4.2 Minimal Neuron Set

Now that we have established correctness of the rankings, we apply the algorithm incrementally to select minimal neurons for each linguistic task that obtain a similar accuracy (we use a threshold $\delta = 0.5$) as using the entire network (all the features). Identifying a minimal set of top neurons enables us to highlight: i) parts of the learned network where different linguistic phenomena are predominantly captured, ii) how localized or distributed information is with respect to different properties.

Table 2 summarizes the results. Firstly we show that in all the tasks, selecting a subset of top N% neurons and retraining the classifier can obtain a similar (sometimes even better) accuracy as using all the neurons (Acc_a) for classification as static features. For lexical tasks such as **POS** or **SEM** tagging, a very small number of neurons (roughly 400 i.e 4% of features in BERT and XLNet) was found to be sufficient for achieving an accuracy (Acc_t) similar to oracle (Acc_a). More complex syntactic tasks such as **Chunking** and **CCG** tagging required larger sets of neurons (up to 2365 – one third of the network in T-ELMo) to accomplish the same. It is interesting to see that all the models, irrespective of their size, required a comparable number of selected neurons, in most of the cases. On the **POS** and **SEM** tagging tasks, besides T-ELMo all other models use roughly the same number of neurons. T-ELMo required more neurons in **SEM** tagging to achieve the task. This

---

[8] See Appendix A.2 for hyperparameters selected for each task.

[9] The choice of 20% is arbitrary. We did not experiment much with it as this was merely to select best lambdas and to demonstrate the efficacy of rankings.

could imply that knowledge of lexical semantics in T-ELMo is distributed in more neurons. In an overall trend, ELMo generally needed fewer neurons while T-ELMo required more neurons compared to the other models to achieve oracle performance. Both these models are much smaller than BERT and XLNet. We did not observe any correlation, comparing results with the size of the models.

Control Tasks: We use *Selectivity* to further demonstrate that our probes (trained using the entire representation and selected neurons) do not memorize from word types but learned the underlying linguistic task. Recall that an effective probe is recommended to achieve high linguistic task accuracy and low control task accuracy. The results (see Table 2) show that selectivity with top neurons (Sel_t) is much higher than selectivity with all neurons Sel_a. It is evident that using all the neurons may contribute to memorization whereas higher selectivity with selected neurons indicates less memorization and efficacy of our neuron selection. We achieve high selectivity when selecting 400 neurons as in the case of POS and SEM. The chunking and CCG tasks require a lot more neurons with CCG requiring up to 33% of the network. Here, the low selectivity indicates that while the information about CCG is distributed into several neurons, a set of random neurons may also be able to achieve a decent performance.

Discussion: Identifying neurons that are salient to a task has various potential applications such as task-specific model compression, by removing the irrelevant neurons with respect to the task or task-specific fine-tuning based on selected neurons. It is however tricky how to model this, for example one complexity is that zeroing out non-salient neurons in the lower layers directly affects any salient neurons in the subsequent layers. A rather direct application to our work is efficient feature-based transfer learning, which has shown to be a viable alternative to the fine-tuning approach (Peters et al., 2019). Feature-based approach uses contextualized embeddings learned from pre-trained models as static feature vectors in the down-stream classification task. Classifiers with large contextualized vectors are not only cumbersome to train, but also inefficient during inference. They have also been shown to be sub-optimal when supervised data is insufficient (Hameed, 2018). BERT-large, for example, is trained with 19,200 (25 layers × 768 dimensions) features. Reducing the feature set to a smaller number can lead to faster training of the classifier and efficient inference. Earlier (in Table 2) we obtained minimal set of neurons with a very tight threshold of $\delta = 0.5$. By allowing a loser threshold, say $\delta = 2$, we can reduce the set of minimal neurons to improve the efficiency even more. See Table 3 for results. For more on this, we refer interested readers to look at Dalvi et al. (2020), where we explored this more formally, expanding our study to the sentence-labeling GLUE tasks (Wang et al., 2018).

5 Analysis

5.1 Layer-wise Distribution

Previous work on analyzing deep neural networks analyzed how individual layers contribute towards a downstream task (Liu et al., 2019; Kim et al., 2020; Belinkov et al., 2020). Here we observe how the neurons, selected from the entire network, spread across different layers of the model. Such an analysis gives an alternative view of which layers contribute predominantly towards different tasks. Figure 1 presents the results. In most cases, lexical tasks such as learning morphology (POS tagging) and word semantics (SEM tagging) are dominantly captured by the neurons at lower layers, whereas the more complicated task of modeling syntax (CCG supertagging) is taken care of at the final layer. An exception to this overall pattern is the BERT model. Top neurons in BERT spread across all the layers, unlike other models where top neurons (for a particular task) are contributed by fewer layers. This reflects that every layer in BERT possesses neurons that specialize in learning particular language properties, while other models have designated layers that specialize in learning those language properties. Different from other models, neurons in the embedding layer show minimum contribution in XLNet consistently across the tasks. Let us analyze the results with respect to each linguistic task.

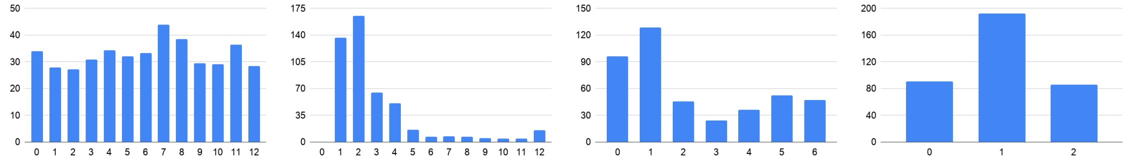
POS Tagging: Every layer in BERT and ELMo contributed towards the top neurons, while the distribution is dominated by lower layers in XLNet and T-ELMo, with an exception of XLNet not choosing any neurons from the embedding layer.

SEM Tagging: Similar to POS, all layers of BERT contributed to the list of top neurons. However, the middle layers showed the most contribution (see layer numbers 4–7 in Figure 1e). This is in line with Liu et al. (2019) who found middle and higher middle layers to give optimal results for the semantic tagging task. On XLNet, T-ELMo and ELMo, the first layer after the embedding layer got the largest share of the top neurons of SEM. This trend is consistent across other tasks, i.e., the core linguistic information is learned earlier in the network with an exception of BERT, which distributes information across the network.

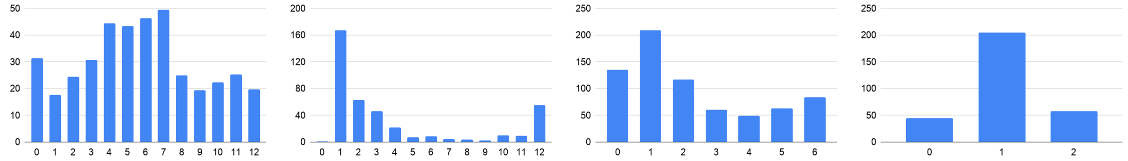
Chunking Tagging: The overall pattern remained similar in the task of chunking. Notice however, a shift in pattern – the contribution from lower layers decreased compared to previous tasks, in the case of BERT. For example, in the SEM task, top neurons were dominantly contributed from lower and middle layers, in chunking middle and higher layers contributed most. This could be attributed to the fact that chunking is a more complex syntactic task and is learned at relatively higher layers.

CCG Supertagging: Compared to chunking, CCG supertagging is a richer syntactic tagging task, almost equivalent to parsing (Bangalore and Joshi, 1999). The complexity of the task is evident in our results as there is a clear shift in the distribution of top neurons moving from middle to higher layers. The only exception again is the BERT model where this information is well spread across the network, but still dominantly preserved in the final layers.

Discussion: Our results are in line with and reinforce the layer-wise analysis presented in Liu et al. (2019). However, unlike their work and all other work on layer-wise probing analysis, which trains a classifier on each layer individually to compare the results, our method trains a single classifier on all layers concatenated to analyze which layers contribute most to the task based on the most relevant selected features. This makes the playing field even



(a) POS – BERT (b) POS – XLNet (c) POS – T-ELMo (d) POS – ELMo



(e) SEM – BERT (f) SEM – XLNet (g) SEM – T-ELMo (h) SEM – ELMo

(m) CCG – BERT (n) CCG – XLNet (o) CCG – T-ELMo (p) CCG – ELMo

Figure 1: How top neurons spread across different layers for each task? X-axis = Layer number, Y-axis = Number of neurons selected from that layer

and results in a sharper analysis. For example, Liu et al. (2019) showed layer 1 in Transformer-ELMo to give the best result on the task of predicting POS tags; however, layers 2 and 3 almost give similar accuracy (see Appendix D1 in their paper). Based on these results, one cannot confidently claim that the task of POS is predominantly captured at layer 1. However, our method clearly shows this result (see Figure 1c).

5.2 Localization versus Distributedness

Next we study how localized or distributed different properties are within a linguistic task (for example nouns or verbs in POS tagging, location in semantic tagging), and across different architectures. Remember that the ranking algorithm extracts neurons for each label t (e.g. LOC:location or EVE:event categories in semantic tagging) in task T, sorted based on absolute weights. The final rankings are obtained by selecting from each label using the neuron ranking algorithm as described in Section 2. This allows us to analyze how localized or distributed a property is, based on the number of neurons that are selected for each label in the task.

