We suspect that this is due to the fact that our best parser is the one with the smallest search space.

4.4 Runtime

The runtime on the test sets of our approach is reported on Table 4. In all cases, the runtime is reasonably fast and we do not need to remove long sentences. Interestingly, the cubic time parser spends most of the time for computing scores with the neural network, even if we use batches to benefit from the GPU architecture while our chart-based algorithm is not paralellized on CPU.

---

5 Conclusion

We proposed a novel family of algorithms for discontinuous constituency parsing achieving state-of-the art results. Importantly, we showed that a specific set of discontinuous constituent trees can be parsed in cubic time while covering most of the linguistic structures observed in treebanks. Despite being based on chart-based algorithms, our approach is fast at test time and we can parse all sentences without pruning or filtering long sentences. Future research could explore neural architectures and training losses tailored to our approach.

Acknowledgments

We thank François Yvon, Kilian Gebhardt, Maximin Coavoux, Vlad Niculae, Djamé Seddah and Carlos Gómez-Rodríguez for their comments and suggestions. We thank Serhii Havrylov for the help with the code. We thank Ivan Titov for comments on the early draft of this paper. We thank Laura Kallmeyer and Kilian Evang for providing us with the script for the discontinuous PTB. We thank Maximin Coavoux for the help with pre-processing the data. We also thank the anonymous reviewers for their comments. The project was supported by the Dutch National Science Foundation (NWO VIDI 639.022.518) and European ResearchCouncil (ERC Starting Grant BroadSem 678254). This work benefited from the Jean-Zay cluster.

Some Languages Seem Easier to Parse Because Their Treebanks Leak

Anders Søgaard
Dpt. of Computer Science
University of Copenhagen
`soegaard@di.ku.dk`

Abstract

Cross-language differences in dependency parsing performance are mostly attributed to treebank size, average sentence length, average dependency length, morphological complexity, and domain differences. In this paper I point to a factor not previously discussed: If we abstract away from words and dependency labels, how many graphs in the test data were seen in the training data? I discuss how to compute graph isomorphisms, and show that, treebank size aside, overlap between training and test graphs explains more of the observed variation than standard explanations such as the above.

1 Introduction

The state of the art in dependency parsing varies a lot across languages: on Polish, the best system in the CoNLL 2018 shared task achieved a labeled attachment score of 94.9% on held-out data; on Basque, the same number was 19.5%. Just a few years ago, a major source of variation was the complexity of the annotation schemes used in the different treebanks; with the Universal Dependencies project,[1] treebanks now follow the same annotation guidelines, but nevertheless, these performance differences persist.[2]

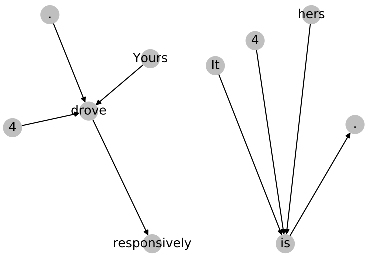

Figure 1: Isomorphic examples from UD-English-Pronouns. Left: *Yours drove responsibly.* Right: *It is hers.* The two sentences are associated with the same unlabeled directed graphs.

Differences are typically attributed to training set size (Vania et al., 2019), linguistic variation (Nivre et al., 2007), sentence length or average gold dependency length (in the test data) (McDonald and Nivre, 2011), and domain differences between training and test data (Foster et al., 2011). Training set size *is* undoubtedly a very strong predictor of parsing performance, but in this paper, overlap between unlabeled graphs in the training and test sections of a treebank is shown to be more predictive than any of the other factors. Specifically, we compute equivalence classes over unlabeled dependency graphs – directed or undirected – and compute the ratio of trees in the treebanks' test sections that are isomorphic to graphs observed in the training section, i.e., the graph-level train-test leakage, and correlate this number with state-of-the-art performance numbers across languages. To the best of our knowledge, no one has previously considered this predictor of parsing performance, and we show that it is more predictive than factors previously discussed in the literature.

Contribution We present a way to quantify graph-level train-test leakage and an empirical evaluation of it across parsing results for 45 languages;

---

[1] `https://universaldependencies.org/`

[2] While Universal Dependencices have made the available dependency treebanks more compatible, treebanks were of course developed using very different protocols; some are automatically or semi-automatically converted from other formalisms, others written with the Universal Dependencies guidelines in mind; some, again, were developed by big teams, some by a single person. While protocol is hard to isolate and study – and while protocol may correlate both positively or negatively with parsing performance, i.e., it is easy to imagine a poorly designed treebank that is easy to parse – the protocol likely has a significant downstream effect on performance; which means we can only hope to explain some of the variance in the experiments below.

November 16–20, 2020.

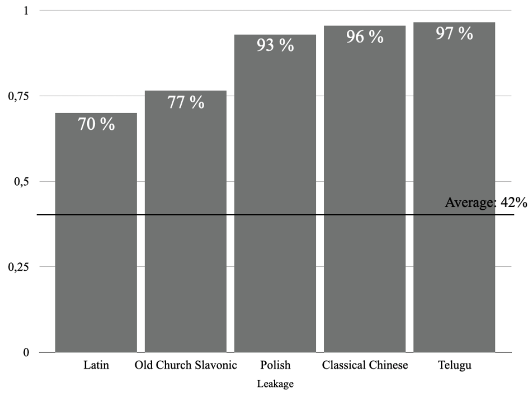

Figure 2: LEAKAGE. The 5 UD treebanks with the most UUG-level train-test leakage.

we show that next to treebank size, graph-level train-test leakage is a better predictor of parsing performance than any of the factors previously considered.

2 Unlabeled Graph Isomorphisms

Exact graph isomorphism is in NP, but it remains an open problem whether it is NP-complete or in P. We use the VF2 algorithm in (Cordella et al., 2001), which is known to be fast in practice with low memory requirements (Foggia et al., 2001). The algorithm proceeds by iteratively expanding a subgraph isomorphism, until this procedure fails, or until the subgraph isomorphism covers the input graphs. We compute isomorphisms over dependency trees in the training set by first reducing the trees to a more abstract graph. In our experiments below, we consider two such reductions: to **undirected, unlabeled graphs** (UUGs; removing labels and edge directions) and to **directed, unlabeled graphs** (DUGs; removing only labels). Once we have computed the isomorphisms, we count how many of the dependency trees in the test data are members of one of these equivalence classes. We then report the fraction of test dependency trees that are isomorphic to at least one dependency tree in the training data. This number can be seen as a metric of graph-level train-test leakage. See Figure 2 for the top 5 most leaking treebanks in the Universal Dependencies project (Version 2.5); the worst has only 3/100 unseen test graphs. In the Appendix, we report the full set of results with UUGs; both for exact computation of isomorphims with VF2, as well as for a heuristic simply matching a set of edge degrees.

3 Usual Suspects

We briefly discuss other factors assumed to be predictive of the performance of dependency parsers.

Treebank size It is trivially true that parser performance depends on treebank size, and it is unsurprising that the correlation is strong. Obviously, if the treebank does not contain *any* training data, supervised parsers will have to resort to blind guessing, and the more data they see, the less variance they have to resolve. That said, it is well established that increasing the size of a treebank often comes with diminishing returns (Sagae et al., 2008). Since treebank size is nevertheless trivially related to parsing performance, we correlate all other factors ϕ *in combination with treebank size* (see §4):

Morphology Previous work has pointed to morphology as a source of lower parsing performance (Tsarfaty et al., 2013; Coltekin and Rama, 2018). In languages with rich morphology, many relations which are expressed implicitly by word order and adjacency in languages like English, are encoded in morphological affixes, which requires subword-level processing to detect (in the tail). Expressing functional information morphologically also allows for a high degree of word-order variation. In our experiments, we use the most predictive morphological feature in WALS[3] and impute the missing values.

Sentence length Parser performance unsurprisingly also depends on input length, i.e., the search space of possible parses (McDonald and Nivre, 2011). This, for example, is why unsupervised dependency parsing has successfully relied on baby steps training (Spitkovsky et al., 2010). We correlate state-of-the-art parser performance with training set size and average test sentence length.

Graph properties McDonald and Nivre (2011) discuss graph properties that seem to correlate with parsing performance. We include average dependency length in our experiments below, which we compute by simply dividing the total length of dependencies by word tokens in the test section.

Open class ratio Nivre and Fang (2017) argue that open word classes (especially nouns and verbs) tend to be harder to attach than other parts of speech, and that languages with many of them will therefore be harder to parse. We therefore evaluate

whether the ratio of nouns and verbs over the total number of tokens in a sentence is predictive of parser performance.

POS bigram perplexity Others have proposed to use the perplexity of a POS bigram language model trained on the treebank's training section and applied to its test section, to predict parser performance (Coltekin and Rama, 2018; Berdicevskis et al., 2018).

Domain divergence Gildea (2001) explore the effect of domain shifts on parsing performance and show that such shifts are often detrimental to the quality of parses. This issue has, since then, been explored in great detail in the domain adaptation literature, but here we simply note that treebanks with train-test divergences may appear harder to parse. In order to compute the impact of train-test divergence on state-of-the-art parsing results, we need to be able to compute it. Several proposals exist in the literature, including Jensen-Shannon divergence (Wu and Huang, 2016), Renyi divergence (Van Asch and Daelemans, 2010), and Wasserstein distance (Shen et al., 2018). We choose to rely on $\mathcal{A}$-distance (Kifer et al., 2004), since it is arguably the most popular divergence measure in domain adaptation, and since we can approximate it efficiently by the accuracy of a linear perceptron trained to discriminate between examples from the train and test splits. Note that Van Asch and Daelemans (2010) explicitly proposed quantifying domain divergence as a way of predicting performance, noting a linear correlation between the two.

4 Empirical Comparison of Factors

We correlate the factors ϕ assumed to influence syntactic dependency parser performance with state-of-the-art performance figures from the CoNLL 2018 shared task, i.e,. the performance of the best performing system per language.[4] See the Appendix for the full statistics. While computing their Pearson's ρ coefficients is standard methodology for validating performance metrics (Lin, 2004; Miculicich Werlen and Popescu-Belis, 2017) and has also been used to evaluate factors predicting system performance (Martin and Foltz, 2004; Søgaard and Haulrich, 2010), this is inadequate in our case: Many factors are potentially covariate, and we are, for example, not interested in factors that correlate strongly with treebank size, e.g., out-of-vocabulary rate or type-token ratio (Kettunen, 2014). Instead we compute the explained variance and mean absolute error of a linear regression model with treebank size and ϕ as input, i.e., $at_s + b\phi + c$ with t_s treebank size and a, b, c learned parameters. We report explained variance and mean absolute error from three-fold cross-validation experiments to avoid overfitting. We make our code publicly available.[5]

Results Our main results are presented in Table 1. Treebank size correlates strongly with parser performance; see the plot in Figure 3 (**Left**). Both **morphological complexity** and **open class ratio** are not very predictive. None of them correlate very strongly with parser performance, and in com-

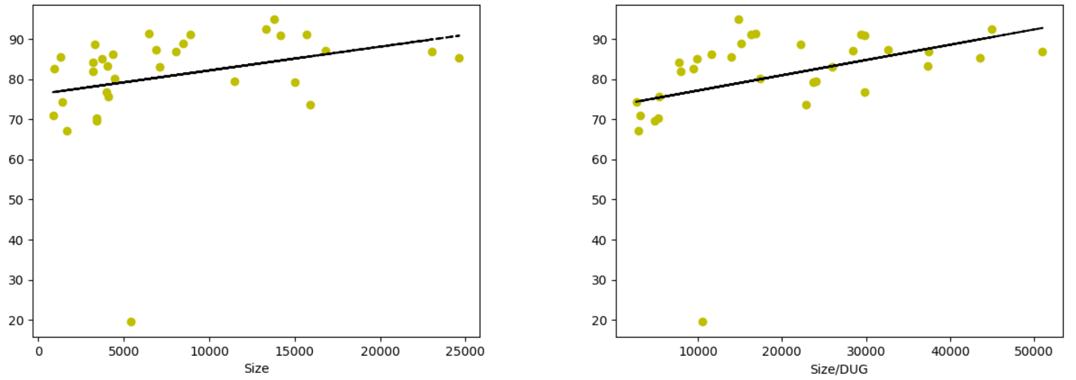

Figure 3: Correlations: Treebank Size (**Left**) and DUG-Iso and Size (**Right**). The outlier in both cases is the Basque treebank.

bination with treebank size, they do not add much predictiver power, it seems. $\mathcal{A}$-distance correlates strongly with parsing performance; the explained variance improves a little, and the error decreases a bit. Average **dependency length** is only weakly, negatively correlated with parsing performance ($\rho \sim 0.067$), a result that is not significant; and the absolute error of the linear regression model decreases only a little from adding the feature; the explained variance improves to 0.05. **Sentence length**, perhaps unsurprisingly, correlates more strongly with parsing performance; and the explained variance of our linear regression model increases a lot from adding this feature.

Graph-level train-test leakage, however, is more predictive of parsing performance than any of these factors. See the correlation of treebank size over DUG-level train-test leakage in Figure 3 (**Right**). It also leads to much better performance of our linear regression model; both in terms of explained variance and mean absolute error. We note that using DUGs to compute the isomorphisms is slightly more predictive than relying on undirected graphs.

5 Related work

The factors evaluated in the above, from Nivre et al. (2007); Van Asch and Daelemans (2010); McDonald and Nivre (2011); Nivre and Fang (2017); Coltekin and Rama (2018); Berdicevskis et al. (2018), were already discussed. A few other factors have been pointed at in the literature that were not applicable to our experiments: Søgaard and Haulrich (2010) show that the perplexity of the derivation orders of a transition-based dependency parser, is also predictive of parser performance. They report Pearson's ρ scores that are considerably higher than those we found. Their study suffers from two biases, though; one imposed by the transition-based parser and the other imposed by the language model used to calculate the perplexity. Moreover, the results they report, are for only the non-convertedd dependency treebanks in the CoNLL 2006 (Buchholz and Marsi, 2006) and CoNLL 2007 (Nivre et al., 2007) treebank releases. These treebanks form a very small set, providing limited statistical support, and, moreover, rely on very different linguistic formalisms and annotation guidelines, leading to very different levels of complexity of derivation. In other words, a comparison would be inconclusive because of the free parameters imposed by the language model and the transition oracle, and the fact that no code is publicly available. Also, their high correlation scores are unlikely to transfer to Universal Dependencies.

6 Discussion and Conclusion

This paper suggested a factor contributing to variance in (universal) dependency parser performance across languages: graph-level train-test leakage in treebanks. This form of leakage can be quantified by computing graph isomorphisms from training sections and counting the ratio of trees in the test sections that are *not* isomorphic with any tree in the training data. I compared this factor to previous attempts to explain variance in parser performance across languages through a series of correlation and linear regression experiments; and showed that graph-level train-test leakage, treebank size aside, is the most predictive factor among those proposed, yet complementary. The result is perhaps not too surprising, since graph isomorphisms correlate with syntactic constructions, which in turn correlate with the occurrence of linguistic markers and tail linguistic phenomena.[6]

The observation that treebanks leak, quite dramatically, at the graph level, is not only interesting for explaining variance in parser performance. It also suggests a new and improved evaluation methodology: Since language is Zipfian, not only at the level of words, but at the level of phrases (Ha et al., 2002; Williams et al., 2015), standard evaluation methodology relying on random samples (Gorman and Bedrick, 2019; Dodge et al., 2019) is biased toward frequent phenomena. Evaluating only on non-isomorphic trees, i.e., leaving out graphs that have been seen at training time from the test sections of treebanks, would reduce this bias. We hope this is a factor that designers of future syntactic treebanks will take into account. It is an open question whether graph-level train-test leakage is predictive of performance in other sentence-level NLP tasks, i.e., whether the ratio of test sentences whose (predicted) syntactic dependency structure is identical to that of one of our training examples, correlates with state-of-the-art performance.

[6] If a parser has seen a graph before, it has seen representations similar to those observed at test time. The higher the leakage, the less a parser needs to generalize. Inspecting equivalence classes, members tend to be structurally very similar, and while graph-based parsers, for example, tend to edge-factorize, this still means that context representations are very similar to previously seen ones.

Discontinuous Constituent Parsing as Sequence Labeling

David Vilares and Carlos Gómez-Rodríguez

Abstract

This paper reduces discontinuous parsing to sequence labeling. It first shows that existing reductions for constituent parsing as labeling do not support discontinuities. Second, it fills this gap and proposes to encode tree discontinuities as nearly ordered permutations of the input sequence. Third, it studies whether such discontinuous representations are learnable. The experiments show that despite the architectural simplicity, under the right representation, the models are fast and accurate.[1]

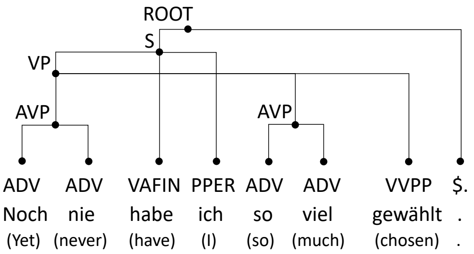

Figure 1: An example of a German sentence exhibiting discontinuous structures, extracted from the NEGRA treebank (Skut et al., 1997). A valid English translation is: *'Never before I have chosen so much.'*

1 Introduction

Discontinuous constituent parsing studies how to generate phrase-structure trees of sentences coming from *non-configurational* languages (Johnson, 1985), where non-consecutive tokens can be part of the same grammatical function (e.g. non-consecutive terms belonging to the same verb phrase). Figure 1 shows a German sentence exhibiting this phenomenon. Discontinuities happen in languages that exhibit free word order such as German or Guugu Yimidhirr (Haviland, 1979; Johnson, 1985), but also in those with high rigidity, e.g. English, whose grammar allows certain discontinuous expressions, such as wh-movement or extraposition (Evang and Kallmeyer, 2011). This makes discontinuous parsing a core computational linguistics problem that affects a wide spectrum of languages.

There are different paradigms for discontinuous phrase-structure parsing, such as chart-based parsers (Maier, 2010; Corro, 2020), transition-based algorithms (Coavoux and Crabbé, 2017; Coavoux and Cohen, 2019) or reductions to a problem of a different nature, such as dependency parsing (Hall and Nivre, 2008; Fernández-González and Martins, 2015). However, many of these approaches come either at a high complexity or low speed, while others give up significant performance to achieve an acceptable latency (Maier, 2015).

Related to these research aspects, this work explores the feasibility of discontinuous parsing under the sequence labeling paradigm, inspired by Gómez-Rodríguez and Vilares (2018)'s work on fast and simple *continuous* constituent parsing. We will focus on tackling the limitations of their encoding functions when it comes to analyzing discontinuous structures, and include an empirical comparison against existing parsers.

Contribution (i) The first contribution is theoretical: to reduce constituent parsing of free word order languages to a sequence labeling problem. This is done by encoding the order of the sentence as (nearly ordered) permutations. We present various ways of doing so, which can be naturally combined with the labels produced by existing reductions for *continuous* constituent parsing. (ii) The second contribution is a practical one: to show how these representations can be learned by neural transducers. We also shed light on whether general-purpose architectures for NLP tasks (Devlin et al., 2019; Sanh et al., 2019) can effectively parse free word order languages, and be used as an alternative to *ad-hoc* algorithms and architectures for discontinuous constituent parsing.

2 Related work

Discontinuous phrase-structure trees can be derived by expressive formalisms such as *Multiple Context Free Grammmars* (Seki et al., 1991) (MCFGs) or *Linear Context-Free Rewriting Systems* (LCFRS) (Vijay-Shanker et al., 1987). MCFGs and LCFRS are essentially an extension of *Context-Free Grammars* (CFGs) such that non-terminals can link to non-consecutive spans. Traditionally, chart-based parsers relying on this paradigm commonly suffer from high complexity (Evang and Kallmeyer, 2011; Maier and Kallmeyer, 2010; Maier, 2010). Let k be the block degree, i.e. the number of non-consecutive spans than can be attached to a single non-terminal; the complexity of applying CYK (after binarizing the grammar) would be $\mathcal{O}(n^{3k})$ (Seki et al., 1991), which can be improved to $\mathcal{O}(n^{2k+2})$ if the parser is restricted to well-nested LCFRS (Gómez-Rodríguez et al., 2010), and Maier (2015) discusses how for a standard discontinuous treebank, $k \approx 3$ (in contrast to $k = 1$ in CFGs). Recently, Corro (2020) presents a chart-based parser for $k = 2$ that can run in $\mathcal{O}(n^3)$, which is equivalent to the running time of a continuous chart parser, while covering 98% of the discontinuities. Also recently, Stanojević and Steedman (2020) present an LCFRS parser with $k = 2$ that runs in $\mathcal{O}(ln^4 + n^6)$ worst-case time, where l is the number of unique non-terminal symbols, but in practice they show that the empirical running time is among the best chart-based parsers.

Differently, it is possible to rely on the idea that discontinuities are inherently related to the *location* of the token in the sentence. In this sense, it is possible to reorder the tokens while still obtaining a grammatical sentence that could be parsed by a continuous algorithm. This is usually achieved with transition-based parsing algorithms and the `swap` transition (Nivre, 2009) which switches the topmost elements in the stack. For instance, Versley (2014) uses this transition to adapt an easy-first strategy (Goldberg and Elhadad, 2010) for dependency parsing to discontinuous constituent parsing. In a similar vein, Maier (2015) builds on top of a fast continuous shift-reduce constituent parser (Zhu et al., 2013), and incorporates both standard and bundled swap transitions in order to analyze discontinuous constituents. Maier's system produces derivations of up to a length of $n^2 - n + 1$ given a sentence of length n. More efficiently, Coavoux and Crabbé (2017) present a transition system which replaces `swap` with a `gap` transition. The intuition is that a reduction does not need to be always applied locally to the two topmost elements in the stack, and that those two items can be connected, despite the existence of a gap between them, using non-local reductions. Their algorithm ensures an upper-bound of $\frac{n(n-1)}{2}$ transitions.[2] With a different optimization goal, Stanojević and Alhama (2017) removed the traditional reliance of discontinuous parsers on averaged perceptrons and hand-crafted features for a recursive neural network approach that guides a `swap`-based system, with the capacity to generate contextualized representations. Coavoux and Cohen (2019) replace the stack used in transition-based systems with a memory set containing the created constituents. This model allows interactions between elements that are not adjacent, without the `swap` transition, to create a new (discontinuous) constituent. Trained on a 2 stacked BiLSTM transducer, the model is guaranteed to build a tree with in $4n$-2 transitions, given a sentence of length n.

A middle ground between explicit constituent parsing algorithms and this paper is the work based on transformations. For instance, Hall and Nivre (2008) convert constituent trees into a non-linguistic dependency representation that is learned by a transition-based dependency parser, to then map its output back to a constituent tree. A similar approach is taken by Fernández-González and Martins (2015), but they proposed a more compact representation that leads to a much reduced set of output labels. Other authors such as Versley (2016) propose a two-step approach that approximates discontinuous structure trees by parsing context-free grammars with generative probabilistic models and transforming them to discontinuous ones. Corro et al. (2017) cast discontinuous phrase-structure parsing into a framework that jointly performs supertagging and non-projective dependency parsing by a reduction to the Generalized Maximum Spanning Arborescence problem (Myung et al., 1995). The recent work by Fernández-González and Gómez-Rodríguez (2020a) can be also framed within this paradigm. They essentially adapt the work by Fernández-González and Martins (2015) and replace the averaged perceptron classifier with pointer networks (Vinyals et al., 2015), adressing

---

[2] Or alternatively $4n - 2$, if we apply additional constraints to the `gap` transition and transitions following a `shift` action. However this comes at a cost of not being able to map more than m gaps within the same discontinuous constituent.

the problem as a sequence-to-sequence task (for dependency parsing) whose output is then mapped back to the constituent tree. And next, Fernández-González and Gómez-Rodríguez (2020b) extended pointer networks with multitask learning to jointly predict constituent and dependency outputs.

In this context, the closest work to ours is the reduction proposed by Gómez-Rodríguez and Vilares (2018), who cast *continuous* constituent parsing as sequence labeling.[3] In the next sections we build on top of their work and: (i) analyze why their approach cannot handle discontinuous phrases, (ii) extend it to handle such phenomena, and (iii) train functional sequence labeling discontinuous parsers.

3 Preliminaries

Let $\mathbf{w} = [w_0, w_1, ..., w_{|\mathbf{w}|-1}]$ be an input sequence of tokens, and $T_{|w|}$ the set of (continuous) constituent trees for sequences of length $|w|$; Gómez-Rodríguez and Vilares (2018) define an encoding function $\Phi : T_{|w|} \rightarrow L^{|w|}$ to map continuous constituent trees into a sequence of labels of the same length as the input. Each label, $l_i \in L$, is composed of three components $l_i = (n_i, x_i, u_i)$:

- n_i encodes the number of levels in the tree in common between a word w_i and w_{i+1}. To obtain a manageable output vocabulary space, n_i is actually encoded as the difference $n_i - n_{i-1}$, with $n_{-1} = 0$. We denote by $abs(n_i)$ the absolute number of levels represented by n_i. i.e. the total levels in common shared between a word and its next one.
- x_i represents the lowest non-terminal symbol shared between w_i and w_{i+1} at level $abs(n_i)$.
- u_i encodes a leaf unary chain, i.e. non-terminals that belong only to the path from the terminal w_i to the root.[4] Note that Φ cannot encode this information in (n_i, x_i), as these components always represent common information between w_i and w_{i+1}.

Figure 2 illustrates the encoding on a continuous example.

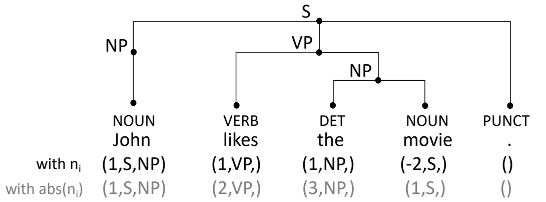

Figure 2: An example of a continuous tree encoded according to Gómez-Rodríguez and Vilares (2018).

Incompleteness for discontinuous phrase structures Gómez-Rodríguez and Vilares proved that Φ is complete and injective for continuous trees. However, it is easy to prove that its validity does not extend to discontinuous trees, by using a counterexample. Figure 3 shows a minimal discontinuous tree that cannot be correctly decoded.

The inability to encode discontinuities lies on the assumption that w_{i+1} will always be attached to a node belonging to the path from the root to w_i (n_i is then used to specify the location of that node in the path). This is always true in continuous trees, but not in discontinuous trees, as can be seen in Figure 3 where c is the child of a constituent that does not lie in the path from S to b.

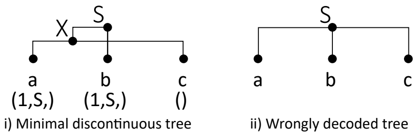

Figure 3: A minimal discontinuous constituent tree that cannot be decoded correctly if we rely on the (Gómez-Rodríguez and Vilares, 2018) linearization.

4 Encoding nearly ordered permutations

Next, we fill this gap to address discontinuous parsing as sequence labeling. We will extend the encoding Φ to the set of discontinuous constituent trees, which we will call $T'_{|w|}$. The key to do this relies on a well-known property: a discontinuous tree $t \in T'_{|w|}$ can be represented as a continuous one using an in-order traversal that keeps track of the original indexes (e.g. the trees at the left and the right in Figure 4).[5] We will call this tree the (canonical) continuous arrangement of t, $\omega(t) \in T_{|w|}$.

---

[3] Related to constituent parsing and sequence labeling, there are two related papers that made early efforts (although not a full reduction of the former to the latter) and need to be credited too. Ratnaparkhi (1999) popularized maximum entropy models for parsing and combined a sequence labeling process that performs PoS-tagging and chunking with a set of shift-reduce-like operations to complete the constituent tree. In a related line, Collobert (2011) proposed a multi-step approach consisting of n passes over the input sentence, where each of them tags every word as being part of a constituent or not at one of the n levels of the tree, using a IOBES scheme.

[4] *Intermediate* unary chains are compressed into a single non-terminal and treated as a regular branches.

[5] This is the discbracket format. See: `https://discodop.readthedocs.io/en/latest/fileformats.html`

Thus, if given an input sentence we can generate the position of every word as a terminal in $\omega(t)$, the existing encodings to predict continuous trees as sequence labeling could be applied on $\omega(t)$. In essence, this is learning to predict a permutation of $\mathbf{w}$. As introduced in §2, the concept of location of a token is not a stranger in transition-based discontinuous parsing, where actions such as `swap` switch the position of two elements in order to create a discontinuous phrase. We instead propose to explore how to handle this problem in end-to-end sequence labeling fashion, without relying on any parsing structure nor a set of transitions.

To do so, first we denote by $\tau : \{0, \ldots, |w| - 1\} \rightarrow \{0, \ldots, |w| - 1\}$ the permutation that maps the position i of a given w_i in $\mathbf{w}$ into its position as a terminal node in $\omega(t)$.[6] From this, one can derive $\pi : W^n \rightarrow W^n$, a function that encodes a permutation of $\mathbf{w}$ in such way that its phrase structure does not have crossing branches. For continuous trees, τ and π are identity permutations. Then, we extend the tree encoding function Φ to $\Phi' : T'_{|w|} \rightarrow L'^{|w|}$ where $l'_i \in L'$ is enriched with a fourth component p_i such that $l'_i = (n_i, x_i, u_i, p_i)$, where p_i is a discrete symbol such that the sequence of p_i's encodes the permutation τ (typically each p_i will be an encoding of $\tau(i)$, i.e. the position of w_i in the continuous arrangement, although this need not be true in all encodings, as will be seen below).

The crux of defining a viable encoding for discontinuous parsing is then in how we encode τ as a sequence of values p_i, for $i = 0 \ldots |\mathbf{w}| - 1$. While the naive approach would be the identity encoding ($p_i = \tau(i)$), we ideally want an encoding that balances minimizing sparsity (by minimizing infrequently-used values) and maximizing learnability (by being predictable). To do so, we will look for encodings that take advantage of the fact that discontinuities in attested syntactic structures are mild (Maier and Lichte, 2011), i.e., in most cases, $\tau(i+1) = \tau(i) + 1$. In other words, permutations τ corresponding to real syntactic trees tend to be nearly ordered permutations. Based on these principles, we propose below a set of concrete encodings, which are also depicted on an example in Figure 4. All of them handle multiple gaps (a discontinuity inside a discontinuity) and cover 100% of the discontinuities. Even if this has little effect in practice, it is an interesting property compared to algorithms that limit the number of gaps they can address (Coavoux and Cohen, 2019; Corro, 2020).

Absolute-position For every token w_i, $p_i = \tau(i)$ only if $i \neq \tau(i)$. Otherwise, we use a special label `INV`, which represents that the word is a fixed point in the permutation, i.e., it occupies the same place in the sentence and in the continuous arrangement.

Relative-position If $i \neq \tau(i)$, then $p_i = i - \tau(i)$; otherwise, we again use the `INV` label.

Lehmer code (Laisant, 1888; Lehmer, 1960) In combinatorics, let $\mathbf{n} = [0, ..., n-1]$ be a sorted sequence of objects, a Lehmer code is a sequence $\sigma = [\sigma_0, ...\sigma_{n-1}]$ that encodes one of the $n!$ permutations of $\mathbf{n}$, namely α. The idea is intuitive: let $\mathbf{n^{i+1}}$ be the *subsequence* of objects from $\mathbf{n}$ that remain available after we have permuted the first i objects to achieve the permutation α, then σ_{i+1} equals the (zero-based) position in $\mathbf{n^{i+1}}$ of the next object to be selected. For instance, given $\mathbf{n} = [0, 1, 2, 3, 4]$ and a valid permutation $\alpha = [0, 1, 3, 4, 2]$, then $\sigma = [0, 0, 1, 1, 0]$. Note that the identity permutation would be encoded as a sequence of zeros.

In the context of discontinuous parsing and encoding p_i, $\mathbf{n}$ can be seen as the input sentence $\mathbf{w}$ where $\pi(\mathbf{w})$ is encoded by σ. The Lehmer code is particularly suitable for this task in terms of compression, as in most of the cases we expect (nearly) ordered permutations, which translates into the majority of elements of σ being zero.[7] However, this encoding poses some potential learnability problems. The root of the problem is that σ_i does not necessarily encode $\tau(i)$, but $\tau(j)$ where j is the index of the word that occupies the ith position in the continuous arrangement (i.e., $j = \tau^{-1}(i)$). In other words, this encoding is expressed following the order of words in the continuous arrangement rather than the input order, causing a non-straightforward mapping between input words and labels. For instance, in the previous example, σ_2 does not encode the location of the object n_2=2 but that of n_3=3.

Lehmer code of the inverse permutation To ensure that each p_i encodes $\tau(i)$, we instead interpret p_i as meaning that w_i should fill the $(p_i + 1)$th currently remaining blank in a sequence σ that is initialized as a sequence of blanks, i.e. $\sigma = [\circ, \circ, ..., \circ]$. For instance, let $\mathbf{n} = [0, 1, 2, 3, 4]$ be

---

[6] Permutations are often defined as mappings from the element at a given position to the element that replaces it, but for our purpose, we believe that the definition as a function from original positions to rearranged positions (following, e.g., (O'Donnell et al., 2007)) is more straightforward.

[7] For a continuous tree, $\sigma_i = 0 \; \forall i \in [0, |w| - 1]$.

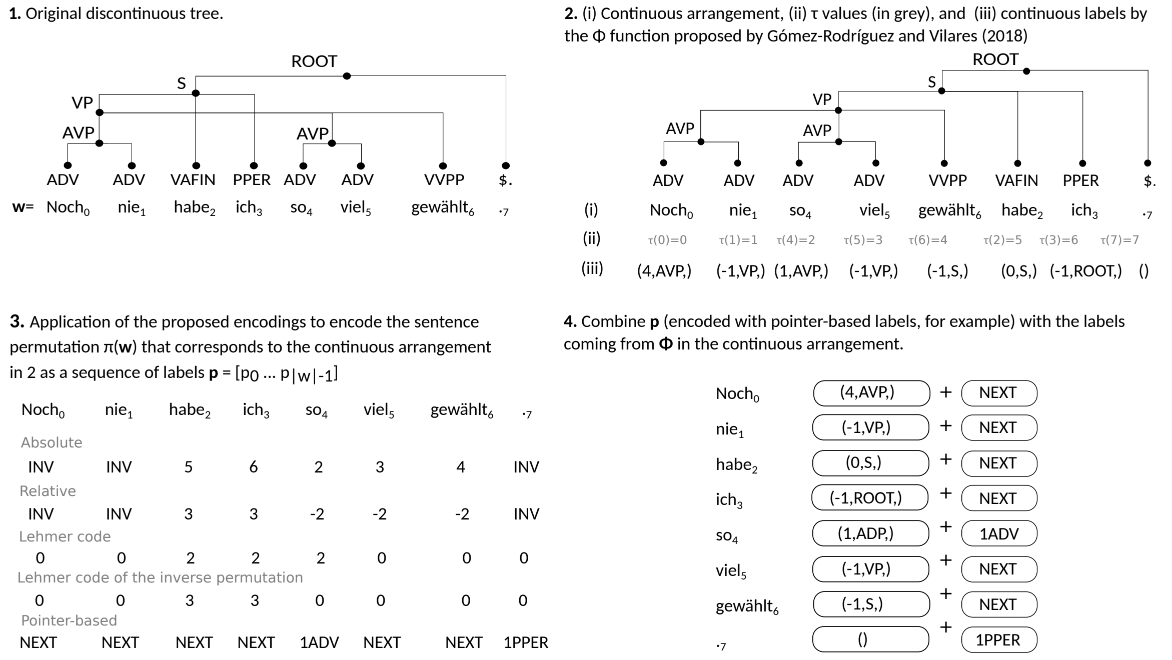

Figure 4: An example of the permutation encodings that allow for discontinuous parsing as sequence labeling

the original input and $\pi(\mathbf{n}) = [0, 1, 3, 4, 2]$ its desired continuous arrangement. At the first and second steps, $n_0 = 0$ and $n_1 = 1$ occupy the first available blanks (so $p_0 = p_1 = 0$), generating partial arrangements of the form $[0, \circ, \circ, \circ, \circ]$ and $[0, 1, \circ, \circ, \circ]$. Then, $n_2 = 2$ would need to fill the third empty blank (so $p_2 = 2$), and we obtain $[0, 0, \circ, \circ, 2]$. After that, n_3 and n_4 occupy the first available blank (so $p_3 = p_4 = 0$). Thus, we obtain the desired arrangement $\sigma = [0, 1, 3, 4, 2]$, and the encoding is $[0, 0, 2, 0, 0]$. It is easy to check that this produces the Lehmer code for the inverse permutation to τ. Hence, it shares the property that the identity permutation is encoded by a sequence of zeros, but it is more straightforward for our purposes as each p_i encodes information about $\tau(i)$, the target position of w_i in the continuous arrangement. Note that this and the Lehmer code coincide iff τ is a self-conjugate permutation (i.e., a conjugate that is its own inverse, see (Muir, 1891)), of which the identity is a particular case.

Pointer-based encoding When encoding $\tau(i)$, the previous encodings generate the position for the target word, but they do not really take into account the left-to-right order in which sentences are naturally read,[8] nor they are linguistically inspired.

In particular, informally speaking, in human linguistic processing (i.e. when a sentence is read from left to right) we could say that a discontinuity is processed when we read a word that continues a phrase other than that of the previously read word. For example, for the running example sentence (Figure 4), from an abstract standpoint we know that there is a discontinuity because $\tau(2) \neq \tau(1) + 1$, i.e., "nie" and "habe" are not contiguous in the continuous arrangement of the tree. However, in a left-to-right processing of the sentence, there is no way to know the final desired position of "habe" ($\tau(2)$) until we read the words "so viel gewählt", which go before it in the continuous arrangement. Thus, the requirement of the previous four encodings to assign a concrete non-default value to the p_is associated with "habe" and "ich" is not too natural from an incremental reading standpoint, as learning p_i requires information that can only be obtained by looking to the right of w_i. This can be avoided by using a model that just processes "Noch nie habe ich" as if it were a continuous subtree (in fact, if we removed "so viel gewählt" from the sentence, the tree would be continuous). Then, upon reading "so", the model notices that it continues the phrase associated with "nie" and not with "ich", and hence inserts it after "nie" in the continuous arrangement.

This idea of incremental left-to-right processing of discontinuities is abstracted in the form of a pointer $\widehat{o}$ that signals the last terminal in the current

---

[8] We use left-to-right in an informal sense to mean that sentences are processed in linear temporal order. Of course, not all languages follow a left-to-right script.

continuous arrangement of the constituent that we are currently filling. That said, to generate the labels this approach needs to consider two situations:

- If w_i is to be inserted right after w_{i-1} (this situation is characterized by $\tau(i-1) < \tau(i) \wedge \nexists j < i \mid \tau(i-1) < \tau(j) < \tau(i)$). This case is abstracted by a single label, p_i=`NEXT`, that means to insert at the position currently pointed by $\widehat{o}$, and then update $\widehat{o} = \tau'_i(i)$, where the function τ'_i is defined as $\tau'_i(x) = \#\{j \leq i \mid \tau(j) \leq \tau(x)\}$. $\tau'_i(x)$ can informally be described as a tentative value of $\tau(x)$, corresponding to the position of w_x in the part of the continuous arrangement that involves the substring $w_0 \dots w_i$.

- Otherwise, w_i should be inserted after some w_{i-x} with $x \geq 1$, which means there is a discontinuity and that the current pointer $\widehat{o}$ is no longer valid and needs to be first updated to point to $\tau'_i(i-x)$. To generate the label p_i we use a tuple (j, t) that indicates that the predecessor of w_i in $\omega(t)$ is the jth preceding word in $\mathbf{w}$ with the PoS tag t. After that, we update the pointer to $\widehat{o} = \tau'_i(i)$. While this encoding could work with PoS-tag-independent relative offsets, or any word property, the PoS-tag-based indexing provides linguistic grounding and is consistent with sequence labeling encodings that have obtained good results in dependency parsing (Strzyz et al., 2019).

Pointer-based encoding (with simplified PoS tags) A pointer-based variant where the PoS tags in (j, t) are simplified (e.g. NNS → NN). The mapping is described in Appendix A.1. Apart from reducing sparsity, the idea is that a discontinuity is not so much influenced by specific information but by the coarse morphological category.

Ill-formed permutations are corrected with post-processing, following Appendix A.2, to ensure that the derived permutations contain all word indexes.

4.1 Limitations

The encodings are complete under the assumption of an infinite label vocabulary. In practice, training sets are finite and this could cause the presence of unseen labels in the test set, especially for the integer-based label components:[9] the levels in common (n_i) and the label component p_i that encodes $\tau(i)$. However, as illustrated in Appendix A.3, an analysis on the corpora used in this work shows that the presence of unseen labels in the test set is virtually zero.

5 Sequence labeling frameworks

To test whether these encoding functions are learnable by parametrizable functions, we consider different sequence labeling architectures. We will be denoting by ENCODER a generic, contextualized encoder that for every word w_i generates a hidden vector $\mathbf{h}_i$ conditioned on the sentence, i.e. ENCODER$(w_i|\mathbf{w})$=$\mathbf{h}_i$. We use a hard-sharing multi-task learning architecture (Caruana, 1997; Vilares et al., 2019) to map every $\mathbf{h}_i$ to four 1-layered feed-forward networks, followed by softmaxes, that predict each of the components of l'_i. Each task's loss is optimized using categorical cross-entropy $\mathcal{L}_t = -\sum log(P(l'_i|\mathbf{h}_i))$ and the final loss computed as $\mathcal{L} = \sum_{t \in Tasks} \mathcal{L}_t$. We test four ENCODERs, which we briefly review but treat as black boxes. Their number of parameters and the training hyper-parameters are listed in Appendix A.4.

Transducers without pretraining We try (i) a 2-stacked BiLSTM (Hochreiter and Schmidhuber, 1997; Yang and Zhang, 2018) where the generation of $\mathbf{h}_i$ is conditioned on the left and right context. (ii) We also explore a Transformer encoder (Vaswani et al., 2017) with 6 layers and 8 heads. The motivation is that we believe that the multi-head attention mechanism, in which a word attends to every other word in the sentence, together with positional embeddings, could be beneficial to detect discontinuities. In practice, we found training these transformer encoders harder than training BiLSTMs, and that obtaining a competitive performance required larger models, smaller learning rates, and more epochs (see also Appendix A.4).

The input to these two transducers is a sequence of vectors composed of: a pre-trained word embedding (Ling et al., 2015) further fine-tuned during training, a PoStag embedding, and a second word embedding trained with a character LSTM. Additionally, the Transformer uses positional embeddings to be aware of the order of the sentence.

---

[9] This is a general limitation also present in previous parsing as sequence labeling approaches (e.g. (Gómez-Rodríguez and Vilares, 2018)), and could potentially happen with any label component, e.g. predicting the non-terminal symbol. However, it is very unlikely that a non-terminal symbol has not been observed in the training set. Also, chart- and transition-based parsers would suffer from this same limitation.

Transducers with pretraining Previous work on sequence labeling parsing (Gómez-Rodríguez and Vilares, 2018; Strzyz et al., 2019) has shown that although effective, the models lag a bit behind state-of-the-art accuracy. This setup, inspired in Vilares et al. (2020), aims to evaluate whether general purpose NLP architectures can achieve strong results when parsing free word order languages. In particular, we fine-tune (iii) pre-trained BERT (Devlin et al., 2019), and (iv) pre-trained DistilBERT (Sanh et al., 2019). BERT and DistilBERT map input words to sub-word pieces (Wu et al., 2016). We align each word with its first sub-word, and use their embedding as the *only* input for these models.

Label Component	#Labels TIGER	#Labels NEGRA	#Labels DPTB
n_i	22	19	34
x_i	93	56	137

p_i as pointer-based	122	$99^\star$	$110^\star$
p_i as pointer-based simplified	81	65	$83^\star$

Table 1: Number of values per label component, merging the training and dev sets (gold setup). $\star$ are codes that generate one extra label with predicted PoS tags (this variability depends on the used PoS-tagger).

6 Experiments

Setup For English, we use the discontinuous Penn Treebank (DPTB) by Evang and Kallmeyer (2011). For German, we use TIGER and NEGRA (Brants et al., 2002; Skut et al., 1997). We use the splits by Coavoux and Cohen (2019) which in turn follow the Dubey and Keller (2003) splits for the NEGRA treebank, the Seddah et al. (2013) splits for TIGER, and the standard splits for (D)PTB (Sections 2 to 21 for training, 22 for development and 23 for testing). See also Appendix A.5 for more detailed statistics. We consider gold and predicted PoS tags. For the latter, the parsers are *trained* on predicted PoS tags, which are generated by a 2-stacked BiLSTM, with the hyper-parameters used to train the parsers. The PoS tagging accuracy (%) on the dev/test is: DPTB 97.5/97.7, TIGER 98.7/97.8 and NEGRA 98.6/98.1. BERT and DistilBERT do not use PoS tags as input, but when used to predict the pointer-based encodings, they are required to decode the labels into a parenthesized tree, causing variations in the performance.[10] Table 1 shows the number of labels per treebank.

Metrics We report the F-1 labeled bracketing score for all and discontinuous constituents, using `discodop` (van Cranenburgh et al., 2016)[11] and the `proper.prm` parameter file. Model selection is based on overall bracketing F1- score.

6.1 Results

Table 2 shows the results on the dev sets for all encodings and transducers. The tendency is clear showing that the pointer-based encodings obtain the best results. The pointer-based encoding with simplified PoS tags does not lead however to clear improvements, suggesting that the models can learn the sparser original PoS tags set. For the rest of encodings we also observe interesting tendencies. For instance, when running experiments using stacked BiLSTMs, the relative encoding performs better than the absolute one, which was somehow expected as the encoding is less sparse. However, the tendency is the opposite for the Transformer encoders (including BERT and DistilBERT), especially for the case of discontinuous constituents. We hypothesize this is due to the capacity of Transformers to attend to every other word through multi-head attention, which might give an advantage to encode absolute positions over BiLSTMs, where the whole left and right context is represented by a single vector. With respect to the Lehmer and Lehmer of the inverse permutation encodings, the latter performs better overall, confirming the bigger difficulties for the tested sequence labelers to learn Lehmer, which in some cases has a performance even close to the naive absolute-positional encoding (e.g. for TIGER using the vanilla Transformer encoder and BERT). As introduced in §4, we hypothesize this is caused by the non-straightforward mapping between words and labels (in the Lehmer code the label generated for a word does not necessarily contain information about the position of such word in the continuous arrangement).

In Table 3 we compare a selection of our models against previous work using both gold and predicted PoS tags. In particular, we include: (i) models using the pointer-based encoding, since they obtained the overall best performance on the dev sets, and (ii) a representative subset of encodings (the absolute positional one and the Lehmer code of the inverse permutation) trained with the best

---

[10] The rest of BERT models do not require PoS tags at all.

Table 2: Comparison of our approaches on the TIGER, NEGRA and DPTB dev splits (with gold PoS tags)

performing transducer. Additionally, for the case of the (English) DPTB, we also include experiments using a `bert-large` model, to shed more light on whether the size of the networks is playing a role when it comes to detect discontinuities. Additionally, we report speeds on CPU and GPU.[12] The experiments show that the encodings are learnable, but that the model's power makes a difference. For instance, in the predicted setup BILSTMs and vanilla Transformers perform in line with predeep learning models (Maier, 2015; Fernández-González and Martins, 2015; Coavoux and Crabbé, 2017), DistilBERT already achieves a robust performance, close to models such as (Coavoux and Cohen, 2019; Coavoux et al., 2019); and BERT transducers suffice to achieve results close to some of the strongest approaches, e.g. (Fernández-González and Gómez-Rodríguez, 2020a). Yet, the results lag behind the state of the art. With respect to the architectures that performed the best the main issue is that they are the bottleneck of the pipeline. Thus, the computation of the contextualized word vectors under current approaches greatly decreases the importance, when it comes to speed, of the chosen parsing paradigm used to generate the output trees (e.g. chart-based versus sequence labeling).

Finally, Table 4 details the discontinuous performance of our best performing models.

Discussion on other applications It is worth noting that while we focused on parsing as sequence labeling, encoding syntactic trees as labels is useful to straightforwardly feed syntactic information to downstream models, even if the trees themselves come from a non-sequence-labeling parser. For example, Wang et al. (2019) use the sequence labeling encoding of Gómez-Rodríguez and Vilares (2018) to provide syntactic information to a semantic role labeling model. Apart from providing fast and accurate parsers, our encodings can be used to do the same with discontinuous syntax.

7 Conclusion

We reduced discontinuous parsing to sequence labeling. The key contribution consisted in predicting a continuous tree with a rearrangement of the leaf nodes to shape discontinuities, and defining various ways to encode such a rearrangement as a sequence of labels associated to each word, taking advantage of the fact that in practice they are nearly ordered permutations. We tested whether those encodings are learnable by neural models and saw that the choice of permutation encoding is not trivial, and there are interactions between encodings

---

[12] For CPU, we used a single core of an Intel(R) Core(TM) i7-7700 CPU @ 3.60GHz. For GPU experiments, we relied on a single GeForce GTX 1080, except for the BERT-large experiments, where due to memory requirements we required a Tesla P40.

Table 3: Comparison against related work on the TIGER, NEGRA and DPTB test splits. The $\star$ symbol indicates that a model used BERT to contextualize the input. The reported speeds are extracted from the related work and therefore results are not directly comparable since the hardware can be different. The $\diamond$ symbol indicates work that reported the speed (in sentences per second) on the dev sets instead.

Model	TIGER			NEGRA			DPTB		
	Dis P	Dis R	Dis F-1	Dis P	Dis R	Dis F-1	Dis P	Dis R	Dis F-1
Pointer-based BiLSTM	41.0	38.1	39.5	34.7	34.5	34.6	46.7	45.0	45.8
Pointer-based Transformer	39.0	43.8	41.2	30.4	37.7	33.6	43.3	47.2	45.2
Pointer-based DistillBERT	42.5	43.9	43.2	41.0	42.0	41.5	37.6	45.0	41.0
Pointer-based BERT	**50.9**	**51.4**	**51.1**	**43.2**	**48.4**	**45.6**	**47.9**	**54.0**	**50.8**

Table 4: Detailed discontinuous performance (Discontinuous Precision, Recall and F1-score) by our best sequence labeling models (predicted PoS tags setup).

and models (i.e., a given architecture may be better at learning a given encoding than another). Overall, the models achieve a good trade-off speed/accuracy without the need of any parsing algorithm or auxiliary structures, while being easily parallelizable.

Acknowledgments

We thank Maximin Coavoux for giving us access to the data used in this work. We acknowledge the European Research Council (ERC), which has funded this research under the European Union's Horizon 2020 research and innovation programme (FASTPARSE, grant agreement No 714150), MINECO (ANSWER-ASAP, TIN2017-85160-C2-1-R), Xunta de Galicia (ED431C 2020/11), and Centro de Investigación de Galicia ”CITIC”, funded by Xunta de Galicia and the European Union (European Regional Development Fund-Galicia 2014-2020 Program), by grant ED431G 2019/01.

Table 6: Mapping from the original labels to coarse labels in the TIGER and NEGRA treebanks

A.2 Postprocessing of corrupted outputs

We describe below the post-processing of the encodings to ensure that the generated sequences can be later decoded to a well-formed tree. Before post-processing the predicted permutation, we make sure that one, and only one label (n_i, x_i, u_i, p_i), can be identified as the last word in the continuous arrangement. This is required because the component n_i encodes unique information for the last word (an empty dummy value, as n_i always encodes information between a word and the next one, which does not exist for the last token); which can conflict with some of the predicted p_is, that might put a different word into the last position. That said, we rely on the value n_i to identify which word should be located as the last one.[13]

Absolute-position and relative-position encodings Given the sequence $\mathbf{p}$ that encodes the permutation $\pi(\mathbf{w})$ of the words of $\mathbf{w}$ in the continuous arrangement $\omega(t)$, we: (i) fill the indexes for which the predicted labels indicate that the token should remain in the same position, i.e. p_i=`INV`, and (ii) for the remaining p_i's we check whether the predicted index has not been yet filled, and otherwise assign it to the closest available index (computed as the minimum absolute difference).

Lehmer encoding Given $\mathbf{p}$ and the list of available word indexes `idxs` (initially all the words), we process the elements in $\mathbf{p}$ in a left-to-right fashion: (i) if the corresponding index encoded at p_i is in `idxs`, then we select the index and remove it from `idxs`, (ii) otherwise, we select the last element in `idxs` and, again, remove it.

Lehmer of the inverse permutation encoding The post-processing is similar to the Lehmer code encoding, but considering the available blanks instead of a list of word indexes.

Pointer-based encodings Given the encoded permutation $\mathbf{p}$, we process the elements left-to-right and: (i) if p_i=`NEXT`, then we apply no post-processing and we consider the word will be inserted after the current pointer $\widehat{o}$ at the moment of decoding, which is always valid. (ii) Otherwise, we are processing an element p_i that encodes the pointer $\widehat{o} = (j, t)$, and try to map it to $\tau'(i)$. If such mapping is not possible, this is because j is greater than the number of previously processed words that

---

[13] If more than one n_i refers to the last word, we consider the one with the largest index.

have the postag t. If so, then we post-process p_i to (k, t), where k was the first processed word with postag t, or to p_i=`NEXT`, if there is no previous word labeled with the postag t.

A.3 Unseen labels in the training set

Table 7 shows some statistics on the number of gold p_i label components that are present in the test sets, but not on the corresponding training or dev splits. We do not show statistics for the label component that represents the number of levels in common (n_i) since for all treebanks the number of missing n_i values on the test sets was zero. For p_i, the missing elements correspond to rare situations. For instance, taking NEGRA as our reference corpus,[14] for the relative index encoding the only missing element was '-29' and occurred a single time in the test set; and for the pointer-based encoding the missing components were just three: '-10 NN' (2 occurrences), '-4 ADV' (1 occurrence), '-4 $[' (1 occurrence).

Encoding	Treebank	Missing elements		
		Unique	Total	%
Absolute	TIGER	6	6	6.5×10^{-3}
	NEGRA	0	0	0
	DPTB	0	0	0
Relative	TIGER	1	8	8.7×10^{-3}
	NEGRA	1	1	5.9×10^{-3}
	DPTB	0	0	0
Lehmer	TIGER	0	0	0
	NEGRA	1	1	5.9×10^{-3}
	DPTB	0	0	0
Inverse Lehmer	TIGER	1	1	1.1×10^{-3}
	NEGRA	0	0	0
	DPTB	0	0	0
Pointer-based	TIGER	1	1	1.1×10^{-3}
	NEGRA	3	4	0.02
	DPTB	0	0	0
Pointer-based simp.	TIGER	1	1	1.1×10^{-3}
	NEGRA	1	1	5.9×10^{-3}
	DPTB	0	0	0

Table 7: Number of unique p_i label components that occur on the test set but not on the training or dev splits, total ocurrences and the corresponding percentage over the total number of labels.

A.4 Training hyper-parameters and size of the trained models

Table 8 shows the hyper-parameters used to train the BiLSTMs, both for the gold and predicted setups. We use pre-trained embeddings for English and German (Ling et al., 2015). The embeddings for English have 100 dimensions, while the German ones only have 60. For the BiLSTMs, we did not do any hyper-parameter engineering and just considered the hyper-parameters reported by Gómez-Rodríguez and Vilares (2018).

Hyperparameter	Value
BiLSTM size	800
# BiLSTM layers	2
optimizer	SGD
loss	cat. cross-entropy
learning rate	0.2
decay (linear)	0.05
momentum	0.9
dropout	0.5
word embs	Ling et al. (2015)
PoS tags emb size	20
character emb size	30
batch size training	8
training epochs	100
batch size test	128

Table 8: Main hyper-parameters for the training of the BiLSTMs, both for the gold and predicted setups

Table 9 shows the configuration used to train the vanilla Transformer encoders. As explained in the paper, we found out that Transformers were more unstable during training in comparison to BILSTMs. To overcome such unstability, we performed a small manual hyper-parameter search. This translated into training during more epochs, with a low learning rate and large dropout.

To fine-tune the BERT and DistilBERT models we use the default fine-tuning setup provided by huggingface.[15] Table 10 shows the hyper-parameters that we have modified. For English, the pre-trained models we relied on were: 'bert-base-cased', 'distilbert-base-cased' (distilled from 'bert-base-cased'), and 'bert-large-cased'. For German, we used 'bert-base-german-dbmdz-cased' and 'distilbert-base-german-cased' (distilled from 'bert-base-german-dbmdz-cased').

Finally, in Table 11 we list the number of parameters for each of the transducers trained on the pointer-based encoding. For the rest of the encodings, the models have a similar number of parameters, as the only change in the architecture is the small part involving the feed-forward output layer that predicts the label component p_i.

More in detail, for BiLSTMs and vanilla Trans-

---

[14] We consider NEGRA as the reference corpus since it was the treebank that showed the largest percentage of missing p_i elements.

formers the TIGER model is the larger than the NEGRA one. This is because for these transducers we only store and use the word embeddings from Ling et al. (2015) that were seen in the training and dev sets, and the TIGER treebank is larger and contains more unique words. Also, we see that for the BiLSTMs the TIGER model is slightly larger than the DPTB one, while for the vanilla Transformer the opposite happens. This is due to the smaller char embedding size in the case of the German Transformers, which is required so the total size of the input vector is divisible by 8, the number of attention heads (the root of the need for the disparity in the char embedding sizes is that the pre-trained English and German embeddings also have a different number of dimensions). On the contrary, for the BERT-based models we use the same pre-trained model for TIGER and NEGRA, for example, which causes these models to have an almost identical number of parameters.

Modularized Syntactic Neural Networks for Sentence Classification

Haiyan Wu, Ying Liu*, **Shaoyun Shi**
Tsinghua University, Beijing, China, 100084
`wuhy17@mails.tsinghua.edu.cn`

Abstract

This paper focuses on tree-based modeling for the sentence classification task. In existing works, aggregating on a syntax tree usually considers local information of sub-trees. In contrast, in addition to the local information, our proposed Modularized Syntactic Neural Network (MSNN) utilizes the syntax category labels and takes advantage of the global context while modeling sub-trees. In MSNN, each node of a syntax tree is modeled by a label-related syntax module. Each syntax module aggregates the outputs of lower-level modules, and finally, the root module provides the sentence representation. We design a tree-parallel mini-batch strategy for efficient training and predicting. Experimental results on four benchmark datasets show that our MSNN significantly outperforms previous state-of-the-art tree-based methods on the sentence classification task.

1 Introduction

Text classification is an important and fundamental problem in natural language processing (NLP). With the increasing spread of the Internet, there are numerous applications of classification of short texts with only one sentence, for example, classifying questions according to what product or which part of the product architecture the question regards, sentiment analysis of customer reviews or tweets, and fast category detection based on news titles. Different from document classification, in which there are more topic words and features of writing styles, a single sentence contains limited information. Thus, understanding the meaning of a sentence is vital.

Although sequential models like long short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and gated recurrent units (GRU) (Cho et al., 2014b) have been widely used and provide excellent performances, it is hard for them to capture the syntactic information, which is essential for understanding sentences (Linzen et al., 2016). To utilize the syntactic information, some works proposed models taking parse trees or dependency trees as inputs (Le and Zuidema, 2015; Teng and Zhang, 2017; Socher et al., 2013; Zhu et al., 2015; Bowman et al., 2016). Previous researchers have empirically verified that these methods help to model sentences (Li et al., 2015). However, to improve the model efficiency and simplify the implementation, these methods binarize trees (Wang et al., 2007; Huang, 2007) so that they can be traversed by recursive neural networks (RvNN) or as a sequence by RNN. Although some models, such as Tree-LSTM (Tai et al., 2015; Looks et al., 2017; Ran and Zhong, 2019), theoretically support original parse trees, child nodes are simply summed, but the relationships among them are not modeled. The authors only conduct experiments on binary trees. Binary trees weaken the syntactic information and conceal the relationships among nodes at the same level or different levels. Latent tree is another way of modeling sentences, but it does not take full advantage of the syntactic information (Cho et al., 2014a; Choi et al., 2018; Williams et al., 2018; Addi et al., 2020). Current graph-based models specifically focus on the dependency tree (Marcheggiani and Titov, 2017; Zhang et al., 2018). Besides, these models do not consider the context information in the bottom-up aggregation. Syntax category labels are also not fully utilized. However, they both can affect the meanings of words and phrases, which should be considered.

In this work, a novel Modularized Syntactic Neural Network (MSNN) is proposed to model syntax trees of sentences. Each node in the tree is transformed into a syntax module in MSNN. The num-

November 16–20, 2020.

ber of distinct syntax modules is the same as the number of distinct syntax category labels. A category label is the syntactic category of a subtree's root, e.g. "NP", "VP", etc. The modules are used to build networks according to tree structures, and there is a one-to-one correspondence between tree structures and network structures. The parameters of modules corresponding to the same category labels are shared. Note that there is no limitation to binary trees, and our implementation of tree-parallel mini-batches based on the original parse trees provides excellent efficiency. Each syntax module aggregates outputs of lower-level modules and outputs a representation vector of the sub-tree. Syntax category labels and global context information are encoded to guide the propagation and better infer the meaning of the sentence. The root module finally outputs the sentence representation, which is further used for classification. We test MSNN on four benchmark datasets, and the results show that it outperforms previous state-of-the-art methods.

The main contributions of this work are listed as follows:

- A novel Modularized Syntactic Neural Network (MSNN) is proposed to model syntax trees for sentence classification. Both category labels and global context information are utilized when modeling sub-trees.
- We provide a design of tree-parallel mini-batches so that binarization of trees is not necessary and structural information is better reserved.
- Experimental results on four benchmark datasets show that MSNN significantly outperforms previous state-of-the-art methods on the sentence classification task.

2 Modularized Syntactic Neural Networks

An example of Modularized Syntactic Neural Networks (MSNN) is shown in Figure 1.

2.1 Global Context Bi-LSTM

Single words contain no sequential information. Meanings of words can be inferred from their context. It is essential to represent words in a certain context. A global context bidirectional LSTM (Bi-LSTM) (Schuster and Paliwal, 1997) is used to generate context-enhanced word vectors and global context vector. Suppose the input sentence s consists of a sequence of words $s = \{w_1, ..., w_t, ..., w_{|s|}\}$, where w_t is the t-th word in the sentence and $|s|$ is the sentence length. We use bold fonts to represent the vectors of words and other objects. The word vectors $\mathbf{w}_t \in \mathbb{R}^d$ can either be randomly initialized or pre-trained vectors, and d is the dimension of word vectors. To enrich word vectors with the context information in the sentence, a Bi-LSTM is applied to the sequence of words $\{w_t\}_{t=1...|s|}$. Let $\mathbf{h}_t^f$ denote the hidden states of the forward LSTM at position t, in which the past context information is included. By another backward LSTM, hidden states containing the future context $\mathbf{h}_t^b$ are formed. The initial hidden states $\mathbf{h}_0$ are zero-initialized. Then the enriched word vector $\mathbf{e}_t$ at position t is

$$\mathbf{e}_t = \mathbf{h}_t^f + \mathbf{h}_t^b + \mathbf{w}_t \tag{1}$$

The global context vector $\mathbf{c}_s$ of sentence s is

$$\mathbf{c}_s = \mathbf{h}_{|s|}^f + \mathbf{h}_1^b \tag{2}$$

$\mathbf{e}_t$ and $\mathbf{c}_s$ are inputs of syntax modules. Global context information is embedded into $\mathbf{e}_t$, so that the information propagation in higher layers is guided by the context.

2.2 Syntax Modules

Previous works use a constant structure to traverse over trees, which do not consider the diversity of syntax category labels. In MSNN, syntax modules are used to construct different network structures according to the syntax trees. Each category label (including POS tags of leaf nodes) l in the syntax tree is mapped to a module $M_l(\cdot)$. Each module takes output vectors of its child nodes as inputs, and it outputs the representation of the sub-tree. The number of distinct syntax modules is the same as the number of distinct syntax category labels. For example, in Figure 1, seven different modules are used to assemble the network: "S, NP, VP, ., PRP\$, NN, VBZ". According to whether a node is a leaf, modules are divided into two categories: leaf POS module and root/intermediate module.

Each word in the sentence w_t has a POS p_t, which shows the categories of words according to their function in a sentence. Words with the same POS have similar syntactic behaviors. In POS module, the enhanced word vector $\mathbf{e}_t$ and the

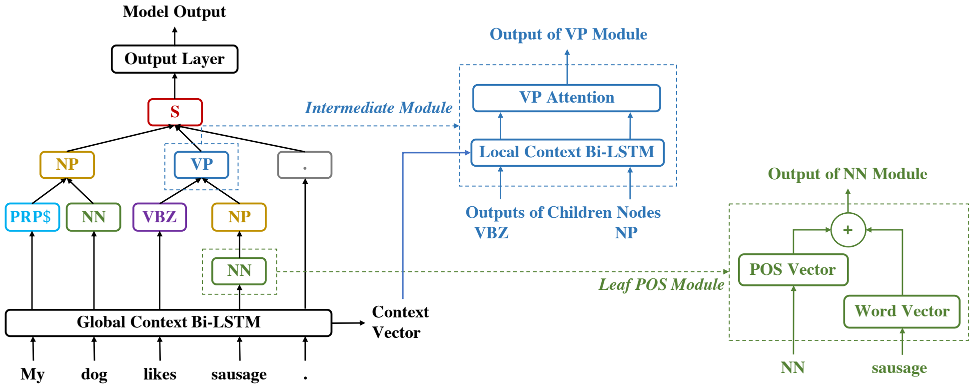

Figure 1: An example of MSNN.

POS vector $\mathbf{p}_t \in \mathbb{R}^d$ are combined:

$$M_{p_t}(\mathbf{e}_t, \mathbf{p}_t) = \mathbf{e}_t + \mathbf{p}_t = \mathbf{m}_{p_t} \tag{3}$$

Vectors of POS labels are randomly initialized and learned during the training. The output $\mathbf{m}_{p_t}$ will be the input of its parent module.

It is necessary to model relationships among sibling nodes because the information from syntactic nodes' sisterhood may reveal useful for sentence classification. Examples may be negation clauses or modifiers. When modeling the sentence as a sequence, it is not easy for RNN, CNN, or other structures to identify their lexical scope. And in a binary tree, coordinate relations among nodes are diluted. The influence of negation clauses or modifiers on some nodes may be hard to capture, especially in long phrases and sentences. In MSNN, suppose a root or intermediate module $M_l(\cdot)$ with label l have n child modules $\{M_{c_1}, M_{c_2}, ..., M_{c_n}\}$, and their output vectors are $\{\mathbf{m}_{c_1}, \mathbf{m}_{c_2}, ..., \mathbf{m}_{c_n}\}$. Then in the $M_l(\cdot)$, firstly, these vectors are modeled by a local context Bi-LSTM:

$$\textit{Bi-LSTM}(\mathbf{c}_s, \mathbf{m}_{c_1}...\mathbf{m}_{c_n}) = \{\mathbf{e}_{c_1}, \mathbf{e}_{c_2}, ..., \mathbf{e}_{c_n}\} \tag{4}$$

where *Bi-LSTM*$(\cdot)$ have the similar structure as the global context Bi-LSTM in section 2.1 but different parameters. The local context Bi-LSTM shares the same parameters among different modules, and the outputs $\mathbf{e}_{c_1}...\mathbf{e}_{c_n}$ are the enriched representations of child nodes. The global context vector $\mathbf{c}_s$ is used to initialize the hidden state and cell state in order to guide the information to propagate in the local syntactic node. The context can affect the semantic meanings of phrases, e.g., representations of syntactic nodes.

Different child nodes contribute more or less to the representation of their parent node. A syntax-aware attention network is then used to aggregate child nodes:

$$\mathbf{k}_{c_i} = \delta(\mathbf{K}\mathbf{e}_{c_i} + \mathbf{b}_k),\ \mathbf{q}_l = \delta(\mathbf{Q}_l(\mathbf{l} \oplus \mathbf{c}_s) + \mathbf{b}_l),$$
$$\mathbf{m}_l = \sum_{j=1}^{n} a_{c_j}\mathbf{e}_{c_j},\ a_{c_i} = \frac{exp(\mathbf{q}_l^\top \mathbf{k}_{c_i})}{\sum_{j=1}^{n} exp(\mathbf{q}_l^\top \mathbf{k}_{c_j})} \tag{5}$$

where $\mathbf{K} \in \mathbb{R}^{d \times d}$ is the global transformation weight matrix for attention keys, and $\mathbf{b}_k \in \mathbb{R}^d$ is the bias vector. Label-related query vector $\mathbf{q}_l$ is used to evaluate whether children are informative for the parent node in such sentence context $\mathbf{c}_s$ and category label $\mathbf{l}$. $\mathbf{Q}_l \in \mathbb{R}^{d \times d}$ is the query transformation weight matrix of category label l, $\mathbf{b}_l$ is the bias vector, and $\mathbf{l} \in \mathbb{R}^d$ is the vector of category label. They are all label-related parameters so that syntax modules of labels have different parameters. $\delta(\cdot)$ is the non-linear activation function and we use the LeakyRelu (Maas et al., 2013). a_{c_i} is the normalized attention weights by a softmax layer. The l-module outputs the representation of the sub-tree $\mathbf{m}_l$ by a weighted sum. In this way, context and syntactic information guide the information to propagate in sub-trees.

The aggregation process goes from bottom to up, and finally, the root module outputs the sentence vector $\mathbf{m}_S$ for further classification.

A fully-connected layer followed by a softmax function is used to give the final predictions of classification. The Cross-Entropy with ℓ_2-regularization is the loss function to train the model.

2.3 Tree-Parallel Mini-Batch

Tree structures of sentences vary a lot. As a deep model, it is essential to construct mini-batches for effective and efficient training and testing. Previous tree-based models usually construct binary

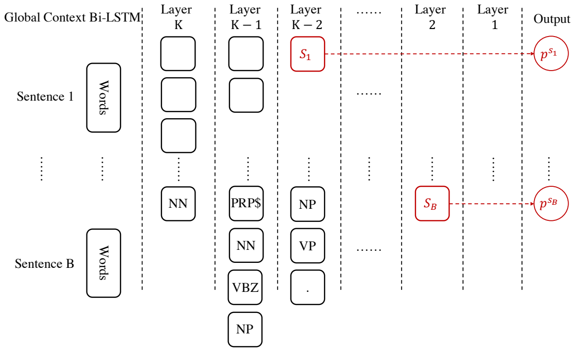

Figure 2: Brief illustration of a tree-parallel mini-batch.

trees to simplify the implementation. However, to form the binarized tree, many intermediate nodes are inserted in the original tree. Some nodes or phrases with coordinate relation in the raw sentences or the original parse trees may now on different levels of binary trees, and their paths and path-lengths to the root vary a lot. In such a situation, the parent-children or brother-sister relationships among nodes are captured implicitly in the binary tree. It is not easy to design good ways to construct features encoding information about node sisterhood. In contrast, we design a way of tree-parallel mini-batches for MSNN, as shown in Figure 2. B is the batch size, e.g., the number of sentences in the batch. K is the maximum number of layers of all trees in the batch. In a batch running, the first step is all sentences going through the global context Bi-LSTM in parallel to obtain enriched word vectors. In the second step, all nodes on the last layer of different trees are calculated simultaneously. And then the last but one layer, and so on. As long as previous layers have been calculated, the required information of current layers is all available. For example, the tree in Figure 1 is shown as the B-th sentence in Figure 2. The number of iterations along layers depends on the maximum depth of trees in the batch. Finally, outputs of all root nodes are gathered for the output layer.

3 Experiments

3.1 Datasets and Settings

We use four text classification datasets from Zhang et al. (2015), including AG's News, DBpedia, Amazon Review Polarity (ARP), Amazon Review Full (ARF). For the sentence classification task, only single-sentence instances are used in each dataset. Some detailed information of datasets is shown in Table 1.

Dataset	#Train	#Valid	#Test	#Class
AG's News	60K	10K	10K	4
DBpedia	70K	7K	7K	14
ARP	400K	80K	80K	2
ARF	500K	100K	100K	5

Table 1: Statistics of evaluation datasets.

MSNN is compared with two sequential models **LSTM** (Hochreiter and Schmidhuber, 1997), **Bi-LSTM** (Schuster and Paliwal, 1997) and two tree-based methods **Tree-LSTM** (Tai et al., 2015), **Gumbel-Tree** (Choi et al., 2018). We use the PyTorch implementation provided by Shi et al. (2018).

All models, including baselines, are trained with Adam (Kingma and Ba, 2014) in mini-batches at the size of 64. The learning rate is 1×10^{-4}, and early-stopping is conducted according to the performance on the validation set. The weight of ℓ_2-regularization λ is manually searched between $\{0, 1\times10^{-5}, 1\times10^{-4}, 1\times10^{-3}, 1\times10^{-2}\}$. Word vectors are randomly initialized. The dimension of word vectors and hidden layers d is 300. We run the experiments with 5 different random seeds and report the average accuracy and standard errors. All models are trained with a GPU (NVIDIA GeForce GTX 1080Ti).

3.2 Results and Discussion

The overall performances are shown in Table 2, in which "w/o" means "without". We can conclude that tree-based models like Tree-LSTM and Gumbel-Tree are better than sequential models LSTM and Bi-LSTM, which shows the superiority of modeling structures of the syntax tree for sentence classification. Gumbel-Tree is slightly better than Tree-LSTM because of a more flexible structure and a similar global context RNN as MSNN. However, it uses the Gumbel softmax (Jang et al., 2017) to form latent trees and does not take full advantage of the syntactic structure information. Although Gumbel-Tree is more flexible in integrating context information and constructing sentence representations, it produces unstable latent trees (Williams et al., 2018). MSNN outperforms these baselines because it utilizes the global context

---

Detailed implementation can be found at `https://github.com/wuhaiyan2014/MSNN`.

Model	AG's News	DBpedia	ARP	ARF

MSNN	**0.9173** ± 0.0008	**0.9797** ± 0.0003	**0.8916** ± 0.0006	**0.5185** ± 0.0011
w/o global RNN	0.9164 ± 0.0010	0.9784 ± 0.0006	0.8875 ± 0.0004	0.5137 ± 0.0002
w/o local RNN	0.9170 ± 0.0006	0.9769 ± 0.0009	0.8885 ± 0.0003	0.5134 ± 0.0005
w/o attention	0.9072 ± 0.0013	0.9741 ± 0.0004	0.8906 ± 0.0005	0.5172 ± 0.0006
w/o category label	0.9145 ± 0.0008	0.9774 ± 0.0003	0.8894 ± 0.0002	0.5134 ± 0.0006

Table 2: Overall performance on four benchmark datasets.

and syntax category labels to guide the information propagation in sub-trees. The meaning of words and phrases can be inferred by their context and syntactic roles. Besides, MSNN based on the tree-parallel mini-batch design is not limited to binary trees, which fully retains the syntactic information. The local RNN and attention network capture the relationship between nodes with the same parent. The improvements of MSNN are larger on DBpedia than that on other datasets. The reason is that most of the sentences in the DBpedia are high-quality declarative sentences, and their tree structures are less complex compared to reviews in Amazon datasets, which contain much noise. Clean syntactic information on DBpedia results in wider discrepancy, not only between MSNN and Gumbel-Tree but also between tree-based methods and Bi-LSTM.

To study the ablation of different parts, we remove the global RNN, local RNN, attention mechanism, or category label information in MSNN. Results show that all these parts contribute to the excellent performance of MSNN. Global RNN enriches word vectors with context information and provides a global context representation of the sentence. Local RNN captures the relationships among nodes on the same level. The attention mechanism dynamically aggregates information from child nodes under the guidance of context and syntax category labels. Category labels also show the roles of words and phrases in the sentence.

The average training time per epoch on the largest ARF dataset under the same validating frequency is shown in Table 3. Generally, sequential methods are much faster than tree-based models because of simple computation graphs. With the help of tree-parallel mini-batch, MSNN largely reduces redundant calculations and is more efficient compared with Gumbel-Tree and Tree-LSTM. Binary trees usually have many more nodes than original trees. Traverse them node by node is slower than calculating nodes in parallel. Besides, directly modeling of origin trees largely retains the structural information.

Model	Time/epoch
LSTM	888s
Bi-LSTM	972s
Tree-LSTM	4,212s
Gumbel-Tree	4,908s
MSNN	3,707s

Table 3: Running time per training epoch on ARF.

4 Conclusion

In this work, a novel model MSNN is proposed to model syntax trees for classification. It uses global context information and syntax category labels to help improve the modeling of sub-trees and thus better sentence representations. A tree-parallel mini-batch strategy is further designed for efficient running and support for non-binary trees. Our future work will include conducting experiments on dependency trees and more NLP tasks.

`Wanqiu.long@ed.ac.uk, bonnie.webber@ed.ac.uk, dyxiong@tju.edu.cn`

Abstract

As different genres are known to differ in their communicative properties and as previously, for Chinese, discourse relations have only been annotated over news text, we have created the TED-CDB dataset. TED-CDB comprises a large set of TED talks in Chinese that have been manually annotated according to the goals and principles of Penn Discourse Treebank, but adapted to features that are not present in English. It serves as a unique Chinese corpus of spoken discourse. Benchmark experiments show that TED-CDB poses a challenge for state-of-the-art discourse relation classifiers, whose F1 performance on 4-way classification is <60%. This is a dramatic drop of 35% from performance on the news text in the Chinese Discourse Treebank. Transfer learning experiments have been carried out with the TED-CDB for both same-language cross-domain transfer and same-domain cross-language transfer. Both demonstrate that the TED-CDB can improve the performance of systems being developed for languages other than Chinese and would be helpful for insufficient or unbalanced data in other corpora. The dataset and our Chinese annotation guidelines has been made freely available.[1]

1 Introduction

Recent years have witnessed increasing attention to the properties of discourse for a wide variety of natural language processing (NLP) tasks, e.g., machine translation (Ohtani et al., 2019; Voita et al., 2019), summarization (Isonuma et al., 2019; Xu et al., 2020), machine reading comprehension (Mihaylov and Frank, 2019). One of those interesting properties is the coherence between clauses and sentences arising from shallow discourse relations. As empirical approaches for modeling discourse relations usually require corpora annotated with such relations, Penn Discourse Treebank (PDTB) (Prasad et al., 2008b), based on the idea that the discourse relations are grounded in an identifiable set of discourse connectives or Altlex expressions, has been widely applied in the field of natural language processing. Largely because PDTB is effective to extract discourse semantic features, it serves as a useful substrate for the development and evaluation of neural models in many downstream NLP applications (Qin et al., 2017; Nie et al., 2019; Narasimhan and Barzilay, 2015).

Because for Chinese, discourse relations have only been annotated over news text and few of the resulting corpora are freely available, we have created the TED-CDB dataset. TED-CDB currently comprises 72 TED talks in Chinese (∼268.1K words), annotated with 15,540 discourse relations — almost 3 times as many as the CDTB (Zhou and Xue, 2015). Because Tonelli et al. (2010) have shown that discourse relations in spoken discourse are expressed differently than in written text, for scenarios involving Chinese spoken discourse (e.g., dialogue, spoken language translation), TED-CDB boasts unprecedented potential for exploitation and application.

Our contributions comprise:

- the largest PDTB-style Chinese discourse corpus over spoken monologues (Section 3.1). Table 1 compares the TED-CDB with other discourse-annotated Chinese corpora.
- new annotation elements to accommodate Chinese-specific discourse phenomena (Section 3.2).
- benchmark results on Level-2 discourse relation classification for future comparison with other models (Section 5).
- experiments with cross-domain and cross-lingual transfer learning that show that the TED-CDB can improve the performance of

systems being developed for languages other than Chinese and would be helpful for insufficient or unbalanced data in other corpora (Section 6).

2 Related Work

Most annotations in PDTB style are conducted on written texts originating from news reports. Before 2015, there has been just one corpus for spoken discourse (Tonelli et al., 2010), where PDTB annotations are constructed on Italian dialogues. Recently, researchers have realized that the PDTB annotation guidelines should be used more widely instead of just being confined to construct corpora of written texts. Zeyrek et al. (2018) annotate 6 TED talks for 7 languages. Scheffler et al. (2019) build a discourse corpus on Twitter Conversations.

Regarding Chinese discourse corpora for discourse relations, as illustrated in Table 1, there are mainly 4 Chinese discourse corpora based on the PDTB framework (Prasad et al., 2008a). Zhou and Xue (2012) present a PDTB-style discourse corpus for Chinese, which is further expanded to contain 164 documents, namely the Treebank (CDTB) (CDTB)(Zhou and Xue, 2015). Huang and Chen (2011b) construct a Chinese discourse corpus with 81 articles. They adopt the top-level senses from PDTB sense hierarchy and focus on the annotation of inter-sentential relations. Zhou et al. (2014) present the CUHK Discourse Treebank. They adapt the annotation scheme of Penn Discourse Treebank 2 (PDTB-2) to Chinese and re-annotate the documents of the Chinese Treebank and with only inter-sentence explicit discourse relations. The largest Chinese discourse relation corpus for written texts is HIT-CDTB (Zhang et al., 2013), which presents a new Chinese discourse relation hierarchy adapted from the PDTB system. Nevertheless, these four corpora can only be acquired by either purchasing or applying from the owners.

Therefore, the scarcity of Chinese datasets, especially the lack of corpora for spoken monologues have significantly inspired to build TED-CDB.

3 The TED-CDB Corpus

This section describes the annotation procedure for TED-CDB, including details on the data, annotation scheme, annotation process and agreement study among the annotators.

3.1 Data Description

TED talks (TED is short for technology, entertainment and design), as examples of planned spoken monologues delivered to a live audience (Greenbaum et al., 1996), are given by experts from different fields and different countries, most of which are translated to various languages.

Hai and Sandra (2020) indicate that Chinese translations as a whole can be reliably distinguished from texts originally written in Chinese, for texts translated into a target language possess linguistic properties that are very different from comparable texts originally written in this language. Hence, we collect two types of TED talks: (1) 26 TED talks originally presented in English and translated into Chinese, and (2) 56 TED talks originally presented in Chinese (in Taipei, Shanghai or Chengdu). Together, these 72 TED talks contain 268,099 words after preprocessing.

3.2 Annotation Scheme

Our annotation scheme has been adapted from the PDTB 3.0 relation hierarchy. In the PDTB 3.0 relation hierarchy, there are 4 top-level senses (Expansion, Temporal, Contingency, Contrast) and their second- or in some cases third- level senses, as shown in table 2. To this hierarchy, an additional second-level sense – Progression – has been added under Expansion, specifically for Chinese.

Discourse relations are taken to hold between two abstract object arguments, named Argument 1 and Argument 2. Generally, the arguments are clauses or sentences. Using the PDTB annotator tool, we annotated an explicit connective, identified its two arguments in which the connective occurs, and then labeled the sense for explicit relation. For implicit relations, when we inferred the type of

Temporal	Synchronous	–
	Asynchronous	Precedence
		Succession

Contingency	Cause	Reason
		Result
		Negative-result
	Condition	Arg1-as-cond
		Arg2-as-cond
	Negative condition	Arg1-as-negcond
		Arg2-as-negcond
	Purpose	Arg1-as-goal
		Arg2-as-goal
		Arg2-as-negGoal
Comparison	Contrast	–
	Similarity	–
	Concession	Arg1-as-denier
		Arg2-as-denier

Expansion	Conjunction	–
	Disjunction	–
	Equivalence	–
	Instantiation	Arg1-as-instance
		Arg2-as-instance
	Level-of-detail	Arg1-as-detail
		Arg2-as-detail
	Substitution	Arg1-as-subst
		Arg2-as-subst
	Execption	Arg1-as-excpt
		Arg2-as-excpt
	Manner	Arg1-as-manner
		Arg2-as-manner

Table 2: PDTB-3 Sense Hierarchy (Webber et al., 2019). The Level-2 senses are used in assessing system performance (Section 5.1).

relation between two arguments, we tried to insert a connective for this relation. If a connective conveys more than one sense or more than one relation can be inferred, multiple senses would be assigned to the token. And we use a set of consistency rules due to specific linguistic properties in Chinese such as ellipsis of subject, pair connectives.

As some syntactic and textual contexts could not been annotated in our previous work (Long et al., 2020), we loosen the constraints on arguments, connectives, and distance of arguments. In this way, more relations are acquired effectively on the same texts, thus revealing the discourse coherence and structure more fully and clearly. The following are the main additions to our annotation scheme, which future efforts at Chinese discourse annotation might consider adopting as well. In the examples throughout the paper, explicit connectives are underlined, while connectives inserted for implicit relations are both underlined and parenthesized. Sense labels are indicated after the connectives.

Relations have been annotated across non-adjacent sentences

While relations between non-adjacent sentences have only been annotated in the PDTB if Arg1 of an explicit connective is not adjacent to Arg2, implicit relations between non-adjacent sentences were not annotated, except in a small-scale study by Prasad et al. (2017) of relations between paragraph-initial sentences and material in the previous text. In contrast, we annotate relations across non-adjacent sentences not only for explicit relations but also implicit relations. We believe that this would be useful for annotating spoken monologues in general, not just for Chinese. That is, in communicating with an audience, speakers often insert material meant to explain the details of the first argument to audience. Relations can be found across non-adjacent sentences in our annotations. The following are two examples – the first, of an explicit relation, and the second, of an implicit relation.

(1) [我们在空间很早的时候，是做了一个接宝藏的游戏]$_1$。[这种设计在现在看起来好像有点不可思议，但是当时确实有效。因为它帮我们留住了一些实在等不了的用户，也避免了用户流失。所以从早一开始，我们空间跟游戏就息息相关了]$_2$。ThenASYCHROUNOUS[后来，我们的团队也参与去做了QQ农场的游戏]$_3$。
“[When we started to do Qzone, we designed a game about collecting treasures]$_1$. [This design may seem a bit weird now, but it worked at the time. Because it helps us retain some users who can’t wait, and also avoids the loss of users. So from the early beginning, our space has been closely related to games]$_2$. [ThenASYNCHRONOUS, we joined to make the game of QQ farm]$_3$. ”

(2) [我的研究告诉我，意识不单单是智力的表现，而是更多的有关于我们的本性，作为活着、能呼吸的有机体]$_1$。 [意识和智力差别是很大的。就算你不聪明你也会感到痛苦，但前提是你得活着]$_2$。(Therefore)RESULT+SPEECHACT[(所以)在 接下来我要讲给你们的故事中，我们对周围世界的意识体验，以及我们自己的存在，都是 被控制的错觉，都源自我们的生命体]$_3$。

“[My research tells me that consciousness is not just a manifestation of intelligence, but more about our nature as a living, breathable organism]$_1$. [The difference between consciousness and intelligence is very large. You will feel pain even if you are not smart, but only if you have to live]$_2$. [(Therefore)RESULT+SPEECHACT stories I want to tell you, our conscious experience of the world around us and our own existence are all controlled illusions, all of which originate from our living bodies]$_3$."

In the above examples, there is an explicit Temporal discourse relation between sentences 1 and 3 in the first example and an implicit relation between sentences 1 and 3 in the second example, and there are several sentences being added between the two non-adjacent sentences, which give details for sentence 1. The intervening materials are annotated as "Arg2-as-detail" with respect to the given Arg1(sentence 1).

Verbs can serve as explicit connectives

We follow the practice in the PDTB-3 of using PropBank annotation of modifier relations (ARG-M) to seed intra-sentential discourse relations (Webber et al., 2019). For Chinese, we adopt conventions from Chinese PropBank Annotation (Xue and Palmer, 2009). This allows additional discourse relations to be included. It is the first work to explore Chinese verbs which can signal discourse relations.

(3) [他失误了]$_1$,making$_{\text{RESULT}}$[使得我们比赛输了]$_2$。
"[He made a mistake]$_1$, [making$_{\text{RESULT}}$ us lose the game]$_2$."

In this example, the verb phrase "使得" can be identified, while the discourse relations can be expressed through a combination of the adverbial of Arg2 and the anaphoric reference to Arg1 as the implicit subject. In terms of Chinese PropBank Annotation, "使得我们比赛输了（made us lose the game)" is the ARGM-ADV, and there is a relation expressing Cause.result between between the two clauses.

(4) [我到柏林]$_1$to$_{\text{PURPOSE}}$[去参加一个16天的德语强化]$_2$。
"[I went to Berlin]$_1$[to$_{\text{PURPOSE}}$ attend a 16 days' German intensive course]$_2$."

In the Example (3),"参加一个16天的德语强化（attend a 16 days' German intensive course)" is the purpose and has been labelled as an ARGM-PRP adjunct in the Chinese PropBank (Xue and Palmer, 2003). There is a verb "去" , which is translated to "to" in this English translation. While the verb "去" is a poly semantic word, and it often refers to "go" in English, it tends to act as a structural auxiliary word in this example. There are several Chinese verbs that have the same function like "来" , "让", "用". They always signal senses of relation like Condition, Purpose, Result and Manner.

Noun phrases can serve as arguments

Noun phrases have been annotated as arguments previously in Chinese discourse corpora like the CDTB (Zhou and Xue, 2015). While the Chinese NomBank (Xue, 2006) annotates the nominalized predicate, and also the Chinese Proposition Bank (Xue and Palmer, 2009) performs similar annotation of nominalized verbs. Accordingly, we do not annotate all noun phrases as arguments but those nouns which are nominalizations of their verbal form. Chinese verbs and their nominalizations share the same form, but we identify this kind of arguments, depending on whether the structure NP + 的 (of) + nominalizations of predicate appears. Moreover, in this structure, the NP can always be regarded as the object or subject of the nominalized predicate for the argument.

(5) [我们对他自由的限制]$_1$ made$_{\text{RESULT}}$[使他没有办法加入]$_2$。
"[Our towards him freedom limitation]$_1$ [made$_{\text{RESULT}}$ him cannot join]$_2$."

The noun phrase in this example is a typical NP + 的 (of) + nominalizations of predicate structure, the nominalized verb "限制" (limit) can be seen as the predicate of the object NP "自由" (freedom). And the rnoun phase can be paraphrased into "我们限制他的自由" (we limit his freedom).

Punctuation can serve as an AltLex

AltLex (Alternative Lexicalizations) are expressions that convey the SENSE of a discourse relation, without being explicit connectives. If the Altlex Expressions like "这导致了" (this cause), "一个例子是" (one example is...), "原因是" (the reason is) appear, the insertion of connectives become redundant. Although this kind of expressions are usually referred to words before, we have actually found that punctuation like colon play the role of Altlex expressions. With it, the relation of details can usually be expressed without adding additional connectives. Colon as AltLex Expression is the first attempt for PDTB-style corpora among all languages.

(6) [我觉得应该为我的接下来其他去参加的伙伴提供以下的几个提示:$_{\text{RESULT}}$]$_1$ [请您带好你的头灯]$_2$。
"[I think I should provide the following tip for those who will attend it:$_{\text{RESULT}}$]$_1$ [please take your headlights]$_2$."

In Example (5), we can see that the colon is sufficient to display the relation between the clauses. Hence, we have reasons to regard it as a special kind of Altlex expressions.

	Agreement	Kappa
Relation type	0.96	0.94
Senses (Top level)	0.94	0.92
Senses (Second level)	0.85	0.83
Senses (Third level)	0.83	0.81

Table 3: Agreement study

3.3 Annotation Process

The annotator team comprised a professor as the supervisor, an experienced annotator and a researcher of PDTB as counselors, 6 master degree candidates as annotators. All annotators are engaged in research on Natural Language Processing and have a certain theoretical foundation of linguistics. With the professional guidance and rich annotation experience, the quality and the efficiency can be initially guaranteed. To ensure annotation quality, the entire annotation process has the following phrases:

- Training and discussion. The experienced annotator trained the six annotators through training meeting, based on the Chinese tutorial[2] we made on PDTB guidelines and our adaptation scheme;
- Self-pre-annotation. The annotators tried to independently annotate the same texts, finding samples for different senses of relations, exploring problems respectively and discussing issues together, and the experienced annotator checked their work and provided advice for each of them. This step repeated three times until the annotators were all well trained;
- Group pre-annotation. To ensure consistency between the annotators, they were divided into two groups to annotate the same texts and compare their annotation;
- Formal annotation. We annotated 10 TED talks per cycle. During each cycle, the annotated texts from the annotators would be handed in to the experienced annotator who gathered problems existing in their annotation and gave suggestions. Uncertain or new issues would be discussed in the weekly meeting. After each cycle, we exchanged the partner between different groups;
- Check and improve. This phase is very critical for minimizing errors.

3.4 Agreement Study

To ensure annotation consistency, we measured annotators' consistency in annotating specific types of relations which are explicit, implicit, Altlex, NoRel, EntRel, Hypophora, senses from the top level to the third level. Kappa is a quantitative measure of reliability for two raters that are rating the same thing, corrected for how often that the raters may agree by chance. The formulas are:

$$K = \frac{P_o - P_e}{1 - P_e}, P_o = P(consistent)/500; \tag{1}$$

$$P_e = P(correct) + P(incorrect); \tag{2}$$

$$P(correct) = (\frac{A+B}{A+B+C+D}) * (\frac{A+C}{A+B+C+D}); \tag{3}$$

$$P(incorrect) = (\frac{C+D}{A+B+C+D}) * (\frac{B+D}{A+B+C+D}); \tag{4}$$

A quantifies instances where both the annotators' annotations are correct; D does so where both annotators' annotations are incorrect. B quantifies instances where annotator 1 is incorrect while annotator 2 is correct, while C does the reverse. P_o refers to the agreement rate for 500 instances. P(consistent) quantifies instances where the annotators are consistent. We compute the Kappa value and agreement rate between two annotators and then get the average Kappa value and agreement rate among the six annotators. Our results of agreement study can be seen from Table 3.

As is indicated in the Table 3, we achieve relatively high agreement results and Kappa value for the discourse relation type and top-level senses ($\geqslant$ 0.9). Moreover, strong results on the second-level and third-level senses were also achieved, with an agreement rate of 0.85 and Kappa value of 0.83 for the second level senses and agreement rate of 0.83 and Kappa value of 0.81 for the third level.

4 Statistics on TED-CDB

Table 4 shows statistics on TED-CDB. The corpus contains 15,540 discourse relations, which is almost three times as large as the number of discourse relations in Chinese Discourse Treebank (Zhou and Xue, 2015). Of these, 5,531 are explicit relations, while 7,015 are implicit. This means that implicit relations are more frequent in Chinese spoken discourse, while approximately the same number of explicit and implicit relation are

---

[2] https://github.com/wanqiulong0923/TED-CDB

RelType	Explicit	Implicit	AltLex	EntRel	Hypophora	Norel	Total
Intra-Sentence	5,301	3,209	943	390	4	0	9,847
Inter-Sentence	230	3,806	91	614	355	597	5,693
Total	5,531	7,015	1,034	1,004	359	597	15,540

Table 4: Distribution of 6 kinds of relations annotated in the TED-CDB, within and across sentences.

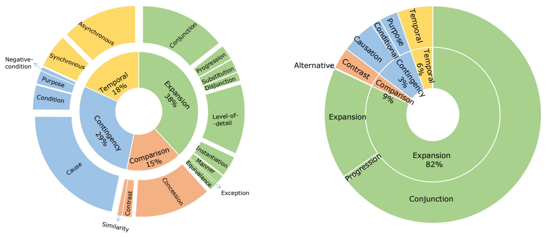

Figure 1: Distribution of the first and second level senses in TED-CDB (a) and CDTB (b)

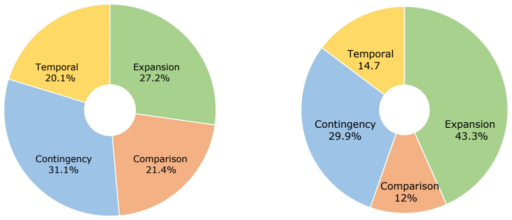

Figure 2: Distribution of the first level senses for explicit relations (a) and implicit relations (b) in TED-CDB.

found in the PDTB-3. There is also a large number of Altlex relations (1034). This type of relations is crucial for automatically identifying discourse relations under the circumstance of no explicit connectives. In our work, we try to detect all possible Altlex expressions that are capable of conveying the discourse relations.

The number of the intra-sentential relations and inter-sentential relations in PDTB-3 are almost the same, but clearly, we can see that the discourse relations in our corpus are more commonly annotated within the sentence, consisting of 9,847 intra-sentential relations and 5,693 inter-sentential relations. The reason perhaps lies in the use of punctuation, which is quite different in Chinese than in English. For example, a comma sometimes serves the same function as a full stop in English (Xue and Yang, 2011). Therefore, a long Chinese sentence may require the use of multiple English sentences to express the same content and preserve grammatically (Li et al., 2014). This may be why there are more intra-sentential relations in Chinese than in English.

We also compared the CDTB and our TED-CDB with respect to the sense distribution. This is displayed in Figure 1(a) and 1(b). CDTB uses an annotation style similar to the PDTB for the texts from the Chinese Treebank corpus. For a discourse relation, one of eight discourse relation senses is assigned. Although all senses in the CDTB are at the same level of the hierarchy, we can map them to the four top-level relation senses in the PDTB hierarchy according to their definitions: Alternative → Expansion; Causation → Contingency; Conditional → Contingency; Conjunction → Expansion;

Contrast → Comparison; Expansion → Expansion; Purpose → Contingency; Temporal → Temporal, progression → Expansion; From Figure 1(b), most relations in CDTB are Expansion, constituting the largest percentage of 82%, while the percentage of other 3 types of relation is less than a quarter. On the contrary, Figure 1(a) clearly shows that TED-CDB sees a balanced and rich distribution over the senses. The percentage of Expansion is higher than other types of relations, but it just represents 38%, while contingency, temporal, and comparison can validate their existence, accounting for 29%, 18% and 15% respectively. Moreover, there are several different second-level senses under each of the four top-level senses, among which Cause is the most.

To explore the discourse differences between implicit and the explicit relations, we compare the distribution of top-level senses between the two corpora. Figure 2(a) and 2(b) show that there are more Contingency relations among the explicits, whereas there are more Expansion relations among the implicits. The statistics also tell us that in explicit relations, "因为" (because) and "所以" (so) are the top two most frequent connectives.

5 Experiments

This section describes benchmark experiments for discourse relation recognition on our dataset.

5.1 Methods

We used the state-of-the-art pretrained language models and fine-tuned them on our corpus to con-

Table 6: Results on level-2 discourse relation classification; F1 score(%) for each level-2 relation in the PDTB-3 hierarchy plus the "Progression" sense relation for both explicit and implicit relation on TED-CDB; Total macro F1 and Total Accuracy are for all level-2 senses in the hierarchy; "-" means there is no the type of sense in the test set.

duct the benchmark test. Particularly, we used the following three baselines:

- BERT, a bidirectional encoder from transformers (Devlin et al., 2019) which is tuned towards two objectives: masked language modeling and next sentence prediction. We adopted two BERT systems: BERT-wwm and BERT-wwm-est (Cui et al., 2019). "-wwm" denotes whole word masking, which means that if a part of a complete word (i.e., wordpiece) is replaced by [mask], the other parts of the same word will also be replaced by the mask. "-est" denotes the model trained on a larger data (5.4B).
- ERNIE (115M)[3], a.k.a Enhanced Representation through Knowledge Integration (Sun et al., 2019), which is trained with not only Wikipedia data but also community QA, Baike (similar to Wikipedia), etc.
- ROBERTa, a robust BERT (Liu et al., 2019). We used ROBERTa-wwm-est-large.[4]

For all models, we used the default hyper-parameters (batch=8, learning_rate=2e-5, epoch=10). BERT-wwm (110M) and BERT-wwm-ext have the same hidden size H=768 trained in different size of tokens (0.4B and 5.4B respectively). And ROBERTa-wwm-est (325M) has hidden size H=1024, which is trained in the same way as ROBERTa but without next sentence prediction, with more training steps.

We adopted the F1 and accuracy rate to evaluate both explicit and implicit relation recognition. Moreover, we evaluated the tasks on both the top level (4-way classification) and second level (18-way classification). We used 80% of the dataset as the training set, 10% as dev set and 10% as test set.

5.2 Results

As can be seen from Table 5 and 6, these pre-trained models perform differently on our dataset, but most of the differences are not large. With respect to the 4-way relation classification, all four models achieve high results for the explicit relations, with average accuracy and average F1 all above 92%. This may indicate good annotation consistency for the explicit relations in the corpus. On the other hand, implicit relation classification is much more difficult for the models, with an average accuracy of 60% and average F1 score of 57%. As for the second level (18-way classification), Table 6 shows

---

[3] https://github.com/PaddlePaddle/ERNIE

[4] https://github.com/ymcui/Chinese-BERT-wwm

	Acc	Macro F1
Expansion	98.92	96.59
Comparison	25.00	40.00
Contingency	11.11	16.67
Temporal	00.00	00.00
Total	93.45	38.31

Table 7: F1 score (%) and total accuracy (%) for level-1 implicit relation classification on CDTB

that the models still obtain quite good results for explicit relations. However, it becomes more challenging for them to classify the implicit relations for the second level. Even the best model among them, ROBERTa-wwm-ext just achieves an accuracy of 49.79% and F1 of 36.45%. In short, we can see how challenging it is for the state-of-the-art models to improve the performance of implicit relation classification on our TED-CDB corpus, which can be used as a testbed for future efforts devoted to spoken discourse relation recognition.

6 Transfer Learning via TED-CDB

We also conducted transfer learning experiments across discourse corpora in different domains and languages. In particular, we considered the following two tasks for transfer learning: (1) training on TED-CDB snf testing on CDTB and (2) training on TED-CDB and testing on TED-MDB. The former is for transfer learning across domains of the same language, while the latter for transfer learning across seven languages within the same domain. The goal of these transfer learning experiments is to investigate if TED-CDB would be helpful for improving the performance of systems being developed for other languages and for insufficient or unbalanced data in other corpora.

6.1 Same-Language Cross-Domain Learning

While the best pre-trained models just can achieve an accuracy of around 60% for 4-way classification and less than 50% for 18-way classification on implicit relations on our dataset, we have noticed that models in previous work (Rutherford et al., 2017) can achieve a significantly higher accuracy of more than 85% on CDTB. Therefore, we used the BERT-wmm model with the same parameters as in our baseline experiments to perform 4-way implicit relation classification on CDTB. Table 7 shows that, although the accuracy of the model is 93.45%, its F1 score is just 38.31%. A closer look at the model performance at each type of sense shows that this high accuracy can be attributed to the most common sense relation, Expansion, on which the accuracy is 98.92%. However, accuracy for the other, less-frequent senses is much lower. In particular, the relation of Temporal gets 0 for both Accuracy and Macro F1. The reason behind this is that the sense distribution of CDTB is quite unbalanced, and most of the annotated relations are Expansion as shown in 1(b), while the number of implicit relation of Temporal can be counted. In other words, the training data for other sense types are not sufficient. Therefore, we wonder whether it is useful that our dataset serves as training set to test all the three types of relations in CDTB, while the relations of Expansion category are removed from both datasets. The model we used here is the BERT-wwm, whose parameters are the same as before.

	Zero-shot for CDTB	TED-CDB
Comparison	50.70	38.16
Contingency	87.35	75.00
Temporal	44.90	70.19
Macro F1	60.98	61.11
Acc	77.00	66.75

Table 8: F1 score (%) and total accuracy (%) for comparison of 3-way implicit relation classification. The left is the result for zero-shot learning from TED-CDB to CDTB, while the right is for TED-CDB.

Table 8 shows the 3-way implicit relation classification results on TED-CDB and those of the zero-shot transfer learning from TED-CDB on CDTB. Compared with the model performance for 3-way implicit relation classification on TED-CDB, Contingency and Comparison get better scores when these three kinds of relations in CDTB are used as the test set for models fine-tuned on TED-CDB. However, for the type of Temporal, the model trained on TED-CDB does not perform well for the CDTB test set. We looked into the test set and discovered that there are only 7 implicit relations of Temporal and that the annotation for several is not consistent with what we tend to annotate, for example:

(6) [集体分东西]$_1$,[他分到的一份肯定最差]$_2$。
“[If the group distribute things]$_1$,[what he gets must be the worst]$_2$. ”

	Expansion		Comparison		Contingency		Temporal		Total Macro F1	
	Cross validation	Zero-shot	Cross validation	Zero-shot	Cross validation	Zero-shot	Cross validation	Zero-shot	Cross validation	Zero-shot
English	55.66	67.30	00.00	45.45	34.27	44.64	38.14	61.54	32.02	54.73
German	31.60	62.30	00.00	29.17	32.55	28.57	37.66	46.67	25.45	41.67
lithuanian	75.58	65.47	00.00	23.81	03.05	36.36	11.90	22.22	22.63	36.97
Polish	13.58	61.92	00.00	22.22	25.46	26.51	20.05	19.51	14.77	32.54
Portuguese	67.16	66.89	00.00	36.36	14.29	30.51	30.67	28.57	28.93	40.58
Russian	55.43	58.09	00.00	27.27	20.75	18.35	20.39	23.53	24.14	31.81
Turkish	00.00	62.26	00.00	34.62	27.19	26.53	27.61	48.28	13.70	42.92

Table 9: F1 Score (%) for cross validation within TED-MDB and zero-shot transfer learning from TED-CDB to TED-MDB; The task is 4-way (level-1) implicit relation classification; Total Macro F1 are for all level-1 senses in each language.

For this example, we might annotate it as contingency. Condition, whereas in CDTB the sense of Temporal is assigned to the two arguments.

6.2 Same-Domain Cross-Language Learning

TED-MDB (Zeyrek et al., 2018) corpus annotation follows the PDTB 3.0 framework. It contains manual annotation of 6 TED talks in seven languages (English, Turkish, European Potuguese, Polish, German, Russian, and Lithuanian). The sub-corpus for each language is quite small, with about 200 implicit discourse relations each, compared with the ∼7.0 K implicit relations in the TED-CDB. Therefore, we can see whether the TED-CDB can help them. For this experiment, the multilingual BERT was used, which is as large as BERT-wwm but the training data is expanded to cover 104 languages. We used the multilingual BERT implementation from Huggingface.[5] The design for these experiments is making a comparison between a cross validation within the TED-MDB and a zero-shot transfer learning from TED-CDB to TED-MDB. Due to the unbalanced distribution of senses in TED-MDB, using the method of Easy Ensemble (Liu, 2009), we divided the Expansion data of every language in the TED-MDB into 4 parts and then each part was added into the data of other types to become the training set. Finally, we integrated these training sets from 6 language into one training set, and the left data for one language would be the test set. Therefore, what we used here is 4-fold cross validation where each fold is used as the test set exactly once. The average test set accuracy is then reported.