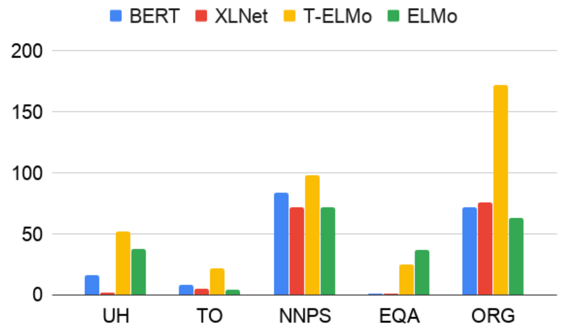

Figure 2: Number of neurons per label: Some properties (e.g., interjections) are localized in fewer neurons, while others (e.g., nouns) are more distributed. Y-axis = number of neurons per label

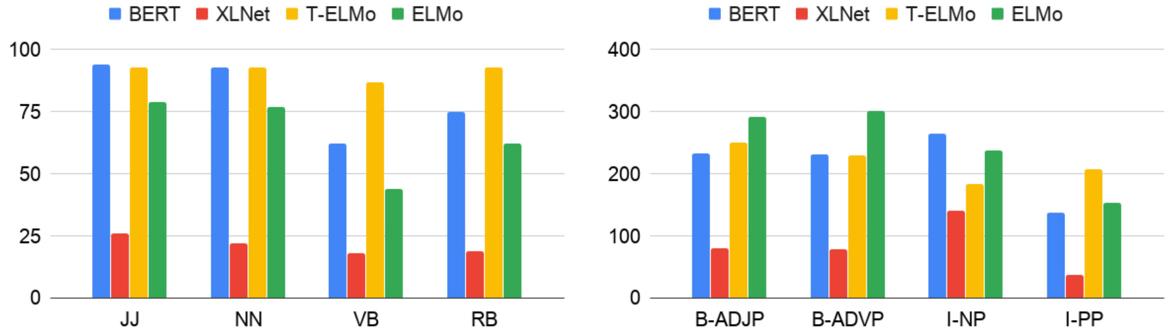
Property-wise: We found that while many properties are distributed, i.e., a large group of neurons is used to predict a label, some properties such as functional or unambiguous words that do not require contextual information are learned using fewer neurons. For example, **UH** (interjections) or the **TO** particle required fewer neurons across architectures compared to **NNPS** (proper noun; plural) in the task of POS tagging (Figure 2). Similarly



(a) POS Tagging

(b) Chunking Tagging

Figure 3: Top neurons in XLNet are more localized towards individual properties compared to other architectures

EQA (equating property, e.g., ***as** tall as you*) is handled with fewer neurons compared to **ORG** (organization property). We observed a similar behavior in the task of chunking, with **I-PRT** (particles inside of a chunk) requiring fewer neurons across different architectures. On the contrary, **B-VP** (beginning of verb phrase) required plenty many.

Layer-wise: Previously we analyzed each linguistic task in totality. We now study whether individual properties (e.g., adjectives) are localized or well distributed across layers in different architectures. We observed interesting cross architectural similarities, for example the neurons that predict the foreign words (**FW**) property were predominantly localized in final layers (BERT: 13, XLNET: 11, T-ELMo: 7, ELMo:3) of the network in all the understudied architectures. In comparison, the neurons that capture common class words such as adjectives (**JJ**) and locations (**LOC**) are localized in lower layers (BERT: 0, XLNET: 1, T-ELMo: 0, ELMo:1). In some cases, we did find variance, for example personal pronouns (**PRP**) in POS tagging and event class (**EXC**) in semantic tagging were handled at different layers across different architectures. See Appendix A.7 for all labels.

Architecture-wise: We found that top neurons in XLNet are more localized towards individual properties compared to other architectures where top neurons are shared across multiple properties. We demonstrate this in Figure 3. Notice how the number of neurons for different labels[10] is much smaller in the case of XLNet, although roughly the same number of total neurons (400 for POS tagging and 960 for chunking on average; see Table 2) were required by all pre-trained models to carry out a task. This means that in XLNet neurons are exclusive towards specific properties compared to other architectures where neurons are shared between multiple properties. Such a trait in XLNet can be potentially helpful in predicting the behavior of the system as it is easier to isolate neurons that are designated toward specific phenomena.

6 Related Work

Rise of neural network has seen a subsequent rise of interpretability of these models. Researchers have explored visualization methods to analyze learned representations (Karpathy et al., 2015; Kádár et al., 2017), attention heads (Clark et al., 2019; Vig, 2019) of language compositionality (Li et al., 2016) etc. While such visualizations illuminate the inner workings of the network, they are often qualitative in nature and somewhat anecdotal.

A more commonly used approach tries to provide a quantitative analysis by correlating parts of the neural network with linguistic properties, for example by training a classifier to predict a feature of interest (Adi et al., 2016; Conneau et al., 2018). Please refer to Belinkov and Glass (2019) for a comprehensive survey of work done in this direction. Liu et al. (2019) used probing classifiers for investigating the contextualized representations learned from a variety of neural language models on numerous word level linguistic tasks. A similar analysis was carried by Tenney et al. (2019) on a variety of sub-sentence linguistic tasks. We extend this line of work to carry out a more fine-grained neuron level analysis of neural language models.

Our work is most similar to Dalvi et al. (2019) who conducted neuron analysis of representations learned from sequence-to-sequence machine trans-

---

[10] Figure 3 only displays selected properties, but the pattern holds across all properties. See Appendix A.7.

lation models. Our work is different from them in that i) we carry out analysis on a wide range of architectures which are deeper and more complicated than RNN-based models and illuminate interesting insights, ii) we automated the grid-search criteria to select the regularization parameters, compared to manual selection of lambdas, which is cumbersome and error-prone. In contemporaneous work, Suau et al. (2020) used *max-pooling* to identify relevant neurons (aka *Expert units*) in pre-trained models, with respect to a specific concept (for example word-sense).

A pitfall to the approach of probing classifiers is whether the probe is faithfully reflecting the property of the representation or just learned the task? Hewitt and Liang (2019) defined control tasks to analyze the role of training data and lexical memorization in probing experiments. Voita and Titov (2020) proposed an alternative that measures *Minimal Description Length* of labels given representations. It would be interesting to see how a probe's complexity in their work (code length) compares with the number of selected neurons according to our method. The results are consistent at least in the ELMo POS example, where layer 1 was shown to have the shortest code length in their work. In our case, most top neurons are selected from layer 1 (see Figure 1d for example). Pimentel et al. (2020) discussed the complexity of the probes and argued for using highest performing probes for tighter estimates. However, complex probes are difficult to analyze. Linear models are preferable due to their explainability; especially in our work, as we use the learned weights as a proxy to get a measure of the importance of each neuron. We used linear classifiers with control tasks as described in Hewitt and Liang (2019). Although we mainly used probing accuracy to drive the neuron selection in this work, and *Selectivity* only to demonstrate that our results reflect the property learned by representations and not probe's capacity to learn – an interesting idea would be to use selectivity itself to drive the investigation. However, it is not trivial how to optimize for selectivity as it cannot be controlled/tuned directly – for example, removing some neurons may decrease accuracy but may not change selectivity. We leave this exploration for future work.

Probing classifiers require supervision for the linguistic tasks of interest with annotations, limiting their applicability. Bau et al. (2019) used unsupervised approach to identify salient neurons in neural machine translation and manipulated translation output by controlling these neurons. Recently, Wu et al. (2020) measured similarity of internal representations and attention across prominent contextualized representations (from BERT, ELMo, etc.). They found that different architectures have similar representations, but different individual neurons.

7 Conclusion

We analyzed individual neurons across a variety of neural language models using linguistic correlation analysis on the task of predicting core linguistic properties (morphology, syntax and semantics). Our results reinforce previous findings and also illuminate further insights: i) while the information in neural language models is massively distributed, it is possible to extract a small number of features to carry out a downstream NLP task, ii) the number of extracted features varies based on the complexity of the task, iii) the neurons that learn word morphology and lexical semantics are predominantly found in the lower layers of the network, whereas the ones that learn syntax are at the higher layers, with the exception of BERT, where neurons were spread across the entire network, iv) closed-class words (for example interjections) are handled using fewer neurons compared to polysemous words (such as nouns and adjectives), v) features in XLNet are more localized towards individual properties as opposed to other architectures where neurons are distributed across many properties. A direct application of our analysis is efficient feature-based transfer learning from large-scale neural language models: i) identifying that most relevant features for a task are contained in layer x reduces the forward-pass to that layer, ii) reducing the feature set decreases the time to train a classifier and also its inference. We refer interested readers to see our work presented in Dalvi et al. (2020) for more details.

A Appendices

A.1 Data and Representations

We used standard splits for training, development and test data for the 4 linguistic tasks (POS, SEM, Chunking and CCG super tagging) that we used to carry out our analysis on. The splits to preprocess the data are available through git repository[11] released with Liu et al. (2019). See Table 4 for statistics. We obtained the understudied pre-trained models from the authors of the paper, through personal communication.