Table 9 shows the results for transfer learning from TED-CDB to TED-MDB and cross validation within TED-MDB for the task of 4-way implicit relation classification. Comparing the performances with and without our TED-CDB as training set suggests that using the model trained on TED-CDB leads to noticeably better performance for all 7 languages in TED-MDB. In addition, when TED-CDB is used for training, the performance for the 7 languages is close to that for TED-CDB data itself as test set. In particular, from the table, it is noteworthy that the performance on Comparison dramatically increases with the model trained on TED-CDB.

7 Conclusion

We have presented TED-CDB, a large-scale dataset for discourse relations on spoken monologues in Chinese. It is equipped with high-quality annotations and linguistic elements tailored for both Chinese and the genre of spoken monologue. The benchmark results of pretrained language models suggest that TED-CDB is a challenging dataset, which can be used to promote further development on discourse relation recognition and discourse-level NLP tasks. Moreover, we display the ability of TED-CDB to help address the issue of insufficient or unbalanced data on other corpora and improve the performance of models for other languages.

QADiscourse - Discourse Relations as QA Pairs: Representation, Crowdsourcing and Baselines

Abstract

Discourse relations describe how two propositions relate to one another, and identifying them automatically is an integral part of natural language understanding. However, annotating discourse relations typically requires expert annotators. Recently, different semantic aspects of a sentence have been represented and crowd-sourced via question-and-answer (QA) pairs. This paper proposes a novel representation of discourse relations as QA pairs, which in turn allows us to crowd-source wide-coverage data annotated with discourse relations, via an intuitively appealing interface for composing such questions and answers. Based on our proposed representation, we collect a novel and wide-coverage QADiscourse dataset, and present baseline algorithms for predicting QADiscourse relations.

1 Introduction

Relations between propositions are commonly termed *Discourse Relations*, and their importance to the automatic understanding of the content and structure of narratives has been extensively studied (Grosz and Sidner, 1986; Asher et al., 2003; Webber et al., 2012). The automatic parsing of such relations is thus relevant to multiple areas of NLP research, from extractive tasks such as document summarization to automatic analyses of narratives and event chains (Li et al., 2016; Lee and Goldwasser, 2019).

So far, discourse annotation has been mainly conducted by experts, relying on carefully crafted linguistic schemes. Two cases in point are PDTB (Prasad et al., 2008; Webber et al., 2019) and RST (Mann and Thompson, 1988; Carlson et al., 2002). Such annotation however is slow and costly. Crowd-sourcing discourse relations, instead of using experts, can be very useful for obtaining larger-scale training data for discourse parsers.

Table 1: Sentences with their corresponding Question-and-Answer pairs. The bottom example shows how *implicit* relations are captured as QAs.

One plausible way for acquiring linguistically meaningful annotations from laymen is using the relatively recent QA methodology, that is, converting a set of linguistic concepts to intuitively simple Question-and-Answer (QA) pairs. Indeed, casting the semantic annotations of individual propositions as narrating a QA pair gained increasing attention in recent years, ranging from QA driven Semantic Role Labeling (QASRL) (He et al., 2015; FitzGerald et al., 2018; Roit et al., 2020) to covering all semantic relations as in QAMR (Michael et al., 2018). These representations were also shown to improve downstream tasks, for example by providing indirect supervision for recent MLMs (He et al., 2020).

In this work we address the challenge of crowd-sourcing information of higher complexity, that of discourse relations, using QA pairs. We present the QADiscourse approach to representing intra-sentential Discourse Relations as QA pairs, and we show that with an appropriate crowd-sourcing setup, complex relations between clauses can be effectively recognized by non-experts. This layman annotation could also easily be ported to other languages and domains.

Specifically, we define the QADiscourse task to be the detection of the two discourse units, and the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2804–2819,
November 16–20, 2020.

labeling of the relation sense between them. The two units are represented in the question body and the answer, respectively, while the question type, as expressed by its prefix, represents the discourse relation sense between them. This representation is illustrated in Table 1 and the types of questions we focus on are detailed in Table 3. This scheme allows us to ask about both *explicit* and *implicit* relations. To our knowledge, there has been no work on collecting such question types in a systematic way.

The contribution of this paper is thus manifold. (i) We propose a novel QA-based representation for discourse relations reflecting a subset of the sense taxonomy of PDTB 3.0 (Webber et al., 2019). (ii) We propose an annotation methodology to crowd-source such discourse-relations QA pairs. And, (iii) given this representation and annotation setup, we collected QADiscourse annotations for about 9000 sentences, resulting in more than 16600 QA pairs, which we will openly release. Finally, (iv) we implement a QADiscourse parser, serving as a baseline for predicting discourse questions and respective answers, capturing multiple discourse-based propositions in a sentence.

2 Background

Discourse Relations Discourse Relations in the Penn Discourse Treebank (PDTB) (Prasad et al., 2008; Webber et al., 2019), as seen in ex. (1), are represented by two arguments, labeled either *Arg1* or *Arg2*, the discourse connective (in case of an explicit relation) and finally the relation sense(s) between the two, in this case both Temporal.Asynchronous.Succession and Contingency.Cause.Reason.

(1) BankAmerica climbed 1 3/4 to 30 (*Arg1*) **after** *PaineWebber boosted its investment opinion on the stock to its highest rating* (*Arg2*).

These relations are called *shallow* discourse relations since, contrary to the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988; Carlson et al., 2002), they do not recursively build a tree. The PDTB organizes their sense taxonomy, of which examples can be seen in Table 3, into three levels, with the last one denoting the direction of the relation. The PDTB annotation scheme has additionally been shown to be portable to other languages (Zeyrek et al., 2018; Long et al., 2020).

QASRL: Back in Warsaw that year, Chopin **heard** Niccolò Paganini **play** the violin, and **composed** a set of variations, Souvenir de Paganini.
What did someone **hear**? Niccolò Paganini play the violin When did someone **compose** something? that year
QAMR: Actor and television host Gary Collins died yesterday at age 74.
What kind of host was Collins? television How old was Gary Collins? 74

Table 2: Examples of QASRL and QAMR annotations.

Semantic QA Approaches Using QA structures to represent semantic propositions has been proposed as a way to generate "soft" annotations, where the resulting representation is formulated using natural language, which is shown to be more intuitive for untrained annotators (He et al., 2015). This allows much quicker, more large-scale annotation processes (FitzGerald et al., 2018) and when used in a more controlled crowd-sourcing setup, can produce high-coverage quality annotations (Roit et al., 2020).

As displayed in Table 2, both QASRL and QAMR collect a set of QA pairs, each representing a single proposition, for a sentence. In QASRL the main target is a predicate, which is emphasized by replacing all content words in the question besides the predicate with a placeholder. The answer constitutes a span of the sentence. The annotation process itself for QASRL is very controlled, by suggesting questions created with a finite-state automaton. QAMR, on the other hand, allows to freely ask all kinds of questions about all types of content words in a sentence.

QA Approaches for Discourse The relation between discourse structures and questioning has been pointed out by Van Kuppevelt (1995), who claims that the discourse is driven by explicit and implicit questions: a writer carries a topic forward by answering anticipated questions given the preceding context. Roberts (2012) introduces the term *Question Under Discussion* (QUD), which stands for a question that interlocuters accept in discourse and engage in finding its answer. More recently, there has been work on annotating QUDs, by asking workers to identify questions raised by the text and checking whether or not these raised questions get answered in the following discourse (Westera and Rohde, 2019; Westera et al., 2020). These QUD annotations are conceptually related to QADiscourse by representing discourse information through QAs, solicited from laymen speakers.

The main difference lies in the propositions captured: we collect questions that have an answer in the sentence, targeting specific relation types. In the QUD annotations (Westera et al., 2020) any type of question can be asked that might or might not be answered in the following discourse.

Previous Discourse Parsing Efforts Most of the recent work on models for (shallow) discourse parsing focuses on specific subtasks, for example on argument identification (Knaebel et al., 2019), or discourse sense classification (Dai and Huang, 2019; Shi and Demberg, 2019; Van Ngo et al., 2019). Full (shallow) discourse parsers tend to use a pipeline approach, for example by having separate classifiers for implicit and explicit relations (Lin et al., 2014), or by building different models for intra- vs. inter-sentence relations (Biran and McKeown, 2015). We also adopt the pipeline approach for our baseline model (Section 6), which performs both relation classification and argument identification, since our QA pairs jointly represent arguments and relations.

Previous Discourse Crowdsourcing Efforts There has been research on how to crowd-source discourse relation annotations. Kawahara et al. (2014) crowd-source Japanese discourse relations and simplify the task by reducing the tagset and extracting the argument spans automatically. A follow-up paper found that the data quality of these Japanese annotations was lacking compared to expert annotations (Kishimoto et al., 2018). Furthermore, Yung et al. (2019) even posit that it is impossible to crowdsource high quality discourse sense annotations and they suggest to re-formulate the task as a discourse connective insertion problem. This approach has previously also been used in other configurations (Rohde et al., 2016; Scholman and Demberg, 2017). Similarly to our QADiscourse approach, inserting connectives also works with soft natural language annotations, as we propose, but it simplifies the task greatly, by only annotating the connective, rather than retrieving complete discourse relations.

3 Representing Discourse Relations as QA pairs

In this section we discuss how to represent shallow *discourse relations* through QA pairs. For an overview, consider the second sentence in Table 1, and the two predicates 'decided' and 'knowing', each being part of a discourse unit. The sense of the discourse relation between these two units can be characterized by the question prefix "Despite what ...?" (see Table 3). Accordingly, the full QA pair represents the proposition asserted by this discourse relation, with the question and answer corresponding to the two discourse units. A complete QADiscourse representation for a text would thus consist of a set of such QAs, representing all propositions asserted through discourse relations.

The Discourse Relation Sense We want our questions to denote relation senses. To define the set of discourse relations covered by our approach, we derived a set of question templates that cover most discourse relations in the PDTB 3.0 (Webber et al., 2019; Prasad et al., 2008), as shown in Table 3. Each question template starts with a question prefix, which specifies the relation sense. The placeholder X is completed to capture the discourse unit referred to by the question, as in Table 1.

Few PDTB senses are not covered by our question prefixes. First, senses with pragmatic specifications like *Belief* and *SpeechAct* were collapsed into their general sense. Second, three *Expansion* senses were not included because they usually do not assert a new "informational" proposition, about which a question could be asked, but rather capture structural properties of the text. One of those is *Expansion.Conjunction*, which is one of the most frequently occurring senses in the PDTB, especially in intra-sentential VP conjunctions, where it makes up about 70% of the sense instances (Webber et al., 2016). Ex. (2) displays a discourse relation with two senses, one of which *Expansion.Conjunction*. While it is natural to come up with a question targeting the causal sense, the conjunction relation does not seem to assert any proposition about which an informational question may be asked.

(2) "Digital Equipment announced its first mainframe computers, *targeting IBM's* ***largest*** *market* and *heating up the industry's* ***biggest*** *rivalry*." (explicit: *Expansion.Conjunction*, implicit: *Contingency.Cause.Result*)

Finally, we removed *Purpose* as a (somewhat subtle) individual sense and subsumed it with our two causal questions.

Our desiderata for the question templates are as follows. First, we want the question prefixes to be applicable to as many scenarios as possible in

PDTB Sense	Question Template
Expansion.Substitution	Instead of what X?
Expansion.Disjunction	What is an alternative to X?
Expansion.Exception	Except when X?
Comparison.Concession	Despite what X?
Comparison.Contrast	What is contrasted with X?
Expansion.Level-of-detail	What is an example of X?
Comparison.Similarity	What is similar to X?
Temporal.Asynchronous	After/Before what X?
	Until/Since when X?
Temporal.Synchronous	While what X?
Contingency.Condition	In what case X?
Contingency.Neg.-cond.	Unless what X?
Expansion.Manner	In what manner X?
Contingency.Cause	What is the result of X?
	What is the reason X

Table 3: Informational PDTB senses mapped to our question templates.

1. And I also **feel** like in a capitalistic **society**, checks and balances **happen** when there **is** competition.
In what case do checks and balances happen? when there is competition in a capitalistic society
2. Whilst **staying** in the hotel, the Wikimedian group **met** two MEPs who **chose** it in-preference to dramatically more-expensive Strasbourg accommodation.
What is contrasted with the hotel? dramatically more-expensive Strasbourg accommodation
3. There were no fare hikes **announced** as both passenger and freight fares had been **increased** last month.
What is the reason there were no fare hikes announced? as both passenger and freight fares had been increased last month
What is the result of both passenger and freight fares having been increased last month? There were no fare hikes announced

Table 4: Example sentences with their corresponding Question-and-Answer pairs.

which discourse relations can occur, while at the same time ideally adhering to a one-to-one mapping of sense to question. Similarly, we avoid question templates that are too general. The WHEN-Question in QASRL (Table 2), for instance, can be used for either Temporal or Conditional relations. Here we employ more specific question prefixes to remove this ambiguity. Finally, as multiple relation senses can hold between two discourse units (Rohde et al., 2018), we similarly allow multiple QA pairs for the same two discourse units.

The Discourse Units The two sentence fragments, typically clauses, that we relate with a question are the discourse units. In determining what makes a discourse unit, we include verbal predicates, noun phrases and adverbial phrases as potential targets. This, for example, would also cover such instances: “Because of the rain ...” or “..., albeit warily”. We call the corresponding verb, noun or adverb heading a discourse unit a *target*.

A question is created by choosing a question prefix, an auxiliary, if necessary, and copying words from the sentence. It can then be manually adjusted to be made grammatical. Similarly, the discourse unit making up the answer consists of words copied from the sentence and can be modified to be made grammatical. Our question and answer format thus deviates considerably from the QASRL representation. By not introducing placeholders, questions sound more natural and easy to answer compared to QASRL, while still being more controlled than the completely free form questions of QAMR. In addition, allowing for small grammatical adjustments introduces valuable flexibility which contribute to the intuitiveness of the annotations.

Relation Directionality Discourse relations are often directional. Our QA format introduces directionality by placing discourse units into either the question or answer. In some question prefixes, a single order is dictated by the question. As seen in ex. 1 of Table 4, because the question asks for the *condition*, the condition itself will always be in the answer. Another ordering pattern occurs for *symmetric* relations, meaning that the relation’s assertion remains the same no matter how the arguments are placed into the question and answer, as in ex. 2 in Table 4. Finally, certain pairs of relation senses are considered *reversed*, such as for causal (reason vs. result) and some of the temporal (before vs. after) question prefixes. In this case, two QA pairs with different question prefixes can denote the same assertion when the target discourse units are reversed, as shown in ex. 3 in Table 4. These patterns of directionality impact annotation and evaluation, as would be described later on.

4 The Crowdsourcing Process

Pool of Annotators To find a suitable group of annotators we followed the Controlled Crowdsourcing Methodology of Roit et al. (2020). We first released two trial tasks, after which we selected the best performing workers. These workers then underwent two short training cycles, estimated to take about an hour each, which involved reading the task guidelines, consisting of 42 slides[1], completing 30 HITs per round and reading personal feedback after each round (preparing these feed-

---

[1] `https://github.com/ValentinaPy/QADiscourse`

backs consumed about 4 author work days). 11 workers successfully completed the training.

For collecting production annotations of the Dev and Test Sets, each sentence was annotated by 2 workers independently, followed by a third worker who adjudicated their QA pairs to produce the final set. For the Train Set, sentences were annotated by a single worker, without adjudication.

Preprocessing In preprocessing, question targets are extracted automatically using heuristics and POS tags: a sentence is segmented using punctuation and discourse connectives (from a list of connectives from the PDTB). For each segment, we treat the last verb in a consecutive span of verbs as a separate target. In case a segment does not contain a verb, but does start with a discourse connective, we choose one of the nouns (or adverbs) as target. The following illustrates our target extraction: *[Despite labor-shortage* ***warnings****,] [80%* ***aim*** *for first-year wage increases of under 4%;] [and 77%* ***say*** *they'd try to* ***replace*** *workers,] [if* ***struck****,] [or would* ***consider*** *it.]*

Annotation Tool and Procedure Using Amazon Mechanical Turk, we implemented two interfaces[2], one for the *QA generation* and one for the *QA adjudication* step.

In the *QA generation* interface, workers are shown a sentence with all target words in bold. Workers are instructed to generate one or more questions that relate two of these target words. The question is generated by first choosing a question prefix, then, if applicable, an auxiliary, then selecting one or more spans from the sentence to form the complete question, and lastly, change it to make it grammatical. Given the generated question, the next step involves answering that question by selecting span(s) from the sentence. Again, the answer can also be amended to be made grammatical.

The *QA adjudication* interface displays a sentence and all the QA pairs produced for that sentence by two annotators. For each QA pair the adjudicator is asked to either label it as *correct*, *not correct* or *correct, but not grammatical*. Duplicates and nonsensical QA pairs labeled as *not correct* are omitted from the final dataset. As a last step, the first author manually corrected all the *not grammatical* instances.

Data and Cost We sampled sentences from the Wikinews and Wikipedia sections of Large Scale QASRL (FitzGerald et al., 2018) while following their Train, Dev & Test splits. Descriptive statistics for the final dataset are shown in Table 5 and 6.

Dataset Split	Sentences	Questions
Wikinews Train	3098	4760
Wikinews Dev	669	1108
Wikinews Test	658	1498
Wikipedia Train	3277	6225
Wikipedia Dev	667	1524
Wikipedia Test	678	1498
Overall	9047	16613

Table 5: Dataset Statistics: Number of sentences containing at least 1 QA annotation and the total number of QAs collected.

QA Prefix	Count	Proportion
In what manner X?	4225	25%
What is the reason X?	3238	19%
What is the result of X?	2735	16 %
What is an example of X?	1757	11 %
After what X?	1099	7 %
While what X?	1060	6 %
In what case X?	509	3 %
Despite what X?	477	3 %
What is contrasted with X?	317	2 %
Before what X?	299	2 %
Since when X?	279	2 %
What is similar to X?	218	1 %
Until when X?	155	1 %
Instead of what X?	105	1 %
What is an alternative to X?	92	$\leq$ 1 %
Except when X?	27	$\leq$ 1 %
Unless what X?	21	$\leq$ 1%

Table 6: Counts of collected question types.

Annotating a sentence of Dev and Test yielded 2.11 QA pairs with a cost of 50.3¢ on average. For Train, the average cost was 37.1¢ for 1.72 QAs per sentence.

5 Dataset Evaluation

5.1 Evaluation Metrics

We aim to evaluate QA pairs, as the output of both the annotation process and the question generation and answering model, which are not the same as discourse relation triplets. There are multiple difficulties that arise when evaluating the QADiscourse setup. We allow multiple labels per proposition pair and thus need evaluation measures suitable for multi-label classification. Annotators are generating the questions and answers, which contrary to a pure categorical labelling task implies that we have to take into consideration question and answer paraphrasing and natural language generation inconsistencies. This requires us to use metrics that create alignments between sets of QAs, which means that existing discourse relation evaluation methods, such as from CoNLL-2015 (Xue et al.,

---

[2] Please refer to the appendix for all UI screenshots.

2015), are not applicable. The following metrics, which we apply for both the quality analysis of the dataset and the parser evaluation, are closely inspired by previous work on collecting semantic annotations with QA pairs (Roit et al., 2020; FitzGerald et al., 2018).

Unlabeled Question and Answer Span Detection (UQA) (F1) This metric is inspired by the question alignment metric for QASRL, which takes into account that there are many ways to phrase a question and therefore an exact match metric will be too harsh. Given a sentence and two sets of QA pairs produced for that sentence, such as gold and predicted sets, we want to match the QAs from the two sets for comparison. A QA pair is aligned with another QA pair that has the maximal *intersection over union* (IOU) ≥ 0.5 on a token-level, or else remains unaligned[3]. Since we allow multiple QA pairs for two targets, we also allow one-to-many and many-to-many alignments. As we are evaluating unlabeled relations at this point, we do not consider relation direction and therefore do not differentiate between question and answer spans.

Labeled Question and Answer Span Detection (LQA) (Accuracy) Given the previously produced alignments from UQA we check for the exact match of aligned question prefixes. For many-to-many and many-to-one alignments we count as correct if there is overlap of at least one question prefix. *Reversed* and *symmetric* question prefixes are converted to a more general label for fair comparison.

5.2 Dataset Quality

Inter-Annotator Agreement (IAA) To calculate the agreement between individual annotators we use the above metrics (UQA and LQA) for different worker-vs-worker configurations. The setup is the following: A set of 4 workers annotates the same sentences (around 60), from which we then calculate the agreement between all the possible pairs of workers. We repeat this process 3 times and show the average agreement scores in Table 7. The scores after adjudication, pertaining to the actual dataset agreement level, are produced by comparing the resulting annotation of two worker triplets, each consisting of two annotators and a separate adjudicator on the same data, averaged over 3 samples of 60 sentences each. These results show that adjudication notably improves agreement.

	UQA	LQA
Before Adjud.	76.87	56.64
After Adjud.	87.44	65.46

Table 7: IAA scores before and after adjudication.

5.3 Agreement with Expert Set

Our Expert set consists of 25 sentences annotated with QA pairs by the first author of the paper. Comparing the adjudicated crowdsourced annotations with the Expert Set yields a UQA (LQA) of **93.9** (**80**), indicating a high quality of our collected annotations. The main issue in disagreement arises from sentences that do not contain overt propositional discourse relations, where workers attempt to ask questions anyways, resulting in sometimes unnatural or overly implicit questions.

5.4 Comparison with PDTB

We crowdsourced QA annotations of 60 sentences from section 20 of the PDTB (commonly used as Train) with our QA annotation protocol. The PDTB arguments are aligned with the QA-pairs using the UQA metric, by considering *Arg1* and *Arg2* as the text spans to be aligned with the question and answer text[4], yielding **83.2** Precision, **87.5** Recall and an F1 of **85.3**.

A manual comparison of the PDTB labels with the Question Prefixes reveals that in most of the cases the senses overlap in meaning, with some exceptions on both sides. 60% of aligned annotations correspond exactly in the discourse relation sense they express. The remaining 40% of the QA-pairs belong to either of the following categories:

(1) Discourse relations that we deemed to be non-informational at the propositional level were many times still annotated with our QA pairs. Take this sentence: [...], *a Soviet-controlled regime remains in Kabul*, the refugees sit in their camps, and *the restoration of Afghan freedom seems as far off as ever*. The PDTB posits an *Exp.Conjunction* relation between the two cursive arguments, which is a relation type that we do not cover in the QA framework, yet our annotators saw an implied causal relation which they expressed with the following (sensible) QA pair: **What is the reason** *the restoration of Afghan freedom seems as far off as ever?* -

---

[3] The average length for tokenized questions and answers is 12.22 and 10.27 respectively.

[4] Such alignment is usually straightforward, since annotators do not add content words when producing QAs.

Frank Carlucci III was named to this telecommunications companyś board, filling the vacancy created by the death of William Sobey last May. (Contingency.Cause.Result)
After what was Frank Carlucci III named to this telecommunications company's board? the death of William Sobey last may *What is the reason* Frank Carlucci III was named to this telecommunications company's board? filling the vacancy created by the death of William Sobey last May

Table 8: Example of a QADiscourse relation which was not captured in the PDTB.

Question Prefix	Count

In what manner	19
While/After/Before what	19
What is an example of	10
Since/Until when	5
In what case	4
Despite what	1

Table 9: Count of QADiscourse Question Prefixes of questions that could be aligned to QAMR.

a soviet-controlled regime remains in Kabul.

(2) Interestingly, we observe that some annotation decision difficulties described in the PDTB (Webber et al., 2019) are also mirrored in our collected data. One of those arising ambiguities is the difference between *Comparison.Contrast* and *Comparison.Concession*, in our case *Despite what* and *What is contrasted with*. In the manually analyzed data sample, 3 such confusions were found between the QADiscourse and the PDTB annotations.

(3) There were 15 instances of PDTB relation senses that were erroneously not annotated with an appropriate QA pair, even though a suitable Question Prefix exists, corresponding to some of the 12.5% recall misses in the comparison.

(4) On the contrary, there were 36 QA instances that capture appropriate propositions which were completely missed in the PDTB [5]. For example, in Table 8, the PDTB only mentions the causal relation, while QADiscourse found both the causal and the temporal sense:

Additionally we noticed that annotators tend to ask "What is similar to..?" questions about conjunctions, indicating that conjoined clauses seem to imply a similarity between them, while the similarity relation in the PDTB is rather used in more explicit comparison contexts. The "In what case..?" questions were sometimes used for adjuncts specifying a time or place. Overall, these comparisons show that agreement with the PDTB is good, with QADiscourse even finding additional valid relations, indicating that it is feasible to crowdsource high-quality discourse relations via QADiscourse.

5.5 Comparison with QAMR and QASRL

While commonly treated as two distinct levels of textual annotations, there are nevertheless some commonalities between shallow discourse relations and semantic roles. This interplay of discourse and semantics has also been noted by Prasad et al. (2015), who made use of clausal adjunct annotations in PropBank to enrich intra-sentential discourse annotations and vice versa. Similarly, we found that there are questions in QASRL, QAMR and QADiscourse which express kindred relations: *Manner*, *Condition*, *Causal* and *Temporal* relations could all be asked about using QASRL-like WH-Question. But then the point of question ambiguity arises: if "When" can be used to ask about conditional relations, it is more often also used to denote temporal relations. This under-specification becomes problematic when attempting to map between QAs and labels from resources such as PropBank. Therefore, despite the propositional overlap of some of the question types, QADiscourse additionally enriches and refines QASRL annotations.

Since QAMR does not restrict itself to predicate-argument relations only, we performed an analysis of whether annotators tend to ask about QADiscourse-type relations in a general QA setting. 965 sentences contain both QAMR and QADiscourse annotations, with 1505 QADiscourse pairs, of which we could align 101 (7%) to QAMR annotations, using the UQA-alignment algorithm. We conclude that QAMR and QADiscourse target mostly different propositions and relation types.

Within the 101 QADiscourse QAs that were aligned with QAMR questions (Table 9), causal and temporal relations are very common, usually expressed, as expected, by "Why" or "When" questions in QAMR. In other cases, the aligned questions express different relation senses. Notably, the QADiscourse *In what manner* relation aligns with a "How" QAMR question only once out of 19 cases. Often, it seems that QADiscourse annotators were tempted to ask a somewhat inappropriate *manner* question while the relation between the predicate and the answer corresponded to a direct semantic role (like location) rather than to a discourse

---

[5] The full list of these instances can be found in the appendix.

She said he "had friends in every political party ..."
QADISC.: *In what manner* did he have friends? QAMR: *Where* does he have friends? ANSWER: in every political party
... your internet access provider can still keep track of what websites you visit, websites can collect information about you and so on.
QADISC.: *What is an example of* something your internet access provider can still keep track of? QAMR: Your provider can keep track of *what?* ANSWER: what websites you visit

Table 10: Examples of interesting aligned cases between QAMR and QADiscourse.

relation (first example in Table 10). The second example in Table 10 corresponds to a case where the predicate-answer relation has two senses, a discourse sense captured by QADiscourse (*What is an example of*), as well as a semantic role ("theme"), captured by a "What" question in QAMR. These observations suggest interesting future research on integrating QADiscourse annotations with semantic role QA annotations, like QASRL and QAMR.

6 Baseline Model for QADiscourse

In this section we aim to devise a baseline discourse parser based on our proposed representation, which accepts a sentence as input and outputs QA pairs for all discourse relations in that sentence, to be trained on our collected data. Similarly to previous work on discourse parsing (Section (1)), our proposed parser is a pipeline consisting of three phases: *(i) question prefix prediction*, *(ii) question generation*, and *(iii) answer generation*.

Formally, given a sentence $X = x_0, ..., x_n$ with a set of indices I which mark target words (based on the target extraction heuristics in Section 4), we aim to produce a set of QA-pairs (Q_j, A_j) using the following pipeline:

1. *Question Prefix Prediction*: Let Ψ be the set of all Question Prefixes, each reflecting a relation sense from the list shown in Table 3. For each target word x_i, such that $i \in I$, we predict a set of possible question prefixes $P_{x_i} \subseteq \Psi$. The set $P = \bigcup_{i \in I} P_{x_i}$ is now defined to be the set of all prefixes for all targets in the sentence.

2. *Question Generation*: For every question prefix $p \in P$ and all its relevant target words $P_p = \{x_i | p \in P_{x_i}\}$, predict question bodies for one or more of the targets $Q_p^1, ..., Q_p^m$.

3. *Answer Generation*: Let a full question FQ_p^j be defined by the concatenation of the question prefix and the corresponding generated question body $FQ_p^j = \langle p, Q_p^j \rangle$. Given a sentence X and the question FQ_p^j, we aim to generate an answer A_p^j.

All in all, we can generate up to $|I| \times |\Psi|$ different QAs per sentence.

6.1 Question Prefix Prediction

In the first step of our pipeline we are given a sentence and a marked target, and we aim to predict a set of possible prefixes reflecting potential discourse senses for the relation to be predicted. We frame this task of predicting a set of prefixes as a multi-label classification task.

To represent I, the input sentence $X = x_0, ..., x_n$ is concatenated with a binary target indicator, and special tokens are placed before and after the target t_i. The output of the system is a set of question prefixes P_{x_i}.

We implement the model using BERT (Devlin et al., 2019) in its standard fine-tuning setting, except that the Softmax layer is replaced by a Sigmoid activation function to support multi-label classification. The predicted question prefixes are obtained by choosing those labels that have a logit $>= \tau = 0.3$, which was tuned on Dev to maximize UQA F1. Since the label distribution is skewed, we add weights to the positive examples for the binary cross-entropy loss.

6.2 Question Generation

Next in our pipeline, given the sentence, a question prefix and its relevant targets in the sentence, we aim to generate question bodies for one or more of the targets. To this end, we employ a Pointer Generator model (Jia and Liang, 2016) such that the input to the model is encoded as follows: $[CLS]$ $x_1, x_2 ... x_n$ $[SEP]$ p $[SEP]$, with $p \in P$ being the question prefix. Additionally, we concatenate a target indicator for all relevant targets P_p. The output is one or more question bodies Q_p separated by a delimiter token: Q_p^1 $[SEP]$ Q_p^2 $[SEP]$ ... Q_p^m.

The model then chooses whether to copy a word from the input, or to predict a word during decoding. We use the ALLENNLP (Gardner et al., 2018) implementation of COPYNET (Gu et al., 2016) and adapt it to work with BERT encoding of the input.

6.3 Answer Generation

To predict the answer given a full question, we use BERT fine-tuned on SQUAD (Rajpurkar et al., 2016).[6] We additionally fine-tune the model on

a subset of our training data (all 5004 instances where we could align the answer to a consecutive span in the sentence). Instead of predicting or copying words from the sentence, this model predicts start and end indices in the sentence.

7 Results and Discussion

After running the full pipeline, we evaluate the predicted set of QA-pairs against the gold set using the UQA and LQA metrics, described in section 5.1. Table 12 shows the results. Note that the LQA is dependent on the UQA, as it calculates the labeled accuracy only for QA pairs that could be aligned with UQA. The Prefix Accuracy measure complements LQA by evaluating the overall accuracy of predicting a correct question prefix. For this baseline model it shows that generally only half of the generated questions have a question prefix equivalent to gold, leaving room for future models to improve upon. While not comparable, Biran and McKeown (2015), for example, mention an F1 of 56.91 for predicting intra-sentential relations.

The scores in Table 13 show the results for the subsequent individual steps, given gold input, evaluated using a matching criterion of intersection over union >= 0.5 with the respective gold span.

We randomly selected a sample of 50 predicted QAs for a qualitative analysis. 22 instances from this sample were judged as correct, and 2 instances were correct despite not being mentioned in Gold. Examples of good predictions are shown on the left column in Table 11. The model is often able to learn when to do the auxiliary flip from clause to question format and when to change the verb form of the target. Interestingly, whenever the model was not familiar with a specific verb, it chose a similar verb in the correct form, for example 'appearing' in Ex. 2. The model is also able to form a question using non-adjacent spans of the sentence (Ex. 1). Some predictions do not appear in the dataset, but make sense nonetheless. The analysis showed 8 non-grammatical but sensible QAs (i.e. ex. 4, where the sense of the relation is still captured), 8 non-sensical but grammatical QAs (ex. 5) and 7 QAs that were neither (ex. 6). Lastly, we found 3 QAs with good questions and wrong answers.

8 Conclusion

In this work, we show that discourse relations can be represented as QA pairs. This intuitive representation enables scalable, high-quality annotation via crowdsourcing, which paves the way for learning robust parsers of informational discourse QA pairs. In future work, we plan to extend the annotation process to also cover inter-sentential relations.

Acknowledgments

We would like to thank Amit Moryossef for his help with the implementation of the frontend, and Julian Michael, Gabriel Stanovsky and the anonymous reviewers for their feedback and suggestions. This work was supported in part by grants from Intel Labs, Facebook, the Israel Science Foundation grant 1951/17 and the German Research Foundation through the German-Israeli Project Cooperation (DIP, grant DA 1600/1-1) and by an ERC-StG grant #677352 and an ISF grant #1739/26.

A Appendices

A.1 Reproducibility information

The code to reproduce the QADiscourse model can be found at `https://github.com/ValentinaPy/QADiscourse`.

Calculating the weights for the Loss of the Prefix Classifier Each question prefix label is weighted by subtracting the label count from the total count of training instances and dividing it by the label count: $weight_x = total\_instances - count_x/(count_x + 1e-5)$.

A.2 Annotation Details

The number of examples and the details of the splits are mentioned in the paper. The data collection process has also been described in the main body of the paper. Here we add a more detailed description of the Target Extraction Algorithm and screenshots of the annotation interfaces.

Target Extraction Algorithm In order to extract targets we use the following heuristics: We split the sentence on the following punctuation: "," ";" ":". This provides an initial incomplete segmentation of clauses and subordinate clauses. We will try to find at least one target in each segment.

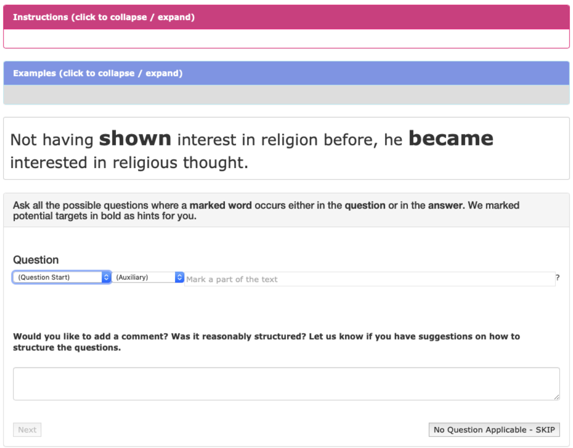
We then split the resulting text spans from 1. using a set of discourse connectives. We had to remove the most ambiguous connectives from the list, whose tokens might also have other syntactic functions, for example "so, as, to, about", etc.

We then check the POS tags of the resulting spans and treat each consecutive span of verbs as a target, with the last verb in the consecutive span being the target. In order to not treat cases such as "is also studying" as separate targets, we treat "V ADV V" also as one consecutive span. In case there is no verb in a given span, we chose one of the nouns as the target, but only if the span starts with a discourse connective. This condition allows us to not include nouns as targets that are simply part of enumerations, while at the same time it helps include eventive nouns, see b) for an example. To improve precision (by 0.02) we also excluded the following verbs "said, according, spoke".

With these heuristics we achieve a Recall of 98.4 and a Precision of 57.4 compared with the discourse relations in Sec. 22 of the PDTB.

Cost Details The basic cost for each sentence was 18¢, with a bonus of 3¢ for creating a second QA pair and then a bonus of 4¢ for every additional QA pair after the first two. Adjudication was rewarded with 10¢ per sentence. On average 50.3¢ were spent per sentence of Dev and Test, with an average of 2.11 QA pairs per sentence. For Train the average cost per sentence is about 37.1¢, with an average of 1.72 QAs.

Annotation Interfaces The following screenshots display the Data Collection and Adjudication interfaces.



Not having **shown** interest in religion before, he **became** interested in religious thought.

Ask all the possible questions where a **marked word** occurs either in the **question** or in the **answer.** We marked potential targets in bold as hints for you.

A.3 Data Examples

Sentence	Question	Answer
An inquest found he'd committed suicide, but some dispute this and believe it was an accident .	Instead of what do some believe it was an accident?	suicide
On Sunday, in a video posted on YouTube, Anonymous announced their intentions saying, "From the time you have received this message, our attack protocol has past been executed and your downfall is underway."	Since when has our attack protocol past been executed and your downfall is underway?	From the time you have received this message
It is unclear why this diet works.	Despite what does this diet work?	Being unclear why
It's a downgraded budget from a downgraded Chancellor [...] Debt is higher in every year of this Parliament than he forecast at the last Budget.	What is similar to it's a downgraded budget?	It's a downgraded Chancellor
According to Pakistani Rangers, the firing from India was unprovoked in both Sunday and Wednesday incidents; Punjab Rangers in the first incident, and Chenab Rangers in the second incident, retaliated with intention to stop the firing.	What is the reason punjab Rangers and Chenab Rangers retaliated?	with intention to stop the firing
The vessel split in two and is leaking fuel oil .	After what did the vessel leak fuel oil?	The vessel split in two
In contrast to the predictions of the Met Office, the Environment Agency have said that floods could remain in some areas of England until March, and that up to 3,000 homes in the Thames Valley could be flooded over the weekend.	What is contrasted with the predictions of the Met Office?	the Environment Agency have said that floods could remain in some areas of England until March, and that up to 3,000 homes in the Thames Valley could be flooded over the weekend

Table 14: Examples for QA pairs that were annotated in the dataset.

Sentence	Question	Answer
Standard addition can be applied to most analytical techniques and is used instead of a calibration curve to solve the matrix effect problem.	Instead of what is standard addition used?	a calibration curve
State officials therefore share the same interests as owners of capital and are linked to them through a wide array of social, economic, and political ties.	What is similar to state officials share the same interests as owners of capital?	are linked to them through a wide array of social, economic, and political ties
Recently, this field is rapidly progressing because of the rapid development of the computer and camera industries.	What is the reason this field is rapidly progressing?	Because of the rapid development of the computer and camera industries
Civilization was the product of the Agricultural Neolithic Revolution; as H. G. Wells put it, "civilization was the agricultural surplus."	In what manner was civilization the product of the Agricultural Neolithic Revolution?	civilization was the agricultural surplus
The portrait shows such ruthlessness in Innocent's expression that some in the Vatican feared that Velázquez would meet with the Pope's displeasure, but Innocent was well pleased with the work, hanging it in his official visitor's waiting room.	Despite what was Innocent well pleased with The work?	The portrait shows such ruthlessness in Innocent's expression that some in the Vatican feared that Velázquez would meet with the Pope's displeasure
All tropical cyclones lose strength once they make landfall.	After what do tropical cyclones lose strength?	once they make landfall
The investigation, led by former Dutch General Patrick Cammaert , is separate from the investigation led by the UN's Human Rights Council.	What is contrasted with the investigation, led by former Dutch General Patrick Cammaert?	the investigation led by the UN's Human Rights Council

Abstract

This paper proposes to adapt self-attention to discourse level for modeling discourse elements in argumentative student essays. Specifically, we focus on two issues. First, we propose structural sentence positional encodings to explicitly represent sentence positions. Second, we propose to use inter-sentence attentions to capture sentence interactions and enhance sentence representation. We conduct experiments on two datasets: a Chinese dataset and an English dataset. We find that (i) sentence positional encodings can lead to a large improvement for identifying discourse elements; (ii) a structural relative positional encoding of sentences shows to be most effective; (iii) inter-sentence attention vectors are useful as a kind of sentence representation for identifying discourse elements.

1 Introduction

Discourse describes how a document is organized. This paper focuses on the task of discourse element identification (DEI) in argumentative student essays. Discourse elements represent the function and contribution of every discourse unit to the discourse. Burstein et al. (2003) formulate discourse elements as 5 categories: *introduction*, *thesis*, *main idea*, *supporting* and *conclusion*, while argument components such as *major claim*, *claim* and *premise* are used as discourse elements in argumentation structure parsing in persuasive essays (Stab and Gurevych, 2014). DEI can benefit automated essay scoring in many aspects: modeling organization, inferring topics and opinions or used as features for scoring systems (Attali and Burstein, 2006; Burstein et al., 2001; Persing et al., 2010; Song et al., 2020).

Despite its importance, DEI is challenging.

First, the ambiguity of sentences makes learning models difficult to distinguish some discourse elements. For example, the *thesis* is defined as expressing the central claim of the author and the *main ideas* support the *thesis* from specific aspects. However, it is hard to distinguish them from their content and style.

Second, the discourse element of a specific sentence depends on context. As a result, considering individual sentences only would have difficulties in identifying discourse elements. The relations and relatedness among multiple sentences should be explored.

Third, the data imbalance problem is serious, e.g., the number of *elaboration* sentences could be 10 times more than the number of *thesis* sentences. The minority discourse elements (such as *thesis*, *main ideas* or *major claim*) are harder to be recalled although they have important roles in many scenarios, e.g., evaluating the organization of essays (Attali and Burstein, 2006).

In this paper, we propose a method to explicitly model sentence positions and relations to improve discourse element identification in argumentative student essays. Our idea is partially motivated by the self-attention mechanism such as (Vaswani et al., 2017). Self-attention is usually applied to capture dependencies between words. We aim to apply self-attention mechanism to describe relations between sentences.

On one hand, position information is important for DEI to give clues on discourse elements beyond content and style, because authors usually hold some conventions to organize content. Position is one of the most useful feature classes in feature-based DEI (Burstein et al., 2003; Stab and Gurevych, 2014). Previous neural network models usually cast DEI as a classification or sequence labeling task and do not explicitly model position information. Motivated by the positional encoding of words, we propose a simple structural positional encoding strategy for a sentence by considering its

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2820–2830,
November 16–20, 2020.

relative position in its essay, relative position of its paragraph in its essay, and its relative position within its paragraph.

On the other hand, relatedness among sentences may also indicate properties of discourse elements. For example, *thesis* sentences should have close relations to the whole essay; main ideas usually locate in similar positions and have high relatedness. Relatedness between discourse elements has shown to be an important indicator of essay coherence (Higgins et al., 2004). We compute inter-sentence attention vectors to represent either element-wise or content-wise relations to other sentences, which bring in additional information beyond individual sentences and enhance sentence representation without extra information.

Experiments show that the proposed approach can get considerable improvements compared with feature-based and neural network based baselines on a Chinese dataset and obtain competitive results compared with the state-of-the-art method on an English dataset. The structural positional encodings of sentences show effectiveness to achieve obvious overall improvements. The inter-sentence attention vectors enhance sentence representation helping identify discourse elements as well.

2 Related Work

2.1 Discourse Element Identification

DEI could be seen as a subtask in discourse structure analysis. It aims to identify discourse elements, determine their functions and establish relationships among them in an argumentative text.

Typical tasks in this line include argumentative zoning (Teufel et al., 1999) , argumentation mining (Mochales and Moens, 2011; Lippi and Torroni, 2016) and analyzing argumentative student essays (Burstein et al., 2003; Stab and Gurevych, 2014). Argumentative zoning identifies arguments in scientific articles (Teufel et al., 1999; Guo et al., 2010). Argumentation mining aims to identify argument components and relations from legal texts (Palau and Moens, 2009; Mochales and Moens, 2011) or argumentative texts (Stab and Gurevych, 2014; Daxenberger et al., 2017).

The solutions to these tasks usually adopt similar machine learning methods but use domain related features. The methods could be roughly classified into the following categories.

Classification based methods cast DEI as a classification problem. Various classifiers have been tested, such as SVM (Stab and Gurevych, 2014), decision trees (Burstein et al., 2003, 2001) and naive Bayes, maximum entropy model (Moens et al., 2007; Palau and Moens, 2009).

Sequence labeling based methods exploit contextual information for DEI with conditional random fields (Hirohata et al., 2008; Song et al., 2015) or recurrent neural networks (Daxenberger et al., 2017).

Establishing relations between sentences is often viewed as a classification tasks as well (Stab and Gurevych, 2014). **Parsing based methods** are also adopted to build more complex structures with techniques like ILP (Stab and Gurevych, 2017) or RST style parsing (Peldszus and Stede, 2015).

Feature engineering. Some common features are shared across these tasks, including syntactic, lexical, semantic and discourse relations. There are also domain related features to further boost the performance. Mochales and Moens (2011) designed special features for argumentation mining in legal texts. Nguyen and Litman (2015) identified claims based on domain words. Lippi and Torroni (2015) modeled syntactic structures for content independent claim detection based on tree kernels.

Our work is mostly related to DEI in argumentative student essays (Burstein et al., 2003; Stab and Gurevych, 2014), which is useful for qualifying essay organization (Persing et al., 2010), argumentation (Persing and Ng, 2016; Wachsmuth et al., 2016) and general writing (Burstein et al., 2003; Ong et al., 2014; Song et al., 2014). The major feature classes proposed by Burstein et al. (2003) and Stab and Gurevych (2014) are used to build a baseline. The features include: position, cue words, lexical features (main verbs, adverbs and connectives) and structural features (such as number of clauses). Some of these features are based on manually collected lexicons.

Deep Learning Methods have achieved great success in many NLP tasks. Eger et al. (2017) proposed neural argumentation mining models based on sequence tagging or dependency parsing. It exploits inter-sentence relations but needs sophisticated language processing. Daxenberger et al. (2017) exploited CNN and LSTM for classifying sentences to identify claims from different domains. It mainly depends on the content of components but does not sufficiently model positions and exploit inter-sentence relatedness.

2.2 Attention Mechanism for Discourse Representation

Attention mechanism was first introduced by (Bahdanau et al., 2015) in the encoder-decoder framework. Attention has the ability to learn important regions within a context and has been widely adopted in deep learning. Liu and Lapata (2018) proposed a structured attention mechanism to derive a tree over a text, akin to an RST discourse tree. Ferracane et al. (2019) evaluated the model, however, found multiple negative results. Attention mechanism has also been applied for RST parsing and its applications (Li et al., 2016; Ji and Smith, 2017; Huber and Carenini, 2019) but it is mostly used for capturing local semantic interactions.

2.3 Self-Attention Mechanism

Vaswani et al. (2017) proposed the self-attention mechanism and achieved state of the art results in many NLP tasks. Since then, self-attention has drawn increasing interests due to flexibility in modeling long range interactions.

Self-attention ignores word order in a sentence. As a result, position representations are developed to cooperate with self-attention. In addition to the sinusoidal position representation proposed by Vaswani et al. (2017), there are also other variations to bias the selection of attentive regions (Shen et al., 2018; Shaw et al., 2018; Yang et al., 2019). In NLP, self-attention is mostly applied to sequential structures such as a sequence of words. Mihaylov and Frank (2019) proposed a discourse-aware self-attention encoder for reading comprehension on narrative texts, where event chains, discourse relations and coreference relations are used for connecting sentences. Self-attention can be also extended to 2d-dimensions for image processing (Parmar et al., 2018) and lattice inputs (Sperber et al., 2019).

3 Baseline

We use Hierarchical BiLSTM (HBiLSTM), which is similar to (Yang et al., 2016), as the base model to model sentence and discourse level representations.

The task is to assign discourse element labels $\mathbf{y} = (y_1, ..., y_n)$ to sentences $(x_1, ..., x_n)$ in a text, where $x_i, 1 \leq i \leq n$, is a sentence of a sequence of words and $y_i \in \mathcal{Y}$, $\mathcal{Y}$ is a set of pre-defined discourse elements.

3.1 Sentence Representation Layer

A sequence of words $x = \{w_1, ..., w_N\}$ is modeled with a RNN encoder and is converted into a sequence of hidden states $\mathbf{H} = \{\mathbf{h}_1, ..., \mathbf{h}_N\}$. The hidden state at the i-th step is

$$\mathbf{h}_i = f\left(\mathbf{e}\left(w_i\right), \mathbf{h}_{i-1}\right), \tag{1}$$

where f is a RNN unit, $\mathbf{e}(w_i) \in \mathbb{R}^d$ is the embedding of a word, and $\mathbf{h}_{i-1}$ is the hidden state of the previous step. The whole sequence could be represented as a fixed length vector $\mathbf{c} = \phi(\{\mathbf{h}_1, \cdots, \mathbf{h}_N\})$ to represent the semantic of a sentence, where $\phi(\cdot)$ is a function to summarize hidden states.

In this work, Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) is used as the RNN unit and the sequence is encoded in a Bidirectional way that a hidden state $\mathbf{h}_i = [\overrightarrow{\mathbf{h}_i}; \overleftarrow{\mathbf{h}_i}]$ is the concatenation of the corresponding hidden states from both directions. The summarization function $\phi(\cdot)$ could be based on the attention mechanism.

3.2 Discourse Representation Layer

In the discourse element layer, we feed sentence representations $\mathbf{C} = (\mathbf{c}_1, ..., \mathbf{c}_n) \in \mathbb{R}^{d \times n}$ to a BiLSTM and use a nonlinear layer to map semantic representations to discourse element representations,

$$\mathbf{D} = \tanh(\mathrm{BiLSTM}\left(\mathbf{C}\right)). \tag{2}$$

3.3 Inference Layer

Finally, we use a linear and a softmax layer to predict the discourse element of every sentence,

$$\mathbf{Y} = \mathrm{softmax}\left(\mathrm{linear}(\mathbf{D})\right), \tag{3}$$

where $\mathbf{Y} \in \mathbb{R}^{|\mathcal{Y}| \times n}$ refers to the probabilities of every sentence over discourse element categories.

The baseline mainly exploits interactions between adjacent sentences, but long distance interactions and sentence positions are not explicitly considered, which may be also important to determine the function of sentences in argumentative discourse.

4 Discourse Self-Attention

We propose the Discourse Self-Attention (DiSA) layer to improve the baseline by explicitly modeling sentence positions and inter-sentence interactions. The architecture is illustrated in Figure 1.

The sentences in an essay are converted to sentence embeddings **C** through the BiLSTM encoder introduced in Section 3.1, which are used as the input of DiSA. DiSA explicitly represents sentence positions, which are integrated with the content representations of sentences to get element representations. DiSA also has an inter-sentence attention module to get both element-wise and content-wise attention vectors of sentences to capture sentence interactions. The attention vectors and element representations are concatenated and fed to a linear layer and a softmax layer for prediction.

4.1 Sentence Positional Encodings (SPE)

Discourse elements in argumentative essays are sensitive to their positions. For example, *introduction* mostly comes before *thesis* or *main ideas* and *main ideas* may occur more often at the beginnings or endings of paragraphs.

Figure 2 shows an essay with 7 sentences and 4 paragraphs as an example. We consider three types of sentence positions for positional encoding.

- **Global position**: The index of a sentence is used to describe its position where we assume sentences in an essay form a sequence.
- **Paragraph position**: An essay has multiple paragraphs. The position of the paragraph that contains the sentence is also important.
- **Local position**: The position of the sentence in its paragraph is informative as well.

We adopt a relative positional encoding approach. We compute the relative positions for the above three position types. For example, the relative global position of the i-th ($i \geq 1$) sentence in an essay E is

$$pos_{global}(i) = \frac{i}{|E|}, \tag{4}$$

where $|E|$ is the number of sentences.

To integrate with sentence representations, we expand $pos_{global}(i)$ to a vector of the same dimension d of the distributed sentence representations by duplicating its value to every dimension, noted as $\mathbf{pos}_{global}(i) \in \mathbb{R}^d$. The relative paragraph position representation $\mathbf{pos}_{para}(i)$ and relative local position representation $\mathbf{pos}_{local}(i)$ are computed in the same way.

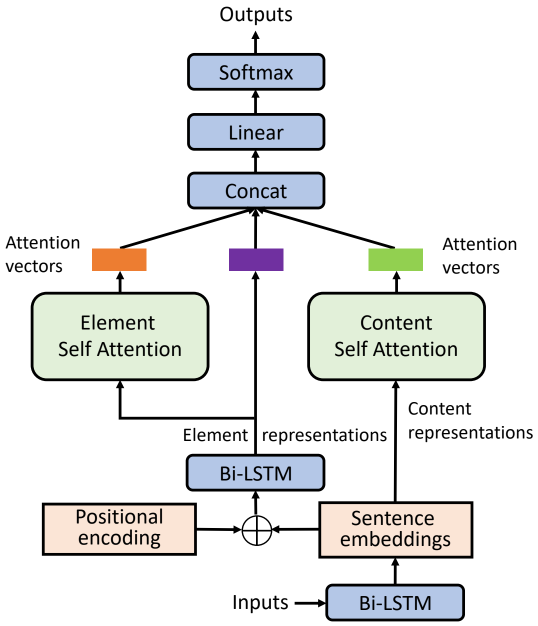

Figure 1: The architecture of Discourse Self-Attention.