Task	Train	Dev	Test	Tags
POS	36557	1802	1963	44
SEM	36928	5301	10600	73
Chunking	8881	1843	2011	22
CCG	39101	1908	2404	1272

Table 4: Data statistics (number of sentences) on training, development and test sets using in the experiments and the number of tags to be predicted

A.2 Hyperparameters

We use elastic-net based regularization to control the trade-off between selecting focused individual neurons versus group of neurons while maintaining the original accuracy of the classifier without any regularization. We do a grid search on L_1 and L_2 ranging from values $0 \ldots 1e^{-7}$. See Table 5 for the optimal values for each task across different architectures.

A.3 Infrastructure and Run Time

Our experiments were run on NVidia GeForce GTX TITAN X GPU card. Grid search for finding optimal lambdas is expensive when optimal number of neurons for the task are unknown. Running grid search would take $\mathcal{O}(MN^2)$ where $M = 100$ (if we try increasing number of neurons in each step by 1%) and $N = 0, 0.1, \ldots 1e^{-7}$. We fix the $M = 20\%$ to find the best regularization parameters first reducing the grid search time to $\mathcal{O}(N^2)$ and find the optimal number of neurons in a subsequent step with $\mathcal{O}(M)$. The overall running time of our algorithm therefore is $\mathcal{O}(M + N^2)$. This varies a lot in terms of wall-clock computation, based on number of examples in the training data, number of tags to be predicted in the downstream task. Including a full forward pass over the pre-trained model to extract the contextualized vector, and running the grid search algorithm to find the best hyperparameters and minimal set of neurons took on average 12 hours ranging from 3 hours (for POS with ELMo experiment) to 18 hours (for CCG with BERT).

A.4 Ablation Study

We reported accuracy numbers on ablating top, random and bottom neurons in the trained classifier, on blind test-set in the main body. In Table 6, we report results on development tests.

A.5 Minimal Neuron Set

We reported minimal number of neurons required to obtain oracle accuracy in the main body, along with the results on *Selectivity*. In Table 7, we report results on development tests.

A.6 Localized versus Distributed Labels

In Section 5.1 we only showed number of features learned for selected labels in each task. Figure 4 shows results for all the tags across different tasks. The results show that some tags are localized and captured by a focused set of neurons while others are distributed and learned within a large set of neurons.

A.7 XLNet versus Others

Notice in Figure 4 that neurons required by each label in XLNet (red bars) are strikingly small compared to other architectures specifically T-ELMo (yellow bars). This is interesting given the fact that total number of neurons required by some of the tasks are very similar. For example task of POS tagging required 400 neurons for BERT and XLNet, 320 for ELMo and 430 in T-ELMo. This means that neurons in XLNet are mutually exclusive towards the properties whereas in other architectures neurons are shared across multiple properties. Due to large tag set (1272 tags) in CCG super tagging, it is not possible to include it among figures.

A.8 Layer-wise Distribution

In Section 5.2 we showed labels are captured dominantly at which layers for a few labels. In Figure 5c we show all labels and which layers they are predominantly captured at, across different architectures.

Dissecting Span Identification Tasks with Performance Prediction

Abstract

Span identification (in short, span ID) tasks such as chunking, NER, or code-switching detection, ask models to identify and classify relevant spans in a text. Despite being a staple of NLP, and sharing a common structure, there is little insight on how these tasks' properties influence their difficulty, and thus little guidance on what model families work well on span ID tasks, and why. We analyze span ID tasks via *performance prediction*, estimating how well neural architectures do on different tasks.

Our contributions are: (a) we identify key properties of span ID tasks that can inform performance prediction; (b) we carry out a large-scale experiment on English data, building a model to predict performance for unseen span ID tasks that can support architecture choices; (c), we investigate the parameters of the meta model, yielding new insights on how model and task properties interact to affect span ID performance. We find, e.g., that span frequency is especially important for LSTMs, and that CRFs help when spans are infrequent and boundaries non-distinctive.

1 Introduction

Span identification is a family of analysis tasks that make up a substantial portion of applied NLP. Span identification (or short, span ID) tasks have in common that they identify and classify contiguous spans of tokens within a running text. Examples are named entity recognition (Nadeau and Sekine, 2007), chunking (Tjong Kim Sang and Buchholz, 2000), entity extraction (Etzioni et al., 2005), quotation detection (Pareti, 2016), keyphrase detection (Augenstein et al., 2017), or code switching (Pratapa et al., 2018). In terms of complexity, span ID tasks form a middle ground between simpler analysis tasks that predict labels for single linguistic units (such as lemmatization (Porter, 1980) or sentiment polarity classification (Liu, 2012)) and more complex analysis tasks such as relation extraction, which combines span ID with relation identification (Zelenko et al., 2002; Adel et al., 2018).

Due to the rapid development of deep learning, an abundance of model architectures is available for the implementation of span ID tasks. These include isolated token classification models (Berger et al., 1996; Chieu and Ng, 2003), probabilistic models such as hidden Markov models (Rabiner, 1989), maximum entropy Markov models (McCallum et al., 2000), and conditional random fields (Lafferty et al., 2001), recurrent neural networks such as LSTMs (Hochreiter and Schmidhuber, 1997), and transformers such as BERT (Devlin et al., 2019).

Though we have some understanding what each of these models can and cannot learn, there is, to our knowledge, little work on systematically understanding how different span ID tasks compare: are there model architectures that work well generally? Can we identify properties of span ID tasks that can help us select suitable model architectures on a task-by-task basis? Answers to these questions could narrow the scope of architecture search for these tasks, and could help with comparisons between existing methods and more recent developments.

In this work, we address these questions by applying *meta-learning* to span identification (Vilalta and Drissi, 2002; Vanschoren, 2018). Meta-learning means "systematically observing how different machine learning approaches perform [...] to learn new tasks much faster" (Vanschoren, 2018), with examples such as architecture search (Elsken et al., 2019) and hyperparameter optimization (Bergstra and Bengio, 2012). Our specific approach is to apply *performance prediction* for span ID tasks, using both task properties and model architectures as features, in order to obtain a better understanding of the differences among span ID tasks.

Concretely, we collect a set of English span ID

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4881–4895,
November 16–20, 2020.

tasks, quantify key properties of the tasks (such as how distinct the spans are from their context, and how clearly their boundaries are marked) and formulate hypotheses linking properties to performance (Section 2). Next, we describe relevant neural model architectures for span ID (Section 3). We then train a linear regressor as a meta-model to predict span ID performance based on model features and task metrics in an unseen-task setting (Section 4). We find the best of these architectures perform at or close to the state of the art, and their success can be relatively well predicted by the meta-model (Section 5). Finally, we carry out a detailed analysis of the regression model's parameters (Section 6), gaining insight into the relationship between span ID tasks and different neural model architectures. For example, we establish that spans that are not very distinct from their context are consistently difficult to identify, but that CRFs are specifically helpful for this class of span ID tasks.

2 Datasets, Span Types, and Hypotheses

We work with five widely used English span ID datasets. All of them have non-overlapping spans from a closed set of span types. In the following, we discuss (properties of) span types, assuming that each span type maps onto one span ID task.

2.1 Datasets

Quotation Detection: PARC and RIQUA. The Penn Attribution Relation Corpus (PARC) version 3.0 (Pareti, 2016) and the Rich Quotation Attribution Corpus (RIQUA, Papay and Padó, 2020) are two datasets for quotation detection: models must identify direct and indirect quotation spans in text, which can be useful for social network construction (Elson et al., 2010) and coreference resolution (Almeida et al., 2014). The corpora cover articles from the Penn Treebank (PARC) and 19th century English novels (RIQUA), respectively. Within each text, quotations are identified, along with each quotation's speaker (or source), and its cue (an introducing word, usually a verb like "said"). We model detection of quotations as well as cues. As speaker and addressee identification are relation extraction tasks, we exclude these span types.

Chunking: CoNLL'00. Chunking (shallow parsing) is an important preprocessing step in a number of NLP applications. We use the corpus from the 2000 CoNLL shared task on chunking (CoNLL'00) (Tjong Kim Sang and Buchholz, 2000). Like PARC, this corpus consists of a subset of the PTB. This dataset is labeled with non-overlapping chunks of eleven phrase types. In our study, we consider the seven phrase types with >100 instances in the training partition: 'ADJP', 'ADVP', 'NP', 'PP', 'PRT', 'SBAR', and 'VP'.

Task	Dataset	freq	len	SD	BD
Quotation	PARC	16480	7.89	1.34	1.43
Quotation	RIQUA	4026	9.84	1.46	1.57
Chunking	CoNLL'00	37168	1.55	1.26	0.64
NER	ChemDNer	6110	1.62	3.08	0.96
NER	OntoNotes	16861	1.63	3.36	1.00

Table 1: Span type metrics (values averaged over all span types in each corpus, weighted by span type frequency, computed on training sets). SD = span distinctiveness, BD = boundary distinctiveness. Values for individual span types can be found in Table 7 in the Appendix.

NER: OntoNotes and ChemDNer. For recognition and classification of proper names, we use the NER layer of OntoNotes Corpus v5.0 (Weischedel et al., 2013) and Biocreative's ChemDNer corpus v1.0 (Krallinger et al., 2015). OntoNotes, a general language NER corpus, is our largest dataset, with over 2.2 million tokens. The NER layer comprises 18 span types, both typical entity types such as 'Person' and 'Organization' as well as numerical value types such as 'Date' and 'Quantity'. We use all span types. ChemDNer is a NER corpus specific to chemical and drug names, comprising titles and abstracts from 10000 PubMed articles. It labels names of chemicals and drugs and assigns them to eight classes, corresponding to chemical name nomenclatures. We use seven span types: 'Abbreviation', 'Family', 'Formula', 'Identifier', 'Systematic', 'Trivial', and 'Multiple'. We exclude the class 'No class' as infrequent (<100 instances).

2.2 Span Type Properties and Hypotheses

While quotation detection, chunking, and named entity recognition are all span ID tasks, they vary quite widely in their properties. As mentioned in the introduction, we know of little work on quantifying the similarities and differences of span types, and thus, span ID tasks.

We now present four metrics which we propose to capture the relevant characteristics of span types, and make concrete our hypotheses regarding their effect on model performance. Table 1 reports frequency-weighted averages for each metric on each dataset. See Table 7 in the Appendix for all span-type-specific values.

Frequency is the number of spans for a span type in the dataset's training corpus. It is well established that the performance of a machine learning model benefits from higher amounts of training data (Halevy et al., 2009). Thus, we expect this property to be positively correlated with performance. However, some architectural choices, such as the use of transfer learning, are purported to reduce the data requirements of machine learning models (Pan and Yang, 2009), so we expect a smaller correlation for architectures which incorporate transfer learning.

Span length is the geometric mean of spans' lengths, in tokens. Scheible et al. (2016) note that traditional CRF models perform poorly at the identification of long spans due to the strict Markov assumption they make (Lafferty et al., 2001). Thus, we expect architectures which rely on such assumptions and which have no way to model long distance dependencies to perform poorly on span types with a high average span length, while LSTMs or transformers should do better on long spans (Khandelwal et al., 2018; Vaswani et al., 2017).

Span distinctiveness is a measure of how distinctive the text that comprises spans is compared to the overall text of the corpus. Formally, we define it as the KL divergence $D_{\text{KL}}(P_{\text{span}}||P)$, where P is the unigram word distribution of the corpus, and P_{span} is the unigram distribution of tokens within a span. A high span distinctiveness indicates that different words are used inside spans compared to the rest of the text, while a low span distinctiveness indicates that the word distribution is similar inside and outside of spans.

We expect this property to be positively correlated with model performance. Furthermore, we hypothesize that span types with a high span distinctiveness should be able to rely more heavily on local features, as each token carries strong information about span membership, while low span distinctiveness calls for sequence information. Consequently, we expect that architectures incorporating sequence models such as CRFs, LSTMs, and transformers should perform better at low-distinctive span types.

Boundary distinctiveness is a measure of how distinctive the starts and ends of spans are. We formalize this in terms of a KL-divergence as well, namely as $D_{\text{KL}}(P_{\text{boundary}}||P)$ between the unigram word distribution (P) and the distribution of boundary tokens (P_{boundary}), where boundary tokens are those which occur immediately before the start of a span, or immediately after the end of a span. A high boundary distinctiveness indicates that the start and end points of spans are easy to spot, while low distinctiveness indicates smooth transitions.

We expect boundary distinctiveness to be positively correlated with model performance, based on studies that obtained improvements from specifically modeling the transition between span and context (Todorovic et al., 2008; Scheible et al., 2016). As sequence information is required to utilize boundary information, high boundary distinctiveness should improve performance more for LSTMs, CRFs, or transformers.

Task Profiles. As Table 1 shows, the metrics we propose appear to capture the task structure of the datasets well: quotation corpora have long spans with low span distinctiveness (anything can be said) but high boundary distinctiveness (punctuation, cues). Chunking has notably low boundary distinctiveness, due to the syntactic nature of the span types, and NER spans show high distinctiveness (semantic classes) but are short and have somewhat indistinct boundaries as well.

3 Model Architectures

For span identification, we use the BIO framework (Ramshaw and Marcus, 1999), framing span identification as a sequence labeling task. As each span type has its own B and I labels, and there is one O label, a dataset with n span types leads to a $2n+1$-label classification problem for each token.

We investigate a set of sequence labeling models, ranging from baselines to state-of-the-art architectures. We group our models by common components, and build complex models through combination of simpler models. Except for the models using BERT, all architectures assume one 300-dimensional GloVe embedding (Pennington et al., 2014) per token as input.

Baseline. As a baseline model, we use a simple token-level classifier. This architecture labels each token using a softmax classifier without access to sequence information (neither at the label level nor at the feature level).

CRF. This model uses a linear-chain conditional random field (CRF) to predict token label sequences (Lafferty et al., 2001). It can access neighboring labels in the sequence of predictions.

LSTM and LSTM+CRF. These architectures incorporate Bi-directional LSTMs (biLSTMs) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997) as components. The simplest architecture, LSTM, passes the inputs through a 2-layer biLSTM network, and then predicts token labels using a softmax layer. The LSTM+CRF architecture combines the biLSTM network with a CRF layer, training all weights simultaneously. These models can learn to combine sequential input and labeling information.

BERT and BERT+CRF. These architectures include the pre-trained BERT language model (Devlin et al., 2019) as a component. The simplest architecture in this category, BERT, comprises a pre-trained BERT encoder and a softmax output layer, which is trained while the BERT encoder is fine-tuned. BERT+CRF combines a BERT encoder with a linear-chain CRF output layer, which directly uses BERT's output embeddings as inputs. In this architecture, the CRF layer is first trained to convergence while BERT's weights are held constant, and then both models are jointly fine-tuned to convergence. As BERT uses WordPiece tokenization (Wu et al., 2016), the input must be re-tokenized for BERT architectures.

BERT+LSTM+CRF. This architecture combines all components previously mentioned. It first uses a pre-trained BERT encoder to generate a sequence of contextualized embeddings. These embeddings are projected to 300 dimensions using a linear layer, yielding a sequence of vectors, which are then used as input for a LSTM+CRF network. As with BERT+CRF, we first train the non-BERT parameters to convergence while holding BERT's parameters fixed, and subsequently fine-tune all parameters jointly.

Handcrafted Features. Some studies have shown marked increases in performance by adding hand-crafted features (e.g. Shimaoka et al., 2017). We develop such features for our tasks and treat these to be an additional architecture component. For architectures with this component, a bag of features is extracted for each token (the exact features used for each dataset are enumerated in Table 5 in the Appendix). For each feature, we learn a 300-dimensional feature embedding which is averaged with the GloVe or BERT embedding to obtain a token embedding. Handcrafted features can be used with the Baseline, LSTM, LSTM+CRF, and BERT+LSTM+CRF architectures. BERT and BERT+CRF cannot utilize manual features, as they have no way of accepting token embeddings as input.

4 Meta-learning Model

Recall that our meta-learning model is a model for predicting the performance of the model architectures from Section 3 when applied to span identification tasks from Section 2. We model this task of performance prediction as linear regression, a well established framework for the statistical analysis of language data (Baayen, 2008). The predictors are task properties, model architecture properties, and their interactions, and the dependent variable is (scaled) F_1 score.

While a linear model is not powerful enough to capture the full range of interactions, its weights are immediately interpretable, it can be trained on limited amounts of data, and it does not overfit easily (see Section 5.1). All three properties make it a reasonable choice for meta-learning.

Predictors and Interactions. As predictors for our performance prediction task, we use the span type properties described above, and a number of binary model properties. For the span type properties [freq] and [span length], we use the logarithms of these values as predictors. The two distinctiveness properties are already logarithms, and so we used them as-is. For model properties, we used four binary predicates: The presence of handcrafted features, of a CRF output layer, of a bi-LSTM layer, and of a BERT layer.

In addition to main effects of properties of models and corpora on performance (does a CRF layer help?), we are also interested in interactions of these properties (does a CRF layer help in particular for longer spans?). As such interactions are not captured automatically in a linear regression model, we encode them as predictors. We include interactions between span type and model properties, as well as among model properties.

All predictors (including interactions) are standardized so as to have a mean of zero and standard deviation of one.

Scaling the Predicted Performance Instead of directly predicting the F_1 score, we instead make our predictions in a logarithmic space, which eases the linearity requirements of linear regression. We cannot directly use the logit function to transform F_1 scores into $F' = \text{logit}\left(\frac{F_1}{100}\right)$ since the presence of zeros in our F_1 scores makes this process ill-defined. Instead, we opted for a "padded" logit transformation $F' = \text{logit}\left((1-\alpha)\cdot\frac{F_1}{100}+\alpha\cdot\frac{100-F_1}{100}\right)$ with a hyperparameter $\alpha \in [0, 0.5)$. This rescales the argument of the logit function from $[0, 1]$ to the smaller interval $[\alpha, 1-\alpha]$, avoiding the zero problem of a bare logit. Through cross-validation (cf. Section 5.1), we set $\alpha = 0.2$. We use the inverse of this transformation to scale the output of our prediction as an F_1 score, clamping the result to $[0, 100]$.