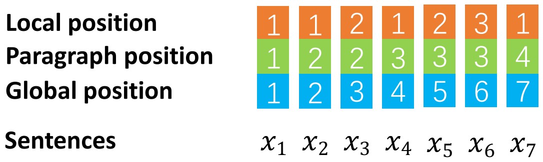

Local position	1	1	2	1	2	3	1
Paragraph position	1	2	2	3	3	3	4
Global position	1	2	3	4	5	6	7
Sentences	x_1	x_2	x_3	x_4	x_5	x_6	x_7

Figure 2: Three types of sentence positions for positional encoding.

The final position representation $\mathbf{pos}(i)$ is formulated as a liner combination of the three relative position representations, i.e.,

$$\mathbf{pos}(i) = \sum_{t \in \{global, local, para\}} \beta_t \mathbf{pos}_t(i), \tag{5}$$

where $\{\beta_t\}$ are parameters to be learnt in training. The element representation of the i-th sentence is

$$\mathbf{e}_i = \tanh(\text{BiLSTM}\,(\mathbf{C}_i + \mathbf{pos}(i))). \tag{6}$$

4.2 Inter-Sentence Attention (ISA)

Self-Attention relates elements at different positions by computing attention between every pair of elements. An attention function is to map a query and a set of key-value pairs to an output. The queries **Q**, keys **K** and values **V** are vectors. We define $\mathbf{Q}, \mathbf{K} \in \mathbb{R}^{d_k \times n}$ and d_k is the dimension. The attention is computed as

$$\boldsymbol{\alpha} = \text{Attn}(\mathbf{Q}, \mathbf{K}) = \text{softmax}(\frac{\mathbf{Q}\mathbf{K}^{\text{T}}}{\sqrt{d_k}}). \tag{7}$$

The output is computed as a weighted sum of the values, i.e., $\boldsymbol{\alpha}\mathbf{V}$. Here, we are interested in the attention vectors rather than the weighted output, because an attention vector reflects the relatedness of a given sentence to every other sentence. We propose the inter-sentence attention (ISA) by applying self-attention to sentence semantic representations $\mathbf{C}$ and discourse element representations $\mathbf{E} = \{\mathbf{e}_i\}$.

- **Element Self-Attention (ElemSA)**: ElemSA models relations among discourse elements. We use $\mathbf{E}$ to get $\mathbf{Q}$ and $\mathbf{K}$, $\mathbf{Q} = \mathbf{E}\mathbf{W}^Q$, $\mathbf{K} = \mathbf{E}\mathbf{W}^K$, where $\mathbf{W}^Q, \mathbf{W}^K \in \mathbb{R}^{d \times d_k}$. We do not use the normalized attention vectors as shown in Equation 7 to capture relative relatedness. Instead, we use $\boldsymbol{\alpha}_e = \tanh(\frac{\mathbf{Q}\mathbf{K}^{\mathrm{T}}}{\sqrt{d_k}})$ as attention vectors.

- **Content Self-Attention (ContSA)**: ContSA explores content relatedness to model sentence interactions. Similarly to ElemSA, we use the sentence semantic representations $\mathbf{C}$ to compute the ContSA vector $\boldsymbol{\alpha}_c$. The parameters are independent from ElemSA.

Adaptive Maxpooling Different essays have different number of sentences. To have a fixed-length attention vector, we borrow the idea of spatial pyramid pooling from image processing (He et al., 2015). It can maintain relatedness information by maxpooling $\boldsymbol{\alpha}_e$ and $\boldsymbol{\alpha}_c$ in local bins. These bins have sizes proportional to the number of an essay's sentences so that the number of bins is fixed regardless of the essay length. We set the number of bins to 1, 2, 4 and 8, respectively. The resulted representations can be seen as descriptions of the relatedness of a sentence to different zones of its essay. These representations are concatenated so that the dimension of the pooled attention vectors $\boldsymbol{\alpha}'_c$, $\boldsymbol{\alpha}'_e$ is 1+2+4+8=15.

Finally, the prediction is made according to

$$\mathbf{Y} = \mathrm{softmax}\left(\mathrm{linear}([\boldsymbol{\alpha}'_e; \boldsymbol{\alpha}'_c; \mathbf{E}])\right), \quad (8)$$

where $\boldsymbol{\alpha}'_c$, $\boldsymbol{\alpha}'_e$ and E are concatenated.

5 Datasets

5.1 The Chinese Dataset

The construction of the Chinese Dataset mainly follows the definition and taxonomy of discourse elements proposed by Burstein et al. (2003). Specifically, we consider the following discourse elements:

Element	**Train**	**Test**	**Total**	**%**
Introduction	2,859	285	3,144	9.5
Thesis	881	151	1,032	3.1
Main Idea	4,443	578	5,021	15.2
Evidence	5,972	679	6,651	20.1
Elaboration	12,405	1,127	13,532	41.0
Conclusion	3,086	333	3,419	10.3
Other	170	20	190	0.6
Total	29,816	3,173	32,989	
# essays	1,112	118	1,230	
Avg. #Chinese chars per essay			843	
Avg. #sentences per essay			27	
Avg. #words per sentence			21	

Table 1: Basic statistics of the Chinese dataset.

- **Introduction** The role of introduction is to introduce background or attract readers' attention before making claims.

- **Thesis** The thesis express the central claim of an author with respect to the essay's topic.

- **Main Idea** The ideas establish foundational ideas or aspects that are related to the thesis.

- **Evidence** The evidence elements provide examples or other evidence that are used to support main ideas and thesis.

- **Elaboration** The elaboration elements further explain main ideas or provide reasons, but contain no examples or other evidence.

- **Conclusion** The conclusion sentence is the extension of the central argument, summarizes the full text, and echos the thesis of the essay.

- **Other** Other elements refer to the ones that do not match the above classes.

The dataset has 1,230 argumentative essays written by high school students, covering diverse topics. These essays were collected from a website LeleKetang.[1] We asked two annotators from the literal arts college to assign discourse elements to sentences from these essays according to a manual. The annotators discussed to reach a consensus and refined the manual for several rounds. We use one annotator's annotation as the gold answer, and the other's annotation as the prediction, and compute the F1 scores to measure the agreement, which is shown in Figure 3.

Table 1 shows the basic statistics of the dataset. The distribution of discourse elements is imbalanced. *Elaboration* and *evidence* sentences are

---

[1] `http://www.leleketang.com/zuowen/`.

[To conclude, **art could play an active role in improving the quality of people's lives,**]$_{s_1}$ [but I think that **governments should attach heavier weight to other social issues such as education and housing needs**]$_{s_2}$ [because **those are the most essential ways enable to make people a decent life.**]$_{s_3}$

Table 2: A sentence from the dataset of (Stab and Gurevych, 2017), with clause level component annotations (in bold), are split into three individual sentences s_1, s_2 and s_3.

Element	Train	Test	Total	%
Major Claim	598	153	751	10.3
Claim	1,202	304	1,506	20.6
Premise	3,023	809	3,832	52.3
Other	999	232	1,231	16.8
Total	5,822	1,498	7,320	
# essays	322	80	402	
Avg. #sentences per essay			19	
Avg. #words per sentence			20	

Table 3: Basic statistics of the English dataset converted from (Stab and Gurevych, 2017).

many more than *thesis* and *main idea* sentences. The type of *other* sentence accounts for a very small percentage of the dataset. The test dataset is 10% of the whole dataset.

5.2 The English Dataset

We also use the English student essay dataset released by Stab and Gurevych (2017). This dataset marks argument components, i.e., *major claim, claim*, and *premise*, at clause level. Table 2 shows an example sentence. The consecutive words in bold form three components, corresponding to *claim, major claim* and *premise*, respectively.

Because our model is at sentence level, we convert the original annotations to sentence level. First, an essay is split into sentences by NLTK. Then if a sentence contains only one argument component, we annotate this sentence as the type of this component; if a sentence contains more than one argument component, we further separate it into multiple sentences to ensure that each sentence has only one argument. The beginning of a new sentence is from the end of the last component. The end of a new sentence is the end of the component it contains. As shown in Table 2, three sentences s_1, s_2 and s_3 are generated from the original example sentence. If a sentence does not have any argument component, its label is *other*. Table 3 shows the basic statistics of the converted dataset.

6 Experiment

6.1 Experimental Settings

The max length of sentences is set to 40 words. Sentences are padded or truncated according to this length. The Tencent pre-trained word embeddings (Song et al., 2018) were used for experiments on the Chinese dataset. The dimension of word embeddings is 200. The Bert tokenizer and embeddings were used for experiments on the English dataset. The dimension of all the BiLSTM hidden layers is 256 on Chinese dataset, and 128 on English dataset. So is the dimension of d_k. The dimension of the attention vectors is 15. The optimizer is stochastic gradient descent (SGD) with a learning rate 0.1. The best models were selected for all settings based on the results on the validation data, which is 10% of the training data.

We use accuracy (Acc.) and macro-F1 as evaluation metrics.

6.2 Comparisons

We compare with the following systems.

- Feature-based. We adapt features from previous feature-based methods (Burstein et al., 2003; Stab and Gurevych, 2014; Song et al., 2015) to build a feature-based CRF model.

- HBiLSTM. The baseline described in Section 3 uses two BiLSTM layers to encode word sequences and sentences.

- BERT. We fine-tune BERT on training data to train a sentence classifier, because the lengths of many Chinese essays exceed the length constraint of BERT and it is expensive to train BERT-like models at discourse level.

6.3 Results on the Chinese Dataset

6.3.1 System Comparisons

Table 4 shows the performance of the baselines and DiSA. We can see that HBiLSTM performs even worse than feature-based approach. HBiLSTM has a low macro-F1 score, indicating that it has difficulties in identifying particular discourse elements. The two end-to-end models do not consider position information and interactions among sentences. The performance of BERT is worse than HBiLSTM. This verifies that sequence modeling is more proper than single sentence classification for this task. DiSA achieves the best performance

Model	Acc.	macro-F1
Feature-based	0.623	0.581
BERT	0.569	0.507
HBiLSTM	0.592	0.540
DiSA	**0.681**	**0.657**

Table 4: System comparisons.

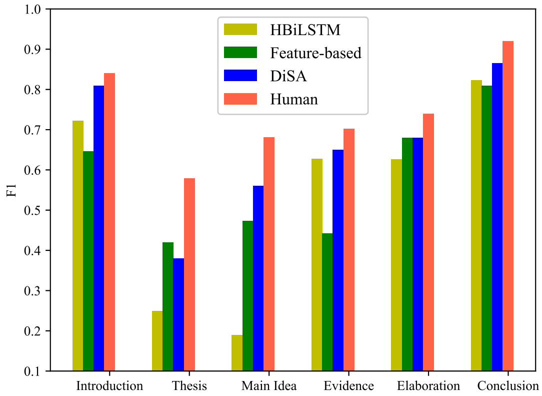

Figure 3: F1 scores on identifying specific discourse elements.

on all metrics, with a large improvement compared with the baselines.

Figure 3 further illustrates system performance on identifying specific discourse elements. The human performance is also measured by considering one annotator's annotation as the answer, and the other one's as the prediction.

The discourse elements that HBiLSTM is unable to accurately identify are *thesis* and *main idea*. Despite their importance for understanding a text, their scale is obviously smaller than other discourse elements, which may bring in obstacles for data-driven approaches.

Feature-based method performs better than HBiLSTM on identifying *thesis* and *main idea*. But it heavily relies on feature-engineering such as manually collected discourse markers and cue words. It does not perform well on identifying *evidence* due to the difficulties in designing related features.

DiSA is also an end-to-end model the same as HBiLSTM but performs much better. We will discuss the impacts of positional encoding and inter-sentence attention in Section 6.3.2 and 6.3.3.

Compared with the feature-based method, DiSA has comparable performance on identifying *thesis* but has superior results on identifying *main idea* (9% higher in F1 score) and *evidence* (21% higher in F1 score).

SPE Type	Acc.	macro-F1
Sinusoidal	0.674	0.638
PosEmbedding	0.657	0.628
RelativeSPE	**0.681**	**0.657**
No SPE	0.595	0.540
$+\mathbf{pos}_{global}$	0.591	0.540
$+\mathbf{pos}_{para}+\mathbf{pos}_{local}$	0.676	0.655

Table 5: The effects of different SPEs.

6.3.2 Analysis of Positional Encodings

This part investigates the effect of sentence positional encodings. We compare our relative sentence positional encoding (**relativeSPE**) with two other encoding strategies which are previously used for word sequences. **Sinusoidal** indicates the sinusoidal positional encoding which is used in Transformer (Vaswani et al., 2017). **PosEmbedding** uses a distributed vector to represent an absolute position. The position embeddings are learned during training. Each of the above three strategies is applied for modeling global position, local position and paragraph position, which are then combined according to Equation 5.

Table 5 lists the results of using different SPEs and modeling different positions. **RelativeSPE** performs best with improvements of 2-3% macro-F1 score compared with **Sinusoidal** and **PosEmbedding**. Without SPE, the metrics drop at least 6.2% compared with using any SPE strategy, and 8.6% compared with **relativeSPE**. If we explicitly add only $\mathbf{pos}_{global}$, the results even decrease. Perhaps recurrent neural networks such as LSTM naturally capture sequential positional information. However, encoding paragraph position ($\mathbf{pos}_{para}$) and local position ($\mathbf{pos}_{local}$) largely improves the performance. This indicates that proper structural positional encodings can exploit richer discourse structures than sequential structures.

6.3.3 Analysis of Inter-Sentence Attention

Table 6 shows the effects of removing inter-sentence attention (ISA) components from DiSA. We can see that both ElemSA and ContSA can make contributions, and ElemSA seems to have a larger effect on macro-F1 score. Removing ISA, the accuracy and the macro-F1 score decreases 1.8% and 2.2%.

Remind that ISA uses attention vectors as representations rather than the final output $\boldsymbol{\alpha}\mathbf{V}$ in the self-attention module. Table 6 also lists the performance that $\boldsymbol{\alpha}\mathbf{V}$ is used to replace attention vectors.

ISA Type	**Acc.**	**macro-F1**
DiSA	0.681	0.657
− ContSA	0.675	0.646
− ElemSA	0.677	0.647
− ISA	0.663	0.635
ISA with $\boldsymbol{\alpha}\mathbf{V}$	0.618	0.600

Table 6: The effects of inter-sentence attention (ISA).

Model	**DiSA**	**− ISA**	Δ
Introduction	**0.796**	0.792	−0.4%
Thesis	**0.383**	0.338	**−4.5%**
Main Idea	**0.577**	0.573	−0.4%
Evidence	**0.627**	0.578	**−4.9%**
Elaboration	**0.689**	0.677	−1.2%
Conclusion	**0.868**	0.850	− 1.8%

Table 7: Macro-F1 scores on identifying specific discourse elements.

The result is not good. This indicates that semantic relation among sentences is more important for DEI than the specific meaning of sentences.

We further analyze ISA's impact on specific discourse elements. As shown in Table 7, ISA affects the identification of the minority discourse element *thesis* most. It also benefits identifying *evidence* which is not a minority discourse element. Thesis sentences often relate to other sentences from different essay zones, while evidence sentences mainly provide facts or examples so they often relate to local context in content. ISA helps capture such patterns. The performance on other types also increases with different degrees.

Anyway, ISA provides a way to build useful representations by exploiting relations between sentences in the same text without any extra burden.

6.4 Results on the English Dataset

Table 8 and Table 9 show main experimental results on the English dataset.

The second column of Table 8 shows the results on distinguishing four component types (i.e., *major claim, claim, premise, other*). DiSA outperforms the baselines with a large margin on both accuracy and macro-F1. Again, removing SPE leads to a large performance decrease.

Stab and Gurevych (2017) conducted argument component classification experiments (classifying a component into *major claim, claim* and *premise*) by assuming that argument components have been correctly distinguished from *other* parts. To compare with their results, during training, the *other* type is removed from the label set and only the losses over *non-other* sentences are accumulated.

	4 classes		**3 classes**	
Model	**Acc.**	**macro-F1**	**Acc.**	**macro-F1**
BERT	0.673	0.596	-	-
HBiLSTM	0.680	0.501	-	-
DiSA	**0.772**	**0.699**	0.806	0.742
DiSA - SPE	0.687	0.529	0.710	0.534
DiSA+Feature	-	-	0.839	0.807
Eger et al. (2017)	-	-	-	0.730
Single-Best	-	-	-	0.773
Joint-Best	-	-	**0.850**	**0.826**

Table 8: Comparisons on the English dataset. Single-BEST and Joint-Best indicate the best results reported in (Stab and Gurevych, 2017), where Joint-Best incorporates relation identification as an auxiliary task.

The third column of Table 8 shows the comparison to the best results from (Stab and Gurevych, 2017). DiSA does not perform competitively based on the distributed representation only, because the baseline uses some strong hand-crafted features, especially the component position features, which rely on the correct argument component information. Thus we build a feature vector by incorporating the indicator features and a component position feature: number of preceding and following components in paragraph, out of 8 categories of features introduced in (Stab and Gurevych, 2017). The vector is concatenated with the distributed representation. This combination obtains improvements, outperforms Single-Best results, and achieves close performance compared with Joint-Best, which considers argumentative relation identification as an auxiliary task. We also attempt to apply the same strategy for the Chinese task. But the improvement is negligible. The reason may be that the indicator phrases used in Chinese essays is much less than in English essays. The English dataset heavily relies on phrases signaling beliefs or argumentative discourse connectors (Daxenberger et al., 2017).

Table 9 shows the macro-F1 scores of DiSA on identifying specific argument components. Without the ISA module, the identification of major claims and claims would decline by 3% and 1.4% absolute F1 score, respectively. This is consistent with the experimental results on the Chinese dataset. As a result, the effectiveness of the SPE and ISA can be verified on both the Chinese and the English datasets.

7 Conclusion

We presented a method DiSA to identify discourse elements in argumentative student essays by explicitly modeling structural positions and inter-

Model	DiSA	– ISA	Δ
Major Claim	**0.649**	0.619	−3.0%
Claim	**0.523**	0.509	−1.4%
Premise	**0.887**	0.882	−0.5%
Other	**0.737**	0.723	−1.4%

Table 9: Macro-F1 scores on identifying specific argument components on the English dataset.

sentence relations. The structural positional encoding considers relative positions of the sentence and its paragraph. Moreover, we use inter-sentence attention vectors to capture sentence relations in content and function. Experiments on a Chinese dataset and an English dataset show that (i) although it is simple, the positional encoding largely improves the performance. This indicates that modeling structural positions is feasible and important to analyze the role of sentences; (ii) discourse elements could be better identified with the help of inter-sentence attention vectors, especially the minority ones and the ones that have distinct relation patterns to other sentences. In future, we plan to evaluate DiSA on other discourse analysis tasks.

Abstract

Existing pre-trained large language models have shown unparalleled generative capabilities. However, they are not controllable. In this paper, we propose MEGATRON-CNTRL, a novel framework that uses large-scale language models and adds control to text generation by incorporating an external knowledge base. Our framework consists of a keyword predictor, a knowledge retriever, a contextual knowledge ranker, and a conditional text generator. As we do not have access to ground-truth supervision for the knowledge ranker, we make use of weak supervision from sentence embedding. The empirical results show that our model generates more fluent, consistent, and coherent stories with less repetition and higher diversity compared to prior work on the ROC story dataset. We showcase the controllability of our model by replacing the keywords used to generate stories and re-running the generation process. Human evaluation results show that 77.5% of these stories are successfully controlled by the new keywords. Furthermore, by scaling our model from 124 million to 8.3 billion parameters we demonstrate that larger models improve both the quality of generation (from 74.5% to 93.0% for consistency) and controllability (from 77.5% to 91.5%).

Context	[FEMALE] was on a long road trip .
Guan et al. (2020)	she had just driven into town . she had been driving for hours . she was so tired she decided to take a nap . when she woke up , she still had n't slept well .
MEGATRON-CNTRL-124M keyword: driving	she was on her way to see a strange country. she had never seen anything like that before. finally she saw a small town that was so small. it was a great little town with a nice park !
MEGATRON-CNTRL-8B keyword: driving	she was driving in the middle of [PLACE]. all of a sudden the tire pressure light came on. she got out to check her tire. it was flat so she used the roadside assistance.
MEGATRON-CNTRL-8B-ANT keyword: attract	she really wanted to see a few attractions. the first one she saw was a giant water park. it was amazing. it ended up being a fun experience.

Table 1: Stories generated by models of increasing capacity and controllability. As the model size grows, story quality becomes increasingly coherent, fluent, and logically consistent. The last row demonstrates how MEGATRON-CNTRL-8B-ANT model controls the story generation with a new keyword, "attract". Note that [MALE] and [FEMALE] denote names and [PLACE] denotes locations.

1 Introduction

Text generation has recently attracted significant attention from the research community as large pre-trained language models, such as GPT-2 (Radford et al., 2018, 2019) demonstrated promising results for generating long, grammatically correct, and fluent text. Finetuning these models has shown significant improvements in downstream tasks, such as persona chat (Wolf et al., 2019). However, one non-negligible drawback of these large models is the lack of knowledge which humans use to produce natural text. For example, GPT-2 based models produce degraded generations that are illogical and ungrammatical for knowledge-driven generation tasks, such as story generation. Guan et al. (2020) therefore introduced commonsense knowledge to the pre-trained language model by further finetuning on commonsense datasets. Although implicit encoding of knowledge is helpful for knowledge incorporation, there is still a lack of training mechanism to teach the model when and what to incorporate from external knowledge.

In addition, these large pre-trained language models are hard to control. Recently, plug-and-play language models Dathathri et al. (2019) addressed whole document controllability by adding a linear classifier on top of GPT-2 to predict whether generated text observes a particular style or property. Keskar et al. (2019) controlled a 1.2B parameter language model generation via the use of

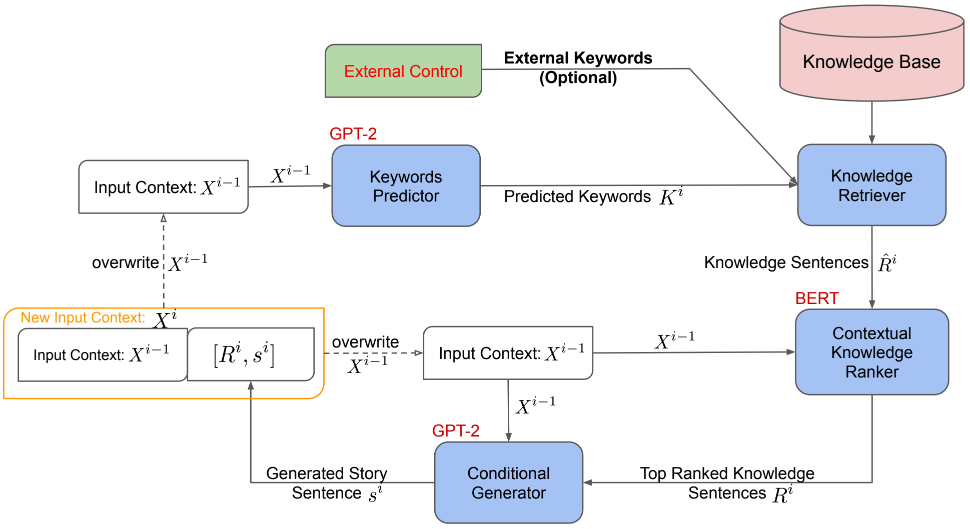

Figure 1: Overview of our generation process. Based on an input context, we generate keywords for future context, use the keywords to retrieve the relevant knowledge from an external knowledge-base, filter them based on their relevance to the context, and use the top scored knowledge sentences to guide the generation.

control codes prepended to the model input. Boyd et al. (2020) controlled the personality of a dialogue agent by conditioning it on prior conversations of a target actor. However, these controlling conditions are predefined, limited in their capability, and are only used once at the beginning to condition the generation of the rest of the document. They do not provide control granularity at either a sentence or sub-document level.

In this work, we address these shortcomings and develop an efficient controllable text generation framework that we apply to the story generation task. In order to provide manual control to users through a set of interpretable keywords, we first develop a keyword predictor model for the next sentence. These keywords are then used to retrieve knowledge sentences from an external knowledge base. Not all the retrieved knowledge is relevant to the story context and often it is noisy. To this end, we introduce a novel contextual ranker that ranks knowledge sentences based on the relevance to the context. As we do not have access to ground-truth supervision for this contextual knowledge ranker, we make use of sentence embedding for weak supervision. The top-ranked knowledge sentences from the knowledge ranker are then fed to the conditional text generator to guide generation. By giving the knowledge in addition to the context, we provide rich information for the generator to attend to and help the model better understand the rationale between sentences. Table 1 shows an example of controllable story generation with increasing model capacity.

Summary of Contributions:

- We propose a novel generation framework that allows dynamical incorporation of external knowledge into language model as well as control for text generation.
- Using both automatic metrics as well as human evaluations, we demonstrate that our model generates more fluent, consistent, and coherent stories with lower repetition rate and higher diversities compared to the previous state-of-the-art on ROC story datasets (Mostafazadeh et al., 2016).
- We showcase the controllability of our model by replacing the keywords used to generate stories. Human evaluation results show that up to 91.5% of the generated stories are successfully controlled by the new keywords .
- We scale our model from 124 million to 8.3 billion parameters and demonstrate that both qualities, as well as controllability of the generations, improve as the model size increases.

2 Framework

In our problem setup, we complete a story using the first sentence as input, similar to Guan et al. (2020). We augment the generation process with an external knowledge-base and develop a methodology that can guide and control the story generation. Our approach consists of the following four steps connected together as shown in Figure 1:

1. Given the story context, a keyword predictor model first predicts a set of keywords for the next sentence yet to be generated.
2. A knowledge retriever then takes the generated keywords and queries an external knowledge-base where each knowledge triple is converted into natural language "knowledge sentences" using templates.
3. A contextual knowledge ranker then ranks the external knowledge sentences based on their relevance to the story context.
4. Finally, a generator takes both the story context as well as the top-ranked knowledge sentences as input and generates the next sentence in the story. The output sentence is appended to the story context and steps 1-4 are repeated.

This formulation naturally allows controllability by replacing the keyword prediction process with manual external keywords. This work uses dynamic planning of the keywords and knowledge at each generation step. This allows the users to participate and control the generation on the go. As a result, they don't need to pre-specify the keywords explicitly. We also note that it is challenging to statically plan all the knowledge needed for generation at the beginning. This issue becomes severe for long generations. To formalize this method, we start by introducing notation used throughout the paper and then detail each aforementioned four steps in the following subsections.

Notation: A knowledge-base, G is defined as a set of knowledge triples $t = (\text{subject}, \text{relation}, \text{object})$. A knowledge sentence, r is defined as $r = T(t)$ by mapping t using predefined templates T. For example, *(eiffel tower, AtLocation, paris)* is transformed into *eiffel tower is at paris*. We should highlight that since our framework transforms the triple knowledge database into natural language sentences, any knowledge base in natural language format can be readily incorporated into our framework. We use superscripts to index *story sentences* and define a story S of length l as a sequence of individual story sentences s^i where $S = \{s^1, s^2, \cdots, s^l\}$. We use $K^i = \{k^i_1, \cdots, k^i_q\}$ to denote the keywords associated with story sentence s^i. A keyword k^i_q is made up of subword tokens from our language model's vocabulary. Note that the number of keywords q per sentence varies and can be zero. We define $R^i = \{r^i_1, \cdots, r^i_v\}$ as the knowledge associated with s^i, where r^i_j denotes the j-th *knowledge sentence* associated s^i. The number of knowledge sentences v varies per sentence and can be zero. Note that $v \neq q$ because a keyword can have multiple knowledge triples associated with it. Given this notation, we define the story context $X^i = \{x^1, \cdots, x^i\}$ where $x^i = [R^i, s^i]$. The goal of this work is to generate x^i given X^{i-1}, that is to first predict the knowledge R^i contained in s^i and then predict s^i itself.

2.1 Keyword Predictor Model

To provide manual control to users, we first develop a keyword predictor model. Given the current story context X^{i-1}, the model predicts a set of keywords K^i for the next sentence yet to be generated. The prediction of keywords instead of directly predicting knowledge triples not only allows us to control the generation in an interpretable manner, but it also helps to greatly reduce the search space for the knowledge triples. We formulate this keyword prediction problem similar to a left-to-right language model where the goal is to predict the string of concatenated keywords:

$$p(K^i|X^{i-1}) = \prod_{j=1}^{q} p(k^i_j|X^{i-1}, K^i_{<j}), \quad (1)$$

where $K_{<j}$ denotes all the predicted keywords up to the jth keyword and p is the probability distribution. We use a GPT-2 (Radford et al., 2019) transformer to model this probability distribution. We optimize the keyword predictor with maximum likelihood training and a next token prediction loss. Following Yao et al. (2019), we provide the labels for K^i by extracting keywords from a ground truth training sentence s^i using the RAKE algorithm (Rose et al., 2010) to train our keyword predictor. Note that our model allows generation of multiple keywords and thus provides the flexibility to choose a subset of them as the control signal to fit in the generation.

2.2 Knowledge Retrieval

In this step, we use the generated keywords K^i in Section 2.1 and retrieve all the related knowledge triples from our knowledge base G. This is simply done by converting all knowledge triples into knowledge sentences using predefined templates and then matching keywords against the knowledge sentences. This results in the knowledge set $\hat{R}^i = \{\hat{r}^i_1, \cdots, \hat{r}^i_z\}$ with size z. Future work will focus on replacing this simple retrieval with a learnable module similar to Guu et al. (2020).

Algorithm 1 Building Pseudo Label of R^i

```
Input: Story sentence $s^i$ and its preceding sentence $s^{i-1}$, USE encoder $U$, RAKE keywords extractor, and knowledge base $G$
Output: Pseudo Label of $R^i$
1: Extract keywords $K^i$ from $s^i$ using RAKE
2: Find $\bar{R} = \{T(t)|t \in G$ and $\exists k^i_j \in K^i$, s.t. $k^i_j \in t\}$
3: Encode each $\bar{r}_j \in \bar{R}$ to $U^r_j$ using USE
4: Encode $[s_{i-1}, s_i]$ to $U^s$
5: Compute cosine similarity $score$ between each $U^r_j$ and $U^s$
6: return $\bar{r}_j$s with the top $N$ highest $score$
```

2.3 Building Pseudo Label of R^i

The main challenge for controlling generation with knowledge is that we have no explicit access to the hidden, latent controlling knowledge humans use to supervise their story writing. That means R^i, the knowledge associated with s^i is not available. We, therefore, propose to use a weakly supervised signal to build the pseudo labels of R^i from s^i. We hypothesize that R^i should 1) overlap with s^i in terms of keywords and 2) have strong connections to both the preceding sentence s^{i-1} and s^i. We include s^{i-1} along with s^i because it is hard to retrieve appropriate knowledge using only s^i due to the ambiguity of natural language. We also did not include other previous context beyond s^{i-1} as additional context overwhelms the information contained in s^i.

Following our hypothesis, we first extract keywords K^i from s^i using RAKE (Rose et al., 2010) and then match K^i with all knowledge triples in G. Transforming the retrieved triples into knowledge sentences gives us our set of $\bar{R}^i$. We then take the sentence s^i and s^{i-1}, concatenate them, and encode them using the Universal Sentence Encoder (USE) (Cer et al., 2018), a widely-used toolkit for semantic similarity, $U^s = U([s^{i-1}, s^i])$, where we denote the encoder of USE as U. For each $\bar{r}^i_j \in \bar{R}^i$, we then calculate the cosine similarity between U^s and $U^r_j = U(\bar{r}_j)$ and sort $\bar{R}^i$ based on this score. We take the top N highest scores $\bar{r}^i_j$ as a pseudo label of R^i. Algorithm 1 describes this process. During the training phase of each following model, we use this pseudo label of R^i to represent R^i.

2.4 Contextual Knowledge Ranker

While knowledge retrieval with keywords reduces the controlling knowledge candidate space from the knowledge base G to the subset $\hat{R}^i$, this set is still large and noisy since words are ambiguous and can have multiple senses. We, therefore, contextualize the knowledge sentences in $\hat{R}^i$ to obtain relevant and useful ones under X^{i-1}. To do this, we develop a contextual knowledge ranker. The model is trained with pseudo-labels extracted with access to the future sentence s^i as described in Sec. 2.3.

We use a BERT model to encode both the context X^{i-1} and each knowledge sentence $\hat{r}^i_j \in \hat{R}^i$. To adapt to the format of BERT, we append a [SEP] token to each R^j and s^j inside the context X^{i-1}. A [CLS] token is then added to the beginning of X^{i-1}. For segment ids, we mark the tokens from the knowledge base as 0 and those from the story as 1. The representation of X^{i-1} and $\hat{r}^i_j$ are then obtained after applying a linear layer on top of the embedding of the [CLS] token:

$$V_x = W_1 \ \text{BERT}_{\text{CLS}}(X^{i-1}),$$
$$V_j = W_2 \ \text{BERT}_{\text{CLS}}(\hat{r}^i_j),$$

where W_1 and W_2 are learnable weights. We then calculate the relevance $score$ C between X^{i-1} and $\hat{r}^i_j$ using the inner product between V_x and V_j as :

$$C^i_j = C(X^{i-1}, \hat{r}^i_j) = V_x V_j \tag{2}$$

We take R^i (Sec. 2.3) as positive samples and $\hat{R}^i \backslash R^i$ as negative samples to train our ranker. Given a positive and a negative knowledge sentence r_p and r_n, we define the ranking loss as

$$L = \max\{0, M - C(X^{i-1}, r_p) + C(X^{i-1}, r_n)\} \tag{3}$$

where M is a margin and determined empirically. Algorithms 2 describe the ranker training process.

At inference time, we simply calculate C_j for all $\hat{r}^i_j \in \hat{R}^i$, sort them based on C^i_j score and pick the top N most relevant knowledge sentences as R^i.

2.5 Conditional Generator

The conditional generator is a language model that incorporates the controlling knowledge and generates the following sentences. It concatenates the story context X^{i-1} and controlling knowledge R^i as input and generates s^i. A GPT-2 transformer is used to model this conditional probability distribution. We describe the concatenated input representation in the Appendix A.5.

Algorithm 2 Knowledge Ranker Training

```
Parameters: BERT model parameters $\Theta$ and ranker model parameters $W_1$ and $W_2$
Input: A story $S^l$ with $l$ sentences and a knowledge base $G$
Initialize $\Theta$ using a pre-trained BERT model and $W_1, W_2$ randomly.
Dataset $D = \emptyset$
Call Algorithm 1 to retrieve $R^1$ from $G$ using $s^1$.
for $i \in \{2, \ldots, l\}$ do
    Call Algorithm 1 to retrieve $R^i$ using $s^i$.
    Get $\hat{R}^i$ using knowledge retrieval (Section 2.2)
    for $j \in \{1, \ldots, N\}$ do
        Sample $r_p$ from $R^i$ and $r_n$ from $\hat{R}^i \backslash R^i$
        $D = D \cup (X^{i-1}, r_p, r_n)$
    end for
end for
for $(X, r_p, r_n) \in D$ do
    Calculate loss $L$ using Equation 3
    Optimize BERT, $W_1, W_2$
end for
return BERT, $W_1, W_2$
```

3 Experimental Setup

3.1 Datasets

We use the ROC story dataset (Mostafazadeh et al., 2016) for our experiments. It consists of 98,161 stories, where each story contains five sentences. 88,344/4,908/4,909 stories are used for train/validation/test sets, respectively. Following Guan et al. (2020), for each sentence, delexicalization is performed by replacing all the names and entities in stories with special placeholders, [*MALE*], [*FEMALE*], and [*NEUTRAL*] for male, female and unknown names and entities, respectively. Given the first sentence of each story, our model's task is to generate the rest of the story. For our external knowledge base, we use ConceptNet (Speer and Havasi, 2012), consists of 600k knowledge triples.

3.2 Models

We used Megatron-LM (Shoeybi et al., 2019) for pre-trained BERT and GPT-2 models to initialize our contextual knowledge ranker and generative models, respectively. For the model configurations, hidden size, number of layers, and attention heads, we used the configurations of BERT and GPT-2 as in Megatron-LM. For generation with our GPT-2 models, we used a top-k sampling scheme (Fan et al., 2018) with $k = 40$ and a softmax temperature of 0.7. We detail the training hyperparameters and the input representations for GPT-2 and BERT in Appendix A.1 & A.2 . Both the keyword predictor and the conditional sentence generator follow the same settings.

To train our contextual knowledge ranker, we set the margin to 5.0. We set the number of knowledge sentences in R^i to 10. Therefore, for a given story context, the top 10 retrieved knowledge sentences from ConceptNet according to USE are chosen as the positive samples. We further select 40 negative samples to compute our margin loss. We then randomly sample 50 (positive, negative) pairs for each story context to train our contextual knowledge ranker. In total, we used $\sim$15 million pairs for training and $\sim$1 million pairs for validation. After training our ranker, we achieve a validation accuracy of 0.9.

3.3 Controllability Experiment Setup

To test the controllability of our model, we perform experiments where we change keywords to their antonyms. With antonyms, we expect maximal change to the story generation. To do that, we first use MEGATRON-CNTRL-124M to generate keywords K and corresponding full story S. Then we identify the first keyword $k_a^i \in K^i$ from K whose antonym is available at WordNet (Miller, 1995). If multiple antonyms for k_a^i are available we sample one with a uniform random probability. Afterwards, we provide the start of story $\{s^1, s^2, \cdots, s^{i-1}\}$, the keywords shared with our original story $\{K^1, K^2, \cdots, K^{i-1}\}$, and the antonym of k_a^i to either MEGATRON-CNTRL-124M or larger models (e.g. MEGATRON-CNTRL-355M). We then let the model finish the generation. We refer to these generations as MEGATRON-CNTRL-ANT, for example, we call the antonym generations from MEGATRON-CNTRL-355M model as MEGATRON-CNTRL-355M-ANT.

3.4 Baselines

We compare our model with the following state-of-the-art story generation models. (1) **Plan and write (Yao et al., 2019):** The authors use an LSTM-based model to first generate a sequence of keywords for planning the story. These keywords are then used to condition the generation. (2) **Knowledge enhanced GPT-2 (Guan et al., 2020):** This work is currently the SOTA for ROC story generation. It finetunes a pre-trained GPT-2 model with knowledge triples from commonsense datasets. Similar to our method, the knowledge triples are converted to sentences with templates. A multitask learning framework is then developed to further finetune the story generation task and classify corrupted stories from real ones. We do not compare to Fan et al. (2019) because Guan et al. (2020) has already shown their model significantly outperforms Fan et al. (2019) and in this work, we compare to Guan et al. (2020). (3) **GPT-2-124M:** This baseline finetunes a GPT-2 model with a next token prediction loss on the story.

3.5 Evaluation

We conduct both automatic as well as human evaluations to assess our generation.

3.5.1 Automatic Evaluation

We use the following metrics to compare different models: **Repeat:** measures the redundancy of the generated story by reporting the percentage of the stories that contain at least one repeated 4-gram (Shao et al., 2019). **Distinct:** measures the diversity of generated stories by reporting the ratio between distinct 4-grams to all generated 4-grams. **Perplexity:** In the inference phase, our models involve two steps of generation: (i) generate set of knowledge sentences, R^i from story context X^{i-1}, (ii) generate story sentence, s^i from X^{i-1} and R^i. To report the perplexity of the conditional generator we sample R^i sequentially before generating each story sentence s^i and report the total perplexity of all sentences s^i for $i \in [2, l]$ where l is the number of sentences in the story.

3.5.2 Human Evaluation on Quality

We conduct human evaluations on Amazon Mechanical Turk[1] (AMT) to analyze the quality of our generations on three aspects: **Fluency**, **Coherence**, and **Consistency**. To evaluate fluency, we show the annotators a pair of generated stories from two models. We ask them to evaluate each sentence independently and choose the story with better overall fluency. Fluency of a story is defined as a measure of intra-sentence linguistic quality and grammatical correctness taken over all sentences of the story. For coherence, we provide the same stories as in fluency but ask to choose the one with better inter-sentence causal and temporal dependencies. We let the annotators choose *tie* for both fluency and coherence.

Different from the settings of fluency and coherence, we only show one generated story to annotators to evaluate consistency. They are required to choose whether the story is logically consistent, based on whether the story self contradicts or not.

We set up these three evaluations as independent AMT tasks to make sure the tasks do not influence each other and introduce spurious correlations between labels. To reduce noise in our labeling process, we only accepted workers with an approval rating over 90% and have over 1k accepted jobs. We further limited the location of the annotators to the United States. For each example, we explicitly ask them to spend at least 15 seconds to evaluate coherency and 10 seconds to evaluate the other two properties. In total, we randomly sample 200 stories and assign five annotators for each story. We adopted majority voting to make final decisions among the five annotators.

3.5.3 Human Evaluation on Controllability

To evaluate how controllable our model is, we conduct another human evaluation just for controllability. We show the annotators the start of a story, original keywords, and the corresponding generation. We then show the antonyms of the keywords, along with the corresponding generated story, and ask the annotators if the new story has changed compared to the original story in accordance with the meaning of the keyword's antonyms. The rest of the AMT settings for these experiments are the same as our consistency experiments.

4 Results

In this section, we first perform automatic and human evaluations with different model sizes and compare our framework to the existing baselines. We then evaluate the controllability of our model and finally show ablation study varying GPT-2 and BERT model sizes. The detailed configuration of the model sizes are shown in Table 2. We provide several generated stories in Appendix A.7 varying the length of the given context. We use M-CNTRL to denote MEGATRON-CNTRL in the tables due to the limited space.

Model Name	Conditional Generator (GPT-2)	Keyword Generator (GPT-2)	Knowledge Ranker (BERT)
M-CNTRL-124M	124M	124M	336M
M-CNTRL-355M	355M	355M	336M
M-CNTRL-774M	774M	774M	336M
M-CNTRL-2B	2.5B	2.5B	336M
M-CNTRL-8B	8.3B	2.5B	336M

Table 2: Number of parameters of our models (M-CNTRL is the short form for MEGATRON-CNTRL).

---

[1] https://www.mturk.com/

Source A	Coherence ↑	Fluency ↑	Source B
M-CNTRL-124M	**78.5%** - 13.0%	**66.5%** - 22.5%	Yao et al. (2018)
M-CNTRL-124M	**46.0%** - 39.0%	**44.5%** - 43.5%	Guan et al. (2020)
M-CNTRL-355M	**56.0%** - 30.5%	**46.5%** - 30.5%	Guan et al. (2020)
M-CNTRL-355M	**52.0%** - 31.5%	**46.5%** - 39.0%	M-CNTRL-124M
M-CNTRL-774M	**44.5%** - 41.5%	**56.0%** - 33.5%	M-CNTRL-355M
M-CNTRL-2B	**50.5%** - 30.5%	**53.0%** - 39.0%	M-CNTRL-774M
M-CNTRL-8B	**46.0%** - 39.5%	46.5% - 46.5%	M-CNTRL-2B

Table 3: Pairwise comparison between our models and baselines. Percentages in the format "A% - B%" indicate how often annotators rank the samples from source A better than from source B for a given category, and vice versa. Percentage pairs do not sum to 100% as the annotators were allowed to choose "tie" as being of equal quality. MEGATRON-CNTRL-124M achieves better results than all baselines. Scaling the models shows better coherence and fluency.

Name	PPL ↓	Repeat ↓	Distinct ↑	Consistency ↑ (Human Eval)
GPT-2-124M	6.98	27.2	74.1	69.5
Yao et al. (2018)	NA	**13.3**	63.7	49.0
Guan et al. (2020)	7.04	22.1	77.1	67.0
M-CNTRL-124M	9.37	20.0	80.1	74.5
M-CNTRL-355M	8.02	19.9	81.6	75.5
M-CNTRL-774M	6.58	21.3	81.6	80.5
M-CNTRL-2B	6.31	21.2	82.6	89.0
M-CNTRL-8B	**6.21**	21.2	**82.8**	**93.0**

Table 4: Evaluation results for the previous state-of-the-art models as well as our algorithm at different sizes. Perplexity, repeat, and distinct are evaluated automatically whereas consistency is obtained using human evaluations. Our smallest model with 124M parameters achieves better distinct and consistency score compared to prior work. Increasing model size up to 8B improves perplexity, distinct, and consistency scores. For reference, the ground truth human writing gives 7.6 score for repeat and 88.9 for distinct.

4.1 Automatic and Human Evaluations

Table 4 shows that our smallest model, MEGATRON-CNTRL-124M achieves better distinct and consistency scores compared to previous work. For repetition, our model is worse than Yao et al. (2019) which was also observed in Guan et al. (2020). The reason could be their small 8M model is better at learning short term statistics (e.g. 4-grams), while large models are better at learning long term dependencies. Compared to other GPT-2 based models (i.e. GPT-2-124M and Guan et al. (2020)), MEGATRON-CNTRL-124M achieves lower repeat and higher distinct scores, hence our model generates less repetitive stories.

We notice from Table 4 that our perplexity (PPL) score is much higher than other GPT-2-based models. Our hypothesis for why this occurs is that other GPT-2-based methods directly model and report $P(s^i|s^1, s^2, \cdots, s^{i-1})$ while our conditional generator models and reports $P(s^i|X^{i-1}, R^i)$. When computing perplexity, $[s^1, s^2, \cdots, s^{i-1}]$ are given ground truth tokens, but R^i and all R in X^{i-1} must be sampled from a distribution that is learned with weak supervision. This sampling introduces noise and non-determinism that results in higher perplexity. This discrepancy is not an issue when analyzing automatic evaluation metrics within our model family. When scaling our model from 124M up to 8B parameters we see a consistent drop in PPL and increase in distinct. This shows larger models can generate better stories with more diversity.

Human evaluation results are presented in last column of Table 4 (consistency) and in Table 3. Comparing MEGATRON-CNTRL-124M to Yao et al. (2019), we achieve much better coherence, fluency, and consistency scores, which shows the benefit of large pre-trained transformer models. Comparing MEGATRON-CNTRL-124M to Guan et al. (2020) which uses a similar base model, we find that fluency is similar, however we should note that Guan et al. (2020) is not controllable and our model has significantly better coherence (+7.0%) in Table 3 and consistency (+7.5%) in Table 4. We attribute this to the use of the retrieved knowledge, R^i. By explicitly providing facts pertinent to the next sentence, the conditional generative model can focus on just generating text. By comparison, a standard autoregressive GPT-2 model is tasked with predicting both the topics and the text of the next sentence.

Scaling this up, and comparing MEGATRON-CNTRL-355M to Guan et al. (2020), our model significantly outperforms in all aspects. Furthermore, a thorough comparison among MEGATRON-CNTRL-355M, MEGATRON-CNTRL-774M, MEGATRON-CNTRL-2B, MEGATRON-CNTRL-8B shows that scaling the model size further almost always improves the quality of generation in terms of fluency, coherence and consistency. For consistency, our best model at 8B parameters achieves a score of 93%.

4.2 Controllability Evaluation

We evaluate the controllability by changing keywords to their antonyms as detailed in Section 3.3 & 3.5. Table 5 shows repeat and distinct for MEGATRON-CNTRL-124M as well as the controlled versions at three different sizes. Altering control with antonym keywords gives lower repeat and higher distinct scores than the original generation. As the model size increases, the repeat stays almost constant while distinct improves. These results show that changing keywords manually results in distinct and not repeated text.

Name	Repeat ↓	Distinct ↑
M-CNTRL-124M	20.0	80.1
M-CNTRL-124M-ANT	17.8	80.9
M-CNTRL-355M-ANT	18.0	81.6
M-CNTRL-8B-ANT	18.5	82.8

Table 5: Comparing controllability of the models by changing the keywords to their antonyms. Controlled generations show less repetition and higher diversity compared to the original one.

Further supporting this hypothesis, evaluation of controllability in Table 6 shows that MEGATRON-CNTRL-124M-ANT achieves a high controllability score of 77.5%. This means that by changing the keywords to their antonym, 77.5% of newly generated stories change their semantic content to follow the new antonym keywords. We also show that larger models are better able to leverage keyword control. Scaling the model size from 124M to 355M and 8B model further improves the controllability score to 84.5% and 91.5%, respectively. We again observe the quality (e.g. coherence) of our controlled generation improves as the model size scales to 8B.

Name	Controllability ↑
M-CNTRL-124M-ANT	77.5%
M-CNTRL-355M-ANT	84.5%
M-CNTRL-8B-ANT	**91.5%**

Table 6: Human evaluation for controllability by changing keywords to their antonyms. Over 77% of our generation changes according to the keywords.

4.3 Ablation Studies

In this section, we conduct the ablation study on the planning strategy and external knowledge. The study of model size can be found in the Appendix A.3.

Name	Repeat ↓	Distinct ↑
M-CNTRL-124M (D)	20.04	80.14
M-CNTRL-124M w/o knowledge (D)	23.59	79.39
M-CNTRL-124M (S)	23.87	79.45
M-CNTRL-124M w/o knowledge (S)	23.98	79.61

Table 7: Ablation studies of static (S) vs dynamic (D) planning strategy, with and without knowledge.

4.3.1 Planning Strategy

In this section, we investigate the effects of planning strategy in our framework. Yao et al. (2019) showed that static planning works better than dynamic planning for LSTM-based models. To introduce the static planning in our model, we predicted all the keywords and relevant knowledge sentences from the starting sentence and generated the entire stories. When we compare these generations with the stories generated by dynamic planning, we see in Table 7 (first and third rows) that dynamic planning outperforms the static planning strategy with higher distinction (+0.7%) and lower repetition (-3.8%) scores. This is due to direct guidance over each sentence provided by the retrieved knowledge from dynamic planning . In contrast, in static planning, the retrieved knowledge sentences are all predicted together at the beginning using only the starting sentence, which makes the supervision for each story sentence weaker and noisier.

4.3.2 External Knowledge

In this section, we investigate the importance of retrieved knowledge. Table 7 (first and second rows) shows that, when excluding the knowledge from our framework (i.e. MEGATRON-CNTRL-124M w/o knowledge), distinction score decreases by 0.8% and repetition increases by 3.6%, highlighting the importance of external knowledge in our approach. Unlike dynamic planning, we observe that in static planning, the external knowledge does not play an important role in the quality of the generations and using or not using the knowledge leads to similar qualities. This observation also confirms that knowledge needs to be planned dynamically.

5 Future Work

Short story sentences in ROC story dataset limits our exploration from several potential research directions. For example, how long the control signal would propagate for longer generations? Investigating this issue using longer story datasets (e.g. WRITINGPROMPTS (Fan et al., 2018)) is a subject for future work. Other interesting direction may include incorporating the structure-level controllability by adding it as either an extra input for the conditional generator or a multitask learning supervision for each sequence.

We also observed that in some cases during the generation, our model simply mentions the given word in the sentence, and talks about things that are not strictly related to or restricted by the given word. For example, the generated story of MEGATRON-CNTRL-8B in Table 15 only mentions the keyword "realize" instead of centering around it. This is caused by the RAKE keywords extractor, which does not always extract the keywords that represent the sentence well. One way to mitigate this issue is to leverage longer context information to identify better keywords which is subject of the future work.

6 Related Work

Knowledge Incorporation of knowledge into language models has shown promising results for downstream tasks, such as factual correct generation (Logan et al., 2019) , commonsense knowledge graph construction (Bosselut et al., 2019), entity typing (Zhang et al., 2019) and etc. More recently, several works have shown that inclusion of learned mechanisms for explicit or implicit knowledge can lead to the state-of-the-art results in Question Answering (Guu et al., 2020; Karpukhin et al., 2020; Lee et al., 2019; Lewis et al., 2020) and dialogue modeling (Roller et al., 2020).

Storytelling There are several different storytelling tasks described throughout the literature. Storytelling can be classified into story completion (Chen et al., 2019), story ending generation (Guan et al., 2019), story generation from prompts (Fan et al., 2018) or titles (Yao et al., 2019), and story generation from a given sentence (Guan et al., 2020). Different approaches have been developed to model the structure of stories with storylines (Yao et al., 2019), skeletons (Xu et al., 2018), Conditional Variational AutoEncoders (Wang and Wan, 2019) and a coarse-to-fine framework (Fan et al., 2019). Other works focus on incorporating commonsense knowledge into story generation with attention-based models (Guan et al., 2019; Chen et al., 2019). Recently, pre-trained language models have been used to finetune on both story completion datasets and commonsense knowledge to further improve the quality of story completion (Guan et al., 2020). However, few works concern the controllability of language model generation, especially for the large pre-trained models that are common in today's literature.

Controllable Generation Controllable text generation has a wide range of applications, including controlling through persona (Zhang et al., 2018; Boyd et al., 2020), politeness (Niu and Bansal, 2018), etc. Wiseman et al. (2018) presented controlling generations by learning latent, discrete templates from data. Fu et al. (2019) discovered the importance of pivot words that determines the sentence attributes and presented a lexical analysis framework. To control large pre-trained models, Keskar et al. (2019) demonstrated the ability to control text generation through a wide range of aspects, such as domains and links. Plug-and-play language models Dathathri et al. (2019) also address whole document controllability by adding a linear classifier on top of GPT-2 to predict whether generated text observes a particular style or property. Prabhumoye et al. (2020) provides a good survey of five modules for control. Differing from these works, we control the generation through keywords backed by external knowledge.