5 Experiment

5.1 Experimental Procedure

Our meta learning experiment comprises two steps: Span ID model training, and meta model training.

Step 1: Span ID model training. We train and subsequently evaluate each model architecture on each dataset five times, using different random initializations. With 12 model architectures and 5 datasets under consideration, this procedure yields $12 \times 5 \times 5 = 300$ individual experiments.

For each dataset, we use the established train/test partition. Since RiQuA does not come with such a partition, we use cross-validation, partitioning the dataset by its six authors and holding out one author per cross-validation step.

We use early stopping for regularization, stopping training once (micro-averaged) performance on a validation set reaches its maximum. To prevent overfitting, all models utilize feature dropout – during training, each feature in a token's bag of input features is dropped with a probability of 50%. At evaluation time, all features are used.

Step 2: Meta learning model training. This step involves training our performance prediction model on the F_1 scores obtained from the first step. For each architecture-span-type pair of the 12 model architectures and 36 span types, we already obtained 5 F_1 scores. This yields a total of $12 \times 36 \times 5 = 2160$ input-output pairs to train our performance prediction model.

We investigate both L^1 and L^2 regularization in an elastic net setting (Zou and Hastie, 2005) but consistently find best cross-validation performance with no regularization whatsoever. Thus, we use ordinary least squares regression.

To ensure that our performance predictions generalize, we use a cross-validation setup when generating model predictions. To generate performance predictions for a particular span type, we train our meta-model on data from all other span types, holding out the span type for which we want a prediction. We repeat this for all 36 span types, holding out a different span type each time, in order to collect performance predictions for each span type.

5.2 Span Identification Results

Step 1 yields 5 evaluation F_1 scores for each architecture–span-type pair. This section summarizes the main findings. Detailed average scores for each pair are reported in Table 8 in the Appendix.

Table 2 lists the micro-averaged performance of each model architecture on each dataset. Unsurprisingly, BERT+Feat+LSTM+CRF, the model with the most components, performs best on three of the five datasets. This provides strong evidence that this architecture can perform well across many tasks. However, note that architecture's dominance is somewhat overstated by only looking at average dataset results. Our analysis permits us to look more closely at results for individual span types, where we find that BERT+Feat+LSTM+CRF performs best on 16 of the 36 total span types, BERT+CRF on 7 span types, Feat+LSTM+CRF on 7 span types, and BERT+LSTM+CRF on 6 span types. Thus, 'bespoke' modeling of span types can evidently improve results.

Even though our architectures are task-agnostic, and not tuned to particular tasks or datasets, our best architectures still perform quite competitively. For instance, on CoNLL'00, our BERT+Feat+LSTM+CRF model comes within 0.12 F_1 points of the best published model's F_1 score of 97.62 (Akbik et al., 2018). For PARC, existing literature does not report micro-averaged F_1 scores, but instead focuses only on F_1 scores for content span detection. In this case, we find that our BERT+Feat+LSTM+CRF model beats the existing state of the art on this span type, achieving an F_1 score of 78.1, compared to the score of 75 reported in Scheible et al. (2016).

5.3 Meta-learning Results

The result of Step 2 is our performance prediction model. Table 3 shows both mean absolute error (MAE), which is directly interpretable as the mean

	BL	Feat BL	CRF	Feat CRF	LSTM	Feat LSTM	LSTM CRF	Feat LSTM CRF	BERT	BERT CRF	BERT LSTM CRF	BERT Feat LSTM CRF
PARC	34.8	31.4	46.6	57.9	64.8	76.9	76.0	81.8	78.7	81.4	82.4	**82.5**
RiQuA	21.7	14.5	19.7	14.4	67.5	76.7	79.6	81.7	79.8	**82.5**	82.1	82.3
CoNLL'00	55.9	60.0	79.7	87.1	87.7	92.3	90.0	93.5	96.3	96.5	96.6	**96.6**
OntoNotes	39.0	27.4	61.2	67.7	58.8	65.1	76.4	84.7	85.9	86.8	86.5	**87.5**
ChemDNer	49.8	19.6	56.9	58.5	57.0	45.7	71.2	75.1	83.3	84.7	**84.9**	84.8

Table 2: Average architecture results on datasets. BL=Baseline, Feat=Hand-crafted features. For each dataset, we micro-average performance over all span types, and average these micro-averages across five trials. For comparability with existing work, we include all span types in these micro-averages, even those which we exclude from our performance prediction. Full performance results for each span type can be found in Table 8.

	MAE	r^2
Full model	11.38	0.73
No interactions	14.00	0.61
Only architecture predictors	18.88	0.37
Only task predictors	20.87	0.22
Empty model	23.78	N/A

Table 3: Evaluation of performance prediction models

difference between predicted and actual F_1 score for each data point, and r^2, which provides the amount of variance accounted for by the model. The full performance prediction model, including both span type and model architecture features, accounts for 73% of the variance, with an MAE of about 11. We see this as an acceptable model fit. To validate the usefulness of the predictor groups and interaction terms, we carry out ablation experiments wherein these are excluded, including a model with no interaction terms, a model with only span type-predictors, a model with only architecture predictors, and an empty model, which only predicts the average of all F_1 scores. The reduced models do better than the empty model,[1] but show marked increases in MAE and corresponding drops in r^2 compared to the full model. While the usefulness of the architecture predictors is expected, this also constitutes strong evidence for the usefulness of the span type predictors we have proposed in Section 2.

Figure 1 shows a scatterplot of predicted and actual F_1 scores. Our meta learning model generally predicts high performances better than low performances. The largest cluster of errors occurs for experiments with an actual F_1 score of exactly zero, arguably an uninteresting case. Thus, we believe that the overall MAE underestimates rather than overestimates the quality of the performance prediction for practical purposes.

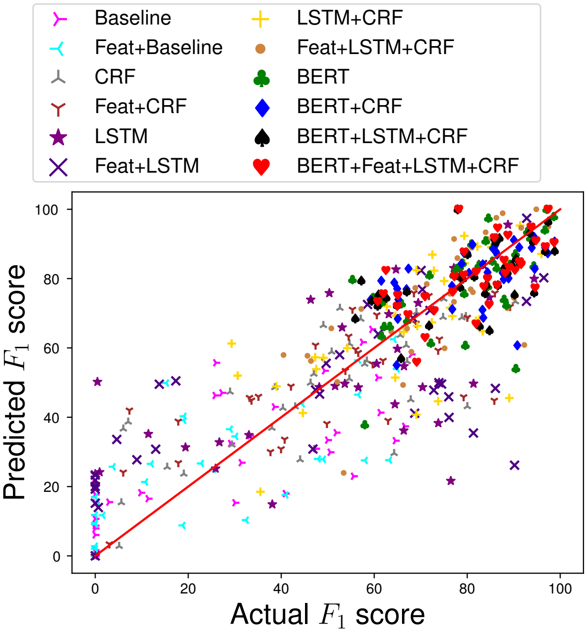

Figure 1: Scatterplot of actual vs. predicted F_1 scores for all 36 span types × 12 model architectures

6 Analysis

We now investigate the linear regression coefficients of our performance prediction model to assess our hypotheses from Section 2. To obtain a single model to analyze, we retrain our regression model on all data points, with no cross-validation.

Table 4 shows the resulting coefficients. Using Bonferroni correction at $\alpha = 0.05$, we consider a coefficient significant if p<0.002. Non-significant

---

[1] For the empty model, r^2 is undefined because the variance of the predictions is zero.

coefficients are shown in parentheses. Due to the scaling of F_1 scores performed as described in section 4, the coefficients cannot be directly interpreted in terms of linear change on the F_1 scale. However, as we standardized all predictors, we can compare coefficients with one another. Coefficients with a greater magnitude have larger effects on F_1 score, with positive values indicating an increase, and negative values a decrease.

When analyzing these coefficients, one must consider main effects and interactions together. E.g., the main effect coefficient for LSTMs is negative, which seems to imply that adding an LSTM will hurt performance. However, the LSTM × [freq] and LSTM × [boundary distinctness] interactions are both strongly positive, so LSTMs should help on frequent span types with high boundary distinctiveness. Our main observations are the following:

Frequency helps, length hurts. The main effects of our span type predictors show mostly an expected pattern. Frequency has a strong positive effect (frequent span types are easier to learn), while length has an even stronger negative effect (long span types are difficult). More distinct boundaries help performance as well. More surprising is the negative sign of the span distinctiveness predictor, which would mean that more distinct spans are more difficult to recognize. However, this might be due to the negative correlation between span distinctiveness and frequency ($r = -0.46$ in standardized predictors) – less frequent spans are, by virtue of their rarity, more distinctive.

BERT is good for performance, especially with few examples. The presence of a BERT component is the highest-impact positive predictor for model performance, with a positive coefficient of 1. This finding is not entirely surprising, given the recent popularity of BERT-based models for span identification problems (Li et al., 2020; Hu et al., 2019). Furthermore, the strong negative value of the (BERT × [freq]) predictor shows that BERT's benefits are strongest when there are few training examples, validating our hypothesis about transfer learning. BERT is also robust: largely independent of span or boundary distinctiveness effects.

LSTMs require a lot of data. While the main effect of LSTMs is negative, this effect is again modulated by the high positive coefficient of the (LSTM × [freq]) interaction. This means that their performance is highly dependent on the amount of training data. Also, LSTMs lead to improvements for long span types and those with distinct boundaries – properties that LSTMs arguably can pick up well but that other models struggle with.

Model predictors

	BERT	−0.05
CRF ×	LSTM	(−0.05)
	BERT	−0.24
LSTM ×	BERT	−0.17

Table 4: Regression coefficients from performance prediction model. Coefficients not statistically significant at $p < 0.002$ (as per Bonferroni correction) in parentheses.

CRFs help. After BERT, the presence of a CRF shows the second-most positive main effect on model performance. Given the strong correlation between adjacent tags in a BIO label sequence, it makes sense that a model capable of enforcing correlations in its output sequence would perform well. CRFs can also exploit span distinctiveness well, presumably by the same mechanism. Surprisingly, CRFs show reduced effectiveness for highly frequent spans with distinct boundaries. We believe that this pattern is best considered as a relative statement: for frequent, well-separated span types CRFs gain less than other model types.

Handcrafted features do not matter much. We find neither a significant main effect of handcrafted features, nor any significant interactions with span type predictors. Interactions with model predictors are significant, but rather small. While a detailed analysis of architecture-wise F_1-scores does show that some architectures, such as pure CRFs, do seem to benefit more from hand-crafted features (see Table 8 in the Appendix), this effect diminishes considerably when model components are mixed.

Combining model components shows diminishing returns. All interactions between LSTM, CRF, and BERT are negative. This demonstrates an overlap in these components' utility. Thus, a simple "maximal" combination does not always perform best, as Table 2 confirms.

7 Related Work

Meta-learning and performance prediction are umbrella terms which comprise a variety of approaches and formalisms in the literature. We focus on the literature most relevant to our work and discuss the relationship.

Performance Prediction for Trained Models. In NLP, a number of studies investigate predicting the performance of models that have been trained previously on novel input. An example is Chen (2009) which develops a general method to predict the performance of a family of language models. Similar ideas have been applied more recently to machine translation (Bojar et al., 2017), and automatic speech recognition (Elloumi et al., 2018), among others. While these approaches share our goal of performance prediction, they predict performance for the same task and model on new data, while we generalize across tasks and architectures. Thus, these approaches are better suited to estimating confidence at prediction time, while our meta-learning approach can predict a model's performance before it is trained.

AutoML. Automated machine learning, or AutoML, aims at automating various aspects of machine learning model creation, including hyperparameter selection, architecture search, and feature engineering (Yao et al., 2018; He et al., 2019) While the task of performance prediction does not directly fall within this research area, a model for predicting performance is directly applicable to architecture search. Within AutoML, the auto-sklearn system (Feurer et al., 2015) takes an approach rather similar to ours, wherein they identify meta-features of datasets, and select appropriate model architectures based on those meta-features. However, auto-sklearn does not predict absolute performance as we do, but instead simply selects good candidate architectures via a k-nearest-neighbors approach in meta-feature space. Other related approaches in AutoML use Bayesian optimization, including the combined model selection and hyperparameter optimization of Auto-WEKA (Thornton et al., 2013) and the neural architecture search of Auto-keras (Jin et al., 2019).

Model Interpretability. A number of works have investigated how to analyze and explain the decisions made by machine learning models. LIME (Mishra et al., 2017) and Anchors (Ribeiro et al., 2018) are examples of systems for explaining a model's decisions for specific training instances. Other works seek to explain and summarize how models perform across an entire dataset. This can be achieved e.g. through comparison of architecture performances, as in Nguyen and Guo (2007), or through meta-modeling of trained models, as was done in Weiss et al. (2018). Our present work falls into this category, including both a comparison of architectures across datasets and a meta-learning task of model performance.

Meta-learning for One- and Few-shot Learning. A recent trend is the application of meta-learning to models for one- or few-shot learning. In this setting, a meta-learning approach is used to train models on many distinct tasks, such that they can subsequently be rapidly fine-tuned to a particular task (Finn et al., 2017; Santoro et al., 2016). While such approaches use the same meta-learning framework as we do, their task and methodology are substantially different. They focus on learning with very few training examples, while we focus on optimizing performance with normally sized corpora. Additionally, these models selectively train preselected model architectures, while we are concerned with comparisons between architectures.

Model and Corpus Comparisons in Survey Papers. In a broad sense, our goal of comparison between existing corpora and modeling approaches is shared with many existing survey papers. Surveys include quantitative comparisons of existing systems' performances on common tasks, producing a results matrix very similar to ours (Li et al., 2020; Yadav and Bethard, 2018; Bostan and Klinger, 2018, i.a.). However, most of these surveys limit themselves to collecting results across models and datasets without performing a detailed quantitative analysis of these results to identify recurring patterns, as we do with our performance prediction approach.

8 Conclusion

In this work, we considered the class of span identification tasks. This class contains a number of widely used NLP tasks, but no comprehensive analysis beyond the level of individual tasks is available. We took a meta-learning perspective, predicting the performance of various architectures on various span ID tasks in an unseen-task setup. Using a number of 'key metrics' that we developed to characterize the span ID tasks, a simple linear regression model was able to do so at a reasonable accuracy. Notably, even though BERT-based architectures expectedly perform very well, we find that different variants are optimal for different tasks. We explain such patterns by interpreting the parameters of the regression model, which yields insights into how the properties of span ID tasks interact with properties of neural model architectures. Such patterns can be used for manual fine-grained model selection, but our meta-learning model could also be incorporated directly into AutoML systems.

Our current study could be extended in various directions. First, the approach could apply the same meta-learning approach to other classes of tasks beyond span ID. Second, a larger range of span type metrics could presumably improve model fit, albeit at the cost of interpretability. Third, we only predict within-corpus performance, and corpus-level similarity metrics could be added to make predictions about performance in transfer learning.

A Training Models

All code used for training span identification and performance prediction models is available for download at our project website: `https://www.ims.uni-stuttgart.de/data/span-id-meta-learning`. All text logs generated during training of span identification models are included.

A.1 Hardware

All span identification models were trained using GeForce GTX 1080 Ti GPUs. Training time varied considerably across architectures – exact training times for individual experiments are found in the corresponding training logs.

The performance prediction model was trained on a CPU in a few seconds.

A.2 Tokenization

For PARC, OntoNotes, and CoNLL'00, which include tokenization information, and we use the datasets' tokenizations directly For RIQUA, we use spaCy (Honnibal and Montani, 2017) to word-tokenize the text. We found that spaCy's tokenization performed particularly poorly for ChemDNer, and so for this corpus we treated all sequences of alphabetic characters as a token, all sequences of numbers as a token, and all other characters as single-character tokens. For ChemDNer, we found that some spans within the corpus still did not align with token boundaries. In these cases, we excluded the spans entirely from the training data, and treated them as an automatic false-negative for evaluation purposes.

For models including a BERT component, tokens were sub-tokenized using word-piece tokenization (Wu et al., 2016) so as to be compatible with BERT. The same bag of token features was given to each word piece. Models predicted BIO sequences for these sub-tokens, and spans were only evaluated as correct when their boundaries matched exactly with the originally-tokenized corpus.

A.3 Hyperparameters

Due to the large number of experiments run, it was infeasible to do a full grid-search for hyperparameters for each architecture-dataset combination. As such, we tried to pick reasonable values for hyperparameters, motivated by existing literature, prior

PARC	Token POS tag Token lemma Constituents containing token Constituents starting at token Constituents ending at token
RIQUA	Token POS tag † Token lemma † Is token a quotation mark? Is token a quotation mark? Is token capitalized? Is token all caps?
CoNLL'00	Token POS tag †
OntoNotes	Token POS tag Is token capitalized? Is token all caps? Character bi- and trigrams Constituents containing token Constituents starting at token Constituents ending at token
ChemDNer	Token POS tag † Token lemma † Is token capitalized? Is token all caps? Is token purely alphabetic? Is token all digits?

Table 5: Hand-crafted features used. Entries marked with a dagger† were predicted using spaCy (Honnibal and Montani, 2017) – others were either manually annotated, or were exactly specified by the tokens' surface forms

research, and implementation defaults of existing libraries. For BERT-based models, our choice of pre-trained model – '`bert-base-uncased`' as provided by the HuggingFace Transformers library (Wolf et al., 2019) – fixed some of these hyperparameters for us. Table 6 enumerates the hyperparameter values used for our architectures.

A.4 Optimizer and Training

All models were trained with the Adam optimizer (Kingma and Ba, 2014). For BERT+CRF and BERT+LSTM+CRF, we train the non-BERT parameters as a first training phase, and then fine-tune all parameters jointly as a second training phase. In these cases, Adam was re-initialized between two training phases. For training all non-BERT architectures, and for first training phase in the BERT+CRF and BERT+LSTM+CRF architectures, an initial learning rate of 0.001 was used. For BERT, and for the second training phase in the BERT+CRF and BERT+LSTM+CRF architectures, an initial learning rate of 2×10^{-5} was used.