7 Conclusion

In this paper, we proposed a novel framework that adds control to text generation with external knowledge. Our model first generates a set of keywords and a knowledge retriever then queries an external knowledge base for triples related to the keywords. Based on the relevance to the story context, a contextual knowledge ranker ranks the retrieved knowledge sentences and feeds the top ones to a conditional generator to generate the next story sentence. Experimental results on the ROC story dataset showed that our model outperforms state-of-the-art models by generating less repetitive, more diverse and logically consistent stories. Human evaluation of the controllability of our model shows that 91.5% of generated stories are successfully controlled by changing keywords to their antonym. In line with current trends, we also demonstrate that using larger pre-trained language models consistently improves both the quality of the generated stories and controllability.

A Appendices

A.1 GPT-2 Hyperparameters:

We used the BPE subword tokenizer from Radford et al. (2019) to tokenize each sentence of the ROC story dataset. The maximum sequence length is set to 1024 learned positional embeddings. An Adam optimizer (Kingma and Ba, 2014) with learning rate of 0.0001 is utilized. We added dropout to both the embedding layer and multi-head attention layers with 0.1 probability. Gradients were clipped to a global gradient norm of 5.0. We finetuned the GPT-2 models for 5 epochs and selected the best one with the lowest perplexity on the validation set.

A.2 BERT Hyperparameters:

We set the maximum sequence length to 512 learned positional embeddings. We used a WordPiece tokenizer with the `bert-large-uncased` vocabulary for tokenization. The model was also optimized with an Adam optimizer with a learning rate of 0.0001, but it used a weight decay of 0.01. Gradients are clipped to a global norm of 1.0. We also added dropout to embedding layer and multi-head attention layers with 0.1 probability. For the selection of margin, we tried 0.1, 0.5, 1.0, and 5.0. The choice of 5.0 gives the best result.

A.3 Model Size

In addition to analyzing the effect of scale on our conditional generative model, we also performed an ablation study on the model size of our GPT-2-based keyword predictor and BERT-based ranker models. The results in Table 8 show that increasing the keyword model size from 774M to 2B reduces the repetition while keeping the other scores similar. Increasing the size of our contextual ranker from 336M to 1.2B reduces the repetition while also decreasing the diversity. It is not clear which one is better. We conjecture that as the positive samples, R^i, we used to train our contextual ranker are weakly supervised, and the fact that we used templates to synthetically convert knowledge triples to knowledge sentences, scaling the model size might be overfitting to noise. We, therefore, use the smaller, more computationally efficient model with 336M parameters for ranker models in all our experiments.

Name (*a*-*b*-*c*)	PPL ↓	Repeat ↓	Distinct ↑
2B-2B-336M	**6.31**	21.2	**82.6**
2B-2B-1.2B	6.35	**19.7**	81.2
2B-774M-1.2B	6.33	20.4	81.4

Table 8: Ablation studies varying keyword prediction model (b) and ranking model (c) keeping the conditional generator fixed (a). Increasing keyword prediction model reduces repetition. Larger ranking models does not give consistently better scores as it may overfit to noise due to the weakly supervised labels.

A.4 Datasets Used for pre-trained Models

The pre-trained GPT-2 models were trained on a 174GB corpora including: Wikipedia (Devlin et al., 2018), OpenWebText (Gokaslan and Cohen, 2019), RealNews (Zellers et al., 2019), and CC-Stories (Trinh and Le, 2018). For BERT models we include BooksCorpus (Zhu et al., 2015) in the training dataset.

A.5 Input Format

For the format of R^j, we add a " SEP " string to separate different knowledge sentences r_k^j in R^j. We add a " EOK " string to denote the end of knowledge sentences.

For the story context $X^{i-1} = \{x^1, x^2, \cdots, x^{i-1}\}$ where $x^j = [R^j, s^j]$, we add a "OS" token to the end of each s^j to denote the end of sentence. At the end of the story, a " |endoftext| " token is appended. We then concatenated X^{i-1} with R^i as the input to conditional generator.

A.6 Preprocessing

We follow the implementation of Guan et al. (2020), to replace " ." with ". ". More details have already been provided in Section 3.1.

A.6.1 Computation Resources

We used up to 20 DGX-1V servers (a total of 160 Tesla V100 32GB GPUs) for our experiments. Our infrastructure is highly optimized for large scale deep learning applications. The servers are connected via NVSwitch with 300 GB/sec bandwidth between GPUs inside a server and 100 GB/sec of interconnect bandwidth between servers using 8 InfiniBand adapters per server. As our story dataset is small, the training of GPT-2 models usually takes less than three hours. For the BERT model, it took eight hours as we have $\sim$ 15 million samples to train.

A.7 Generation Examples

A.7.1 Single Sentence Context

We present five generation examples keeping the context fixed to one sentence.

Context: [MALE] and his friends are bored on a weekend day.
Guan et al. (2019) they decided to sneak into a movie . they got a bunch of popcorn and a movie . then , they made it to a movie . now , they have a really good time .
MEGATRON-CNTRL-124M keyword: go, decides it is going to be a big night. [MALE] and his friends decide to go out. they get drunk and have a great time. when they are done they feel happy.
MEGATRON-CNTRL-8B keyword: go, decides they decided to go to the video game store. [MALE] picks out a new video game. [MALE] and his friends have fun playing the new video game. [MALE] is no longer bored.
MEGATRON-CNTRL-8B-ANT keyword: come a new tv show begins to come on the local channel. [MALE] is excited to watch his favorite tv show. he watches his show and they all laugh together. [MALE] and his friends have a fun time watching their favorite show.

Table 9: Example 1

Context: [MALE] had a heavy duty backpack.
Guan et al. (2019) he took it to the airport . he checked his pockets . [MALE] did not have a bag . [MALE] was sad .
MEGATRON-CNTRL-124M keyword: took he took it to the store one morning. he put it on the shelf at the store. a coworker looked at it. then he told [MALE] he hated lugging around.
MEGATRON-CNTRL-8B keyword: took he took it to the army base camp. he packed it with items like food , ammo , and tools. he took it to the jungle every day. one day , he took it out and his backpack exploded.
MEGATRON-CNTRL-8B-ANT keyword: abstain he abstained from buying another backpack. [MALE] used the old backpack for years. his old backpack was a big burden. [MALE] bought a new backpack with greater weight capacity.

Table 10: Example 2

Context: [NEUTRAL] 's blind date insisted on going to the new sushi place.
Guan et al. (2019) she accepted without saying a word . later , he picked out a sushi roll . [NEUTRAL] was so happy with her new sushi rolls . she had to wait for him to come back .
MEGATRON-CNTRL-124M keyword: sure, date she decided to go to the restaurant. she ordered a blowfish. they gave her a small grin. she had a great time.
MEGATRON-CNTRL-8B keyword: thought, rude [NEUTRAL] was nervous because he was worried she would be rude. but at the table , she was sweet and friendly. and she was very nice , even though she ate little sushi. [NEUTRAL] wondered if maybe blind dates were actually very wonderful !
MEGATRON-CNTRL-8B-ANT keyword: uncertain [NEUTRAL] was uncertain. she was not a sushi person but agreed to try it. [NEUTRAL] and her blind date ordered salmon sushi. the salmon sushi was delicious.

Table 11: Example 3

Context: [MALE] hiked up the local hill.
Guan et al. (2019) he stopped and picked up his brush . he used that brush to brush his teeth . afterwards , he was ready to ride back home . he went on his way home .
MEGATRON-CNTRL-124M keyword: top he got a great view from the top. his legs felt great. he climbed up the mountain and felt much better. he went back to the hill and reached the top.
MEGATRON-CNTRL-8B keyword: top he was at the top of the hill looking down. the weather looked beautiful. the clouds suddenly passed. the sun began to shine over the land again.
MEGATRON-CNTRL-8B-ANT keyword: bottom he saw a huge boulder at the bottom. he could n't believe its size. he had to climb to the top of the hill. he was afraid he would fall if he stood on top.

Table 12: Example 4

Context: her favorite glasses were ruined.
Guan et al. (2019) she was really upset . she had no choice but to buy new ones . she went to the mall to shop and found a great pair . she bought them and was so happy .
MEGATRON-CNTRL-124M keyword: wore she wore them every day. then she had a horrible accident. her sister had broken them. she had to buy new ones.
MEGATRON-CNTRL-8B keyword: wore she wore them daily. she got them at the shoe store. she found them and they were her favorite. after a while they got broken.
MEGATRON-CNTRL-8B-ANT keyword: refresh she was desperate to refresh them. she found a recipe online. she poured bleach in them. she was glad to have functional glasses.

Table 13: Example 5

A.7.2 Varying Number of Sentences in the Context

We present three generation examples varying the number of sentences in the context.

Context: [MALE] and his friends are bored on a weekend day. it is going to be a big night.
MEGATRON-CNTRL-124M keyword: go, decides [MALE] and his friends decide to go out. they get drunk and have a great time. when they are done they feel happy.
MEGATRON-CNTRL-8B keyword: decides [MALE] decides to watch horror movies. his friends join him. they watch horror movies all night.
MEGATRON-CNTRL-8B-ANT keyword: stop they stop by a local arcade after the baseball game. [MALE] turns on his favorite arcade game. [MALE] 's favorite game makes him feel happy.

Table 14: The context contains two sentences.

Context: [MALE] liked trading commodities. one day [MALE] was trading several products. [MALE] noticed that he gained a lot of money from the new trades.
MEGATRON-CNTRL-124M keyword: lost, money [MALE] invested the money into stocks. [MALE] lost all of his trading profits.
MEGATRON-CNTRL-8B keyword: realize [MALE] realized that the new trades were his best trading idea. [MALE] quit his old job and went full time on his new trading idea.
MEGATRON-CNTRL-8B-ANT keyword: keep [MALE] decided to keep doing this. now [MALE] had a successful trading career.

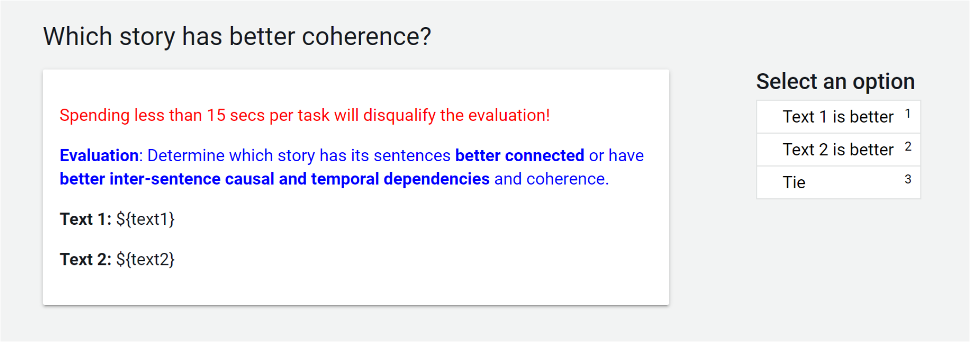
Table 15: The context contains three sentences.

Context: we went to a dinner and show one night. the first guy we saw was really nice. after that we asked him out. he agreed.
MEGATRON-CNTRL-124M keyword: got we got into a bad argument.
MEGATRON-CNTRL-8B keyword: NONE (no keywords) we had a really good time.
MEGATRON-CNTRL-8B-ANT keyword: end we ended up dating exclusively.

Table 16: The context contains four sentences.

A.8 Human Evaluation Interface for Annotators

Below we provide the interfaces used for human evaluations (coherence, fluency, logical consistency, and controllability).



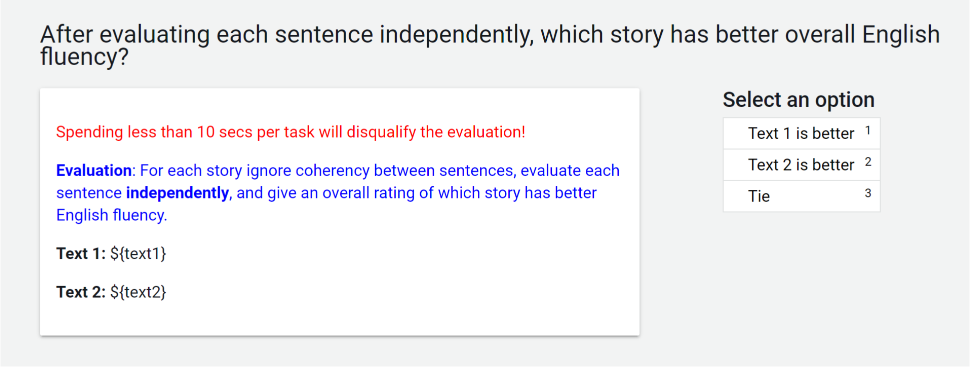
Which story has better coherence?

Spending less than 15 secs per task will disqualify the evaluation!

Evaluation: Determine which story has its sentences **better connected** or have **better inter-sentence causal and temporal dependencies** and coherence.

Text 1: ${text1}

Text 2: ${text2}



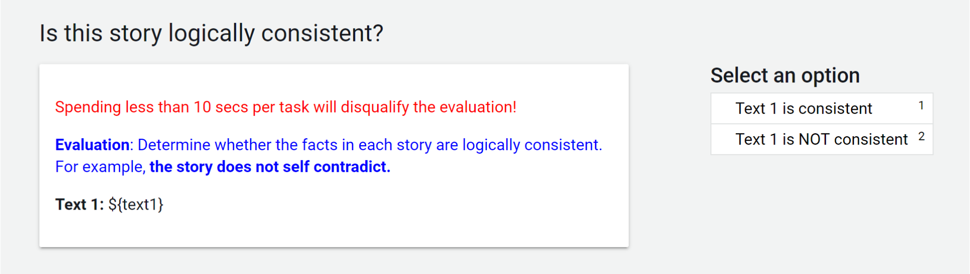
After evaluating each sentence independently, which story has better overall English fluency?

Spending less than 10 secs per task will disqualify the evaluation!

Evaluation: For each story ignore coherency between sentences, evaluate each sentence **independently**, and give an overall rating of which story has better English fluency.

Text 1: ${text1}

Text 2: ${text2}

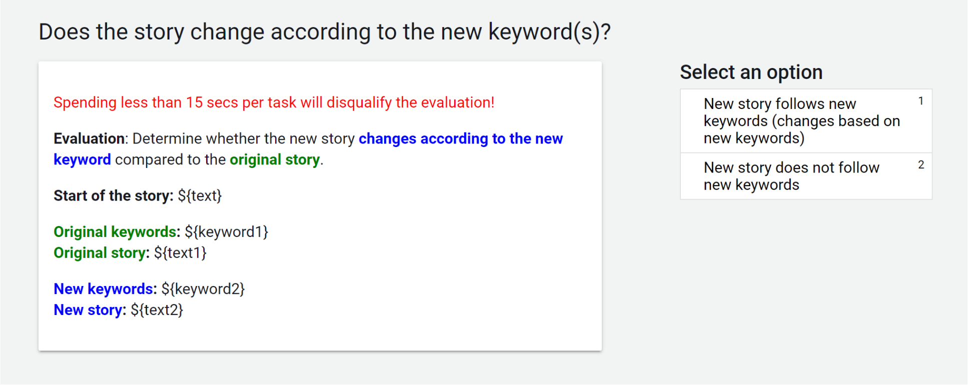


Is this story logically consistent?

Spending less than 10 secs per task will disqualify the evaluation!

Evaluation: Determine whether the facts in each story are logically consistent. For example, **the story does not self contradict.**

Text 1: ${text1}



Does the story change according to the new keyword(s)?

Spending less than 15 secs per task will disqualify the evaluation!

Evaluation: Determine whether the new story **changes according to the new keyword** compared to the **original story**.

Start of the story: ${text}

Original keywords: ${keyword1}
Original story: ${text1}

New keywords: ${keyword2}
New story: ${text2}

Incomplete Utterance Rewriting as Semantic Segmentation

Qian Liu[†][*], Bei Chen[§], Jian-Guang Lou[§], Bin Zhou[†], Dongmei Zhang[§]
[†]School of Computer Science and Engineering, Beihang University, China
[§]Microsoft Research, Beijing, China
[†]{qian.liu, zhoubin}@buaa.edu.cn; [§]{beichen, jlou, dongmeiz}@microsoft.com

Abstract

Recent years the task of incomplete utterance rewriting has raised a large attention. Previous works usually shape it as a machine translation task and employ sequence to sequence based architecture with copy mechanism. In this paper, we present a novel and extensive approach, which formulates it as a semantic segmentation task. Instead of generating from scratch, such a formulation introduces edit operations and shapes the problem as prediction of a word-level edit matrix. Benefiting from being able to capture both local and global information, our approach achieves state-of-the-art performance on several public datasets. Furthermore, our approach is four times faster than the standard approach in inference.

1 Introduction

Turn	**Utterance** (*Translation*)
$\mathbf{x}_1$ (A)	北京今天天气如何 *How is the weather in Beijing today*
$\mathbf{x}_2$ (B)	北京今天是阴天 *Beijing is cloudy today*
$\mathbf{x}_3$ (A)	为什么总是这样 *Why is always this*
$\mathbf{x}_3^*$	北京为什么总是阴天 *Why is Beijing always cloudy*

Table 1: An example dialogue between user A and B, including the context utterances ($\mathbf{x}_1$, $\mathbf{x}_2$), the incomplete utterance ($\mathbf{x}_3$) and the rewritten utterance ($\mathbf{x}_3^*$).

A dramatic progress has been achieved in single-turn dialogue modeling such as open-domain response generation (Shang et al., 2015), question answering (Rajpurkar et al., 2016), etc. By contrast, multi-turn dialogue modeling is still in its infancy, as users tend to use incomplete utterances which usually omit or refer back to entities or concepts appeared in the dialogue context, namely ellipsis and coreference. According to previous studies, ellipsis and coreference exist in more than 70% of the utterances (Su et al., 2019), for which a dialogue system must be equipped with the ability of understanding them. To tackle the problem, early works include learning a hierarchical representation (Serban et al., 2017; Zhang et al., 2018) and concatenating the dialogue utterances selectively (Yan et al., 2016). Recently, researchers focus on a more explicit and explainable solution: the task of **I**ncomplete **U**tterance **R**ewriting (**IUR**, also known as context rewriting) (Kumar and Joshi, 2016; Su et al., 2019; Liu et al., 2019a; Pan et al., 2019; Elgohary et al., 2019; Zhou et al., 2019). IUR aims to rewrite an incomplete utterance into an utterance which is semantically equivalent but self-contained to be understood without context. As shown in Table 1, the incomplete utterance $\mathbf{x}_3$ not only omits the subject "北京"(Beijing), but also refers to the semantic of "阴天"(cloudy) via "这样"(this). By explicitly recovering the hidden semantics behind $\mathbf{x}_3$ into $\mathbf{x}_3^*$, IUR makes the downstream dialogue modeling more precise.

To deal with IUR, a natural idea is to transfer models from coreference resolution (Clark and Manning, 2016). However, this idea is not easy to realize, as ellipsis also accounts for a large proportion. Despite being different, coreference and ellipsis both can be resolved without introducing out-of-dialogue words in most cases. That is to say, words of the rewritten utterance are nearly from either the context utterances or the incomplete utterance. Observing it, most previous works employ the pointer network (Vinyals et al., 2015) or the sequence to sequence model with copy mechanism (Gu et al., 2016; See et al., 2017). However, they generate the rewritten utterance

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2846–2857,
November 16–20, 2020.

from scratch, neglecting a key trait that the main structure of a rewritten utterance is always the same as the incomplete utterance. To highlight it, we imagine the rewritten utterance as the outcome after a series of edit operations (i.e. substitute and insert) on the incomplete utterance. Taking the example from Table 1, $\mathbf{x}_3^*$ can be obtained by substituting “这样”(this) in $\mathbf{x}_3$ with “阴天”(cloudy) in $\mathbf{x}_2$ and inserting “北京”(Beijing) before “为什么”(Why), much easier than producing $\mathbf{x}_3^*$ via decoding word by word. These edit operations are carried out between word pairs of the context utterances and the incomplete utterance, analogous to semantic segmentation (a well-known task in computer vision): Given relevance features between word pairs as an image, the model is to predict the edit type for each word pair as a pixel-level mask (elaborated in Section 3). Inspired by the above, in this paper, we propose a novel and extensive approach which formulates IUR as semantic segmentation[1]. Our contributions are as follows:

- As far as we know, we are the first to present such a highly extensive approach which formulates the incomplete utterance rewriting as a semantic segmentation task.
- Benefiting from being able to capture both local and global information, our approach achieves state-of-the-art performance on several datasets across different domains and languages.
- Furthermore, our model predicts the edit operations in parallel, and thus obtains a much faster inference speed than traditional methods.

2 Related Work

The most related work to ours is the line of incomplete utterance rewriting. Recently, it has raised a large attention in several domains. In question answering, previous works include non-sentential utterance resolution using the sequence to sequence based architecture (Kumar and Joshi, 2016), incomplete follow-up question resolution via a retrieval sequence to sequence model (Kumar and Joshi, 2017) and sequence to sequence model with a copy mechanism (Elgohary et al., 2019; Quan et al., 2019). In conversational semantic parsing, Liu et al. (2019b) proposed a novel approach which considers the structures of questions, while Liu et al. (2019a) imposed an intermediate structure span and decomposed the incomplete utterance rewriting into two sub-tasks. In dialogue generation, Pan et al. (2019) presented a cascaded model which first picks words from the context via BERT, and then combines these words to generate the rewritten utterance, and Su et al. (2019) distinguished the weights of context utterances and the incomplete utterance using a hyper-parameter λ. Different from all of them, we formulate the task as a semantic segmentation task.

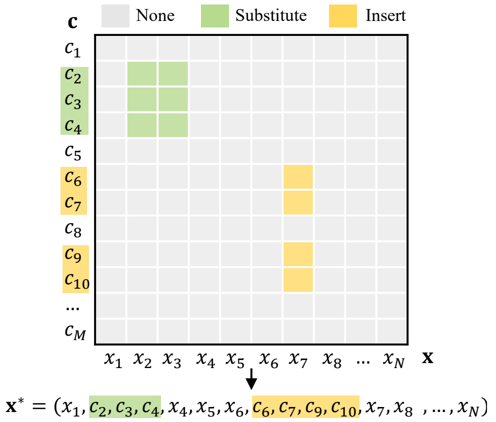

Figure 1: The illustration of the word-level edit matrix applied in our formulation. Each cell belongs to one of three edit types: `None`, `Substitute` and `Insert`.

Our work is also closely related to coreference resolution. It is an active task that has been studied years, and deep learning based methods have achieved state-of-the-art performance via the paradigm of scoring span or mention pairs (Clark and Manning, 2015, 2016; Lee et al., 2017, 2018). Researchers also explored to use unsupervised contextualized representations to enhance the coreference resolution. Joshi et al. (2019) applied SpanBERT (Joshi et al., 2020) to enhance the span representation in coreference resolution, and Wu et al. (2020) formulated coreference resolution as query-based span prediction and employed SpanBERT to solve it as a machine reading task. The above works only focus on coreference resolution, while our work deals with coreference and ellipsis under a unified approach.

From the perspective of the methodology, our work is correlated with directions of edit-based text generation and semantic similarity measurement. Wu et al. (2019) proposed a prototype-then-edit paradigm for open-domain response generation, while Malmi et al. (2019) cast text generation as a text editing task and tackled it with a

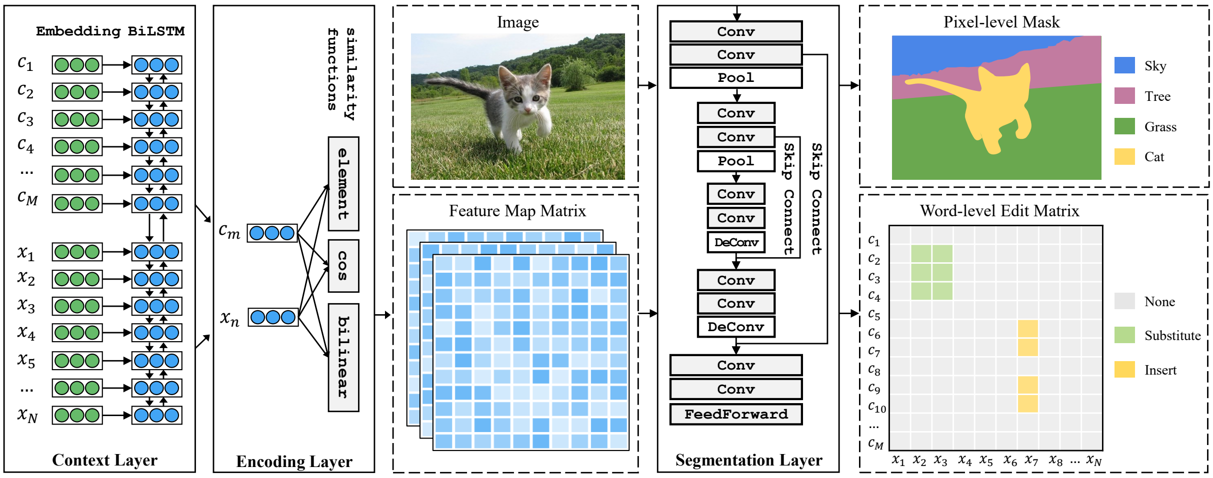

Figure 2: The illustration of the word-level edit matrix construction. The dashed boxes represent the intermediate results of our proposed model (**bottom**) and their counterparts in semantic segmentation (**above**). Inside the segmentation layer, a "Conv" module consists of a convolutional neural network, batch normalization and an activation function ReLU. "Pool" and "DeConv" are short for max pooling and deconvolution neural network respectively.

sequence tagging approach. Our work is different from theirs since we model the editing process between two sentences as a semantic segmentation task. As for semantic similarity measurement, similar to us, both He and Lin (2016) and Pang et al. (2016) used convolutional neural networks to capture similarities between sentences.

3 Incomplete Utterance Rewriting as Semantic Segmentation

In this section, we will have a glance at the fundamental idea behind our approach: incomplete utterance rewriting as semantic segmentation.

In a multi-turn dialogue, given the context utterances $(\mathbf{x}_1, \cdots, \mathbf{x}_{t-1})$ and the incomplete utterance $\mathbf{x}_t$, IUR is to rewrite $\mathbf{x}_t$ to $\mathbf{x}_t^*$ using contextual information, where $\mathbf{x}_t^*$ has the same meaning with $\mathbf{x}_t$. The rewritten utterance $\mathbf{x}_t^*$ has self-contained semantics and can be understood solely. To produce $\mathbf{x}_t^*$, our approach formulates the problem as a semantic segmentation task. Concretely, we concatenate all the context utterances to produce an M-length word sequence $\mathbf{c} = (c_1, c_2, \cdots, c_M)$. To separate context utterances in different turns, we insert a special word [S] between each context utterance. Meanwhile, the incomplete utterance is denoted by $\mathbf{x} = (x_1, x_2, \cdots, x_N)$. As mentioned, the rewritten utterance $\mathbf{x}^*$ can be obtained by editing the incomplete utterance $\mathbf{x}$ with in-dialogue words (i.e. words in $\mathbf{c}$). To model edit operations between $\mathbf{x}$ and $\mathbf{c}$, we define a $M \times N$ matrix Y, where the entry $Y_{m,n}$ indicates the edit type between c_m and x_n. There are three kinds of edit types: `Substitute` means replacing the span in $\mathbf{x}$ with the corresponding context span in $\mathbf{c}$; `Insert` aims to insert the context span before a certain token in $\mathbf{x}$, and `None` represents no operation. For example, as shown schematically in Figure 1, we can edit $\mathbf{x}$ by replacing (x_2, x_3) with (c_2, c_3, c_4) and insert (c_6, c_7, c_9, c_{10}) before x_7. It is notable that we append a special word [E] to $\mathbf{x}$, to enable `Insert` take place after $\mathbf{x}$. More concrete examples can be found in Section 5.3.

Then, we propose to emit such a matrix Y in a way analogous to the task of semantic segmentation. Specially, we build a $M \times N$ feature map via capturing the word-to-word relevance between $\mathbf{c}$ and $\mathbf{x}$. Taking the feature map as an image, the output word-level edit matrix Y is parallel to the pixel-level mask in semantic segmentation, which bridges IUR and semantic segmentation. Such a formulation comes with several key advantages: (i) **Easy**: compared with traditional methods generating the rewritten utterance from scratch, such a formulation introduces edit operations to lower the difficulty of generation; (ii) **Fast**: these edits are predicted concurrently, so our model naturally enjoys the fast inference speed than conventional models which decode word by word; (iii) **Transferable**: taking the formulation as a bridge between IUR and semantic segmentation, one can transfer empirical models from the community of semantic segmentation with ease.

4 Methodology

As shown in Figure 2, our approach firstly obtains the word-level edit matrix through three neural layers. Then based on the word-level edit matrix, it applies a generation algorithm to produce the rewritten utterance. Since the model yields a U-shaped architecture (illustrated later), we name our approach as **R**ewritten **U**-shaped **N**etwork (**RUN**).

4.1 Word-level Edit Matrix Construction

To construct a word-level edit matrix, our model passes through three neural layers: a context layer, an encoding layer and a subsequent segmentation layer. The context layer produces a context-aware representation for each word in both $\mathbf{c}$ and $\mathbf{x}$, based on which the encoding layer forms a feature map matrix $\mathbf{F}$ to capture word-to-word relevance. Finally a segmentation layer is applied to emit the word-level edit matrix.

Context Layer As shown in the left of Figure 2, at first the concatenation of $\mathbf{c}$ and $\mathbf{x}$ passes by the word embedding ϕ to get the representation for each word in both utterances. The embedding is initialized using GloVe (Pennington et al., 2014), and then updated along with other parameters. On top of the joint word embedding sequence $\big(\phi(c_1),\cdots,\phi(c_M),\phi(x_1),\cdots,\phi(x_N)\big)$, Bidirectional Long Short-Term Memory Network (BiLSTM) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997) is applied to capture contextual information inter and intra utterances. Although $\mathbf{c}$ and $\mathbf{x}$ are jointly encoded by BiLSTM (see the left of Figure 2), below we distinguish their hidden states for clear illustration. For a word $c_m(m=1,\ldots,M)$ in $\mathbf{c}$, its hidden state is denoted by $\mathbf{u}_m$ obtained through BiLSTM, while the hidden state $\mathbf{h}_n$ is for word $x_n(n=1,\cdots,N)$ in the incomplete utterance.

Encoding Layer On top of the context-aware hidden states, we consider several similarity functions to encode the word-to-word relevance. Concretely, for each word x_n in the incomplete utterance and c_m in the context utterances, their relevance is captured by a D-dimensional feature vector $\mathbf{F}(x_n, c_m)$. It is produced by concatenating element-wise similarity (Ele Sim.), cosine similarity (Cos Sim.) and learned bi-linear similarity (Bi-Linear Sim.) between them as:

$$\mathbf{F}(x_n, c_m) = \big[\mathbf{h}_n \odot \mathbf{u}_m; \cos(\mathbf{h}_n, \mathbf{u}_m); \mathbf{h}_n \mathbf{W} \mathbf{u}_m\big], \quad (1)$$

where $\mathbf{W}$ is a learned parameter. These similarity functions are expected to model the word-to-word relevance from different perspectives, important for the follow-up edit type classification. However, they concentrate on local rather than global information (see discussion in Section 5.3). To capture global information, a segmentation layer is proposed.

Segmentation Layer Taking the feature map matrix $\mathbf{F} \in \mathbb{R}^{M\times N\times D}$ as a D-channel image, the segmentation layer is to predict the word-level edit matrix $Y \in \mathbb{R}^{M\times N}$, analogous to a pixel-level mask. Inspired by UNet (Ronneberger et al., 2015), the layer is formed as a U-shaped structure: two down-sampling blocks and two up-sampling blocks with skip connection. A down-sampling block contains two separate “Conv” modules and a subsequent max pooling. Each down-sampling block doubles the number of channels. Intuitively, the down-sampling block expands the receptive fields of each cell, hence providing rich global information for the final decision. An up-sampling block contains two separate “Conv” modules, and a subsequent deconvloution neural network. Each up-sampling block halves the number of channels and concatenates the correspondingly cropped feature map in down-sampling as the output (skip connect in Figure 2). Finally a feedforward neural network is employed to map each feature vector to one of three edit types, obtaining the word-level edit matrix Y. By incorporating an encoding layer and a segmentation layer, our model is able to capture both local and global information.

BERT Enhanced Embedding Since pretrained language models have been proven to be effective on several tasks, we also experiment with employing BERT (Devlin et al., 2019) to augment our model via BERT enhanced embedding.

4.2 Rewritten Utterance Generation

Once a word-level edit matrix is emitted, a subsequent generation algorithm is applied for producing the rewritten utterance. As indicated in Figure 1, to apply edit operations without ambiguity, we assume each edit region in Y is a rectangle. However, the predicted Y is not guaranteed to meet this requirement, indicating the need for a standardization step. Therefore, the overall procedure of generation is divided into two stages: first the algorithm delimits standard edit regions via searching minimal covering rectangles for each connected region; then it manipulates the incomplete utterance based on these standard edit regions to produce the rewritten utterance. Since the second step has been illustrated in Section 3, in the following we concentrate on the first standardization step.

In the standardization step, we employ the two-pass algorithm (also known as Hoshen–Kopelman algorithm) to find connected regions (Hoshen and Kopelman, 1976). In a nutshell, the algorithm makes two passes over the word-level edit matrix. The first pass is to assign temporary cluster labels and record equivalences between clusters in an order of left to right and top to down. Concretely, for each cell, if its neighbors (i.e. left or top cells with the same edit type) have been assigned temporary cluster labels, it is labeled as the smallest neighboring label. Meanwhile, its neighboring clusters are recorded as equivalent. Otherwise, a new temporary cluster label is created for the cell. The second pass is to merge temporary cluster labels which are recorded as equivalent. Finally, cells with the same label form a connected region. For each connected region, we use its minimal covering rectangle to serve as the output of our model.

4.3 Distant Supervision

As mentioned in Section 3, the expected supervision for our model is the word-level edit matrix, but existing datasets only contain rewritten utterances. Therefore, we use a procedure to automatically derive (noisy) word-level edit matrices (i.e. distant supervision), and use these examples to train our model. We use the following process to build our training set. First, we find a **L**ongest **C**ommon **S**ubsequence (**LCS**) between $\mathbf{x}$ and $\mathbf{x}^*$. Then, for each word in $\mathbf{x}^*$, if it is not in LCS, it is marked as Add. Conversely, for each word in $\mathbf{x}$ but not in LCS, it is marked as Del. Contiguous words with the same mark are merged into one span. By a span-level comparison, any Add span in $\mathbf{x}^*$ with a Del counterpart (i.e. under the same context) relates it to `Substitute`. Otherwise, the span is inserted into $\mathbf{x}$, corresponding to `Insert`.

Taking the example from Table 1, given $\mathbf{x}$ as "为什么总是这样"(Why is always this) and $\mathbf{x}^*$ as "北京为什么总是阴天"(Why is Beijing always cloudy), their longest common subsequence is "为什么总是"(Why is always). Therefore, with "这样"(this) in $\mathbf{x}$ being marked as Del and "阴天"(cloudy) in $\mathbf{x}^*$ being marked as Add, they correspond to the edit type `Substitute`. In comparison, since "北京"(Beijing) cannot find a counterpart, it is related to the edit type `Insert`.

5 Experiments

In this section, we conduct thorough experiments to demonstrate the superiority of our approach.

5.1 Experimental Setup

Datasets We conduct experiments on four public datasets across different domains: Open-Domain Dialogue (Multi Pan et al., 2019, Rewrite Su et al., 2019), Task-Oriented Dialogue (Task Quan et al., 2019) and Question Answering in Context (Canard Elgohary et al., 2019). We use the same data split for these datasets as their original paper, and some statistics are shown in Table 3.

Baselines We consider a bunch of baselines, including LSTM-based models, Transformer-based models and state-of-the-art models on each dataset. (i) **LSTM-based models** consist of the vanilla sequence to sequence model with attention (L-Gen) (Bahdanau et al., 2015), the pointer network architecture (L-Ptr) (Vinyals et al., 2015) and the hybrid pointer generator network (L-Ptr-Gen) (See et al., 2017). (ii) **Transformer-based models** consist of the basic transformer model (T-Gen) (Vaswani et al., 2017), the transformer-based pointer network (T-Ptr), and the transformer-based pointer generator (T-Ptr-Gen). (iii) **State-of-the-art models** consist of Syntactic (Kumar and Joshi, 2016), PAC (Pan et al., 2019), GECOR (Quan et al., 2019), L-Ptr-λ and T-Ptr-λ (Su et al., 2019). We refer readers to their papers for more details. It is remarkable that above methods all generate rewritten utterances from scratch.

Evaluation We employ both automatic metrics and human evaluations to evaluate our approach. As in literature (Pan et al., 2019), we examine RUN using the widely used automatic metrics BLEU, ROUGE, EM and Rewriting F-score. (i) **BLEU**$_n$ (**B**$_n$) evaluates how similar the rewritten utterances are to the golden ones via the cumulative n-gram BLEU score (Papineni et al., 2002). (ii) **ROUGE**$_n$ (**R**$_n$) measures the n-gram overlapping between the rewritten utterances and the golden ones, while **ROUGE**$_L$ (**R**$_L$) measures the longest matching sequence between them (Lin, 2004). (iii) **EM** stands for the exact match ac-

curacy, which is the strictest evaluation metric. (iv) **Rewriting Precision**$_n$, **Recall**$_n$ and **F-score**$_n$ ($\mathcal{P}_n, \mathcal{R}_n, \mathcal{F}_n$) emphasize more on words from $\mathbf{c}$ which are argued to be harder to copy (Pan et al., 2019). Therefore, they are calculated on the collection of n-grams that contain at least one word from $\mathbf{c}$. As validated by Pan et al. (2019), above automatic metrics are credible indicators to reflect the rewrite quality. However, none of automatic metrics reflects the utterance fluency or the improvement on downstream tasks. Therefore, human evaluations are included to evaluate the fluency of rewritten utterances and their boost on the downstream task.

Implementation Details Our implementation was based on PyTorch (Paszke et al., 2019), AllenNLP (Gardner et al., 2018) and HuggingFace's transformers library (Wolf et al., 2019). Since the distribution of edit types is severely unbalanced (e.g. `None` accounts for nearly 90%), we employed weighted cross-entropy loss and tuned the weight on development sets. We used Adam (Kingma and Ba, 2015) to optimize our model and set the learning rate as 1e-3, except for BERT as 1e-5. The embedding size and hidden size in BiLSTM are 100 and 200 respectively. Specifically, BERT mentioned above refer to BERT$_{\text{base}}$. All results of baselines without specific marks were reproduced by ours using OpenNMT with beam size as 4 (Klein et al., 2017).

Connection Words Similar to pointer network (Vinyals et al., 2015), RUN is restricted to predict words which have appeared in the dialogue. Although most examples work well under the restriction, there still exist a few cases which rely on certain words to generate fluent utterances. For example, when rewriting possessive pronouns such as “their”, we usually need an extra word “of” to enhance the fluency. Such common words, named after *connection words*, improve fluency of the rewritten utterances. In practice, we append a small list of connection words to the tail of $\mathbf{c}$, enabling our model to pick connection words as well. For each dataset, their connection word list is automatically derived from the training data.

5.2 Model Comparison

Table 2 and Table 4 show experimental results of our approach and baselines on MULTI and REWRITE. As shown, our approach outperforms all baselines significantly. Taking MULTI as an

	T-Ptr-Gen	77.1	+3.5	374 ms	0.22 ×
-	RUN (Ours)	79.4	+5.8	21 ms	3.90×

Table 8: The inference speed comparison between RUN and baselines. Beam stands for the beam size in beam search, not applicable for RUN. Latency is computed as the time to produce a single sentence without data batching, averaged over the development set of REWRITE. All models are implemented in PyTorch on a single NVIDIA V100.

example, our approach exceeds the best baseline L-Ptr-Gen by a large margin, reaching a new state-of-the-art performance on almost all automatic metrics. To illustrate, our approach improves the previous best model by 6.4 points and 10.0 points on $\mathbf{B}_1$ and $\mathcal{F}_1$ respectively. Furthermore, our approach leaves a striking impression when augmented with BERT. It not only fully surpasses the best sequence generation baseline with BERT (i.e. T-Ptr-λ+BERT on REWRITE), but also obtains a considerable boost over a cascade model designed for stimulating potential of BERT (i.e. PAC on MULTI). Even for the most challenging metric **EM** on REWRITE, RUN with BERT improves 8.9 points, demonstrating the superiority of our model. Besides, our approach also achieves comparable or better results against all baselines on TASK and CANARD, as shown in Table 5.

Besides automatic results, we perform two groups of human evaluation to answer (i) how fluent the rewritten utterances are and (ii) how much IUR can contribute to downstream tasks. For the evaluation of fluency, we randomly sampled 500 dialogues in the development set of REWRITE. Then we fed them to representative IUR models and presented generated rewritten utterances to 10 judges, who are asked to decide which of the rewritten utterances is of higher fluency in pairwise comparisons. Ties are acceptable. Table 6 shows the evaluation results. In comparison to the best baseline T-Ptr-λ, our model only loses in 20.4% cases, which is extremely competitive.

To access the influence of IUR on downstream tasks, we choose multi-turn response selection as a representative, which aims to retrieve suitable responses from a candidate pool considering the context. Concretely, an SMN model trained on the Douban Conversation Corpus is selected as the backbone in multi-turn response selection (Wu et al., 2017). At first we sampled 300 dialogues from the development set of MULTI as the input to IUR models. Then their predicted rewritten utterances and the context utterances were fed into the SMN model, to help it select suitable responses.

Variant	$\mathcal{F}_1$	$\mathcal{F}_2$	$\mathcal{F}_3$	$\mathbf{B}_2$	$\mathbf{R}_2$
RUN	60.3	47.8	39.4	87.9	83.2
w/o Edit	0.0	0.0	0.0	77.4	75.6
w/o U-shape Seg.	55.2	41.4	33.1	86.1	82.5
w/o Ele Sim.	60.4	47.1	38.3	86.8	82.6
w/o Cos Sim.	62.3	48.4	39.2	85.3	82.3
w/o Bi-Linear Sim.	61.6	48.0	39.0	85.8	82.6

Table 9: The ablation results on the development set of MULTI. "w/o Edit" means directly using the current utterance as the rewritten utterance. "w/o U-shape seg." means that our segmentation layer is replaced by a feed-forward neural network with comparable parameters. The remaining variants ablate different similarity functions in the encoding layer.

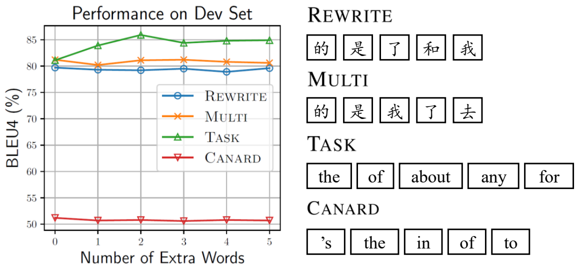

Figure 3: (**Left**) BLEU4 ($\mathbf{B}_4$) performance with different number of connection words on the development sets of different datasets. (**Right**) Connection words in decreasing order of frequency on each dataset.

The response candidate pool was formed by all utterances in MULTI. Finally, 5 workers were asked to evaluate responses following a multi-scale rating from 0 to 2: 0 means the response is not related to the dialogue; 1 means the response is related but not interesting enough; and 2 means the response is satisfying. To illustrate more clearly, we also conduct human rating evaluation on responses under the settings of original dialogue (i.e. without rewriting, relying on the SMN model itself to understand the context) and gold dialogue (i.e. human rewriting). As shown in Table 7, our model achieves the highest response quality score among IUR models, improving the original setting by 19% relatively. Considering that the SMN model is capable of aggregating implicit context information, it is non-trivial for our model to further improve the response quality.

5.3 Closer Analysis

We conduct a series of experiments to analyze our model deeply. First we conduct an inference speed comparison between our model and representative baselines under the same run-time environment. Then we verify the effectiveness of components in our model by a thorough ablation study. Meanwhile, we touch how the amount of connection words affect the performance. Finally, we present two real cases to illustrate our model concretely.

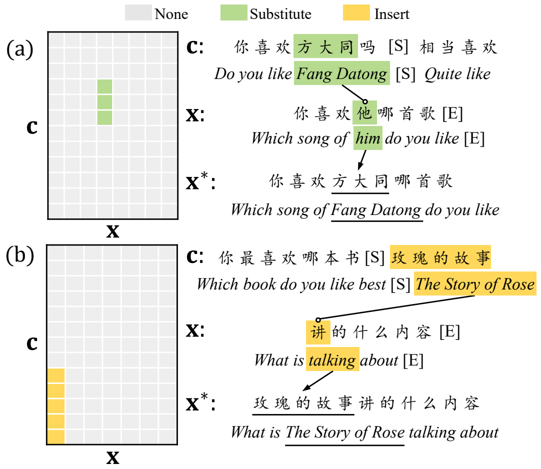

Figure 4: The illustration of (**Left**) the word-level edit matrix and (**Right**) the rewritten utterance generation process of two real cases (a) and (b) from REWRITE.

Inference Speed Table 8 compares inference speed between our model and baselines. Since L-Ptr-λ and T-Ptr-λ are not implemented under PyTorch, we do not show their inference time for fair consideration. Noticing the beam size would affect the inference time of baselines, we also show the results with beam size as 1. Using the simplest L-Gen as a standard, one can find that our model is nearly four times faster, with the highest improvement $\Delta\mathbf{B}_4$. Meanwhile, our model is the only one which can improve both performance and inference speed, significantly surpassing all baselines.

Ablation Study To verify the effectiveness of different components in our model, we present a thorough ablation study in Table 9. As expected, "w/o Edit" causes a huge drop on all evaluation metrics. Notably, the extreme drop on $\mathcal{F}_n$ indicates that it is more suited for IUR than common metrics. "w/o U-shape Seg.", which ablates the segmentation layer, also brings a great performance drop. Without our segmentation layer capturing global information, an encoding layer only achieves comparable performance with L-Gen, suggesting there are considerable benefits with bridging IUR and semantic segmentation. We also ablates different feature similarity functions (i.e. "w/o Ele Sim.", "w/o Cos Sim." and "w/o Bi-

Linear Sim.") for an in-depth analysis. As shown in Table 9, ablating each similarity function will hurt most metrics. Meanwhile, our model does not depend on any similarity function severely, showing its robustness. Furthermore, we explore how the amount of connection words affect the performance in Figure 3. As indicated, except TASK, the number of connection words affect slightly. Nevertheless, it shows a positive effect overall, providing a way to generate out-of-dialogue words. We present two real cases in Figure 4 from REWRITE to illustrate the rewritten process of our model concretely. For both (a) coreference and (b) ellipsis, our model deals with them flexibly.

5.4 Discussion

While our approach has made some progress, it still has several limitations. First, our model severely relies on the word order implied by the dialogue. It makes our model vulnerable to some complex cases (i.e. multiple `Insert` corresponds to one position). The second limitation is that we predict edit types of each cell independently, ignoring the relationship between neighboring edit types. It is hopefully resolved by the conditional random field algorithm (Arnab et al., 2018).

The above limitations may raise concerns about the performance upper bound of our approach. In fact, it is not an issue. On three out of four datasets used in the experiments, more than 85% examples could be tackled perfectly by our approach (87.6% in TASK, 91.0% in REWRITE, 95.3% in MULTI). The number in CANARD is relatively low (42.5%) since human annotators introduce many new words in rewriting. Nevertheless, the BLEU upper bound in CANARD could be as high as 72.5% with our approach, which is acceptable.

The last point we focus on is why similarities can be good features for determining edits. We think it can be elaborated from two aspects. For coreference, the similarity function is suitable for identifying whether two spans refer to the same entity. For ellipsis, the similarity function is an effective indicator to find matching anchors, which indicate the possible insertion positions.

6 Conclusion & Future Work

In this paper, we present a novel and extensive approach which formulates the incomplete utterance rewriting as a semantic segmentation task. On top of the formulation, we carefully design a U-shaped rewritten network, which outperforms existing baselines significantly on several datasets. In the future, we will investigate on extending our approach to more areas.

Abstract

A sequence-to-sequence (seq2seq) learning with neural networks empirically shows to be an effective framework for grammatical error correction (GEC), which takes a sentence with errors as input and outputs the corrected one. However, the performance of GEC models with the seq2seq framework heavily relies on the size and quality of the corpus on hand. We propose a method inspired by adversarial training to generate more meaningful and valuable training examples by continually identifying the weak spots of a model, and to enhance the model by gradually adding the generated adversarial examples to the training set. Extensive experimental results show that such adversarial training can improve both the generalization and robustness of GEC models.

Clean	His reaction should give you an idea as to whether this matter is or is not your business .
Direct Noise	~~His~~ reaction should give you an as idea to whether this ~~matter is~~ or so is not your business .
Back Translation	His reaction should give you the idea ~~as to~~ whether this matter is or is not your business .
Adversarial Example	His reaction should gave you an idea as to whether this matter is or n't their business .

Table 1: Example ungrammatical sentences generated by different methods. The direct noise method seems to add some meaningless noises to the original sentence. Most of the grammatical errors generated by the back translation are those produced by replacing prepositions, and inserting or deleting articles. The example generated by our adversarial attack algorithm looks more meaningful and valuable.

1 Introduction

The goal of Grammatical Error Correction (GEC) is to identify and correct different kinds of errors in the text, such as spelling, punctuation, grammatical, and word choice errors, which has been widely used in speech-based dialogue, web information extraction, and text editing software.

A popular solution tackles the grammatical error correction as a monolingual machine translation task where ungrammatical sentences are regarded as the source language and corrected sentences as the target language (Ji et al., 2017; Chollampatt and Ng, 2018a). Therefore, the GEC can be modeled using some relatively mature machine translation models, such as the sequence-to-sequence (seq2seq) paradigm (Sutskever et al., 2014).

They are many types of grammatical errors and all of them can occur in a sentence, which makes it impossible to construct a corpus that covers all kinds of errors and their combinations. Deep learning so far is data-hungry and it is hard to train a seq2seq model with good performance without sufficient data. Therefore, recent studies have turned the focus to the methods of generating high-quality training samples (Xie et al., 2018; Lichtarge et al., 2019; Zhao et al., 2019). Generating pseudo training data with unlabeled corpora can be roughly divided into direct noise and back translation (Kiyono et al., 2019). The former applies text editing operations such as substitution, deletion, insertion and shuffle, to introduce noises into original sentences, and the latter trains a clean-to-noise model for error generation. However, the noise-corrupted sentences are often poorly readable, which are quite different from those made by humans. The sentences generated by the back translation also usually cover a few limited types of errors only[1], and it is difficult for the back translation to generate the errors not occurred in the training set. Although these methods can produce many ungrammatical

---

[1] Most of the errors are generated by replacing prepositions and inserting or deleting articles, which occur more frequently in the GEC training set.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2858–2869,
November 16–20, 2020.

examples, most of them have little contribution to improving the performance.

We also found that the resulting models are still quite vulnerable to adversarial examples, although they are trained with the data augmented by their methods. Taking a state-or-the-art system of Zhao et al. (2019) on CoNLL-2014 (Ng et al., 2014) as an example, we generate adversarial samples by intentionally introducing few grammatical errors into the original clean sentences under a white-box setting[2]. The model's performance of $F_{0.5}$ drops from 0.592 to 0.434 if just one grammatical error is added into each sentence, to 0.317 if three errors are added. To our knowledge, we first show in this study that adversarial examples also exist in grammatical error correction models.

Inspired by adversarial attack and defense in NLP (Jia and Liang, 2017; Zhao et al., 2017; Cheng et al., 2018), we explore the feasibility of generating more valuable pseudo data via adversarial attack, targeting the weak spots of the models, which can improve both the quality of pseudo data for training the GEC models and their robustness against adversarial attacks. We propose a simple but efficient method for adversarial example generation: we first identify the most vulnerable tokens with the lowest generation probabilities estimated by a pre-trained GEC model based on the seq2seq framework, and then we replace these tokens with the grammatical errors people may make to construct the adversarial examples.

Once the adversarial examples are obtained, they either can be merged with the original clean data to train a GEC model or used to pre-train a model thanks to their coming with great numbers. The examples generated by our method based on the adversarial attack are more meaningful and valuable than those produced by recent representative methods, such as the direct noise and the back translation (see Table 1). Through extensive experimentation, we show that such adversarial examples can improve both generalization and robustness of GEC models. If a model pre-trained with large-scale adversarial examples is further fine-tuned by adversarial training, its robustness can be improved about 9.5% while without suffering too much loss (less than 2.4%) on the clean data.

2 Related Work

2.1 Grammatical Error Correction

The rise of machine learning methods in natural language processing (NLP) has led to a rapid increase in data-driven GEC research. The predominant paradigm for the data-driven GEC is arguably sequence-to-sequence learning with neural networks (Yuan and Briscoe, 2016; Xie et al., 2016; Sakaguchi et al., 2017; Schmaltz et al., 2017; Ji et al., 2017), which is also a popular solution for machine translation (MT).