Hyperparameter	Value
Input dimensionality	300
LSTM units	300
Softmax output layer units	300
CRF units	300
LSTM layers	2
LSTM dropout probability	0.5
Learning rate (non-BERT)	1×10^{-3}
Learning rate (BERT)	2×10^{-5}

Table 6: Hyperparameter choices

A.5 Early Stopping

To guide early stopping, micro-averaged F_1 scores on the development set were computed after every epoch. These were computed for all span types, including those which were subsequently excluded from our meta-model. For datasets which had no dedicated development partition, a portion of the training set was held out for this purpose. After each epoch, model parameters were saved to disk if the development-set F_1 score exceeded the best seen so far. An exponential moving average of these F_1 scores was kept, and training terminated when an epoch's F_1 score fell below this average. For BERT+CRF and BERT+LSTM+CRF, this same early stopping procedure was used for both training phases. The training logs list development set performance at each epoch for each experiment.

A.6 Features

Table 5 lists all manual features that were used in models with the "Feat" component.

B Full Tables

Table 7 lists the span type properties of all span types from all datasets. Table 8 shows average F_1 score for each combination of span type and model architecture.

Abstract

Deep transformer models have pushed performance on NLP tasks to new limits, suggesting sophisticated treatment of complex linguistic inputs, such as phrases. However, we have limited understanding of how these models handle representation of phrases, and whether this reflects sophisticated composition of phrase meaning like that done by humans. In this paper, we present systematic analysis of phrasal representations in state-of-the-art pre-trained transformers. We use tests leveraging human judgments of phrase similarity and meaning shift, and compare results before and after control of word overlap, to tease apart lexical effects versus composition effects. We find that phrase representation in these models relies heavily on word content, with little evidence of nuanced composition. We also identify variations in phrase representation quality across models, layers, and representation types, and make corresponding recommendations for usage of representations from these models.

1 Introduction

A fundamental component of language understanding is the capacity to combine meaning units into larger units—a phenomenon known as *composition*—and to do so in a way that reflects the nuances of meaning as understood by humans. Transformers (Vaswani et al., 2017) have shown impressive performance in NLP, particularly transformers using pre-training, like BERT (Devlin et al., 2019) and GPT (Radford et al., 2018, 2019), suggesting that these models may be succeeding at composition of complex meanings. However, because transformers (like other contextual embedding models) typically maintain representations for every token, it is unclear how and at what points they might be combining word meanings into phrase meanings. This contrasts with models that incorporate explicit phrasal composition into their architecture, e.g. RNNG (Dyer et al., 2016; Kim et al., 2019), recursive models for semantic composition (Socher et al., 2013), or transformers with attention-based composition modules (Yin et al., 2020).

In this paper we take steps to clarify the nature of phrasal representation in transformers. We focus on representation of two-word phrases, and we prioritize identifying and teasing apart two important but distinct notions: how faithfully the models are representing information about the *words* that make up the phrase, and how faithfully the models are representing the nuances of the *composed phrase meaning* itself, over and above a simple account of the component words. To do this, we begin with existing methods for testing how well representations align with human judgments of meaning similarity: similarity correlations and paraphrase classification. We then introduce controlled variants of these datasets, removing cues of word overlap, in order to distinguish effects of word content from effects of more sophisticated composition. We complement these phrase similarity analyses with classic sense selection tests of phrasal composition (Kintsch, 2001).

We apply these tests for systematic analysis of several state-of-the-art transformers: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b), DistilBERT (Sanh et al., 2019), XLNet (Yang et al., 2019b) and XLM-RoBERTa (Conneau et al., 2019). We run the tests in layerwise fashion, to establish the evolution of phrase information as layers progress, and we test various tokens and token combinations as phrase representations. We find that when word overlap is not controlled, models show strong correspondence with human judgments, with noteworthy patterns of variation across models, layers, and representation types. However, we find that correspondence drops substantially once word overlap is controlled, suggesting that although these transformers contain faithful repre-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4896–4907,
November 16–20, 2020.

sentations of the lexical content of phrases, there is little evidence that these representations capture sophisticated details of meaning composition beyond word content. Based on the observed representation patterns, we make recommendations for selection of representations from these models. All code and controlled datasets are made available for replication and application to additional models.[1]

2 Related work

This paper contributes to a growing body of work on analysis of neural network models. Much work has studied recurrent neural network language models (Linzen et al., 2016; Wilcox et al., 2018; Chowdhury and Zamparelli, 2018; Gulordava et al., 2018; Futrell et al., 2019) and sentence encoders (Adi et al., 2016; Conneau et al., 2018; Ettinger et al., 2016). Our work builds in particular on analysis of information encoded in contextualized token representations (Bacon and Regier, 2019; Tenney et al., 2019b; Peters et al., 2018; Hewitt and Manning, 2019; Klafka and Ettinger, 2020) and in different layers of transformers (Tenney et al., 2019a; Jawahar et al., 2019). The BERT model has been a particular focus of analysis work since its introduction. Previous work has focused on analyzing the attention mechanism (Vig and Belinkov, 2019; Clark et al., 2019), parameters (Roberts et al., 2020; Radford et al., 2019; Raffel et al., 2020) and embeddings (Shwartz and Dagan, 2019; Liu et al., 2019a). We build on this work with a particular, controlled focus on the evolution of phrasal representation in a variety of state-of-the-art transformers.

Composition has been a topic of frequent interest when examining neural networks and their representations. One common practice relies on analysis of internal representations via downstream tasks (Baan et al., 2019; Ettinger et al., 2018; Conneau et al., 2019; Nandakumar et al., 2019; McCoy et al., 2019). One line of work analyzes word interactions in neural networks' internal gates as the composition signal (Saphra and Lopez, 2020; Murdoch et al., 2018), extending the Contextual Decomposition algorithm proposed by Jumelet et al. (2019). Another notable branch of work constructs synthetic datasets of small size to investigate compositionality in neural networks (Liška et al., 2018; Hupkes et al., 2018; Baan et al., 2019). Some work controls for word content, as we do, to study composition at the sentence level (Ettinger et al., 2018; Dasgupta et al., 2018). We complement this work with a targeted and systematic study of phrase-level representations in transformers, with a focus on teasing apart lexical properties versus reflections of accurate compositional phrase meaning.

Our work relates closely to classic work on two-word phrases, which have used methods like landmark tests (Kintsch, 2001; Mitchell and Lapata, 2008, 2010), or compared against distribution-based phrase representations (Baroni and Zamparelli, 2010; Fyshe et al., 2015). Our work also draws on work using correlation with similarity judgments (Finkelstein et al., 2001; Gerz et al., 2016; Hill et al., 2015; Conneau and Kiela, 2018) and paraphrase classification (Ganitkevitch et al., 2013; Wang et al., 2018; Zhang et al., 2019; Yang et al., 2019a) to assess quality of models and representations. We build on this work by combining these methods together, applying them to a systematic analysis of transformers and their components, and introducing controlled variants of existing tasks to isolate accurate composition of phrase meaning from capturing of lexical information.

3 Testing phrase meaning similarity

Our methods begin with familiar approaches for assessing representations via meaning similarity: correlation with human phrase similarity judgments, and ability to identify paraphrases. The goal is to gauge the extent to which models arrive at representations reflecting the nuances of composed phrase meaning understood by humans. We draw on existing datasets, and begin by testing models on the original versions of these datasets—then we tease apart effects of word content from effects of more sophisticated meaning composition by introducing controlled variants of the datasets. The reasoning is that strong correlations with human similarity judgments, or strong paraphrase classification performance, could be influenced by artifacts that are not reflective of accurate phrase meaning composition per se. In particular, we may see strong performance simply on the basis of the amount of overlap in word content between phrases. To address this possibility, we create controlled datasets in which word overlap is no longer a cue to similarity.

As a starting point we focus on two-word phrases, as these are the smallest phrasal unit and the most conducive to these types of lexical con-

trols, and because this allows us to leverage larger amounts of annotated phrase similarity data.

3.1 Phrase similarity correlation

We first evaluate phrase representations by assessing their alignment with human judgments of phrase meaning similarity. For testing this correspondence, we use the **BiRD** (Asaadi et al., 2019) dataset. BiRD is a bigram relatedness dataset designed to evaluate composition, consisting of 3,345 bigram pairs (examples in Table 1), with source phrases paired with numerous target phrases, and human-rated similarity scores ranging from 0 to 1.

In addition to testing on the full dataset, we design a controlled experiment to remove effects of word overlap, by filtering the dataset to pairs in which the two phrases consist of the same words. We refer to these pairs as "AB-BA" pairs (following terminology of the authors of the BiRD dataset), and show examples in the lower half of Table 1.

We run similarity tests as follows: given a model *M* with layers *L*, for ith layer $l_i \in L$ and a source-target phrase pair, we compute representations of source phrase $p^i_{rep}(\text{src})$ and target phrase $p^i_{rep}(\text{trg})$, where rep is a representation type from Section 4, and we compute their cosine $\cos(p^i_{rep}(\text{src}), p^i_{rep}(\text{trg}))$. Pearson correlation $\boldsymbol{r_i}$ of layer l_i is then computed between cosine and human-rated score for all source-target pairs.