Some task-specific techniques have been proposed to tailor the seq2seq for the GEC task. Ji et al. (2017) proposed a hybrid neural model using word and character-level attentions to correct both global and local errors. Zhao et al. (2019) explicitly applied the copy mechanism to the GEC model, reflecting the fact that most words in sentences are grammatically correct and should not be changed. Diverse ensembles (Chollampatt and Ng, 2018a), rescoring (Chollampatt and Ng, 2018b), and iterative decoding (Ge et al., 2018; Lichtarge et al., 2018) strategies also have been tried to tackle the problem of incomplete correction.

Although the advancement of the GEC has made an impressive improvement, the lack of training data is still the main bottleneck. Very recently, data augmentation techniques began to embark on the stage (Xie et al., 2018; Zhao et al., 2019). The GEC models that achieved the competitive performance (Kiyono et al., 2019; Zhao et al., 2019; Lichtarge et al., 2019; Grundkiewicz et al., 2019) were usually pre-trained on large unlabeled corpora and then fine-tuned on the original training set.

2.2 Textual Adversarial Attack

Fooling a model by perturbing its inputs, which is also called an adversarial attack, has become an essential means of exploring the model vulnerabilities. To go a further step, incorporating adversarial samples in the training stage, also known as adversarial training, could effectively improve the models' robustness. Depending on the degree of access the target model, adversarial examples can be constructed in two different settings: white-box and black-box settings. An adversary can access the model's architecture, parameters, and input feature representations in the white-box setting while not in the black-box one. The white-box attacks typically yield a higher success rate because the knowledge of target models can guide the genera-

---

[2] In contrast to a black-box setting, an attacker can access to the model's architecture, parameters, and training data set under the white-box setting.

tion of adversarial examples. However, the black-box attacks do not require access to target models, making them more practicable for many real-world attacks.

Textual adversarial attack for adversarial samples has been applied to several NLP tasks such as text classification (Ebrahimi et al., 2017; Samanta and Mehta, 2017; Liang et al., 2017), machine translation (Zhao et al., 2017; Cheng et al., 2018), reading comprehension (Jia and Liang, 2017), dialogue systems (Cheng et al., 2019), and dependency parsing (Zheng et al., 2020). Text adversarial example generation can be roughly divided into two steps: identifying weak spots and token substitution. Many methods including random selection (Alzantot et al., 2018), trial-and-error testing at each possible point (Kuleshov et al., 2018), analyzing the effects on the model of masking input text (Samanta and Mehta, 2017; Gao et al., 2018; Jin et al., 2019), comparing attention scores (Hsieh et al., 2019), or gradient-based methods (Ebrahimi et al., 2017; Lei et al., 2018; Wallace et al., 2019) have been proposed to select the vulnerable token. The selected tokens then will be replaced with similar ones to change the model prediction. Such substitutes can be chosen from nearest neighbors in embedding spaces (Alzantot et al., 2018; Jin et al., 2019), synonyms in a prepared dictionary (Samanta and Mehta, 2017; Ebrahimi et al., 2017), typos (Liang et al., 2017), paraphrases (Lei et al., 2018), or randomly selected ones (Gao et al., 2018).

3 Method

3.1 Baseline Model

We formally define the GEC task and then briefly introduce the seq2seq baseline. As we mentioned above, the GEC can be modeled as an MT task by viewing an ungrammatical sentence $\boldsymbol{x}$ as the source sentence and a corrected one $\boldsymbol{y}$ as the target sentence. Let $\mathcal{D} = \{(\boldsymbol{x}, \boldsymbol{y})\}_n$ be a GEC training dataset. The seq2seq model first encode a source sentence having N tokens into a sequence of context-aware hidden representations $h^s_{1:N}$, and then decodes the target hidden representations h^t_i from the representations of $h^s_{1:N}$. Finally, the target hidden representations can be used to produce the generation probability $p(y_i|y_{1:i-1})$, also called *positional score* $g(y_i)$, and to generate the output sequence $y_{1:i-1}$ through the projection matrix W^H and softmax layer as follows.

$$h^s_i = encoder(x_i) \tag{1}$$

$$h^t_i = decoder(y_{1:i-1}, h^s_{1:N}) \tag{2}$$

$$p(y_i|y_{1:i-1}, \boldsymbol{x}) = softmax(h^t_i W^H) \tag{3}$$

$$g(y_i) = log(p(y_i|y_{1:i-1}, \boldsymbol{x})) \tag{4}$$

The negative log-likelihood of generation probabilities is used as the objective function, where θ are all the model parameters to be trained.

$$\mathcal{L}(\theta) = -\frac{1}{|\mathcal{D}|} \sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{D}} \log(p(\boldsymbol{y}|\boldsymbol{x})) \tag{5}$$

3.2 Adversarial Example Generation

We found that adversarial examples also exist in the GEC models and up to 100% of input examples admit adversarial perturbations. Adversarial examples yield broader insights into the targeted models by exposing them to such maliciously crafted examples. We try to identify the weak spots of GEC models by a novel adversarial example generation algorithm that replaces the tokens in a sentence with the grammatical mistakes people may make. Our adversarial example generation algorithm also uses the two-step recipe: first determining the important tokens to change and then replacing them with the grammatical mistakes that most likely occur in the contexts.

3.2.1 Identifying Weak Spots

We use the positional scores to find the vulnerable tokens (or positions) that most likely can successfully cause the models to make mistakes once they are modified. The lower the positional score of a token is, the lower confidence the model gives its prediction, and the more likely this prediction will be changed. Using the positional scores also brings another advantage that helps us reduce the bias in the generated pseudo data where too many grammatical errors are caused by the misuse of function words, such as prepositions and articles.

We found that the words having relatively lower positional scores are lexical or open class words such as nouns, verbs, adjectives and adverbs. Besides, rare and out-of-vocabulary words are also given low positional scores. By adding the pseudo examples generated by making small perturbations to those tokens, we can force a GEC model to better explore the cases that may not be encountered before. If the function words are used correctly, the model usually gives higher positional scores to them; otherwise, the model will lower its confidence in the prediction by decreasing such scores, which is precisely what we expect.

We here formally describe how to use the positional scores to locate the weak spots of a sentence. Like (Bahdanau et al., 2014; Ghader and Monz, 2017), we first use the attention weights $\boldsymbol{\alpha_{i,j}}$ of a seq2seq-based model to obtain the soft word alignment between the target token y_i and the source one x_j by Equation (6) and (7) below:

$$q_i, k_j = h_i^t W^Q, h_j^s W^K \tag{6}$$

$$\boldsymbol{\alpha_{i,j}} = softmax(\frac{q_i \cdot k_j}{\sqrt{d_k}}) \tag{7}$$

where W^Q and W^K denote the projection matrices required to produce the representations of a query q_i and a key k_j from which an attention score can be computed, and d_k is the dimension of h_j^s. We then can obtain a word alignment matrix $\boldsymbol{A}$ from the attention weights $\boldsymbol{\alpha_{i,j}}$ as follows:

$$\boldsymbol{A}_{i,j}(\boldsymbol{\alpha}) = \begin{cases} 1 & j = \arg\max_{j'} \boldsymbol{\alpha}_{i,j'} \\ 0 & o/w \end{cases} \tag{8}$$

When $\boldsymbol{A}_{i,j} = 1$, we known that y_i is aligned to x_j. If y_i is identified as a vulnerable token, we try to make perturbation to x_j to form an attack. The positional scores $g(y_i)$ are obtained by the GEC model trained on the original training set. If the token's positional score $g(y_i)$ is less than a given threshold ϵ, we take x_j as a candidate to be modified to fool the target GEC model.

$$\boldsymbol{A}_{i,j} = 1, g(y_i) < \epsilon \tag{9}$$

3.2.2 Word Substitution-based Perturbations

Although adversarial examples have been studied recently for NLP tasks, previous work almost exclusively focused on semantic tasks, where the attacks aim to alter the semantic prediction of models (e.g., sentiment prediction or question answering) without changing the meaning of original texts. Once a vulnerable position is determined, the token at that position is usually replaced with one of its synonyms. However, generating adversarial examples through such synonym-based replacement is no longer applicable to the GEC task.

Motivated by this, we propose two methods to replace vulnerable tokens. One is to create a correction-to-error mapping from a GEC training set and get a suitable substitute using this mapping. If there are multiple choices, we sample a substitute from those choices according to the similarity of their context. Another is to generate a substitute based on a set of rules that imitates human errors. We give a higher priority to the former than the latter when generating the adversarial examples for the GEC.

Context-Aware Error Generation From a parallel training set of GEC, we can build a correction-to-error mapping, by which given a token, we can obtain its candidate substitutes (with grammatical errors) and their corresponding sentences. Assuming that a token is selected to be replaced, and its candidate substitutes are retrieved by the mapping, we want the selected substitute can fit in well with the token's context and maintain both the semantic and syntactic coherence. Therefore, we define a function s based on the edit distance (Marzal and Vidal, 1993) to estimate the similarity scores between two sentences. This function allows us to estimate how well a substitute's context sentence c_i' is similar to an original sentence c_i to be intentionally modified. To encourage the diversity of generated examples, we choose to sample a substitute from the candidates according to the weights w_i derived from their sentences' similarity scores to the original one as follows.

$$w_i = \begin{cases} s(c_i, c_i') & s(c_i, c_i') > \lambda \\ \lambda & s(c_i, c_i') \leq \lambda \end{cases} \tag{10}$$

$$e \sim (U_i)^{1/w_i} \tag{11}$$

Equation (11) describes a weighted random sampling (Efraimidis and Spirakis, 2006) process in which the weights are calculated by the function $s(c_i, c_i')$ and truncated by a threshold λ. Note that polysemous words should be carefully handled. For example, the word "change" has two semantic terms with different part-of-speech of noun and verb, which produce different errors. Therefore, we remove the candidates that do not have the same part-of-speech as the original token.

Rule-based Error Generation If we cannot find any candidate substitute, we use a set of predefined rules to generate the substitute. Table 2 lists diverse word transformations for error generation according to the tokens' part-of-speech. To maintain the sentence's semantics to the greatest extent, we just transform the nouns to their singular and plural counterparts instead of searching the synonyms from dictionaries. For verbs, we randomly choose their present, progressive, past, perfect, or third-person-singular forms. Adjectives and corre-

Type of tokens	Perturbation
Noun	To its singular or plural forms
Verb	Change its tense or number (third-person-singular form)
Adjective	To its adverb form
Adverb	To its adjective form
Numerals Proper Nouns	Remaining unchanged
Punctuation	Deletion
Others	<unk> or Deletion

Table 2: Rule-based word perturbations according to the part-of-speech.

sponding adverbs will be switched into each other, and we also allow them to be replaced by their synonyms here to make the model select more suitable adjectives or adverbs. For numbers and proper nouns, the safe strategy is keeping the word unchanged. All of articles or determiners, prepositions, conjunctions, pronouns have been mapped by context-aware error generation strategy before, the remaining rare words or symbols can be deleted directly or labeled as <unk>.

Besides, when a sentence contains more than one vulnerable point, we can choose to integrate these errors into the sentence to obtain a sentence with multiple grammatical errors or to generate errors separately and obtain more adversarial examples. According to our practice, the former is more suitable for later adversarial training. Finally, the GEC models are supposed to correct the crafted sentences. If the results are different from the unmodified version, the adversarial examples are considered to be generated successfully. Our algorithm of adversarial examples generation for GEC is shown in Algorithm 1.

3.3 Adversarial Training

We also show that GEC models' robustness can be improved by crafting high-quality adversaries and including them in the training stage while suffering little to no performance drop on the clean input data. In this section, we conduct adversarial training with sentence pairs generated by large unlabeled corpora and adopt the pre-training and fine-tuning training strategy.

Leveraging Large Unlabeled Corpora The standard BEA-19 training set (Bryant et al., 2019) has only about $640,000$ sentence pairs, which is very insufficient for the GEC task. Thus, the clean sentences in large unlabeled corpora, such as Wikipedia or Gigaword (Napoles et al., 2012), and One billion word benchmark (Chelba et al., 2013), are usually used as seeds to generate ungrammatical sentences for data augmentation. Some studies found that the more unlabeled corpora used, the more improvement the GEC model will achieve (Kiyono et al., 2019). Unlabeled corpora also contribute to correct out-of-training-set errors. If a sentence in the test set contains these unseen errors, the GEC model training without external corpora is hard to correct. Therefore, We also leverage the unlabeled corpora and obtain large-scale adversarial examples for the later training.

Algorithm 1 Adversarial examples generation

```
Input:
    $\boldsymbol{x}$: A grammatical sentence with $n$ words.
    $f$: A target GEC model.
    $D_t$: The training corpus of GEC.
    $\epsilon$: A threshold to select vulnerable tokens.
Output:
    $S$: Adversarial examples set towards $\boldsymbol{x}$.
Set $S = \varnothing$ and extract the correction-to-error mappings $m(x)$ $x \in M$, from the corpus $D_t$;
for each $j \in [1, n]$ do
    Calculate the position score $g(y_i) = f(x_j)$
    if $g(y_i) < \epsilon$ then
        if $x_j \in M$ then
            sample the error $e$ from $m(x_j)$
        else
            Obtain $e$ by rule-base method $r(x_j)$
        end if
        $\boldsymbol{x'} = [x_{1:j-1}, e, x_{j+1:n}]$
        if $f(\boldsymbol{x'}) \neq \boldsymbol{x}$ then
            $S = S \cup \{\boldsymbol{x'}\}$
        end if
    end if
end for
return $S$;
```

Training strategy Adversarial training by means of adding the adversarial examples into the training set can effectively improve the models' robustness. However, Some studies show that the models tend to overfit the noises, and the accuracy of the clean data will drop if the number of adversarial examples dominates the training set. Zhao et al. (2019) and Kiyono et al. (2019) adopt the pre-training and fine-tuning strategy to alleviate the noise-overfit problem. Similarly, our model is pre-trained with adversarial examples then fine-tuned on the original training set instead of adding the large-scale data to the training set directly. The training strategy can be formally divided into four steps:

(1) Train a base model f on training set D_t.

(2) Generate the adversarial examples set D_e on unlabeled sentences by attacking f .

(3) Pre-train the model f on the D_e.

(4) Fine-tune it on the training set D_t.

We also can use adversarial training to improve the model's robustness:

(5) Generate adversarial examples set D_{adv} from the training set D_t [Optional].

(6) Add examples into the training set and train the model on $D_t = D_t \cup D_{adv}$ [Optional].

We can alternately run the step (5) and (6) to further improve models' robustness.

4 Experiments

4.1 Datasets and Evaluations

Like the previous studies of GEC models, we use the BEA-2019 workshop official dataset[3] (Bryant et al., 2019) as our training and validation data. We remove the sentence pairs with identical source and target sentences from the training set and sample about 1.2M sentences without numerals and proper nouns from the Gigaword dataset[4] as our unlabeled data for pre-training. Table 3 shows the statistics of the datasets.

Dataset	#sent pairs	#split
BEA-train	635582	train
BEA-valid	4384	valid
CoNLL-2014	1312	test
JFLEG	747	test
Gigaword*	1.2M	pre-train

Table 3: The statistics of data sets used in our experiments. A subset of Gigaword, denoted by Gigaword*, was randomly sampled from the entire Gigaword[4]. The sentences containing numerals or proper nouns were not be sampled.

Our reported results are measured by the MaxMatch (M^2) scores [5] (Dahlmeier and Ng, 2012) on CoNLL-2014 (Ng et al., 2014) and use the GLEU metric for JFLEG [6] (Napoles et al., 2017). Following Ge et al. (2018); Junczys-Dowmunt et al. (2018); Chollampatt and Ng (2018a); Zhao et al. (2019), we apply spell correction with a $50,000$-word dictionary extracted in Lang-8 corpus (Tajiri et al., 2012) before evaluation.

4.2 Models and Hyper-parameter Settings

We adopt Transformer (Vaswani et al., 2017) as our baseline seq2seq model implemented in the `fairseq` toolkit (Ott et al., 2019), and apply byte-pair-encoding(BPE) (Sennrich et al., 2015) to source and target sentences and the number of merge operation is set to $8,000$.

The base model is iterated 20 epochs on the training set. For adversarial examples generation, we set the threshold ϵ to -0.2, and use the edit distance to calculate the context similarity with the minimum weight $\lambda = 0.1$. To avoid the sentences being changed beyond recognition, we choose at most 6 tokens with the lowest positional score to attack. After generation, we use these data to pre-train the base model for 10 epochs and then fine-tune on the training set for 15 epochs. Our model is also further fine-tuned by adversarial training several epochs. Here, "one epoch" means that we generate an adversarial example against the current model for each sentence in the training set, and the model is continuously trained on those generated examples for three normal epochs. We also implement other data augmentation methods as comparison models on the same unlabeled data and training settings. For direct noise, the operation choice is made based on the categorical distribution $(\mu_{add}, \mu_{del}, \mu_{replace}, \mu_{keep}) = (0.1, 0.1, 0.1, 0.7)$, then shuffle the tokens by adding a normal distribution bias $N(0, 0.5^2)$ to the positions and re-sort the tokens For back translation, we trained a reverse model with original sentence pairs and generated the error sentences with diverse beam strength $\beta = 6$ following Kiyono et al. (2019)[7].

To measure the model's robustness, we conduct adversarial attacks on the model by our adversarial examples generation method to add one or three errors to the test text, respectively (to ensure that errors are always generated during the attack, we set $\epsilon = 0$). We measure the models' robustness by the drop of $F_{0.5}$ scores and the correction rates of newly added errors. Due to the randomness of the

Table 4: Results of different GEC models on CoNLL-2014 and JFLEG. The model, indicated by **ADV**, is first pre-trained with our adversarial examples and then fine-tuned on the training set. The upper part of the table lists the results of the models trained with different data augmentation methods. The bottom shows the results of recently proposed GEC models. Our model outperforms the models trained with other data augmentation methods and achieves comparable performance to other competitors. However, the comparison is not direct, we only use 1.2M unlabelled data, much less than Kiyono et al. (2019) (70M) and Lichtarge et al. (2019) (170M).

		ATK-1		ATK-3	
Model	$F_{0.5}$	**Drop**	**Corr. Rate%**	**Drop**	**Corr. Rate%**
Transformer	49.1	−12.8	18.9	**−24.2**	18.8
Direct Noise	53.3	−17.0	12.8	−28.6	12.6
Back Translation	53.6	−16.4	19.7	−27.9	19.6
Zhao et al. (2019)[8]	**59.5**	−16.1	16.7	−27.8	19.5
ADV	56.4	−14.0	26.5	−26.7	26.7
ADV†	54.0	−13.8	36.0	−26.5	31.7
ADV††	52.0	**−12.1**	**39.5**	−26.2	**34.5**

Table 5: Results of the adversarial attacks on CoNLL-2014 dataset. **ATK-1** and **ATK-3** respectively denote the attacks with adding one and three errors into each test example. **Drop** denotes the performance drop in $F_{0.5}$ on the adversarial examples and **Corr. Rate%** denotes the correction rate of newly added errors. The model, indicated by **ADV**, is first pre-trained with our adversarial examples and then fine-tuned on the training set. The model of **ADV**† is initialized with **ADV**, and then adversarially trained only with one epoch, and the model of **ADV**†† is also initialized with **ADV**, but adversarially trained after three epochs. Our models have less performance degradation than others under the two attacks while achieving higher correction rates for newly added errors.

attacks, we average the results of 10 attacks.

4.3 Results of GEC Task

We compare our model pre-training with adversarial examples to the ones training with the data generated by other data augmentation methods. Table 4 shows the results. We achieve 7.3% improvements of $F_{0.5}$ on the base model and also leave a large margin to direct noise (+3.1%) and back translation (+2.8%), which proves that the adversarial examples crafted by our method have a more significant contribution to improving the model. We also compare our model with the current top single models. Our model outperforms Junczys-Dowmunt et al. (2018) and reach the same level of as Lichtarge et al. (2019), Grundkiewicz and Junczys-Dowmunt (2018). Notably, Lichtarge et al. (2019) pre-trained their model with the data generated by back translation on a subset of Wikipedia, which contains 170M sentences, and we only use 1.2M unlabeled data, which also indicates the high value of our adversarial examples. Similarly, Zhao et al. (2019) leveraged 30M unlabeled data (direct noise) and Kiyono et al. (2019) 70M (back translation) for pre-training, taking the performance of the model to a new level.

We also conducted ablation experiments to evaluate the different components of our adversarial error generation model. If a random strategy is used to select the weak spots, the $F_{0.5}$ score drops

Table 6: The correction rates of the newly added errors versus different types of part-of-speech. ”NN” denotes noun, ”VB” verb, ”JJ” adjective, ”RB” adverb, ”IN” preposition, ”PRP” personal and possessive pronoun. **ATK-1** and **ATK-3** respectively denote the attacks with adding one and three error into each test example. **ADV**, **ADV**† and **ADV**†† are used to denote the same models as Table 5.

to 55.0. If only the context-aware generator is used for word substitution, the resulting $F_{0.5}$ score is 55.8, and the model achieves 56.2 in $F_{0.5}$ for rule-based generator only. The experimental results show that our strategy of identifying vulnerable token is more effective than the random way, and the two error generators all contribute to improving the models' performance and robustness.

4.4 Analysis of Adversarial Attack

We conduct the attack experiments on the base, pre-trained and adversarially trained models, including the model provided by Zhao et al. (2019)[8]. Table 5 shows the results of adversarial attack experiments. Under the attack, our models dropped the less in $F_{0.5}$ scores and achieved the higher newly added error correction rate, which indicates our adversarial examples can be used to substantially improve GEC models' robustness. The results in Table 5 are worth exploring, from which we can draw several other conclusions: (i) Current seq2seq-based GEC models, including some state-of-the-art models, are vulnerable to adversarail examples. (ii) The models using the direct noise method for data augmentation, Zhao et al. (2019)) for example, are less robust to adversarial attacks even than their vanilla versions. It is likely to be associated with the editing operations of direct noise injecting a lot of task-irrelevant noise, which might be detrimental to the robustness of the model. (iii) Combined with adversarial training, the robustness of the model can be improved continually at the cost of acceptable loss in performance. We also analyzed the trade-off between generalization and robustness at the adversarial training stage. The results are visualized in Figure 1.

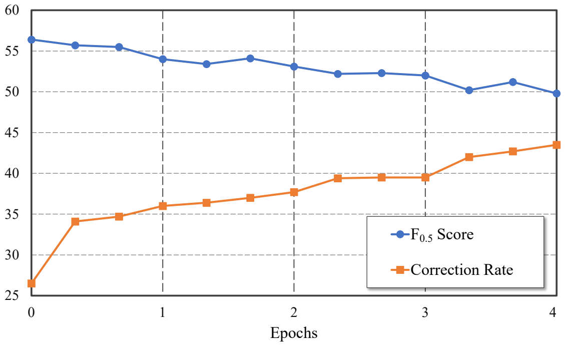

Figure 1: Trade-off between generalization and robustness. The blue and orange lines respectively denote the scores of $F_{0.5}$ (generalization) and the correction rates (robustness) with four different training epochs. The model's robustness will continue to improve with a slight drop in performance.

We would also like to know which type of words to modify is most likely to form a successful attack. Therefore, we calculate the correction rates of the newly added errors with different types of part-of-speech. Table 6 shows that: (i) The robustness of the model after adversarial training is significantly improved against the attack that tries to replace the lexical words such as nouns and verbs. It shows that the generated examples by our adversarial attack algorithm cover a variety of grammatical errors involving various POS types. (ii) The errors involving adjectives and adverbs are less likely to be corrected without adversarial examples. Whether an adjective or adverb is properly used heavily relies on the context, making it difficult for the GEC systems to correct them all. (iii) Not surprisingly, most of the prepositions errors are inherently hard to correct, even for native speakers.

---

5 Conclusion

In this paper, we proposed a data augmentation method for training a GEC model by continually adding to the training set the adversarial examples, particularly generated to compensate the weakness of the current model. To generate such adversarial examples, we first determine an important position to change and then modify it by introducing specific grammatical issues that maximize the GEC model's prediction error. The samples generated by our adversarial attack algorithm are more meaningful and valuable than those produced by recently proposed methods, such as the direct noise and the back translation. Experimental results demonstrate that the GEC models trained with the data augmented by these adversarial examples can substantially improve both generalization and robustness.

Optimizer	Adafactor (Shazeer and Stern, 2018)
Learning Rate Schedule	Fixed learning rate 3×10^{-5}
Stopping Criterion	Use the model with best validation perplexity on BEA-valid
Gradient Clipping	1.0
Beam Search size	5
Adversarial Training	
Number of Epochs	3 (each time)
Loss Function	Label smoothed cross entropy
Optimizer	Adafactor ($\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 1 \times 10^{-8}$)
Learning Rate Schedule	Fixed learning rate 3×10^{-5}
Gradient Clipping	1.0
Beam Search size	5

Table 8: Hyper-parameter settings for training. Kiyono et al. (2019) conducted an empirical study of pre-training with pseudo data and we follow many settings with them. We conducted our experiments on 4 TITAN Xp GPUs. Each epoch took 20 minutes during pre-training, and 10 minutes during fine-tuning and base model training. The time spent on adversarial training depends on the number of adversarial examples, about 20-30 minutes each epoch.

Homophonic Pun Generation with Lexically Constrained Rewriting

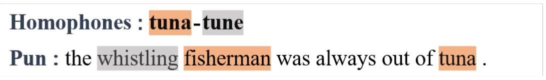
Abstract

Punning is a creative way to make conversation enjoyable and literary writing elegant. In this paper, we focus on the task of generating a pun sentence given a pair of homophones. We first find the constraint words supporting the semantic incongruity for a sentence. Then we rewrite the sentence with explicit positive and negative constraints. Our model achieves the state-of-the-art results in both automatic and human evaluations. We further make an error analysis and discuss the challenges for the computational pun models.

1 Introduction

In this work, we mainly study the homophonic puns where two meanings relying on the same (or similar) sounding signs. As Figure 1 shows, the pun exploits the sound similarity between “tuna” and “tune”. The word (“tuna”) appearing in the sentence that triggers humor is a pun word, while its homophonic word (“tune”) is the alternative word. The semantics of the homophones are expressed by two words independently (“whistling”, “fisherman”). On the surface, there is one interpretation: “the fisherman had no tuna”. Implied by “whistling” and the pronunciation of “tuna”, there is another interpretation:“the whistling fisherman sang out of tune”.



Homophones : **tuna**-**tune**
Pun : the whistling fisherman was always out of tuna .

Figure 1: An example of a homophonic pun.

Early models for pun generation are mainly relying on templates (Lessard and Levison, 1992; Binsted and Ritchie, 1994, 1997; Lessard, 1992; McKay, 2002; Ritchie et al., 2007; Hong and Ong, 2009). To improve the diversity of generated puns, Yu et al. (2018) propose a neural approach to generate puns conditioning on two meanings of the target word. Based on it, Luo et al. (2019) introduce a word sense classifier as the discriminator to generate homographic puns by adversarial generative network. However, neural generative models usually mimic the norm and the generated sentences are lack of novelty. To make the generated puns more creative, He et al. (2019) first sample a sentence containing the alternative word from the corpus. They then replace the alternative word with the pun word and insert a topic word. This retrieve-and-edit approach is brilliant. However, the part-of-speech (POS) tags of the pun words and its alternative words are different in 46.08% puns in the gold pun dataset (Miller et al., 2017). Directly replacing the alternative word with the pun word usually leads to grammar errors in the generated sentence. As there are tons of sentences containing the alternative word, it is also necessary to rank the sentences purposefully.

To address the issues above, we propose a constraint selection algorithm to extract the candidate sentence containing the alternative word and its corresponding constraints. Then our lexically constrained rewriting model (LCR) generates puns by rewriting the normal sentences with constraints. In this way, the different semantic meanings of two homophones are expressed naturally in a generated sentence. Both automatic and human evaluation results demonstrate the efficacy of our model[1].

2 Our Method

The framework of our model is shown in Figure 2. Given a pair of homophones, we retrieve sentences containing the alternative word (“tune”) and pun word (“tuna”). Next, we extract the most suitable

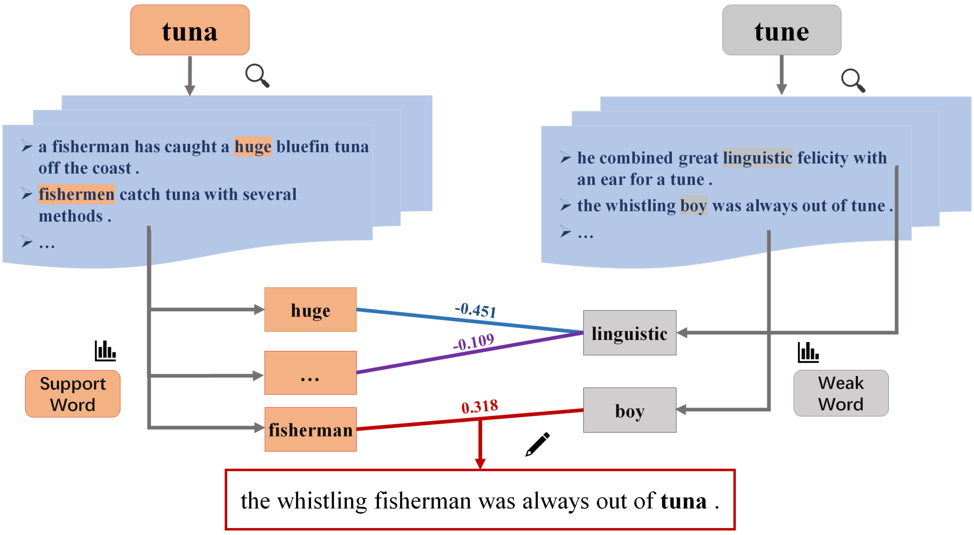

Figure 2: Overview of our pun generation process.

weak word ("boy") and the corresponding support word ("fisherman") to form constraints. Positive constraints contain the pun word and its support word. Negative constraints contain the alternative word and its weak word. Finally, we rewrite the candidate sentence with lexical constraints to generate a homophonic pun.

2.1 Constraints Extraction

Incongruity is a leading theory in computational humor. We achieve it by rewriting the sentences with lexical constraints. For each pair of homophones, we obtain a set of candidate sentences C. For the i-th candidate sentence, we extract words weakly related to the alternative word to compose the weak word vocabulary W_i. The words in the whole corpus which have the same POS tag with each word w in W_i and are strongly related to the pun word compose the support word vocabulary $S_{i,w}$. We use Point-wise Mutual Information (PMI) to evaluate the relatedness between two words (e.g. x, y) (Church and Hanks, 1990) :

$$PMI(x, y) = \log_2 \frac{p(x, y)}{p(x) \cdot p(y)}. \qquad (1)$$

To make the pun words more plausible, we hope to replace the weak word with a support word. Keep $||W_i|| = nw$ words with lowest PMI scores in W_i and $||S_{i,w}|| = ns$ words with highest PMI scores in $S_{i,w}$. For each sentence, there are $nw * ns$ pairs of possible constraints. To keep the edited sentences grammatical, we need to select one pair which results in the most reasonable modifications. As Algorithm 1 shows, for each homophone pair, we go through the corpus and calculate scores for their candidate sentences. We train a Continuous Bag of Words model (CBOW) to obtain the word embeddings (Mikolov et al., 2013). Inspired by Mao et al. (2018), we use OUT-IN vectors to measure the similarity between a word and its given

```
**Algorithm 1** Constraint Selection Algorithm.
Require: $C$: a set of candidate sentences containing the alternative word $a$
Require: $M$: a trained CBOW model. $v_a^i$ denotes the input vector of word $a$. $v_a^o$ denotes the output vector of word $a$. $v_{context}^i$ denotes the average input vectors of the words in the $context$.
Require: $W$: a list of the weak word vocabulary sets.
Require: $S$ : a list of the support word vocabulary sets.
Require: $p$ : corresponding pun word
$Sim(x, y)$ calculates the cosine similarity between two vectors $x, y$.
$R = \emptyset$
For any sentence $C_i \in C$:
$context$ = the set consisting of the words in $C_i$ excluding $a$.
  For any weak word $w$ in $W_i$:
    For any support word $s$ in $S_{i,n}$:
      $q \leftarrow$ the set consists of the words in $context$ excluding $w$ and including $p$.
      $Score_{i,w,s} \leftarrow Sim(v_w^i, v_s^i) + Sim(v_s^o, v_q^i) - Sim(v_p^i, v_s^i)$
      $R \leftarrow R \cup Score_{i,w,s}$
Return $C_i, w, s$ where $Score_{i,w,s} = maxR$
```

contexts, and use IN-IN vectors to measure the similarity between two words.[2] The support word should play the same role as the weak word and fits the contexts well. For a specific support word, its contexts are likely to contain all the words in the candidate sentence except for the alternative word and its weak word. So we remove these two words and add the pun word to form the potential contexts q. We calculate the similarity between the support word and its potential contexts q, to evaluate the fitness of the support word. In practice, $S_{i,w}$ always contains inflections of the pun word, which can make the generated sentences redundant and less likely to be a pun. So the similarity between the pun word and its support word is negatively correlated to the final score. In our case, we do not consider verbs as weak words.[3]

2.2 Lexically Constrained Rewriting

With the extracted constraints, we further generate homophonic puns by rewriting the candidate sentence. Following Hu et al. (2019a), we train a generator in an end-to-end way. Given a source sentence x, the generator aims to rewrite it as $\tilde{y}$. In the end-to-end model, $\tilde{y}$ maximizes the conditional probability given by a model θ and an input sequence x:

$$\tilde{y} = argmax_y p_\theta(y|x), y \in Y \qquad (2)$$

where Y is the space of possible outputs. Traditional beam search can not guarantee the outputs conformed to the constraints.

Researchers propose algorithms to place constraints in natural and meaningful ways (Hokamp and Liu, 2017; Post and Vilar, 2018). However, previous works ignore the situation that some constraints may share a prefix. To avoid repeating, the constraints that have not been generated are organized into a trie. For positive constraints, there is a counter to indicate that how many times the constraint must be generated. When a constraint is generated, its counter is decremented. For negative constraints, the trie does not need any counters. At each time step, the generation of an active phrase is blocked by setting the costs of all word IDs marked in the current node to infinity. Hypotheses are ranked by sentence number, number of unmet constraints, and sequence scores. We keep the top-k hypotheses. In this way, both positive constraints and negative constraints can be satisfied without repeating. We call our model Lexically Constrained Rewriting Model (**LCR**).

3 Experiments

3.1 Data Set

We use PARABANK (Hu et al., 2019b), a large-scale English paraphrase dataset to train the rewriting model. Following previous work (He et al., 2019), we use BookCorpus (Zhu et al., 2015) as retrieval corpus. And we use the homophone pairs in 2017 SemEval task 7 (Doogan et al., 2017) for testing.

3.2 Experimental Setting

We train a CBOW model on BookCorpus with a context window ($width = 5$) to learn 300-dimensional word vectors. In our constraint selection algorithm, we keep $w = 3$ weak words for each sentence and $s = 5$ support words for each weak word. In the decoding phrase, we set the beam size $k = 5$.

3.3 Baseline Models

RE: Retrieve a sentence containing the pun word.

RE+S: Sample one sentence containing the alternative word and replace it with the corresponding pun word.

NJD (Yu et al., 2018): Retrained the model on the BookCorpus. Use two homophones as the inputs for decoding.

SURGEN (He et al., 2019): Given a pair of homophones, their retrieve-and-edit approach generates a homophonic pun.

3.4 Evaluation Metrics

3.4.1 Automatic Evaluation

Following Yu et al. (2018), the diversity is measured by the ratio of distinct unigrams (d.-1%) and bigrams (d.-2%). *w.-num* denotes the number of distinct words in the outputs. As Table 1 shows, the neural model **NJD** tends to generate normal sentences and obtains the lowest scores. It generates sentences using very limited vocabulary. Gold puns sometimes share the similar structure, for example : "old storekeepers never die , they just sale away" and "old school superintendents never die , they just lose their principals", which causes a lower diversity and fewer *w.-num*.

---

[2] IN vectors are input vectors of a trained CBOW model. OUT vectors are output vectors of a trained CBOW model.

[3] Replacing verbs can result in the transformations of other words, which changes the candidate sentence to a great extent.

Models	*w.-num*	*d.-1(%)*	*d.-2(%)*
RE	**7,628**	46.76	88.75
RE+S	7,129	42.88	87.07
SURGEN	6,650	45.40	88.18
NJD	4,435	23.86	49.36
LCR	7,062	**56.00**	**93.22**
GOLD	6,432	48.10	87.18

Table 1: Results of automatic evaluation.

Models	*Gram.*	*Flue.*	*Pun.*	*Fun.*	*Overall*
RE	**4.51**	**4.14**	1.44	1.27	2.87
RE+S	4.32	3.85	2.77	1.43	3.11
NJD	3.75	3.41	1.74	1.31	2.49
SURGEN	4.13	3.72	2.71	1.84	2.91
LCR	4.50	4.11	**2.82**	**2.15**	**3.35**
GOLD	4.69	4.52	4.01	3.57	4.29

Table 2: Results of human evaluation.

RE outputs human-written sentences retrieved in the corpus and shows good diversity. By swapping the alternative words with corresponding pun words, **RE+S** obtains equivalent diversity to **RE**. Our model (**LCR**) rewrites retrieved sentences with constraints and generates sentences with creativity and highest diversity.

3.4.2 Human Evaluation

Pun is a creative form of language which is hard to evaluate automatically. For a comprehensive evaluation, we ask annotators to do the human evaluation. We randomly sampled 100 outputs of different models including gold puns and ask native speakers to score the sentences from 1 to 5 on five aspects: (1) *Grammar (Gram.)* Is the sentence grammatically correct? (2) *Fluency (Flue.)* Is the sentence fluent and easy to understand? (3) *Pun (Pun.)* Is this sentence a pun? (4) *Funniness (Fun.)* How funny is the sentence? (5) *Overall* How is the overall quality of this pun? Table 2 shows the results of human evaluation. Our model (**LCR**) outperforms other models in terms of *Pun, Funniness* and *Overall* quality as a pun. As **RE** outputs human-written sentences in BookCorpus, it obtains highest scores in two terms: *Grammar* and *Fluency.* The sentences from **RE** are grammatical and fluent but lack of ambiguity. Thus, it obtains the lowest scores in *Pun* and *Funniness*. With a swap of pun word and alternative word, **RE+S** introduces incongruity to the retrieved sentences and makes them funnier. However, when the usages of pun word and alternative word are different, a swap makes the sentences not readable and decreases the *Grammar* and *Fluency.* **NJD** is a neural language model. Given two homophones, it generates sentences according to the limited input knowledge, which always leads to sentences of low quality. **SURGEN** edits the sentences generated by **RE+S**. Topic words are inserted in the sentences to benefit pun generation. However, due to inconsistent types, the topic words sometimes do not fit in its contexts. The similar issue appears when directly swapping the alternative word with pun word. **LCR** carefully chooses support words which fit the contexts and place them naturally by rewriting the sentences with constraints. The generated sentences are both interesting and grammatical.

3.5 Case Study

Pun/Alternative Word: board-bored	
RE	but now there is no time left... let 's send her on **board**!
RE+S	he brought his other hand to cup my cheek as his eyes went dark and **board** into mine.
NJD	go to the board, i'm not going to be able to do so.
SURGEN	the gulls went on, "but i am pretty sure you won't be **board** for long."
LCR	your bedding is **board**.
GOLD	do hotel managers get **board** with their jobs ?
Pun/Alternative Word: rune-ruin	
RE	i'd once had a necklace like hers, except mine had been shaped like a spider **rune**.
RE+S	when that time comes, i will guide your hand so that you do not **rune** the moment.
NJD	"however, it is **rune**, " he said.
SURGEN	when the millennia pass, i will guide your hand so that you do not **rune** the moment.
LCR	there was nothing but desolation and **rune**.
GOLD	the study of ancient symbols will lead you to **rune**.

Figure 3: Examples of model outputs.

Examples generated by different models are in Figure 3. The sentence generated by **RE** can only be interpreted in one way. **RE+S** and **SURGEN** introduce grammar errors by directly replacing alternative words with pun words. The sentence generated by **NJD** is fragmentary and cannot inspire people to think about another interpretation. **LCR** can generate fluent puns. **GOLD** pun triggers humor in a similar way.

3.6 Error Analysis

We analyze our model outputs one by one and list the overall situation in Figure 4. We find there are mainly five reasons for unsuccessful pun generation:

(1) *Imperfect Constraints*: Pun is a creative language full of imagination. Extracting strongly related words as support words sometimes does not

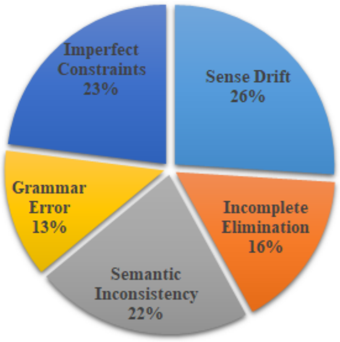

Figure 4: Overview of error types.

work. For example, given "maid-made", "a china doll was marked in tiny letters : maid in usa" is a good pun. However, "doll" is not so related to "maid" and we cannot extract it as a support word.

(2) *Sense Drift*: When rewriting the sentences with constraints, the word collocations can be modified and the sense of the alternative word will disappear, e.g. when "air" means "a distinctive but intangible quality surrounding a person or thing", it is always used as "... an air of", "have a ... air". We rewrite the candidate sentence ("... and with an air of freedom however specious.") with constraints (negative constraints: "air", "freedom"; positive constraints: "err", "principle"). The model outputs "principles err ... and with an atmosphere of liberty, however specious". Instead of the expected collocation "an err of ...", it turns out to be "an atmosphere of liberty". The expected sense of "air" disappears and "principles err" cannot trigger people to think of another interpretation.

(3) *Incomplete Elimination*: When the usages of the given homophone pair are very different, an inflection of the alternative word will be decoded in the result to keep the original semantic meaning of the input sentence. For example, given "sum-sun", the candidate is "add one more likeness ... let me and my sun beget a man". Our model rewrite it as "sum up one more likeness, ... let me and my sunshine beep a man".

(4) *Semantic Inconsistency*: The generated sentence is grammatical but the semantic of the sentence is full of contradictions, e.g. "brilliant mourning lights in the old town", where "mourning" is conflicted with "brilliant" emotionally.

(5) *Grammar Error*: When the usages of two homophones are similar, pun word will replace the alternative word in the rewriting process. However, the alternative word has its own collocations and causes the grammar error in the output texts, e.g., given "zinc-sink", the model outputs "his enemy's solution could **zinc (sink)** him **into** deep dejection". There is much room for our model to improve the semantic consistency by introducing related modules.

4 Conclusion

In this work, we propose to generate homophonic puns with lexically constrained rewriting. We retrieve sentences containing the alternative word as candidate sentences. And then we use constraint selection algorithm to rank candidate sentences and choose support word to imply the semantics of the pun word. Finally we rewrite the sentence with constraints. Our model outperforms previous works on the task of homophonic pun generation. However,as discussion in error analysis, there are several challenges to solve in the future.

How to Make Neural Natural Language Generation as Reliable as Templates in Task-Oriented Dialogue

Abstract

Neural Natural Language Generation (NLG) systems are well known for their unreliability. To overcome this issue, we propose a data augmentation approach which allows us to restrict the output of a network and guarantee reliability. While this restriction means generation will be less diverse than if randomly sampled, we include experiments that demonstrate the tendency of existing neural generation approaches to produce dull and repetitive text, and we argue that reliability is more important than diversity for this task. The system trained using this approach scored 100% in semantic accuracy on the E2E NLG Challenge dataset, the same as a template system.

1 Introduction

The goal of task oriented dialogue is to help a user achieve a narrow goal, such as booking a restaurant or movie ticket. The final step of a conversational interface is generating a response to the user; more specifically, performing surface realization of some structured data containing relevant information.

Research into neural NLG systems for the surface realization task is popular because such systems may have advantages over the dominant rule and template-based systems: neural NLG systems trained on datasets may be both easier to maintain and to scale to new domains, as well as generating more natural responses (Wen et al., 2015; Guo and Zhao, 2017). But neural NLG systems are not without problems. They are widely considered too unreliable for business applications; they have a tendency to *hallucinate* facts, unsupported by the structured data they were given (Wiseman et al., 2017).

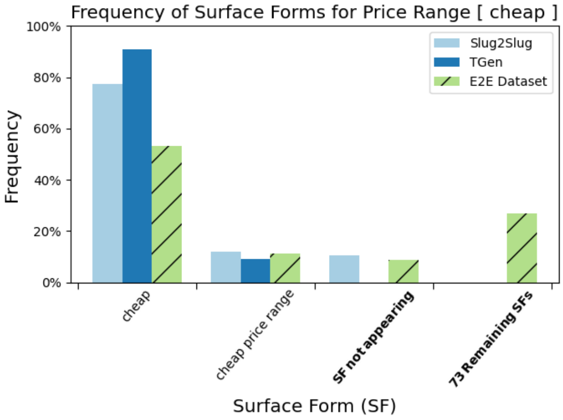

Figure 1: Surface forms used to express the attribute-value pair: PriceRange[Cheap]. **SF not appearing**: no surface form was found in the utterance, **73 Remaining SFs**: surface forms other than *cheap* and *cheap price range*

A less well known issue is the template-like generation of neural NLG systems (Wei et al., 2019). Figure 1 highlights this issue; neural NLG systems (TGen and Slug2Slug) are far less diverse than the training data (E2E Dataset) in their usage of surface forms that express an attribute. Intuitively, one might expect that a neural NLG system trained on a dataset with 75 different surface forms to express an attribute would use a wide variety of them – instead we see only the top two most common surface forms in use.

We highlight the issue of lack of diversity, not to provide a specific solution to it, but rather to provide some context for our proposal which relates to *reliability* of neural NLG systems. Given that our main goal is reliability, we wondered if there were some way to *lean into* the blandness and lack of diversity of existing neural systems.

We propose a data-oriented and model-agnostic solution. Using the E2E NLG Challenge dataset (Dušek et al., 2019b), we experiment with an augmented input sequence that includes the surface form of each attribute-value pair. By including the surface form in the input sequence, we can use a restricted decoding strategy when generating an

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2877–2888,
November 16–20, 2020.

utterance. This guarantees reliability. By sacrificing a small amount of unconstrained diversity, we are able to achieve 100% semantic accuracy on the E2E dataset.

2 Frequency of Surface Forms

To compare the diversity of the E2E training data with that of the generated text, we looked at the surface forms used to express each attribute-value pair. This is enabled by a set of regular expressions released by Dušek et al. (2019a)[1]. The regular expressions capture the entire phrase used to express an attribute-value pair, focusing on the content words and attempting as much as possible to leave out the function words, e.g.

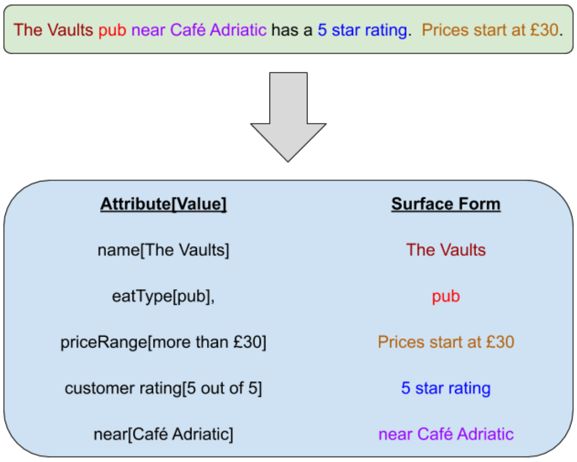
```
(?:(?:price|range).*)?
 (?:inexpensive|cheap)(?:ly)?
 (?:.*(?:price\w|range))?
```

We counted the surface forms used for a given attribute-value pair, in both the dataset and generated text, and plotted them against each other, see Figure 1 and additional figures in the supplementary material. While there was an average of 133 different surface forms for each attribute-value pair in the E2E dataset, the neural systems, on average, only generated 3 of the most common surface forms. This convinced us that the diversity was hardly any better than templates, which by default only use a single surface form per attribute.

3 Method

How can a neural NLG system generate text from a set of attribute-value pairs and ensure that they appear correctly in the generated text? As opposed to templates, which are static, neural NLG systems are statistical generators and provide no inherent guarantees of accuracy. Thus we propose augmenting the input sequence with the surface form of each attribute-value pair. This augmented input sequence enables us to restrict the text that is generated in a way that provides guaranteed accuracy.

Finding Surface Forms The first step in this process is finding the surface forms in a given utterance. We want to find the content words used to describe attribute-value pairs in a human authored sentence. But this is not a straightforward task. Specially designed regular expressions (Dušek et al., 2019a) or heuristics involving dependency relations (Oraby et al., 2019) must be used.



The Vaults pub near Café Adriatic has a 5 star rating. Prices start at £30.

Attribute[Value]	Surface Form
name[The Vaults]	The Vaults
eatType[pub],	pub
priceRange[more than £30]	Prices start at £30
customer rating[5 out of 5]	5 star rating
near[Café Adriatic]	near Café Adriatic

Figure 2: First, use regular expressions to find the surface forms in a target utterance. Then, use the surface forms to construct an augmented input sequence.

Augmented Input Sequence Once the surface forms of each attribute-value pair in a target utterance are found, we add them to the input sequence, as shown in Figure 2. Only the input is altered, the target utterance remains the same.

How can we add surface forms to an input sequence from the validation or test sets without peeking at its target utterance? A simple heuristic we have used is to choose the most common surface form for each attribute-value from the training set.

Restricted Decoding Why do we focus so much on surface forms? Because when surface forms are part of the input, we can add restrictions to the generation strategy, e.g. beam search, which guarantee that all, and only, the surface forms provided have been expressed (Zhong et al., 2017).

Furthermore, by including all the necessary content words in the input sequence, it is possible to limit the vocabulary used during generation to only these content words and a couple of hundred function words. This would enable the use of a constrained softmax (Hu et al., 2015) – an optimization that can greatly speed up the decoding step.

4 Experimental Setup

We performed experiments with the E2E NLG Challenge dataset (Dušek et al., 2019b). It is a task-oriented dialogue dataset, collected using crowd sourcing, focused on the surface realization of attribute-value pairs describing restaurants.

---

[1] `https://github.com/tuetschek/e2e-cleaning`

4.1 Applying the Surface Forms Method

To extract the surface form of each attribute-value pair from a target utterance, we used modified regular expressions from Dušek et al. (2019a). The input sequence was constructed in the format of a single token representing an attribute-value pair followed by multiple tokens for the surface form, e.g. **eatType_pub** *pub* **customer_rating_5_out_of_5** *5 star rating*. The order of the attribute-value pairs remained the same as in the original dataset.

If the surface form of an attribute-value pair was not found in the target utterance then a *missing* token was added instead. Any additional attribute-values, those that appeared in the target utterance but not in the input, were ignored. To avoid peeking at the target utterance when adding surface forms to the validation and test sets, the most common surface form for each attribute-value pair from the training set was used.

The task proved to be simple enough for the model that only minimal restricted decoding was necessary. We added a single rule to the beam search: if *restaurant* does not appear in the input then it should not appear in the output.

4.2 Modelling

Our baseline is a sequence-to-sequence model with copy attention, trained on the E2E dataset, using the neural machine translation framework OpenNMT (Klein et al., 2017). To test our method, we trained a model with the same hyperparameters (see the appendix for details) on the surface form augmented version of the E2E dataset.

4.3 Reference Systems

The E2E NLG Challenge organisers released the generated outputs of all participant systems. In our analysis, we compare with three of these systems:

1. the E2E baseline, TGen (Dušek and Jurcicek, 2016), a neural system with a semantic reranker as a final step to improve accuracy
2. the overall winner of E2E, Slug2Slug (Juraska et al., 2018), a neural system, also with a reranker, trained using an augmented dataset in which attribute-value pairs are aligned to individual sentences in the utterance
3. a template based-system, TUDA (Puzikov and Gurevych, 2018), which, by using a set of handwritten templates, was able to express attributes more reliably than all other systems and came in second place in the challenge's human evaluation.

Table 2: N-gram overlap metrics for validation and test sets. System architectures are coded with colours and symbols: ♡seq2seq, ♢augmented data, ♠template-based

4.4 Evaluation

To evaluate the performance of our proposed approach we focus on semantic accuracy. Semantic accuracy scoring was also provided by Dušek et al. (2019a). It reports the number of generated utterances that: correctly express all attribute-value pairs (OK), have additional pairs (Added), are missing pairs (Missing), have both missing and added pairs (A+M).

For completeness, we report results from the E2E NLG Challenge's official scoring script, which is comprised of the following n-gram overlap metrics; BLEU (Papineni et al., 2002), NIST (Doddington, 2002), METEOR (Lavie and Agarwal, 2007), ROUGE (Lin, 2004), and CIDEr (Vedantam et al., 2015). The validation and test sets contain multiple human-authored references for each input sequence, which helps to alleviate some of the issues with n-gram overlap metrics.

5 Results

5.1 Semantic Accuracy

Table 1 demonstrates that the semantic accuracy of our proposed method is on par with that of the template system; both achieve 100% accuracy, whereas the neural systems struggle, with the best system, Slug2Slug, only achieving 92%. Our baseline OpenNMT system performs particularly poorly as

Table 3: Examples of generated text are coded with colours and symbols: ♡SLUG2SLUG, ♢OPENNMT + SURFACE FORMS, ♠TUDA

it does not use a semantic reranker. In a business setting, where automated task-oriented dialogue is most likely to be applied, nothing less than 100% accuracy is typically acceptable, especially when it comes to a relatively new technology like deep neural networks.

5.2 N-gram Overlap Metrics

According to the automated results on the E2E validation and test sets, shown in Table 2, semantic accuracy and n-gram overlap metrics have little correlation. The highest scoring system in many of the n-gram metrics, the OpenNMT baseline, is the worst performing in semantic accuracy, while the template system scores highest in METEOR but lowest in all other metrics. Overall, we infer that the n-gram metrics results are ambiguous, making it difficult to draw useful conclusions from them.

5.3 Generated examples

In Table 3, we compare randomly selected examples from Slug2Slug, our Surface Forms system and TUDA. In each of the examples, the systems appear to follow a very similar sentence structure to each other. In the E2E human evaluation for naturalness, Slug2Slug came second while TUDA came eighth, compared with the human evaluation for overall quality in which Slug2Slug came first and TUDA second. Dušek et al. (2019a) hypothesised that the lower performance in naturalness may be linked to sentence length; template systems tend to be slightly longer than neural ones. Slug2Slug has an average utterance length of 24 tokens, while TUDA has an average length of 32 tokens. Our system has an average length of 23, which is closer to that of Slug2Slug. This suggests that our approach has the potential to combine the reliability of template systems with the perceived naturalness of neural ones.

6 Discussion

This is not the first data-focused approach to improving accuracy; Balakrishnan et al. (2019) also proposed a constrained decoding strategy. The difference between our decoding strategies lies in the guarantees provided. Their approach focuses on an augmented target utterance, as opposed to input sequence, in which special bracket tokens are used to surround surface forms. e.g. **[__ARG_AREA_CITY_CENTRE__** *city centre* **]**. Their constrained decoding strategy guarantees that when an opening bracket is generated, a closing bracket will also be generated. However this provides no guarantee as to what will be contained within the brackets. What sets our method apart is that: we can guarantee the text will actually be generated as requested, we generate shorter sequences (no bracket tokens in the output) and have the option for a restricted vocabulary, which speeds up decoding.

The major weakness of both approaches, however, is the difficulty of extracting surface forms from human-authored text. We were able to avail of the hand-crafted regular expressions of Dusek et al in our E2E experiments, but moving to another dataset would entail a similar exercise. A method to do this automatically would be convenient. Some work has already been done by Oraby et al. (2019), in which dependency trees were used to find adjectives that describe a specific list of food related nouns. In the Surface Realization shared task (Mille et al., 2018), the deep task dataset was created by pruning function words from a dependency tree, leaving only content words remaining.

In our proposed method, surface forms still need to be joined together with function words. We believe neural networks are well suited for this task because they are good at generating natural sounding, though sometimes nonsensical, text. By combining neural generation with constraints based on content words included in the input sequence, we aim to achieve both reliability and naturalness.

An alternate approach, which we did not compare with, is automatic template generation (Biran et al., 2016; Wiseman et al., 2018). However, as with neural generation, when applied to the E2E task it has issues with reliability. Mille and Dasiopoulou (2017) used an automated template generation approach on the E2E shared task and their accuracy score was similar to that of a neural system, 92% (Dušek et al., 2019b), mostly due to missing attributes in templates.

However, the question remains: why pursue this approach when templates perform satisfactorily? We believe that neural NLG systems are easier to maintain, generate more natural text, and, as surface form extraction improves, they also become more scalable: to new domains, languages, and, possibly even, personalization.

In our proposed approach, we purposefully remove a neural NLG system's ability to generate diverse text. While this may seem perverse, we consider reliability to be the most important starting point. Diversity can always be increased later. If augmenting an input sequence with surface forms allows us to restrict decoding and generate utterances that are as reliable as templates, then this is an approach worth investigating further.

Acknowledgments

A Replication Instructions

Dataset The E2E dataset contains a training set of 42,061 pairs of meaning representations and human authored utterances, 4,672 pairs in the development set, and 4,693 in the test set. Download the dataset from `https://github.com/tuetschek/e2e-dataset`.

We used the delexicalization script provided by the organizers in the TGen repository `https://github.com/UFAL-DSG/tgen/tree/master/e2e-challenge`. This module replaces the names of restaurants which appeared in the *Name* and *Near* attributes with a generic value, X-Name and X-Near.

Main experiment repository All the experiments are done with python modules and bash scripts. These are available in our *main repository* `https://github.com/Henry-E/reliable_neural_nlg`

Experiment steps

1. First the delexicalised data is converted into source and target files. It uses modified regular expressions from the e2e-cleaning repository. `https://github.com/tuetschek/e2e-cleaning`

2. Inside the *scripts/* folder of our main repository there are bash scripts for running the preprocessing required by OpenNMT and the actual training. We use our own fork of OpenNMT; the only changes made were to the beam search decoding code. `https://github.com/Henry-E/surface_realization_opennmt-py`

3. Using a trained model, a translate script generates text dev or test set. See *scripts/translate_surface_forms.sh* in our main repository.

4. Generated text is still in a raw format and requires relexicalisation and detokenization, see the python module *modules/relex_and_detok.py*.

Full hyperparameter details are available in the main repository. Here is a short synopsis of the model: A sequence-to-sequence model with copy attention, using the adam optimizer with learning rate 0.001, 2 layers, 300 dimension word vectors, 600 dimension LSTM cells, and shared embeddings between encoder and decoder. We train for 20 epochs of the data, this takes 15 minutes using two NVIDIA 1080 Ti gpu cards. We then choose the checkpoint with the highest validation set accuracy. We try to select a checkpoint before overfitting becomes noticeable, usually around the 15 epoch mark.

Evaluation

1. We calculate n-gram metric scores using the E2E-metrics module `https://github.com/tuetschek/e2e-metrics`

2. To calculate semantic accuracy we use a minimally modified version of the slot_error.py module from `https://github.com/tuetschek/e2e-cleaning`. We noticed it was incorrectly grouped together attributes in a small number of cases (we saw less than 5). This change improved Slug2Slug's results, as it now showed that it had fewer missing attributes.

System outputs from the E2E NLG Challenge participants can be found at `https://github.com/tuetschek/e2e-eval`

B Ordering and Relationship of attributes

Note that while we extract the surface forms and include them in the source sequence, they do not appear in the same order in the input as in the target sentence. This adds an extra requirement at test time to provide a reasonable order for the attribute-value pairs, and when an order which has not been seen commonly enough during training time is used during test time errors are likely to occur. Slug2Slug also noted this in their paper. In an experiment, they randomised the order of attribute-value pairs in the input sequence to augment the training data but found that this significantly decreased performance.

We have also omitted discussion of the more complex, but complete, notion of hierarchy of inputs and their relationship to each other, which can be used to give more control over how attributes in a sentence are expressed. This was touched upon in both the Surface Realization Shared Task (Mille et al., 2018) (hierarchical dependency relations link together tokens) and in the Constrained Decoding paper of Balakrishnan et al. (2019) (discourse relations link together attributes-value pairs).

Abstract

Generating text from structured data is challenging because it requires bridging the gap between (i) structure and natural language (NL) and (ii) semantically underspecified input and fully specified NL output. Multilingual generation brings in an additional challenge: that of generating into languages with varied word order and morphological properties. In this work, we focus on Abstract Meaning Representations (AMRs) as structured input, where previous research has overwhelmingly focused on generating only into English. We leverage advances in cross-lingual embeddings, pretraining, and multilingual models to create multilingual AMR-to-text models that generate in twenty one different languages. For eighteen languages, based on automatic metrics, our multilingual models surpass baselines that generate into a single language. We analyse the ability of our multilingual models to accurately capture morphology and word order using human evaluation, and find that native speakers judge our generations to be fluent.

1 Introduction

Generating text from structured data has a variety of applications in natural language processing. Tasks such as decoding from tables (Lebret et al., 2016; Sha et al., 2018), question answering from knowledge bases (Fan et al., 2019a), and generation from RDF Triples (Gardent et al., 2017), knowledge graphs (Marcheggiani and Perez-Beltrachini, 2018) and linguistic meaning representations (Konstas et al., 2017) face similar challenges: interpreting structured input and writing fluent output. We focus on generating from graph structures in the form of Abstract Meaning Representations (AMR) (Banarescu et al., 2013). Previous work has largely focused on generating from AMR into English, but we propose a multilingual approach that can decode into twenty one different languages.

Compared to multilingual translation, decoding from structured input has distinct challenges. Translation models take natural language input and must faithfully decode into natural language output. However, as shown in Zhao et al. (2020), bridging the gap between structured input and linear output is a difficult task. In addition, in structured input such as graphs, the input is usually semantically under-specified. For example, in AMRs, function words are missing and tense and number are not given. Thus, generation from structured input must bridge the gap between (i) structure and string and (ii) underspecified input and fully specified output. Multilinguality brings a third challenge — that of generating in languages that have varied morphological and word order properties.

Annotating natural language with AMR is a complex task and training datasets only exist for English[1], so previous work on AMR-to-text generation has overwhelmingly focused on English. We create training data for multilingual AMR-to-Text models, by taking the EUROPARL multilingual corpus and automatically annotating the English data with AMRs using the `jamr` semantic parser. We then use the English AMRs as the input for all generation tasks. To improve quality, we leverage recent advances in natural language processing such as cross-lingual embeddings, pretraining and multilingual learning. Cross-lingual embeddings have shown striking improvements on a range of cross-lingual natural language understanding tasks (Devlin et al., 2019; Conneau et al., 2019; Wu and Dredze, 2019; Pires et al., 2019). Other work has shown that the pre-training and fine-tuning approaches also help improve generation performance (Dong et al., 2019; Song et al., 2019; Lawrence et al., 2019; Rothe et al., 2019). Finally, multilingual models, where a single model

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2889–2901,
November 16–20, 2020.

is trained to translate from multiple source languages into multiple target languages, are achieving increasingly better results in machine translation (Johnson et al., 2017; Firat et al., 2017; Aharoni et al., 2019; Arivazhagan et al., 2019).

By combining these techniques, we demonstrate that fluent generation is possible for multilingual AMR-to-Text models. We use automatic and human evaluation to assess performance on (1) EUROPARL data with silver English-centric AMR as input and the 21 EUROPARL languages as target and (2) on LDC2015E86 data with gold English-centric AMR as input and English, Spanish, Italian, and German as target. Our results demonstrate, for the first time, that it is possible to generate from AMRs into multiple languages. We show that multilingual models have strong performance compared to single-language baselines and produce fluent output, based on the judgments of native speakers. We further investigate how factors, such as differences in the size of the training data, differences in language word order and morphological properties, and differences in the set of languages used for training many-to-one models, impact results. We will make code and models available, to aid research in multilingual AMR-to-Text Natural Language Generation.

2 Related Work

AMR-to-Text Generation. Initial work on AMR-to-text generation adapted methods from statistical machine translation (MT) (Pourdamghani et al., 2016), grammar-based generation (Mille et al., 2017), tree-to-string transducers (Flanigan et al., 2016), and inverted semantic parsing (Lampouras and Vlachos, 2017). Neural approaches explored sequence-to-sequence models where the AMR is linearized (Konstas et al., 2017) or modeled with a graph encoder (Marcheggiani and Perez-Beltrachini, 2018; Damonte and Cohen, 2019; Ribeiro et al., 2019; Song et al., 2018; Zhu et al., 2019). As professionally-annotated AMR datasets are in English, all this work focuses on English.

One exception is the work of Sobrevilla Cabezudo et al. (2019) which uses automatic translation to translate the English text of the LDC AMR data into Brazilian Portuguese and align English with the Portuguese translation to create Portuguese-centric AMRs. However, this work focuses only on one language. In contrast, we consider generation into twenty one languages. We use very different methods and generate from English-centric AMRs, not target-language AMRs.

Multilingual MR-to-Text Generation. While work on AMR-to-Text generation has mostly focused on generation into English, the Multilingual Surface Realization shared tasks (Mille et al., 2018, 2019) have made parallel MR/Text datasets available for 11 languages. Two tracks are proposed: a shallow track where the input is an unordered, lemmatized dependency tree and a deep track where the dependency tree edges are labelled with semantic rather than syntactic relations and where function words have been removed.

The participants approaches to this multilingual generation task use gold training data and mostly focus on the shallow track where the input is an unordered lemmatized dependency tree and the generation task reduces to linearization and morphological realization. The models proposed are pipelines that model each of these subtasks and separate models are trained for each target language (Kovács et al., 2019; Yu et al., 2019; Shimorina and Gardent, 2019a,b; Castro Ferreira and Krahmer, 2019). In this work, we focus instead on more abstract, deeper, input (AMRs) and propose end-to-end, multilingual models for all target languages.

3 Method

To generate from AMRs, we use neural sequence to sequence models that model the input AMR with a Transformer Encoder and generate natural language with a Transformer Decoder. For all languages, the input is an English-centric AMR that was derived automatically using the `jamr` semantic parser from English text. We pre-train both the AMR encoder and the multilingual decoder and we leverage crosslingual embeddings.

3.1 Encoding English AMR

Abstract Meaning Representations are semantic representations that take the form of a rooted, directed acyclic graph. AMR abstracts away syntax such that sentences with similar meanings have similar AMR graphs. Full detail is not kept by the AMR — for example, elements such as verb tense are lost. While we focus on decoding from AMR input, the structured form is reflective of other structured inputs used in tasks such as generating from semantic role labels (Fan et al., 2019c) or RDF triples (Gardent et al., 2017).

Figure 1: **Generating into Multiple Languages from English AMR.**

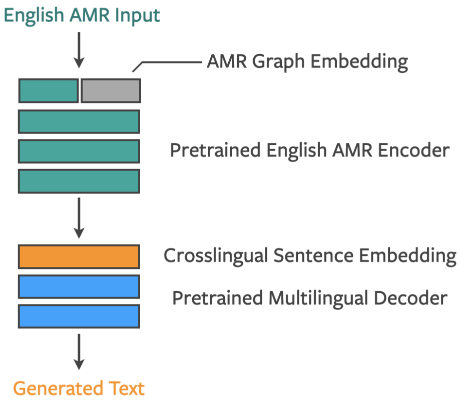

Figure 2: **One-to-Many Architecture for Multilingual AMR-to-Text Generation.** The English-centric AMR input is linearized and modeled with graph embeddings with a pre-trained Transformer Encoder. Text is generated with a pre-trained Transformer Decoder initialized with cross-lingual embeddings.

The AMR graph is first linearized into a sequence of tokens as shown in Figure 1 after preprocessing following (Konstas et al., 2017) (see Section 4.1 for a detailed description). Rather than model the graph structure directly, following Fan et al. (2019a), we model the graph using a *graph embedding*. The graph embedding provides additional information to the Transformer Encoder by encoding the depth of each node in the rooted graph and the subgraph each node belongs to. Concretely, each token has a word and position embedding, and additionally an indicator of depth calculated from the root and an indicator of which subtree the node belongs to (with all subtrees stemming from the root). These additional embeddings are concatenated to the word and position embeddings. Such information allows the Transformer Encoder to capture some graph structure information, while still modeling a sequence. This is depicted in Figure 2.

To create a one-to-many multilingual model, we model a *language embedding* on the encoder side to allow the decoder to distinguish which language to generate into. This technique has been previously used in multilingual translation (Arivazhagan et al., 2019). The English AMR begins with a token that indicates the decoder side language.

To improve the quality of the encoder, we incorporate large-scale pretraining on millions of sequences of AMR by adopting the generative pretraining approach proposed in Lewis et al. (2019a). This pretraining incorporates various noise operations, such as masking (Devlin et al., 2019), span masking (Fan et al., 2019a), and shuffling. Previous work has shown that pretraining is effective for providing neural models with additional information about the structure of natural language and improving model quality (Dong et al., 2019; Song et al., 2019; Lawrence et al., 2019). As models increase in size, smaller training datasets (such as human-annotated AMR) are often not large enough to fully train these models. The entire encoder is pretrained on silver AMRs, as shown in Figure 2.

3.2 Multilingual Decoding from AMR

The Transformer Decoder attends to the encoded English AMR, a graph of concepts and relations, and generates text into many different languages with varied word order and morphology.

As displayed in Figure 2, we use both language model pretraining and crosslingual embeddings to improve decoder quality. Monolingual data from various languages is used to pretrain each language model. Further, we incorporate crosslingual embeddings. These embeddings aim to learn universal representations that encode sentences into shared embedding spaces. Various recent work in crosslingual embeddings (Conneau and Lample, 2019) show strong performance on other multilingual tasks, such as XNLI (Conneau et al., 2018), XTREME (Hu et al., 2020), and MLQA (Lewis et al., 2019b). We use the embeddings from XLM (Conneau and Lample, 2019) to initialize the multilingual embeddings of our decoder.

3.3 Model Training

To train our one-to-many multilingual AMR-to-text generation model, we use pairs of English AMR and text in multiple different languages. The English AMR does not need to be aligned to sentences in multiple languages. Instead, we create one AMR-to-text corpus for each language and concatenate all of them for training a multilingual model. During the training process, the pretrained AMR encoder and pretrained crosslingual decoder are finetuned on our multilingual AMR-to-text training corpus.

4 Experimental Setting

We describe the various sources of data used to create multilingual AMR-to-text generation models and describe the implementation and evaluation.

4.1 Data

Pretraining For encoder pretraining on silver AMR, we take thirty million sentences from the English portion of CCNET[2] (Wenzek et al., 2019), a cleaned version of Common Crawl (an open source version of the web). We use `jamr`[3] to parse English sentences into AMR. For multilingual decoder pretraining, we take thirty million sentences from each language split of CCNET.

Multilingual Data We use EUROPARL, an aligned corpus of European Union parliamentary debates. Each language in EUROPARL is aligned to English. We study the twenty one languages available in EUROPARL: Bulgarian, Czech, Danish, Dutch, English, German, Greek, Spanish, Estonian, Finnish, French, Hungarian, Italian, Lithuanian, Latvian, Polish, Portuguese, Romanian, Slovak, Slovenian, and Swedish. The earliest releases in EUROPARL were prepared with a fixed common testing set across all languages, but later releases in ten new languages do not have a validation or test set. Thus, for the languages where the standard split is applicable, we report results on the common testing set, splitting it in half for validation and testing. For languages where there is no evaluation set, we take a part of the training set and reserve it for validation and another portion for testing. We use `jamr` to parse the English text of the Europarl corpus into AMRs. This creates a corpus of automatically created silver English AMRs aligned with sentences in twenty one European languages.

Gold AMR We also evaluate our models (trained on silver AMRs) on gold AMR where available. For this, we use the CROSSLINGUAL AMR dataset from Damonte and Cohen (2018)[4].The corpus was constructed by having professional translators translate the English text of the LDC2015E86 test set into Spanish, Italian, German, and Chinese. We only evaluate on languages where we have training data from EUROPARL (i.e. we do not include Chinese as it is not in EUROPARL).

Preprocessing All data remains untokenized and cased. For AMR, we follow Konstas et al. (2017) in processing the `jamr` output into a simpler form. We remove variable names and instance-of relation (/) before every concept. However, we do not anonymize entities or dates, as improvements in modeling have allowed for better representations of rare words such as entities. We learn a sentencepiece model with 32K operations to split the English AMR into subword units. On the decoder side, we apply the sentencepiece model and vocabulary of XLM (Conneau and Lample, 2019). We choose to use the existing XLM sentencepiece and vocabulary so that the XLM cross-lingual embeddings can be used to initialize our models. For the encoder, we do not use existing vocabularies, as they do not capture the AMR graph structure.

4.2 Models

We implement our models in `fairseq-py` (Ott et al., 2019). We use large Transformer (Vaswani et al., 2017) sequence-to-sequence models and train all models for 50 epochs with LayerDrop (Fan et al., 2019b), which takes around 2 days. We initialize all weights with the pretrained models. When combining crosslingual word embeddings and encoder and decoder pretraining, we initialize all weights

Table 1: **Results on 21 Languages in Europarl**. The English-XX baseline (generation into a single language) combines all modeling improvements. When training on multiple seeds, the standard deviation is around 0.1 to 0.3 BLEU, making the difference between the multilingual baseline and the addition of our modeling improvements statistically significant.

with pretraining, then use crosslingual word embeddings. We do not perform extensive hyperparameter search, but experimented with various learning rate values to maintain stable training with pretrained initialization. To generate, we decode with beam search with beam size 5. Our pretrained models are available for download.[5]

4.3 Monolingual and Translation Baselines

We compare our multilingual models both to monolingual models (one model trained for each language) and to a hybrid NLG/MT baseline. For the latter, we first generate with the AMR-to-English model and then translate the generation output to the target language using MT. Our translation models are Transformer Big models trained with LayerDrop (Fan et al., 2019b) for 100k updates on public benchmark data from WMT where available and supplemented with mined data from the `ccMatrix` project (Schwenk et al., 2019). We trained translation models for languages where large quantities of aligned bitext data are readily available, and cover a variety of languages.

4.4 Evaluation

We evaluate with detokenized BLEU using `sacrebleu` (Post, 2018). We conduct human evaluation by asking native speakers to evaluate word order, morphology, semantic faithfulness (with respect to the reference) and paraphrasing (how much the generation differs from the reference) on a 3 point scale. The evaluation was done online. For each language, evaluators annotated 25 test set sentences with high BLEU score and 25 sentences with low BLEU score. We removed sentences that were shorter than 5 words. As it is difficult to ensure high quality annotations for 21 languages using crowdsourcing, we relied on colleagues by reaching out on NLP and Linguistics mailing lists. As a result, the number of evaluators per language varies (cf. Table 3).

Table 3: **Human Evaluation**. Native speakers assess fifty sentences on a scale of 1 to 3, with 3 the highest score. Good Paraphrases are sentences with high scores (2 or 3) for both Semantic Accuracy and Paraphrasing.

We evaluate multilingual AMR-to-Text generation models in 21 languages. We conduct an ablation study which demonstrates the improvements in modeling performance induced by incorporating graph embeddings, cross lingual embeddings, and pretraining. Finally, we analyze model performance with respect to several linguistic attributes (word order, morphology, paraphrasing, semantic faithfulness) using both automatic metrics and human evaluation.

4.5 Multilingual AMR-to-Text Generation

Monolingual vs. Multilingual Models. We compare English-XX baselines trained to generate from AMR into a single language with multilingual models. We note that as the English-XX models specializes for each language, they have less to model with the same parameter capacity. Results are shown in Table 1. Overall, multilingual models perform well — on 18 of the 21 languages, the performance measured by BLEU is stronger than the monolingual baseline.

One advantage of multilingual AMR-to-Text generation is increased quantities of AMR on the encoder side. This is particularly helpful when the size of the training data is low. For instance, Estonian (*et*) sees a 2.3 BLEU point improvement from multilingual modeling. Conversely, languages such as English, Swedish and French benefit less from multilingual modeling, most likely because there is sufficient data for those languages already. More generally, there is a marked difference between languages for which the training data is large and those for which the training data is smaller. When the training data is large (1.9 to 2M training instances, top part of Table 1), the average improvment is +0.36 BLEU (Min:-0.2, Max:+0.9) whereas for languages with smaller training data (400 to 620K training instances, bottom part of Table 1[6]), the average improvement is +1.75 (Min:+1, Max:+2.3). These trends are similar to observations on other tasks — namely that pretraining is most helpful when there is not sufficient training data in the task itself to train strong representations.

5 Results

Performance on Gold English AMR We evaluate our models trained on silver AMR on the CROSSLINGUAL AMR dataset from Damonte and Cohen (2018) where the input is a gold English-centric AMR and the output is available in three European languages: Spanish, French, and Italian. The results are shown in Table 2. Similar to the trends seen when generating from silver AMR, we find that multilingual models have strong performance. BLEU scores are lower than on EUROPARL as the models are tested out of domain (training on parliamentary debates but testing on newswire and forum data domains).

On English LDC data, we compare to existing work. Even though it is trained on silver AMRs

---

[6] For many languages, such as Slavic languages, it is because the EU expanded to include these countries later on. Thus there is less European Parliamentary proceeding data.

and out of domain, non-LDC data, the multilingual model compares well with previous work (see Table 2). When finetuned on the LDC2015E86 train set, our model improves on English by over 1 BLEU point, outperforming all previous work except Zhu et al. (2019). This work directly models the graph structure of AMR with structure aware attention to improve Transformer architectures — this is orthogonal to our main aim of multilingual generation and can be incorporated in future work.

Impact of Modeling Improvements. For the multilingual model, we display the effect of incrementally adding additional modeling improvements (cf. Table 1). Each improvement is essentially universally helpful across all considered languages, though some have a greater improvement on performance than others.

Comparison to the Hybrid NLG/MT Baseline. Compared to the NLG/MT baseline, our multilingual models provide comparable results while providing an arguably simpler approach (end-to-end rather than pipeline) and training on much lower quantities of parallel data — on German and French (very high resource languages with millions of examples of training data), there is slightly stronger performance. On other languages we compare to, the translation models perform a bit worse.

We further conduct a human evaluation study on Spanish, Italian, and German. We ask evaluators to assess the morphology, word order, and semantic accuracy of our Multilingual AMR to Text system compared to this hybrid English AMR to Text + Machine Translation baseline. We show in Table 4 that the two models score very similarly in human evaluation, indicating the strength of this fully multilingual system in producing fluent output.

5.1 Analysis of Multilingual Generation

A core challenge for multilinguality is that languages differ with respect to word order and morphology, so models must learn this per language. We use automatic and human evaluation to investigate how these differences affect performance.

Morphology Instead of operating on words, our models use sentencepiece (Wu et al., 2016), a data-driven approach to break words into subwords. As shown in Wu and Dredze (2019), in transfer-based approaches to natural language understanding tasks, the proportion of subwords shared between the source and the transfer language impacts performance. We therefore explore the relation between the proportion of subwords and words shared between the AMR and the output vocabulary. Figure 4 displays this relationship, with weak positive correlation for both word and subword overlap.

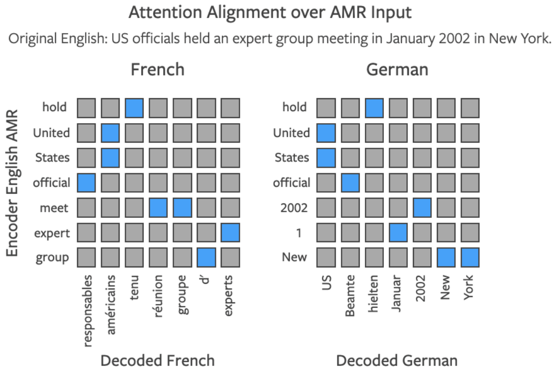

Figure 3: **Attention alignment** when decoding in French and German from the same input AMR.

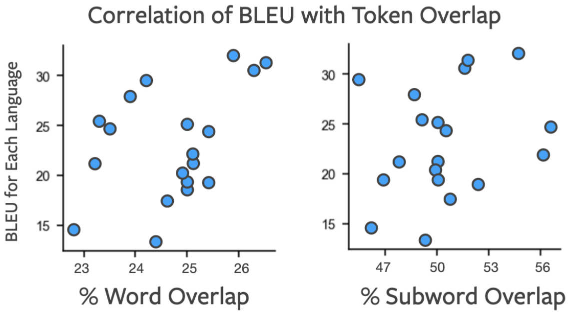

Figure 4: **Relationship between BLEU Score and Token Overlap** for all 21 languages. Correlation coefficient between word overlap and BLEU is 0.42, and coefficient between subword overlap and BLEU is 0.26.

We further assess morphology by asking human evaluators to grade the morphology of sentences (*Is the morphology correct? Are agreement constraints e.g., verb/subject, noun/adjective respected?*) on a scale from 1 to 3 with 3 being the highest score. As Table 3 shows, there is not much difference in performance between languages even though there is a marked difference in terms of agreement constraints between e.g., Finnish and English. Between annotators, agreement was high — the standard deviation across was low, with the exception of Romanian, Hungarian, and Spanish (as shown in Table 3). This demonstrates the surprisingly high ability of multilingual models to generalize across languages.

Word Order To assess the impact of varied word orders by language, we ask human evaluators to

Evaluation	Morphology	Word Order	Semantic Accuracy
Spanish			
Machine Translation	2.9	2.7	2.0
Multilingual AMR to Text	2.8	2.9	2.1
Italian			
Machine Translation	3.0	2.9	2.2
Multilingual AMR to Text	2.9	3.0	2.1
German			
Machine Translation	2.8	2.9	2.0
Multilingual AMR to Text	3.0	3.0	2.2

Table 4: **Human Evaluation of our approach compared to the Hybrid English AMR to Text + Machine Translation baseline using Gold AMR from LDC2015E86**. Two native speakers per language assess fifty sentences each on a scale of 1 to 3, with 3 being the highest score.

English	**Generation**	This point will certainly be the subject of subsequent further debates in the council.
	Reference	This is a point that will undoubtedly be discussed later in the Council.
French	**Generation**	Je ne suis pas favorable à des exceptions à cette règle.
	Reference	A mon avis, il n'est pas bon de faire des exceptions à cette règle.
Swedish	**Generation**	Därför röstade vi inte för detta betänkande.
	Reference	Vi har därför inte röstat för detta betänkande.

Table 5: **Example Paraphrases** generated by our multilingual model.

Model	es	fr	it	pt	ro
One Language	25.2	20.3	18.9	22.2	32.1

All Languages	25.3	20.5	19.3	22.4	32.2
		da	**de**	**nl**	**sv**
One Language		21.3	17.0	18.5	18.7
Germanic Family		21.8	21.9	19.6	19.3
All Languages		21.9	17.5	19.4	19.5

Table 6: **Performance when training with increasingly more languages.** Training one multilingual AMR-to-Text model with languages in the related language family improves performance.

judge if the word order is natural. As shown in Table 3, for all languages except Latvian and Romanian, the score is very high (close to 3) indicating that the model learns to decode into multiple languages even though word order differs. The agreement between annotators was high, with low standard deviation (see Table 3). Further, the attention pattern between the encoder English AMR and the decoder clearly reflects the word order of the various languages. This is illustrated in Figure 3, where the activation pattern mirrors the word order difference between French (1) and German (2).

(1) *ont tenu (une réunion de groupe)*$_{\mathrm{OBJ}}$ *(en Janvier 2020)*$_{\mathrm{TIME}}$ *(à New York)*$_{\mathrm{LOC}}$

(2) *hielten (im Januar 2020)*$_{\mathrm{TIME}}$ *(in New York)*$_{\mathrm{LOC}}$ *(eine Gruppestreffen)*$_{\mathrm{OBJ}}$

Training on Related Languages Multilingual models have the potential to benefit from similarities between languages. Languages of the same family often have shared morphological characteristics and vocabulary. First, we analyze the performance of training on languages within a family. Table 6 displays that a model trained on languages within a family has the strongest performance.

Second, we analyze languages within the same family. For four families: Romance, Germanic, Uralic, and Slavic, we create multilingual models trained on pairs. One pair is for the most related languages within that family (e.g. Spanish and Portuguese) and another pair is for the farthest languages within that family (e.g. Spanish and Romanian). We determine which pairs are close and far from Ahmad et al. (2019). Results in Figure 5 display that training on pairs of closely related languages has better performance than pairs of less closely related languages, even within a family. Multilingual models could pick up on similarities between languages to improve performance.

Semantic Accuracy and Paraphrasing. We ask human evaluators to grade the faithfulness of the hypothesis compared to the reference on a scale of 1 to 3. As shown in Table 3, the overall semantic accuracy is very high (note a score of 2 indicates *minor differences*). We also asked annotators to

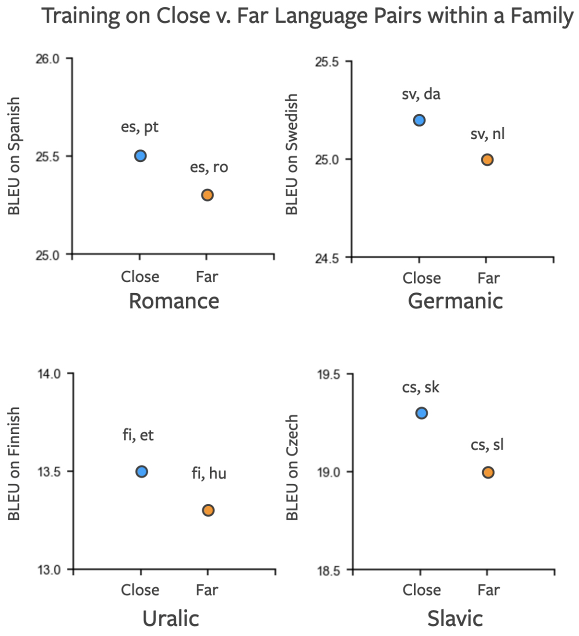

Figure 5: **BLEU difference training on Close v. Far Languages within One Family**. Training on a close pair consistently improves performance compared to training on a far pair, even within a language family.

evaluate how different the generated sentence was from the reference. When coupled with the semantic accuracy score, this allows us to evaluate generation of true paraphrases i.e., sentences with the same meaning as the reference but different surface form. In Table 3, *Good Paraphrases* indicates the percentage of cases that scored highly (2 or 3) with respect to both semantic adequacy and paraphrasing. A large majority of generated sentences are labeled as valid paraphrases by native speakers, indicating (i) that despite underspecified input, the written sentence retains the meaning of the reference and (ii) that this underspecification allows for the generation of paraphrases. This also suggests that BLEU scores only partially reflect model performance as good paraphrases typically differ from the reference and are likely to get lower BLEU score even though they may be semantically accurate. Table 5 shows some examples illustrating the paraphrasing potential of the approach.

6 Conclusion

Abstract Meaning Representations were designed to describe the meaning of English sentences. As such they are heavily biased towards English. AMR concepts are either English words, PropBank framesets ("want-01") or special, English-based keywords (e.g., "date-entity"). The structure of AMRs is also influenced by English syntax. For instance, the main relation of *"I like to eat"* is the concept associated with its main verb ("like") whereas given the corresponding German sentence *"Ich esse gern" (Lit. "I eat willingly")*, the main predicate might have been chosen to be "eat" ("essen"). In other words, AMRs should not necessarily be viewed as an interlingua (Banarescu et al., 2013). Nonetheless, our work suggests that it can be used as one: given an English-centric AMR it is possible to generate the corresponding sentence in multiple languages. This is in line with previous work by (Damonte and Cohen, 2019) which shows that despite translation divergences, AMR parsers can be learned for Italian, Chinese, German and Spanish which all map into an English-centric AMR.

A Appendix

A.1 Model Training Details

For our baseline models, we train Transformer Big architectures with 240M parameters. We set the learning rate to 0.001 with the inverse square root learning rate schedule from Vaswani et al. (2017), warming up for 4000 updates. We train with the Adam optimizer with no weight decay and label smoothing 0.1. We set the encoder and decoder layerdrop to 0.1, and set the standard dropout to 0.3 as well. We experiment with dropout values between $0.1, 0.2, 0.3$. We set the number of maximum tokens per batch to 3584. We tune based on the validation loss at training time. We train for a fixed number of updates $(100,000)$ and take the best checkpoint by validation loss. We train using 8 GPUs. The overall training time varies depending on the amount of training data available. Overall, we train for about a day and a half to two days, though good performance can be achieved within a day. The remaining training only marginally improves the quality as measured by BLEU.

For the multilingual models, we train with the same parameters as above, except the parameter size is slightly larger: around 250M parameters. The reason for this is the increased size of the XLM vocabulary that we use for initializing our cross-lingual embeddings. We again tune the dropout values between $0.1, 0.2, 0.3$. As we use pretraining and pretrained cross-lingual embeddings, we lower the learning rate to 0.0001. A smaller learning rate can be used because the model parameters are initialized to a much better starting point. We warm up for 8000 updates to ease the learning rate schedule at the beginning of training. We experimented with a variety of learning rates between $0.001 - 0.00001$, and tried five different values in this range. We chose the best performing value based on validation loss. The convergence speed is faster for multilingual models due to the pretraining initialization. Good performance can be achieved within half a day, though for experimental consistency we continue to train for the full $100,000$ updates to compare to the baseline.

To generate from our models, we decode with beam search with beam size 5. We experiment with beam size values between $4, 5$ and length penalty values between $0.4, 0.6, 1, 1.2$. We tune these values based on validation BLEU and use the best performing values to decode on the test set. Our decoding process is as follows: generate with the model on the validation set, remove the sentencepiece markers, then use the `sacrebleu` library for evaluation. As we use `sacrebleu`, we provide detokenized text.

Exploring the Linear Subspace Hypothesis in Gender Bias Mitigation

Abstract

Bolukbasi et al. (2016) presents one of the first gender bias mitigation techniques for word embeddings. Their method takes pre-trained word embeddings as input and attempts to isolate a linear subspace that captures most of the gender bias in the embeddings. As judged by an analogical evaluation task, their method virtually eliminates gender bias in the embeddings. However, an implicit and untested assumption of their method is that the bias subspace is actually linear. In this work, we generalize their method to a kernelized, non-linear version. We take inspiration from kernel principal component analysis and derive a non-linear bias isolation technique. We discuss and overcome some of the practical drawbacks of our method for non-linear gender bias mitigation in word embeddings and analyze empirically whether the bias subspace is actually linear. Our analysis shows that gender bias is in fact well captured by a linear subspace, justifying the assumption of Bolukbasi et al. (2016).

1 Introduction

Pre-trained word representations are a necessity for strong performance on modern NLP tasks. These embeddings now serve as input to neural methods (Goldberg, 2017), which recently have become the standard models in the field. However, because these representations are constructed from large, human-created corpora, they naturally contain societal biases encoded in that data; gender bias is among the most well studied of these biases (Caliskan et al., 2017). Both a-contextual word embeddings (Mikolov et al., 2013; Pennington et al., 2014) and contextual word embeddings (Peters et al., 2018; Devlin et al., 2019) have been shown to encode gender bias (Bolukbasi et al., 2016; Caliskan et al., 2017; Zhao et al., 2019; May et al., 2019; Karve et al., 2019). More importantly, the bias in those embeddings has been shown to influence models for downstream tasks where they are used as input, e.g. coreference resolution (Rudinger et al., 2018; Zhao et al., 2018).

Bolukbasi et al. (2016) present one of the first methods for detecting and mitigating gender bias in word embeddings. They provide a novel linear-algebraic approach that post-processes word embeddings in order to partially remove gender bias. Under their evaluation, they find they can nearly perfectly remove bias in an analogical reasoning task. However, subsequent work (Gonen and Goldberg, 2019; Hall Maudslay et al., 2019) has indicated that gender bias still lingers in the embeddings, despite Bolukbasi et al. (2016)'s strong experimental results. In the development of their method, Bolukbasi et al. (2016) make a critical and unstated assumption: Gender bias forms a linear subspace of word embedding space. In mathematics, linearity is a strong assumption and there is no reason *a-priori* why one should expect complex and nuanced societal phenomena, such as gender bias, should be represented by a linear subspace.

In this work, we present the first non-linear gender bias mitigation technique for a-contextual word embeddings. In doing so, we directly test the linearity assumption made by Bolukbasi et al. (2016). Our method is based on the insight that Bolukbasi et al. (2016)'s method bears a close resemblance to principal component analysis (PCA). Just as one can kernelize PCA (Schölkopf et al., 1997), we show that one can kernelize the method of Bolukbasi et al. (2016). Due to the kernelization, the bias is removed in the feature space, rather in the word embedding space. Thus, we also explore pre-image techniques (Mika et al., 1999) to project the bias-mitigated vectors back into $\mathbb{R}^d$.

As previously noted, there are now multiple bias removal methodologies (Zhao et al., 2018, 2019; May et al., 2019) that have succeed the method by Bolukbasi et al. (2016). Furthermore Gonen and Goldberg (2019) point out multiple flaws in Bolukbasi et al. (2016)'s bias mitigation technique

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2902–2913,
November 16–20, 2020. ©2020 Association for Computational Linguistics

and the aforementioned methods. Nonetheless we believe that this method has received sufficient attention from the community such that research into its properties is both interesting and useful.

We test our non-linear gender bias technique in several experiments. First, we consider the Word Embedding Association Test (WEAT; Caliskan et al., 2017); we notice that across five non-linear kernels and convex combinations thereof, there is seemingly no significant difference between the non-linear bias mitigation technique and the linear one. Secondly, we consider the professions task (Bolukbasi et al., 2016; Gonen and Goldberg, 2019) that measures how word embeddings representing different professions are potentially gender-stereotyped. Again, as with the WEAT evaluation, we find that our non-linear bias mitigation technique performs on par with the linear method. We also consider whether the non-linear gender mitigation technique removes indirect bias from the vectors (Gonen and Goldberg, 2019); yet again, we find the non-linear method performs on par with the linear methods. As a final evaluation, we evaluate whether non-linear bias mitigation hurts semantic performance. On Simlex-999 (Hill et al., 2015), we show that similarity estimates between the vectors remain on par with the linear methods. We conclude that much of the gender bias in word embeddings is indeed captured by a linear subspace, answering this paper's titular question.

2 Bias as a Linear Subspace

The first step of Bolukbasi et al. (2016)'s technique is the discovery of a subspace $B \subset \mathbb{R}^d$ that captures most of the gender bias. Specifically, they stipulate that this space is linear. Given word embeddings that live in $\mathbb{R}^d$, they provide a spectral method for isolating the bias subspace. In this section, we review their approach and show how it is equivalent to principal component analysis (PCA) on a specific design (input) matrix. Then, we introduce and discuss the implicit assumption made by their work; we term this assumption the **linear subspace hypothesis** and test it in §4.

Hypothesis 1. *Gender bias in word embeddings may be represented as a linear subspace.*

2.1 Construction of a Bias Subspace

We will assume the existence of a fixed and finite vocabulary V, each element of which is a word $\mathbf{w}_i$. The hard-debiasing approach takes a set of N sets $\mathcal{D} = \{D_n\}_{n=1}^N$ as input. Each set D_n contains words that are considered roughly semantically equivalent modulo their gender; Bolukbasi et al. (2016) call the D_n **defining sets**. For example, $\{man, woman\}$ and $\{he, she\}$ form two such defining sets. We identify each word with a unique integer i for the sake of our indexing notation; indeed, we exclusively reserve the index i for words. We additionally introduce the function $f : [|V|] \to [N]$ that maps an individual word to its defining set. In general, the defining sets are not limited to a cardinality of two, but in practice Bolukbasi et al. (2016) exclusively employ defining sets with a cardinality of two in their experiments. Using the sets D_n, Bolukbasi et al. (2016) define the matrix $\boldsymbol{C}$

$$\boldsymbol{C} := \sum_{n=1}^{N} \frac{1}{|D_n|} \sum_{i \in D_n} (\mathbf{w}_i - \boldsymbol{\mu}_{D_n})(\mathbf{w}_i - \boldsymbol{\mu}_{D_n})^\top$$

where we write $\mathbf{w}_i$ for the i^{th} word's embedding and the empirical mean vector $\boldsymbol{\mu}_{D_n}$ is defined as

$$\boldsymbol{\mu}_{D_n} := \frac{1}{|D_n|} \sum_{i \in D_n} \mathbf{w}_i$$

Bolukbasi et al. (2016) then extract a bias subspace B using the singular value decomposition (SVD). Specifically, they define the bias subspace to be the space spanned by the first k rows of $\boldsymbol{V}$ where

$$\boldsymbol{V}\boldsymbol{S}\boldsymbol{V}^\top = \mathrm{SVD}(\boldsymbol{C}) \tag{1}$$

Since $\boldsymbol{C}$ is symmetric and positive semi-definite, the SVD is equivalent to an eigendecomposition as our notation in Equation 1 shows. We assume the rows of $\boldsymbol{V}$, the eigenvectors of $\boldsymbol{C}$, are ordered by the magnitude of their corresponding eigenvalues.

2.2 Bias Subspace Construction as PCA

As briefly noted by Bolukbasi et al. (2016), this can thus be cast as performing principal component analysis (PCA) on a recentered input matrix. We prove this assertion more formally. We first prove that the matrix $\boldsymbol{C}$ may be written as an empirical covariance matrix.

Proposition 1. *Suppose* $|D_n| = 2$ *for all* n. *Then we have*

$$\boldsymbol{C} = \frac{1}{2} \sum_{i=1}^{2N} \boldsymbol{W}_{i,\cdot}^\top \boldsymbol{W}_{i,\cdot} \tag{2}$$

where we define the design matrix $\boldsymbol{W}$ *as:*

$$\boldsymbol{W}_{i,\cdot} = \left(\mathbf{w}_i - \boldsymbol{\mu}_{D_{f(i)}}\right)^\top \tag{3}$$

Proof.

$$\begin{aligned}
\boldsymbol{C} &= \sum_{n=1}^{N} \frac{1}{|D_n|} \sum_{i \in D_n} (\mathbf{w}_i - \boldsymbol{\mu}_{D_n})(\mathbf{w}_i - \boldsymbol{\mu}_{D_n})^\top \\
&= \frac{1}{2} \sum_{n=1}^{N} \sum_{i \in D_n} (\mathbf{w}_i - \boldsymbol{\mu}_{D_n})(\mathbf{w}_i - \boldsymbol{\mu}_{D_n})^\top \\
&= \frac{1}{2} \sum_{i=1}^{2N} \left(\mathbf{w}_i - \boldsymbol{\mu}_{D_{f(i)}}\right)\left(\mathbf{w}_i - \boldsymbol{\mu}_{D_{f(i)}}\right)^\top \\
&= \frac{1}{2} \sum_{i=1}^{2N} \boldsymbol{W}_{i,\cdot}^\top \boldsymbol{W}_{i,\cdot}
\end{aligned}$$

where $\boldsymbol{W}_{i,\cdot} \in \mathbb{R}^{2N \times d}$ is defined as above. ☐

Next, we show that the matrix is centered, which is a requirement for PCA.

Proposition 2. *The matrix* $\boldsymbol{W}$ *is row-wise centered.*

Proof.

$$\begin{aligned}
\frac{1}{2} \sum_{i=1}^{2N} \boldsymbol{W}_{i,\cdot}^\top &= \frac{1}{2} \sum_{i=1}^{2N} \left(\mathbf{w}_i - \boldsymbol{\mu}_{D_{f(i)}}\right) \\
&= \frac{1}{2} \sum_{n=1}^{N} \sum_{i \in \mathcal{D}_n} (\mathbf{w}_i - \boldsymbol{\mu}_{D_n}) \\
&= \frac{1}{2} \sum_{n=1}^{N} \left(-2\boldsymbol{\mu}_{D_n} + \sum_{i \in \mathcal{D}_n} \mathbf{w}_i\right) \\
&= \frac{1}{2} \sum_{n=1}^{N} (2\boldsymbol{\mu}_{D_n} - 2\boldsymbol{\mu}_{D_n}) = 0
\end{aligned}$$

☐

Remark 3. *The method of Bolukbasi et al. (2016) may be considered principal component analysis performed on the matrix* $2\boldsymbol{C}$.

Proof. As the algebra in proposition 1 and proposition 2 show we may formulate the problem as an SVD on a mean-centered covariance matrix. One view of PCA is performing matrix factorization on such a matrix. ☐

3 Bolukbasi et al. (2016)

In this section, we review the bias mitigation technique introduced by Bolukbasi et al. (2016). When possible, we take care to reformulate their method in terms of matrix notation. They introduce a two-step process that **neutralizes** and **equalizes** the vectors to mitigate gender bias in the embeddings. The underlying assumption of their method is that there exists a linear subspace $B \subset \mathbb{R}^d$ that captures most of the gender bias.

3.1 Neutralize

After finding the linear bias subspace B, the gist behind Bolukbasi et al. (2016)'s approach is based on elementary linear algebra. We may decompose any word vector $\mathbf{w}$ as the sum of its orthogonal projection onto the bias subspace (range of the projection) and its orthogonal projection onto the complement of the bias subspace (null space of the projection), i.e.

$$\mathbf{w} = \mathbf{w}_B + \mathbf{w}_{\perp B} \tag{4}$$

We may then re-embed every vector as

$$\mathbf{w}_{\text{ntr}} := \mathbf{w} - \mathbf{w}_B = \mathbf{w}_{\perp B} \tag{5}$$

We may re-write this in terms of matrix notation in the following manner. Let $\{\mathbf{v}_k\}_{k=1}^K$ be an orthogonal basis for the linear bias subspace B. This may be found by taking the eigenvectors $\boldsymbol{C}$ that correspond to the top-K eigenvalues with largest magnitude. Then, we define the projection matrix onto the bias subspace as $\boldsymbol{P}_K = \sum_{k=1}^K \mathbf{v}_k \mathbf{v}_k^\top$ it follows that the matrix $(\boldsymbol{I} - \boldsymbol{P}_K)$ is a projection matrix on the complement of B. We can then write the neutralize step using matrices

$$\mathbf{w}_{\text{ntr}} := (\boldsymbol{I} - \boldsymbol{P}_K)\,\mathbf{w} \tag{6}$$

The matrix formulation of the neutralize step offers a cleaner presentation of what the neutralize step does: it projects the vectors onto the orthogonal complement of the bias subspace.

3.2 Equalize

Bolukbasi et al. (2016) decompose words into two classes. The neutral words which undergo neutralization as explained above, and the gendered words, some of which receive the equalizing treatment. Given a set of **equality sets** $\mathcal{E} = \{E_1, \ldots, E_L\}$ which we can see as a greater extension of the defining sets $\mathcal{D}$, i.e. $E_i = \{guy, gal\}$, Bolukbasi et al. (2016) then proceed to decompose each of the words $\mathbf{w} \in \mathcal{E}$ into their gendered and neutral counterparts, setting their neutral component to a constant (the mean of the equality set) and the gendered component to its mean-centered projection into the gendered subspace:

$$\mathbf{w}_{\text{eq}} := \boldsymbol{\nu} + Z\,(\mathbf{w}_B - \boldsymbol{\mu}_B) \tag{7}$$

where we define the following quantities:

$$
\begin{aligned}
Z &:= \frac{\sqrt{1 - ||\boldsymbol{\nu}||_2^2}}{||\mathbf{w}_B - \boldsymbol{\mu}_B||_2} \\
\boldsymbol{\mu} &:= \frac{1}{|E_i|} \sum_{\mathbf{w} \in E_i} \mathbf{w} \\
\boldsymbol{\nu} &:= (\boldsymbol{I} - \boldsymbol{P}_K)\, \boldsymbol{\mu}
\end{aligned}
$$

the “normalizer” Z ensures the vector is of unit length. This fact is left unexplained in the original work, but Hall Maudslay et al. (2019) provide a proof in their appendix.

4 Bias as a Non-Linear Subspace

We generalize the framework presented in Bolukbasi et al. (2016) and cast it to a non-linear setting by exploiting its relationship to PCA. Thus, the natural extension of Bolukbasi et al. (2016) is to kernelize it analogously to Schölkopf et al. (1997), which is the kernelized generalization of PCA. Our approach preserves all the desirable formal properties presented in the linear method of Bolukbasi et al. (2016).

4.1 Adapting the Design Matrix

The idea behind our non-linear bias mitigation technique is based on kernel PCA (Schölkopf et al., 1998). In short, the idea is to map the original word embeddings $\mathbf{w}_i \in \mathbb{R}^d$ to a higher-dimensional space $\mathcal{H}$ via a function $\boldsymbol{\Phi} : \mathbb{R}^d \to \mathcal{H}$. We will consider cases where $\mathcal{H}$ is a reproducing kernel Hilbert space (RKHS) with reproducing kernel $\kappa(\mathbf{w}_i, \mathbf{w}_j) = \langle \boldsymbol{\Phi}(\mathbf{w}_i), \boldsymbol{\Phi}(\mathbf{w}_j) \rangle$ where the notation $\langle \cdot, \cdot \rangle$ refers to an inner product in the RKHS. Traditionally, one calls $\mathcal{H}$ the feature space and will use this terminology throughout this work. Exploiting the reproducing kernel property, we may carry out Bolukbasi et al. (2016)'s bias isolation technique and construct a non-linear analogue.

We start the development of bias mitigation technique in feature space with a modification of the design matrix presented in Eq. (3). In the RKHS setting the non-linear analogue is

$$
\boldsymbol{W}^{\boldsymbol{\Phi}}_{i,\cdot} := \boldsymbol{\Phi}(\mathbf{w}_i) - \boldsymbol{M}^{\boldsymbol{\Phi}}_{D_{f(i)}}, \quad \forall\, \mathbf{w}_i \in V \tag{8}
$$

where we define

$$
\boldsymbol{M}^{\boldsymbol{\Phi}}_{D_n} := \frac{1}{|D_n|} \sum_{i \in D_n} \boldsymbol{\Phi}(\mathbf{w}_i) \tag{9}
$$

As one can see, this is a relatively straightforward mapping from the set of linear operations to non-linear ones.

4.2 Kernel PCA

Using our modified design matrix, we can cast our non-linear bias mitigation technique as a form of kernel PCA. Specifically, we form the following matrix

$$
\boldsymbol{C}^{\boldsymbol{\Phi}} = \frac{1}{2} \sum_{i=1}^{2N} (\boldsymbol{W}^{\boldsymbol{\Phi}}_{i,\cdot})^\top \boldsymbol{W}^{\boldsymbol{\Phi}}_{i,\cdot}
$$

Our goal is to find the eigenvalues λ_k and their corresponding eigenfunctions $\boldsymbol{V}^{\boldsymbol{\Phi}}_k \in \mathcal{H}$ by solving the eigenvalue problem

$$
\boldsymbol{C}^{\boldsymbol{\Phi}}\, \boldsymbol{V}^{\boldsymbol{\Phi}}_k = \lambda_k \boldsymbol{V}^{\boldsymbol{\Phi}}_k \tag{10}
$$

Computing these directly from Equation 10 is impossible since $\mathcal{H}$'s dimension may be prohibitively large or even infinite. However, Schölkopf et al. note that $\boldsymbol{V}^{\boldsymbol{\Phi}}_k$ is spanned by $\{\boldsymbol{\Phi}(\mathbf{w}_i)\}_{i=1}^{2N}$. This allows us to rewrite Eq. (10) as

$$
\boldsymbol{V}^{\boldsymbol{\Phi}}_k = \sum_{i=1}^{2N} \alpha_i^k\, \boldsymbol{\Phi}(\mathbf{w}_i) \tag{11}
$$

where there exist coefficients $\alpha_i^k \in \mathbb{R}$. Now, by substituting Eq. (11) and Eq. (10) into the respective terms in $\lambda \langle \boldsymbol{\Phi}(\mathbf{w}_i), \boldsymbol{V}^{\boldsymbol{\Phi}}_k \rangle = \langle \boldsymbol{\Phi}(\mathbf{w}_i), \boldsymbol{C}\, \boldsymbol{V}^{\boldsymbol{\Phi}}_k \rangle$, Schölkopf et al. (1997) derive a computationally feasible eigendecomposition problem. Specifically, they consider

$$
2N\lambda_k\, \boldsymbol{\alpha}^k = \boldsymbol{K}\boldsymbol{\alpha}^k \tag{12}
$$

where $\boldsymbol{K}_{ij} = \langle \boldsymbol{\Phi}(\mathbf{w}_i), \boldsymbol{\Phi}(\mathbf{w}_j) \rangle$. Once all the $\boldsymbol{\alpha}^k$ vectors have been estimated the inner product between an eigenfunction $\boldsymbol{V}^{\boldsymbol{\Phi}}_k$ and a point $\mathbf{w}$ can be computed as

$$
\begin{aligned}
\beta_k(\mathbf{w}) &= \langle \boldsymbol{V}^{\boldsymbol{\Phi}}_k, \boldsymbol{\Phi}(\mathbf{w}_i) \rangle \\
&= \sum_{i=1}^{2N} \alpha_i^k\, \kappa(\mathbf{w}_i, \mathbf{w})
\end{aligned} \tag{13}
$$

A projection into the basis $\{\boldsymbol{V}^{\boldsymbol{\Phi}}_k\}_{k=1}^K$ can then be carried out by applying the projection operator $\mathrm{P}_K : \mathcal{H} \to \mathcal{H}$ as follows:

$$
\mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{w}) = \sum_{k=1}^{K} \beta_k(\mathbf{w})\, \boldsymbol{V}^{\boldsymbol{\Phi}}_k \tag{14}
$$

where K is the number of principal components. Projection operator P_K is analogous to the linear projection $\boldsymbol{P}_K$ introduced in §3.1.

4.3 Centering Kernel Matrix

We can perform the required mean-centering operations on the design matrix by centering the kernel matrix in a similar fashion to Schölkopf et al. (1998). For the case of equality sets of size 2, which is what Bolukbasi et al. use in practice, we realize that the centered design matrix reduces to pairwise differences:

$$\boldsymbol{W}^{\boldsymbol{\Phi}}_{i,\cdot} = \frac{1}{2}(\boldsymbol{\Phi}(\mathbf{w}_i) - \boldsymbol{\Phi}(\mathbf{w}_j)), \qquad (15)$$
$$\mathbf{w}_i, \mathbf{w}_j \in D_n \wedge \mathbf{w}_j \neq \mathbf{w}_i$$

which leads to a very simple re-centering in terms of the Gram matrices:

$$\tilde{\boldsymbol{K}} = \boldsymbol{K}^{(11)} - \boldsymbol{K}^{(12)} - (\boldsymbol{K}^{(12)})^{\top} + \boldsymbol{K}^{(22)}$$

where

$$\boldsymbol{K}^{(xy)}_{ij} = \frac{1}{2}\kappa\left(\boldsymbol{W}^{(x)}_{i,\cdot}, \boldsymbol{W}^{(y)}_{j,\cdot}\right),$$
$$\boldsymbol{W}^{(z)}_{i,\cdot} = \begin{cases} \mathbf{w}_{\pi_{1+i \bmod 2}(\hat{f}(\lceil \frac{i}{2} \rceil))} & z = 1 \\ \mathbf{w}_{\pi_{2-i \bmod 2}(\hat{f}(\lceil \frac{i}{2} \rceil))} & z = 2 \end{cases} \qquad (16)$$

where $\hat{f} : [N] \rightarrow [|V|] \times [|V|]$ maps a defining set index to a tuple containing the word indices in the corresponding defining set and $\pi_1, \pi_2 : [|V|] \times [|V|] \rightarrow [|V|]$ are projection operators which return the first or second elements of a tuple respectively. In simpler terms, Eq. (16) is creating two matrices: matrix $\boldsymbol{W}^{(1)}$ which is constructed by looping over the definition sets and placing pairs within the same definition set as adjacent rows, then $\boldsymbol{W}^{(2)}$ is constructed in the same way but the order of the adjacent pairs is swapped relative to $\boldsymbol{W}^{(1)}$. Once we have this pairwise centered Gram matrix $\tilde{\boldsymbol{K}}$ we can apply the eigendecomposition procedure described in Equation 12 directly on $\tilde{\boldsymbol{K}}$. We note that carrying out this procedure using a linear kernel recovers the linear bias subspace from Bolukbasi et al. (2016).

4.4 Inner Product Correction (Neutralize)

We now focus on neutralizing and equalizing the inner products in the RKHS rather than correcting the word embeddings directly. Just as in the linear case, we can decompose the representation of a word in the RKHS into biased and neutral components

$$\boldsymbol{\Phi}(\mathbf{w}) = \mathrm{P}_K^{\perp}\, \boldsymbol{\Phi}(\mathbf{w}) + \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{w}), \qquad (17)$$

which provides a nonlinear equivalent for Eq. (6)

$$\begin{aligned} \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{w}) &= \mathrm{P}_K^{\perp}\, \boldsymbol{\Phi}(\mathbf{w}) & (18) \\ &= \boldsymbol{\Phi}(\mathbf{w}) - \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{w}) \end{aligned}$$

Proposition 4. *The corrected inner product in the feature space for two neutralized words* $\mathbf{z}, \mathbf{w}$ *is given by*

$$\begin{aligned} &\langle \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{z}), \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{w}) \rangle & (19) \\ &\quad = \kappa(\mathbf{z}, \mathbf{w}) - \sum_{k=1}^{K} \beta_k(\mathbf{z})\, \beta_k(\mathbf{w}) \end{aligned}$$

Proof.

$$\begin{aligned} &\Big\langle \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{z}), \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{w}) \Big\rangle = \\ &\quad \Big\langle \boldsymbol{\Phi}(\mathbf{z}) - \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{z}), \boldsymbol{\Phi}(\mathbf{w}) - \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{w}) \Big\rangle \end{aligned}$$

Applying Eq. (13) and Eq. (14)

$$\begin{aligned} &= \kappa(\mathbf{z}, \mathbf{w}) - \sum_{k=1}^{K} \beta_k(\mathbf{w}) \sum_{i=1}^{2N} \alpha_i^k \kappa(\mathbf{z}, \mathbf{w}_i) \\ &- \sum_{k=1}^{K} \beta_k(\mathbf{z}) \sum_{i=1}^{2N} \alpha_i^k \kappa(\mathbf{w}, \mathbf{w}_i) + \sum_{k=1}^{K} \beta_k(\mathbf{w}) \beta_k(\mathbf{z}) \\ &= \kappa(\mathbf{z}, \mathbf{w}) - \sum_{k=1}^{K} \beta_k(\mathbf{w}) \sum_{i=1}^{2N} \alpha_n^k \kappa(\mathbf{z}, \mathbf{w}_i) \\ &= \kappa(\mathbf{z}, \mathbf{w}) - \sum_{k=1}^{K} \beta_k(\mathbf{w}) \beta_k(\mathbf{z}), & (20) \end{aligned}$$

where

$$\beta_k(\mathbf{w}) = \boldsymbol{V}_k^{\boldsymbol{\Phi}\top} \boldsymbol{\Phi}(\mathbf{w}) = \sum_{i=1}^{2N} \alpha_i^k\, \kappa(\mathbf{w}, \mathbf{w}_i)$$

as derived by Schölkopf et al. (1998). □

An advantage of this approach is that it will not rely on errors due to the approximation of the pre-image. However, it will not give us back a set of debiased embeddings. Instead, it returns a debiased metric, thus limiting the classifiers and regressors we could use. Equation Eq. (19) provides us with an $\mathcal{O}(KNd)$ approach to compute the inner product between two feature-space neutralized words.

4.5 Inner Product Correction (Equalize)

To equalize, we may naturally convert Eq. (7) to its feature-space equivalent. We define an equalizing function

$$\boldsymbol{\theta}_{\mathrm{eq}}(\mathbf{w}_i) := \boldsymbol{\nu}^{\boldsymbol{\Phi}} + Z^{\boldsymbol{\Phi}}\, \mathrm{P}_K \left(\boldsymbol{\Phi}(\mathbf{w}_i) - \boldsymbol{M}^{\boldsymbol{\Phi}}_{E_{g(i)}} \right)$$

where we define

$$\boldsymbol{\nu}^{\boldsymbol{\Phi}} := \mathrm{P}_K^{\perp}\, \boldsymbol{M}^{\boldsymbol{\Phi}}_{E_{g(i)}}$$
$$Z^{\boldsymbol{\Phi}} := \frac{\sqrt{1 - ||\nu_{\boldsymbol{\Phi}}||^2}}{||\, \mathrm{P}_K(\boldsymbol{\Phi}(\mathbf{w}) - \boldsymbol{M}^{\boldsymbol{\Phi}}_{E_{g(i)}})||}$$

where $g : [|V|] \to [L]$ maps an individual word index to its corresponding equality set index. Given vector dot products in the linear case follow the same geometric properties as inner products in the RKHS we can show that $\boldsymbol{\theta}_{\mathrm{eq}}(\mathbf{w})$ is unit norm follows directly from the proof for Proposition 1 in (Hall Maudslay et al., 2019) which can be found in Appendix A of Hall Maudslay et al. (2019).

Proposition 5. *For any two vectors in the observed space* $\mathbf{w}, \mathbf{z}$ *and their corresponding representations in feature space* $\boldsymbol{\Phi}(\mathbf{w}), \boldsymbol{\Phi}(\mathbf{z})$ *the inner product* $\langle \boldsymbol{\Phi}(\mathbf{w}) - \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{w}), \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{z}) \rangle$ *is* 0.

Proof.

$$\langle \boldsymbol{\Phi}(\mathbf{w}) - \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{w}), \mathrm{P}_K\, \boldsymbol{\Phi}(\boldsymbol{e}) \rangle$$
$$= \langle \boldsymbol{\Phi}(\mathbf{w}), \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{z}) \rangle - \langle \mathrm{P}_k\, \boldsymbol{\Phi}(\mathbf{w}), \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{z}) \rangle$$
$$= \sum_{k=1}^{K} \beta_k(\mathbf{w})\beta_k(\mathbf{z}) - \sum_{k=1}^{K} \beta_k(\mathbf{w})\beta_k(\mathbf{z}) = 0$$

□

Proposition 6. *For a given neutral word* $\mathbf{w}$ *and a word in an equality set* $\boldsymbol{e} \in \mathcal{E}$ *the inner product* $\langle \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{w}), \boldsymbol{\theta}_{\mathrm{eq}}(\boldsymbol{e}) \rangle$ *is invariant across members in the equality set* $\mathcal{E}$.

Proof.

$$\langle \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{w}), \boldsymbol{\theta}_{\mathrm{eq}}(\boldsymbol{e}) \rangle \overset{(i)}{=} \langle \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{w}), \boldsymbol{\nu}^{\boldsymbol{\Phi}} \rangle$$
$$= \frac{1}{|E|} \sum_{i \in E} \langle \boldsymbol{\Phi}_{\mathrm{ntr}}(\mathbf{w}), \mathrm{P}_K^{\perp}\, \boldsymbol{\Phi}(\mathbf{w}_i) \rangle$$
$$= \frac{1}{|E|} \sum_{i \in E} \langle \mathrm{P}_K^{\perp}\, \boldsymbol{\Phi}(\mathbf{w}), \mathrm{P}_K^{\perp}\, \boldsymbol{\Phi}(\mathbf{w}_i) \rangle$$
$$\overset{(ii)}{=} \frac{1}{|E|} \sum_{i \in E} \left(\kappa(\mathbf{w}, \mathbf{w}_i) - \sum_{k=1}^{K} \beta_k(\mathbf{w})\beta_k(\mathbf{w}_i) \right)$$

where *(i)* follows from proposition 5 and *(ii)* follows from proposition 4. □

At this point we have completely kernelized the approach in Bolukbasi et al. (2016). Note that a linear kernel reduces to the method described in Bolukbasi et al. (2016) as we would expect. We can see an initial disadvantage that equalizing via inner product correction has in comparison to Bolukbasi et al. (2016) and that is that we now require switching in between three different inner products at test time depending on whether the words are neutral or not. To overcome this in practice, we neutralize all words and do not use the equalize correction, however we present it for completeness.

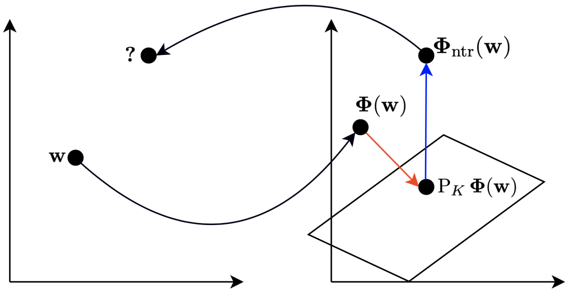

Figure 1: Pre-image problem illustration for the neutralised embeddings (null-space). The plane represents represents the bias subspace in the RKHS.

5 Computing the Pre-Image

As mentioned in the previous section, a downfall of the metric correction approach is that it does not provide us embeddings that we can use in downstream tasks: the bias-mitigated embeddings only exist in feature space. Thus, when it comes to transfer tasks such as classification we are limited to kernel methods such (i.e. support vector machines). One way to resolve this problem is by obtaining the pre-image of the corrected representations in the feature space.

Finding the pre-image is a well studied problem for kernel PCA (Kwok and Tsang, 2004). The goal is to fine the pre-image mappings $\Gamma : \mathcal{H}_K \oplus \mathcal{H}_K^{\perp} \to \mathbb{R}^d$, $\Gamma^{\perp} : \mathcal{H}_K^{\perp} \to \mathbb{R}^d$ and $\Gamma^{\top} : \mathcal{H}_K \to \mathbb{R}^d$ that compute (or approximate) the pre-images for $\boldsymbol{\Phi}(\mathbf{w}_i), \boldsymbol{\Phi}^{\perp}_{\mathrm{P}_K}(\mathbf{w}_i)$ and $\boldsymbol{\Phi}_{\mathrm{P}_K}(\mathbf{w}_i)$, respectively. In our case, with the pre-image maping, the neutralize step from Bolukbasi et al. (2016) becomes

$$\mathbf{z}_i^{\star} = \Gamma^{\perp}\left(\boldsymbol{\Phi}(\mathbf{w}_i) - \mathrm{P}_K\, \boldsymbol{\Phi}(\mathbf{w}_i)\right) \qquad (21)$$

In general, we will not have access to $\Gamma^{\perp}$ so we discuss the following approximation scheme.

Additive Decomposition Approach. Alternatively, following Kandasamy and Yu (2016), we can construct an approximation to Γ that additively decomposes over the direct sum $\oplus$. We decompose Γ additively over the direct sum $\mathcal{H}_K \oplus \mathcal{H}_K^{\perp}$. That

kernel	$\kappa(\mathbf{w}_i, \mathbf{w}_j)$
Cosine	$\frac{\mathbf{w}_i^\top \mathbf{w}_j}{\lVert\mathbf{w}_i\rVert_2 \, \lVert\mathbf{w}_j\rVert_2}$
RBF Kernel	$\exp\left(-\gamma \, \lvert\lvert\mathbf{w}_i - \mathbf{w}_j\rvert\rvert_2^2\right)$
Sigmoid Kernel	$\tanh(\gamma \, \mathbf{w}_i^\top \mathbf{w}_j + c_0)$
Polynomial Kernel	$(\gamma \, \mathbf{w}_i^\top \mathbf{w}_j + c_0)^d$
Laplace Kernel	$\exp(-\gamma \, \lvert\lvert\mathbf{w}_i - \mathbf{w}_j\rvert\rvert_1)$
Convex Combination	$\sum_{\ell=1}^{L} \alpha_\ell \, \kappa_n(\mathbf{w}_i, \mathbf{w}_j)$,

Table 1: Different kernels used throughout experiments.

is, we assume that the pre-image mappings have the following form:

$$\Gamma(\boldsymbol{\Phi}(\mathbf{w})) = \Gamma^{\perp}\left(\boldsymbol{\Phi}^{\perp}_{\mathrm{P}_K}(\mathbf{w})\right) + \Gamma^{\top}(\boldsymbol{\Phi}_{\mathrm{P}_K}(\mathbf{w}))$$

$$\Gamma^{\perp}\left(\boldsymbol{\Phi}^{\perp}_{\mathrm{P}_K}(\mathbf{w})\right) = \Gamma(\boldsymbol{\Phi}(\mathbf{w})) - \Gamma^{\top}(\boldsymbol{\Phi}_{\mathrm{P}_K}(\mathbf{w}))$$

Given that we will always know that the pre-image of $\Gamma(\boldsymbol{\Phi}(\mathbf{w}))$ exists and is $\mathbf{w}$, we can select Γ to return $\mathbf{w}$ resulting in:

$$\Gamma^{\perp}\left(\boldsymbol{\Phi}^{\perp}_{\mathrm{P}_k}(\mathbf{w})\right) = \mathbf{w} - \Gamma^{\top}(\boldsymbol{\Phi}^{\top}(\mathbf{w})) \tag{22}$$

We then learn an analytic approximation for $\Gamma^{\top}$ using the method in Bakır et al. (2004). Note that most pre-imaging methods, e.g., Mika et al. (1999) and Bakır et al. (2004), are designed to approximate a pre-image $\Gamma^{\top}$ and do not generalize to approximating the pre-image mappings Γ and $\Gamma^{\perp}$. This is because such methods explicitly optimise for pre-imaging representations in the space $\Gamma^{\top}$ using points in the training set as examples of their pre-image, for the null-space $\Gamma^{\perp}$ we have no such examples.

6 Experiments and Results

We carry out experiments across a range of benchmarks and statistical tests designed to quantify the underlying bias in word embeddings (Gonen and Goldberg, 2019). Our experiments focus on quantifying both direct and indirect bias as defined in Gonen and Goldberg (2019); Hall Maudslay et al. (2019). Furthermore we also carry out word similarity experiments using the Hill et al. (2015) benchmark in order to asses that our new debiased spaces still preserve the original properties of word embeddings (Mikolov et al., 2013).

6.1 Experimental Setup

Across all experiments we apply the neutralize metric correction step to all word embeddings, in contrast to Bolukbasi et al. (2016) where the equalize step is applied to the equality sets $\mathcal{E}$ and the neutralize step to a set of neutral words as determined in Bolukbasi et al. (2016). We show in Tab. 3 that applying the equalize step does not bring an enhancement over neutralizing all words. We varied kernel hyper-parameters using a grid search and found that they had little effect on performance, as a result we used default initialisation strategies as suggested in Schölkopf et al. (1998). Unless mentioned otherwise, all experiments use the inner product correction approach introduced in §4.4.

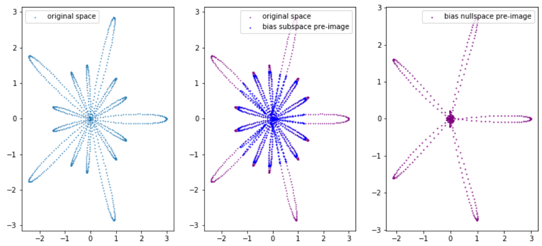

Figure 2: 2D toy example of non-linear component removal using Kernel PCA and the pre-image (neutralize step) described in §5.

6.2 Kernel Variations

The main kernels used throughout experiments are specified in Tab. 1. We also explored the following compound kernels: (i) convex combinations of the Laplace, radial basis function (RBF), cosine and sigmoid kernels; (ii) convex combinations of cosine similarity, RBF, and sigmoid kernels; (iii) convex combinations of RBF and sigmoid kernels; (iv) polynomial kernels up to 4th degree. We only report the results on the most fundamental kernels out of the explored kernels.

6.3 Direct Bias: WEAT

The Word Embeddings Association Test Caliskan et al. (WEAT; 2017) is a statistical test analogous to the implicit association test (IAT) for quantifying human biases in textual data (Greenwald and Banaji, 1995). WEAT computes the difference in relative cosine similarity between two sets of target words X and Y (e.g. careers and family) and two sets of attribute words A and B (e.g. male names and female names). Formally, this quantity is Cohen's d-measure (Cohen, 1992) also known as the effect size: The higher the measure, the more biased the embeddings. To quantify the significance of the estimated d, Caliskan et al. (2017) define

Targets	Original		PCA		KPCA (rbf)		KPCA (sig)		KPCPA (lap)

Table 3: Effect of the equalize step

the null-hypothesis that there is no difference between the two sets of target words and the sets of attribute words in terms of their relative similarities (i.e. $d = 0$). Using this null hypothesis, Caliskan et al. (2017) then carry out a one-sided hypothesis test where failure to reject the null-hypothesis ($p > 0.05$) means that the degree of bias measured by d is not significant.

We obtain WEAT scores across different kernels (Tab. 2). We observe that the differences between the linear and the non-linear kernels is small and, in most cases, the linear kernel has a smaller value for the effect size indicating a lesser degree of bias in the corrected space. Overall, we conclude that the non-linear kernels do not reduce the linear bias as measured by WEAT further than the linear kernels. We also experiment with polynomial kernels and obtain similar results, which can be found in Tab. 7 of App. A.

Embeddings	Original	PCA	KPCA(rbf)	KPCA(sig)	KPCA(lap)
Word2Vec	0.740	0.675	0.678	0.675	0.708

Word2Vec	0.974	0.702	0.716	0.715	0.720
Glove	0.978	0.757	0.754	0.753	0.914

Table 5: Classification accuracy results on male versus female terms.

6.4 Professions (Gonen and Goldberg, 2019)

We consider the professions dataset introduced by Bolukbasi et al. (2016) and apply the benchmark defined in Gonen and Goldberg (2019). We find the neighbors (100 nearest neighbors) of each word using the corrected cosine similarity and count the number of male neighbors. We then report the Pearson correlation coefficient between the number of male neighbors for each word and the original bias of that word. The original bias of a word vector $\mathbf{w}$ is given by the cosine similarity $\cos(\mathbf{w}, \boldsymbol{he} - \boldsymbol{she})$ in the original word embedding space. We can observe from the results in Tab. 4 that the non-linear kernels yield only marginally different results which in most cases seem to be slightly worse, i.e. their induced space exhibits marginally higher correlations with the original biased vector space.

6.5 Indirect Bias

Following Gonen and Goldberg (2019), we build a balanced training set of male and female words using the 5000 most biased words according to the bias in the original embeddings as described in Section 6.4, and then train an RBF-kernel support vector machine (SVM) classifier (Pedregosa et al., 2011) on a random sample of 1000 (training set) of them to predict the gender, and evaluate its generalization on the remaining 4000 (test set). We can perform classification in our corrected RKHS with any SVM kernel $\kappa_{\text{svm}}(\mathbf{\Phi}_{\text{ntr}}(\mathbf{w}), \mathbf{\Phi}_{\text{ntr}}(\mathbf{z}))$ that can be written in the forms [1] $\kappa_{\text{svm}}(\langle \mathbf{w}, \mathbf{z} \rangle)$ or $\kappa_{\text{svm}}(||\mathbf{w} - \mathbf{z}||^2)$ since we can use the kernel trick in our corrected RKHS $\langle \mathbf{\Phi}_{\text{ntr}}(\mathbf{w}), \mathbf{\Phi}_{\text{ntr}}(\mathbf{z}) \rangle = \tilde{\kappa}(\mathbf{w}, \mathbf{z})$ to compute the inputs to our SVM kernel, resulting in

$$\begin{aligned} &\kappa_{\text{svm}}(||\mathbf{w} - \mathbf{z}||^2) \\ &\quad = \kappa_{\text{svm}}(\tilde{\kappa}(\mathbf{w}, \mathbf{w}) - 2\tilde{\kappa}(\mathbf{w}, \mathbf{z}) + \tilde{\kappa}(\mathbf{z}, \mathbf{z})). \end{aligned} \tag{23}$$

It is clear that the RBF kernel is an example of a kernel that follows Eq. (23).

We can see that the bias removal induced by non-linear kernels results in a slightly higher classification accuracy (shown in Tab. 5) of gendered words for GoogleNews Word2Vec embeddings (Mikolov et al., 2013) and a slightly lower classification accuracy for GloVe embeddings (Pennington et al., 2014) (with the exception of the Laplace kernel which has a very high classification accuracy). Overall for the RBF and the sigmoid kernels there is no improvement in comparison to the linear kernel (PCA), the Laplace kernel seems to have notably worse results than the others, still being able to classify gendered words at a high accuracy of 91.4% for GloVe embeddings.

6.6 Word Similarity: SimLex-999

The quality of a word vector space is traditionally measured by how well it replicates human judgments of word similarity. We use the SimLex-999 benchmark by Hill et al. (2015) which provides a ground-truth measure of similarity produced by 500 native English speakers. Similarity scores by our method are computed using Spearman correlation between embedding and human judgments are reported. We can observe that the metric corrections only slightly change the Spearman correlation results on SimLex-999 (Tab. 6) from the original embedding space. We can thus conclude that the embedding quality is mostly preserved.

Embeddings	Original	PCA	KPCA(rbf)	KPCA(sig)	KPCA(lap)
Word2Vec	0.121	0.119	0.118	0.118	0.118
Glove	0.302	0.298	0.298	0.298	0.305

Table 6: Correlation on SimLex-999 using GoogleNews Word2Vec and GloVe embeddings. The significance level is $\alpha = 0.05$ with $p < 0.001$.

7 Conclusion

We offer a non-linear extension to the method presented in Bolukbasi et al. (2016) by connecting its bias space construction to PCA and subsequently applying kernel PCA. We contend our extension is natural in the sense that it reduces to the method of Bolukbasi et al. (2016) in the special case when we employ a linear kernel and in the non-linear case it preserves all the desired linear properties in the feature space. This allows us to provide equivalent constructions of the neutralize and equalize steps presented.

We compare the linear bias mitigation technique to our new kernelized non-linear version across a suite of tasks and datasets. We observe that our non-linear extensions of Bolukbasi et al. (2016) show no notable performance differences across a set of benchmarks designed to quantify gender bias in word embeddings. Furthermore, the results in Tab. 7(App. A) show that gradually increasing the degree of non-linearity has again no significant change in performance for the WEAT (Caliskan et al., 2017) benchmark. Thus, we provide empirical evidence for the linear subspace hypothesis; our results suggest representing gender bias as a linear subspace is a suitable assumption. We would like to highlight that our results are specific to our proposed kernelized extensions and does not imply that all non-linear variants of (Bolukbasi et al., 2016) will yield similar results. There may very well exist a non-linear technique that works better, but we were unable to find one in this work.

A Polynomial Kernel Results

For experimental completeness, we provide direct bias experiments on WEAT using a range of polynomial kernels. The results are displayed in Tab. 7. The results for the polynomial kernels suggest the same conclusions we arrived at in the main text, i.e. a linear kernel is generally enough.

Lifelong Language Knowledge Distillation

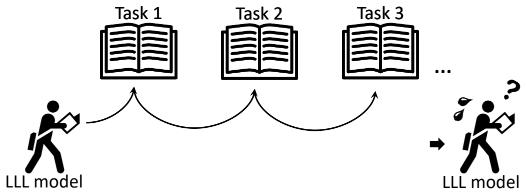
Abstract

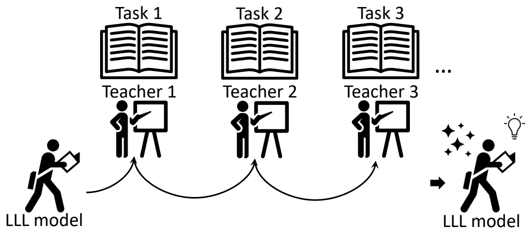
It is challenging to perform lifelong language learning (LLL) on a stream of different tasks without any performance degradation comparing to the multi-task counterparts. To address this issue, we present Lifelong Language Knowledge Distillation (L2KD), a simple but efficient method that can be easily applied to existing LLL architectures in order to mitigate the degradation. Specifically, when the LLL model is trained on a new task, we assign a teacher model to first learn the new task, and pass the knowledge to the LLL model via knowledge distillation. Therefore, the LLL model can better adapt to the new task while keeping the previously learned knowledge. Experiments show that the proposed L2KD consistently improves previous state-of-the-art models, and the degradation comparing to multi-task models in LLL tasks is well mitigated for both sequence generation and text classification tasks.[1]

1 Introduction

Training a single model to learn a stream of different tasks sequentially usually faces the catastrophic forgetting problem (McCloskey and Cohen, 1989): after learning a new task, the model forgets how to handle the samples from previous tasks. Lifelong learning manages to accumulate the knowledge and retain the performance of previously learned tasks. It is important especially for real-world natural language processing (NLP) applications, because these applications need to interact with many users from different domains everyday, and the language usage also evolves from time to time. Hence, various NLP tasks have been studied for lifelong learning in the previous work, including sentiment analysis (Chen et al., 2015; Xia et al., 2017), conversational agents (Lee, 2017), word and sentence representation learning (Xu et al., 2018; Liu et al., 2019), text classification, and question answering (d'Autume et al., 2019).



(a) Normal Lifelong Language Learning.



(b) Lifelong Language Knowledge Distillation.

Figure 1: The difference between LLL and L2KD.

In recent, LAMOL (Sun et al., 2020) improved the performance of LLL by a general framework: 1) it followed the idea about considering many NLP tasks as question answering (QA) (McCann et al., 2018) and adapted all tasks into the language modeling (LM) form. In the unified framework, it can perform LLL on many NLP tasks by generating answers based on the contexts and the questions using a single language model, and 2) it outperformed the previous methods by a considerable margin and is only 2%-3% worse than the multi-tasking upper bound, which jointly learns all tasks in a mixed dataset.

This paper further improves LLL by introducing Lifelong Language Knowledge Distillation (L2KD), which can be flexibly applied upon the LAMOL architecture or other LLL methods for sequence generation learning.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2914–2924,
November 16–20, 2020.

The motivation of our work mainly comes from how to efficiently compress the knowledge under a lifelong language learning framework. If the model can learn a new task in an efficient way, the previously learned knowledge may not be affected and thus the problem of catastrophic forgetting can be mitigated.

Inspired by knowledge distillation (Bucila et al., 2006; Hinton et al., 2015; Kim and Rush, 2016), in which a student (smaller) model is trained to imitate the behavior of a teacher (larger) model in order to reach the performance closer to the teacher model, the LLL model in L2KD can be seen as a weak learner that needs to compress knowledge from different tasks into a compact single model. Thus LLL can benefit from the similar procedure of knowledge distillation, although the model size is equal to its teacher model. The similar idea about distilling knowledge from equal-size models has also been studied in born-again neural network (Furlanello et al., 2018), multitask learning (Clark et al., 2019) and lifelong computer vision learning (Hou et al., 2018), but never been explored in lifelong language learning research.

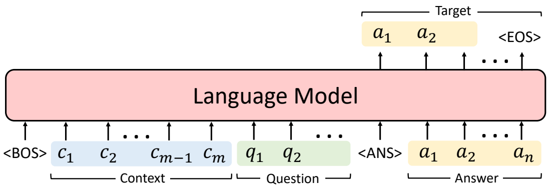
In L2KD, we train a new teacher model when facing a new task, and the LLL model imitates the behavior of its teacher at each training stage, as illustrated in Figure 1. This method only needs a little extra time to train a disposable teacher model for each new task, and the teacher model can be discarded when learning the next task; therefore, there is no extra memory or model capacity required for the target LLL model, making the proposed model more memory-efficient for real-world usage.

2 Proposed Approach

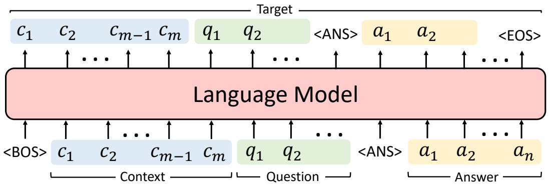
Before describing how L2KD works, in Section 2.1 we briefly introduce the architecture of LAMOL (Sun et al., 2020), which L2KD is built upon. Then we introduce different knowledge distillation strategies in Section 2.2, and how to apply them to L2KD in Section 2.3.

2.1 LAMOL: Language Modeling for Lifelong Language Learning

In the setting of LAMOL, all samples in language datasets have three parts: *context*, *question* and *answer*. We can simply concatenate these three parts into a single sentence and train the model to generate the answer based on the context and question prior to it, as illustrated in Figure 2a.



(a) Learning to solve target tasks (QA).



(b) Learning to generate pseudo-data (LM).

Figure 2: Illustration of learning QA and LM in LAMOL.

Besides generating answers for the given questions, the model simultaneously learns to model the whole training sample, as illustrated in Figure 2b. By doing that, when training on the next task, the model can generate training samples for the previous tasks and train on both data from the new task and the generated pseudo-data for the prior tasks. Thus the model would forget less when adapting to the new tasks.

LAMOL can outperform previous regularization-based (Schwarz et al., 2018; Aljundi et al., 2018) or memory-based (Lopez-Paz et al., 2017; Yogatama et al., 2019) LLL methods by a large margin. While most of previous methods usually get results slightly better than the finetuning baseline (doing nothing to prevent forgetting), LAMOL already get significant results that are very close to the multitasking upper bound and only 2%-3% worse (Sun et al., 2020) than it. Thus, in this paper, we focus on how to apply L2KD based on LAMOL.

2.2 Knowledge Distillation

Language Modeling The training objective for normal language modeling is to minimize the negative log-likelihood (NLL) in predicting the next word (hard target):

$$\mathcal{L}_{\text{NLL}}(x;\theta) = \sum_{t=t_0}^{T} -\log P(x_t \mid x_{<t};\theta),$$

where x_t denotes the t-th word in the sentence, $x_{<t}$ denotes all words prior to x_t, and θ is the parameters of the language model.

In knowledge distillation, instead, we minimize the prediction errors between student and teacher models. The target unit for considering the errors can be done in the word level or the sequence level.

Word-Level (Word-KD) We minimize the cross-entropy between the output distributions from student and teacher models when predicting the next word:

$$\mathcal{L}_{\text{Word-KD}}(x; \theta_S; \theta_T) = \sum_{t=t_0}^{T} \sum_{k=1}^{|\mathcal{V}|} -P(\mathcal{V}_k \,|x_{<t}; \theta_T) \log P(\mathcal{V}_k \mid x_{<t}; \theta_S),$$

where the input $x_{<t}$ is from the ground truth sequence. $\mathcal{V}$ denotes the vocabulary set and $\mathcal{V}_k$ is the k-th word in $\mathcal{V}$. θ_S and θ_T are parameters of the student model and teacher model respectively.

Sequence-Level (Seq-KD) Similar to Kim and Rush (2016), we minimize the negative log-likelihood directly on the greedy decode or beam search output sequence $\hat{x}$ from the teacher model as the hard target, just like normal language modeling:

$$\mathcal{L}_{\text{Seq-KD}}(\hat{x}; \theta_S) = \sum_{t=t_0}^{T} -\log P(\hat{x}_t \mid \hat{x}_{<t}; \theta_S).$$

Seq-KD is usually applied for improving weak non-autoregressive translation (NAT) models (Zhou et al., 2020) by reducing the multi-modality problem in machine translation datasets (Gu et al., 2018).

Soft Sequence-Level (Seq-KD$_{\text{soft}}$) We further investigate whether the soft target plus the teacher decoded sequence can help the model more, so we conduct Seq-KD$_{\text{soft}}$, in which we perform Word-KD on the greedy decode or beam search outputs from the teacher model. The only difference between Seq-KD$_{\text{soft}}$ and Word-KD is that the input $x_{<t}$ of Word-KD is now replaced with $\hat{x}_{<t}$, the output sequence from the teacher model:

$$\mathcal{L}_{\text{Seq-KD}_{\text{soft}}}(\hat{x}; \theta_S; \theta_T) = \sum_{t=t_0}^{T} \sum_{k=1}^{|\mathcal{V}|} -P(\mathcal{V}_k \,|\hat{x}_{<t}; \theta_T) \log P(\mathcal{V}_k \mid \hat{x}_{<t}; \theta_S).$$

Note that no matter what kind of loss we use in knowledge distillation, the teacher model is always fixed. Hence, the optimization process of finding parameters θ_S^* of the LLL model can be written as follows:

$$\theta_S^* = \arg\min_{\theta_S} \mathcal{L}_{\text{KD}}.$$

Algorithm 1 L2KD: Lifelong Language Knowledge Distillation

```
Input: current task dataset $D_m$, teacher model with parameters $\theta_T$, knowledge distillation loss function $\mathcal{L}_{\text{KD}}$, pseudo-data sample rate $\gamma$.
Output: LLL model parameters $\theta_S$.
Optimize teacher model on $D_m$ to get parameters $\theta_T$.
Sample $\gamma \cdot |D_m|$ pseudo-data from $\theta_S$ to form $D_{\text{prev}}$.
for all training samples$\{X_i^m\}_{i=1}^n \in D_m$ do
    for $i = 1$ to $n$ do
        update $\theta_S$ to minimize $\mathcal{L}_{\text{KD}}(X_i^m; \theta_S; \theta_T)$
    end for
    Sample $n' = \gamma n$ samples $\{X_j^{\text{prev}}\}_{j=1}^{n'}$ from $D_{\text{prev}}$
    for $j = 1$ to $n'$ do
        update $\theta_S$ to minimize $\mathcal{L}_{\text{NLL}}(X_j^{\text{prev}}; \theta_S)$
    end for
end for
```

2.3 L2KD: Lifelong Language Knowledge Distillation

Knowledge distillation can be applied to minimizing both LM and QA loss in LAMOL. Assuming that there is a stream of tasks with datasets $\{D_1, D_2, ...\}$, our LLL model has learned from D_1 to D_{m-1} and now was adapted to D_m. First we train a teacher model on D_m by minimizing the negative log-likelihood loss both for LM and QA in LAMOL and obtain the model parameters θ_T^m.

Now our LLL model (with parameters θ_S) can be trained on D_m by knowledge distillation from the teacher model. Given a training sample $X_i^m = \{x_1, x_2, ..., x_T\} \in D_m$ (including the context, question and answer), we minimize

$$\begin{aligned} \mathcal{L}_{\text{new}}(X_i^m;\theta_S;\theta_T^m) &= \mathcal{L}_{\text{new}}^{\text{QA}} + \mathcal{L}_{\text{new}}^{\text{LM}} \\ \mathcal{L}_{\text{new}}^{\text{QA}} &= \mathcal{L}_{\text{Word-KD}}(X_i^m; \theta_S; \theta_T^m; t_0 = a_1) \\ \mathcal{L}_{\text{new}}^{\text{LM}} &= \mathcal{L}_{\text{Word-KD}}(X_i^m; \theta_S; \theta_T^m; t_0 = 0), \end{aligned}$$

where a_1 denotes the start position of the answer. Here we take Word-KD for illustration, but we can also replace the text in the answer part with the teacher-generated answers, so as to conduct Seq-KD$_{\text{soft}}$ or Seq-KD.

Besides training on samples from D_m, the LLL model also generates pseudo-data D_{prev} for previous tasks. For samples in D_{prev}, however, we cannot perform knowledge distillation here, because in our setting the teacher models of previous tasks will be discarded after adapting to the next task. Therefore, given the generated data $X_i^{\text{prev}} \in D_{\text{prev}}$, we only minimize NLL loss here:

$$\begin{aligned}\mathcal{L}_{\text{prev}}(X_i^{\text{prev}};\theta_S) &= \mathcal{L}_{\text{prev}}^{\text{QA}} + \mathcal{L}_{\text{prev}}^{\text{LM}}\\ \mathcal{L}_{\text{prev}}^{\text{QA}} &= \mathcal{L}_{\text{NLL}}(X_i^{\text{prev}};\theta_S;t_0=a_1)\\ \mathcal{L}_{\text{prev}}^{\text{LM}} &= \mathcal{L}_{\text{NLL}}(X_i^{\text{prev}};\theta_S;t_0=0).\end{aligned}$$

Finally we jointly optimize two loss and obtain the parameters θ_S^* for the LLL model:

$$\theta_S^* = \arg\min_{\theta_S}\Big(\sum_{X_i^m \in D_m} \mathcal{L}_{\text{new}} + \sum_{X_i^{\text{prev}} \in D_{\text{prev}}} \mathcal{L}_{\text{prev}}\Big)$$

The training procedure is detailed in Algorithm 1.

3 Experimental Setup

To evaluate the proposed method, we conduct a set of experiments detailed below.

3.1 Model and Training Details

We build our proposed approach based on the implementation of LAMOL[2] to make the results comparable. We use the same pre-trained small GPT-2 (Radford et al., 2019) for all single-task teacher, multitask and LLL models, and train the GPT-2 nine epochs for each dataset. We use the best setting in LAMOL: using task-specific tokens as begin-of-sentence tokens, and the pseudo-data sample rate is 0.2. During inference, we use greedy decoding to generate sequence. More details can be found in Appendix A.

3.2 Datasets

To evaluate the capability of L2KD on diverse sequence generation tasks, we pick the following three tasks from DecaNLP (McCann et al., 2018):

- **WikiSQL** (Zhong et al., 2017): a dataset for developing natural language interfaces for relational databases, in which the model needs to generate structured queries from natural language.
- **CNN/DailyMail** (See et al., 2017): a text summarization dataset collected from online news articles.
- **MultiWOZ** (Budzianowski et al., 2018): a multi-domain wizard-of-oz dataset for task-oriented dialogue modeling, in which the model needs to generate the semantic state sequences based on the given partial dialogues.

Note that we skip machine translation dataset (IWSLT) in DecaNLP here, because GPT-2 does not contain a multilingual vocabulary. These three datasets focus on *different tasks*, representing the most general case in LLL.

Dataset	**Metric**	**# Train**	**# Test**
Sequence Generation for Different Tasks			
WikiSQL	lfEM	6,525	15,878
CNN/DailyMail	ROUGE	6,604	2,250
MultiWOZ	dsEM	2,536	1,646
Sequence Generation for Different Domains			
E2E NLG	ROUGE	6,000	2,000
RNNLG (rest.)		6,228	1,039
RNNLG (hotel)		6,446	1,075
RNNLG (tv)		8,442	1,407
RNNLG (laptop)		7,944	2,649
Text Classification for Different Tasks			
AGNews	Exact Match	115,000	7,600
Yelp		115,000	7,600
Amazon		115,000	7,600
DBPedia		115,000	7,600
Yahoo		115,000	7,600

Table 1: Dataset sizes and the evaluation metrics.

However, in real-world scenarios, it is more common that the LLL model is trained to solve the same task, but in *different domains* that change through time. Thus we conduct the experiments on the following natural language generation (NLG) datasets with five different domains:

- **E2E NLG** (Novikova et al., 2017): a dataset for training end-to-end natural language generation systems in the *restaurant domain*.
- **RNNLG** (Wen et al., 2015): a dataset for NLG in spoken dialogue system application domains. It contains four domains: *San Francisco restaurant search* (rest.), *San Francisco hotel search* (hotel), *Television sale/search* (tv), *Laptop sale/search* (laptop). We use the full dataset for the first three domains and the reduced set for the laptop domain for keeping them balance.

Although our method is mainly designed for sequence generation tasks, we also use five different text classification datasets to evaluate whether the proposed method also benefits text classification tasks. We use the random sampled subsets released by Sun et al. (2020), each of which has 115,000 training and 7,600 testing instances.

- **DBPedia**: Articles on Wikipedia, including 14 classes for their categories.
- **Yahoo**: QA pairs on the Yahoo! platform, including 10 classes for their categories.

Due to the limitation of computational resources and the data imbalance, we reduce the big datasets (WikiSQL, CNN/DailyMail, E2E NLG, RNNLG (laptop)) to a smaller size by random sampling. The reduced data size and other data statistics in the experiments are detailed in Table 1.

4 Results and Discussion

We discuss the results for three settings: 1) different sequence generation tasks, 2) same tasks in different domains, and 3) different text classification tasks in order to validate the effectiveness of the proposed approach.

4.1 Different Sequence Generation Tasks

In the experiments, we perform lifelong learning on the WikiSQL (SQL), CNN/DailyMail (CNN) and MultiWOZ (WOZ) datasets with six different permutation orders, and test the performance at the end of the training streams. The detailed results are shown in Table 2, where the average scores indicate the average of three tasks for overall comparison. Note that the evaluation metrics of these three tasks are all ranging from 0 to 100. The overall results of six orders compared with single-task methods and multitask upper bounds are shown in Table 3.

In Table 2, the first baseline is **(a) Finetune**, in which we directly train three tasks one after another without preventing catastrophic forgetting. It is obvious that the Finetune model would forget one or two tasks learned before the final one. **(b) LAMOL** is the current state-of-the-art approach that significantly reduce the catastrophic forgetting for comparison. In the rows (c)-(e), it is shown that applying L2KD upon LAMOL significantly outperforms LAMOL for almost all cases, no matter which knowledge distillation strategy is used: **(c) Word-KD**, **(d) Seq-KD$_{\text{soft}}$**, **(e) Seq-KD**. We also observe that among three different knowledge distillation strategies, **(e) Seq-KD** consistently improves the most on the CNN/DailyMail dataset, which is probably caused by the noisy nature of this summarization dataset. Therefore, sequence-level knowledge distillation produces a easy-to-learn answer comparing to the original complex answer, so that the LLL model can learn better on it.

On the other hand, for other two tasks (MultiWOZ, WikiSQL), **(c) Word-KD** and **(d) Seq-KD$_{\text{soft}}$** improve more for most cases. Because the target sequences of these two tasks are relatively simple, where MultiWOZ focuses on producing semantic state sequences from dialogues, and WikiSQL produces the structured query sequences from the given natural language sentences, the target sequences usually contain the patterns less complex than natural language. So, in these

	Non-Lifelong Methods	**WOZ**	**CNN**	**SQL**	**Avg**
(1)	Single QA	84.8	25.5	63.1	**57.8**

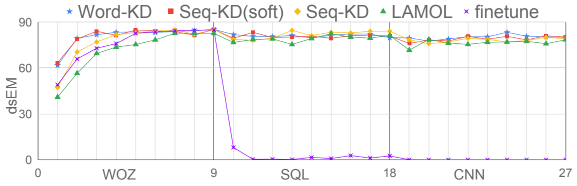
(e)	(b) + Seq-KD	80.9	**28.0**	60.6	56.5
	STD of Lifelong Methods				
(f)	Finetune	43.3	9.6	32.9	28.6
(g)	LAMOL	6.0	**0.7**	3.2	3.3
(h)	(g) + Word-KD	2.7	**0.7**	**2.8**	2.1
(i)	(g) + $\text{Seq-KD}_{\text{soft}}$	**1.8**	1.0	3.0	**1.9**
(j)	(g) + Seq-KD	3.4	0.9	3.1	2.5

Table 3: Averaged results at the final task of the lifelong learning procedures over six orders, comparing to single task and multitask upper bound. The bold numbers are the best in the group.

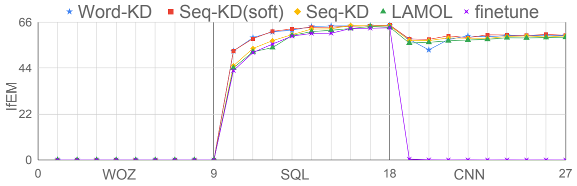
cases, the soft targets may bring more advantages than teacher decoding sequences for the LLL model to learn from.

In Table 3, the overall performance (averaged over six permutation orders) is compared with single-task methods and multi-task upper bounds. There are two training methods here: optimizing QA loss only (in rows (1)(3)(5)) or optimizing both QA and LM loss (in rows (2)(4)(6)), as illustrated in Figure 2. For multi-task models, we find that the same training steps (9 epochs on the mixed set) may not lead the models to converge (in row (3)(4)), so we additionally train multi-task models for three times longer (27 epochs on the mixed set) in rows (5)(6).

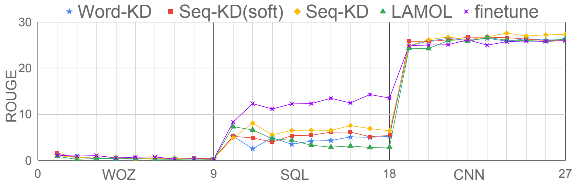
The second part of Table 3 shows the average performance in lifelong learning of six permutation orders. It is clear that L2KD significantly improves the average score from 54.9 in **(b) LAMOL** to 57.1 in **(d)** $\textbf{Seq-KD}_{\textbf{soft}}$. The performance of $\text{Seq-KD}_{\text{soft}}$ is only 0.7% worse than the multi-task upper bound, 57.8 in **(6)** $\textbf{Multi}_{\textbf{long}}$ **QA+LM**. Hence, the results show that L2KD can bridge the gap between lifelong learning and multi-task learning.



(a) Learning curve of WOZ.



(b) Learning curve of SQL.



(c) Learning curve of CNN.

Figure 3: The learning curves of different LLL methods in the order of WOZ → SQL → CNN.

Note that we can also apply similar distillation strategy on multitask learning to obtain a stronger upper bound, which might be a more fair comparison. Thus, we add Seq-KD to **(6)** $\textbf{Multi}_{\textbf{long}}$ **QA+LM** by making the model learn from five single-task teachers and the results are shown in row (7). We observe that the improvement on multitask learning is only 0.2%, while L2KD can improve LAMOL by 2.2%. This result indicates that the benefits brought by knowledge distillation may be saturated for multitask learning, but is not saturated for L2KD. The gap between lifelong learning and multi-task learning is still reduced even if we apply similar strategy on both of the models.

The third part of Table 3 shows the standard deviations of six permutation orders. As mentioned in Sun et al. (2020), if an algorithm has smaller standard deviation over different training orders, it means that the algorithm is more robust and not susceptible to learning orders. It can be found that the average standard deviation of LAMOL is reduced from 3.3 to 1.9 with $\textbf{Seq-KD}_{\textbf{soft}}$. Therefore, both soft target training and teacher decode sequence can stabilize the training process of LLL and make it more order-agnostic.

To further analyze the performance change when

Method	e2e	rest	hotel	tv	laptop	Avg
Single$_{\text{(QA)}}$	48.8	64.0	65.4	70.8	73.0	64.4
Single$_{\text{(QA+LM)}}$	48.8	64.2	65.5	71.0	72.8	64.5
Multi$_{\text{(QA)}}$	49.2	**65.6**	**67.2**	72.7	**74.8**	**65.9**
Multi$_{\text{(QA+LM)}}$	**49.5**	65.2	66.7	**73.4**	74.6	**65.9**
Left-to-right (e2e → rest → hotel → tv → laptop)						
LAMOL	**50.1**	58.7	61.5	73.7	72.0	63.2
+ Word-KD	44.9	60.0	62.8	**76.7**	73.3	63.5
+ Seq-KD$_{\text{soft}}$	46.9	58.4	63.2	76.4	73.6	63.7
+ Seq-KD	48.6	**62.2**	**66.4**	74.7	**75.5**	**65.5**
Right-to-left (laptop → tv → hotel → rest → e2e)						
LAMOL	**49.8**	65.0	65.9	75.8	77.0	66.7
+ Word-KD	49.3	**67.6**	**68.7**	76.8	77.7	**68.0**
+ Seq-KD$_{\text{soft}}$	49.4	66.6	68.0	76.7	77.4	67.6
+ Seq-KD	49.7	65.9	66.7	**77.4**	**78.8**	67.7