3.2 Paraphrase classification

We further investigate the nature of phrase representations by testing their capacity to support binary paraphrase classification. This test allows us to explore whether we will see better alignment with human judgments of meaning similarity if we use more complicated operations than cosine similarity comparison. For the classification tasks, we draw on **PPDB 2.0** (Pavlick et al., 2015), a widely-used database consisting of paraphrases with scores generated by a regression model. To formulate our binary classification task, after filtering out low-quality paraphrases (discussed in Section 5), we use phrase pairs (source phrase, target phrase) from PPDB as positive pairs, and randomly sample phrases from the complete PPDB dataset to form negative pairs (source phrase, random phrase).

Because word overlap is also a likely cue for paraphrase classification, we filter to a controlled version of this dataset as well, as illustrated in Table 2. We formulate the controlled experiment here as holding word overlap between source phrase and target phrase to be exactly 50% for both positive and negative samples. Our choice of 50% word overlap in this case is necessary for construction of a sufficiently large, balanced classification dataset (AB-BA pairs in PPDB are too few to support classifier training, and AB-BA pairs are more likely to be non-paraphrases). Note, however, that by controlling word overlap to be exactly 50% for all phrase pairs, we still hold constant the *amount* of word overlap between phrases, which is the cue that we wish to remove. As an additional control, each source phrase is paired with an equal number of paraphrases and non-paraphrases, to avoid the classifier inferring labels based on phrase identity.

Formally, for each model layer l_i and representation type rep, we train

$$\text{CLF}^i_{rep} = \text{MLP}([\boldsymbol{pair^i_{rep}}])$$

where $\boldsymbol{pair^i_{rep}}$ represents embedding concatenations of each source phrase and target phrase:

$$\boldsymbol{pair^i_{rep}} = [\boldsymbol{p^i_{rep}(src)}; \boldsymbol{p^i_{rep}(trg)}]$$

The classifier is trained on binary classification of whether concatenated inputs represent paraphrases.

4 Representation types

A variety of approaches have been taken for representing sentences and phrases when all tokens output contextualized representations, as in our tested transformers. To clarify the phrasal information present in different forms of phrase representation, we experiment with a number of different combinations of token embeddings as representation types.

Formally, let $[T_0, \cdots, T_k]$ be an input sequence of length $k + 1$, with corresponding embeddings

	data infrastructure (neg)

Table 2: Examples of classification items. Classification labels between target phrase and source phrase are in parentheses. Upper half shows normal examples, and lower half shows controlled items.

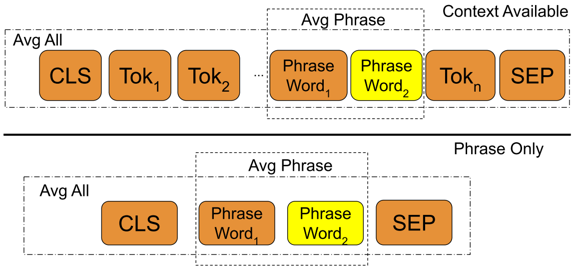

Figure 1: Example input sequences (BERT format). CLS is a special token at beginning of sequence. Tokens in yellow correspond to Head-Word. Avg-Phrase contains element-wise average of phrase word embeddings. Avg-All averages embeddings of all tokens.

at ith layer $[\boldsymbol{e}^i_0, \cdots, \boldsymbol{e}^i_k]$. Assume the phrase spans the sequence $[a, b]$, where $0 \leq a \leq b \leq k$. Because two-word phrases are atypical inputs for these models, we experiment both with inputs of the two-word phrases alone ("phrase-only"), as well as inputs with the phrases embedded in sentences ("context-available"). This is illustrated in Figure 1 along with phrase representation types.

We test the following forms of phrase representation, drawn from each model and layer separately:

CLS Depending on specific models, this special token can be the first or last token of the input sequence (i.e. $\boldsymbol{e}^i_0$ or $\boldsymbol{e}^i_k$). In many applications, this token is used to represent the full input sequence.

Head-Word In each phrase, the head word is the semantic center the phrase. For instance, in the phrase "public service", "service" is the head word, expressing the central meaning of the phrase, while "public" is a modifier. Because phrase heads are not annotated in our datasets, we approximate the head by taking the embedding of the final word of the phrase. This representation is proposed as a potential representation of the whole phrase, if information is being composed into a central word:

$$\boldsymbol{p}^i_{hw} = \boldsymbol{e}^i_b$$

Avg-Phrase For this representation type we average the embeddings of the tokens in the target phrase (dashed box in Figure 1). This type of averaging of token embeddings is a common means of aggregate representation (Wieting et al., 2015).

$$\boldsymbol{p}^i_{ap} = \frac{1}{b - a + 1} \sum_{x=a}^{b} \boldsymbol{e}^i_x$$

Avg-All Expanding beyond the tokens in "Avg-Phrase", this representation averages embeddings from the full input sequence.

$$\boldsymbol{p}^i_{aa} = \frac{1}{k + 1} \sum_{x=0}^{k} \boldsymbol{e}^i_x$$

SEP With some variation between models, the SEP token is typically a separator for distinguishing input sentences, and is often the last token ($\boldsymbol{e}^i_k$) or second to last token ($\boldsymbol{e}^i_{k-1}$) of a sequence.

5 Experimental setup

Embeddings of each token are obtained by feeding input sequences through pre-trained contextual encoders. We investigate the "base" version of five transformers: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b), DistilBERT (Sanh et al., 2019), XLNet (Yang et al., 2019b) and XLM-RoBERTa (Conneau et al., 2019). For the models analyzed in this paper, we are using the implementation of Wolf et al. (2019),[2] which is based on PyTorch (Paszke et al., 2019).

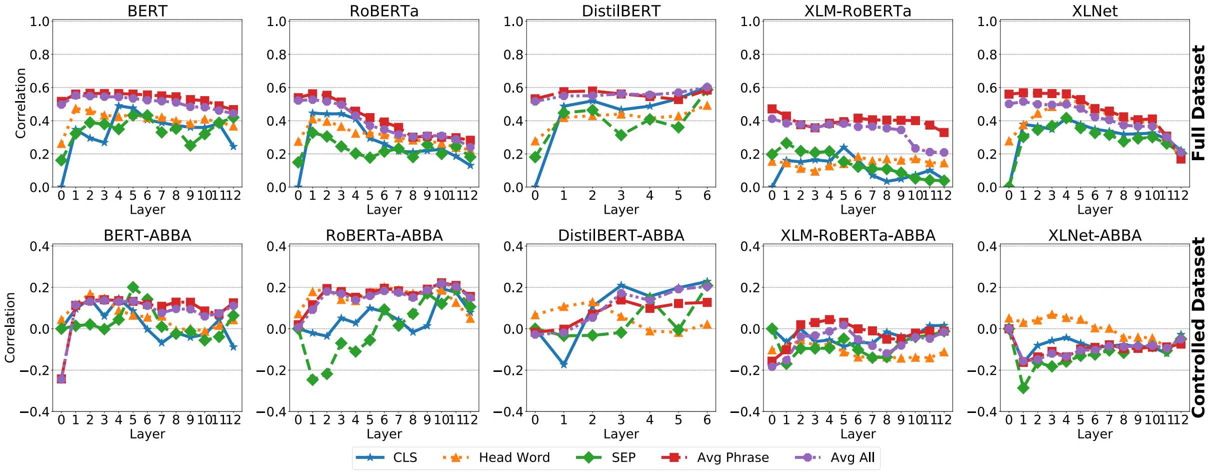

Figure 2: Correlation on BiRD dataset, phrase-only input setting. First row shows results on full dataset, and second row on controlled AB-BA pairs. Layer 0 corresponds to input embeddings passing to the model.

For correlation analysis, we first use the complete BiRD dataset, consisting of 3,345 phrase pairs.[3] We then test with our controlled subset of the data, consisting of 410 AB-BA pairs. For classification tasks, we first do preprocessing on PPDB 2.0,[4] filtering out pairs containing hyperlinks, non-alphabetical symbols, and trivial paraphrases based on abbreviation or tense change. For our initial classification test, we use 13,050 source-target phrase pairs (of varying word overlap) from this preprocessed dataset. We then test with our controlled dataset, consisting of 11,770 source-target phrase pairs (each with precisely 50% word overlap). For each paraphrase classification task, 25% of selected data is reserved for testing. We use a multi-layer perceptron classifier with a single hidden layer of size 256 with ReLU activation, and a softmax layer to generate binary labels. We use a relatively simple classifier following the reasoning of Adi et al. (2016), that this allows examination of how easily extractable information is in these representations.

For both correlation and classification tasks, we experiment with phrase-only inputs and context-available (full-sentence) inputs. To obtain sentence contexts, we search for instances of source phrases in a Wikipedia dump, and extract sentences containing them. For a given phrase pair, target phrases are embedded in the same sentence context as the source phrase, to avoid effects of varying sentence position between phrases of a given pair. [5]

6 Results

6.1 Similarity correlation

Full dataset The top row of Figure 2 shows correlation results on the full BiRD dataset for all models, layers, and representation types, with phrase-only inputs. Among representation types, Avg-Phrase and Avg-All consistently achieve the highest correlations across models and layers. In all models but DistilBERT, correlation of Avg-Phrase and Avg-All peaks at layer 1 and decreases in subsequent layers with minor fluctuations. Head-Word and SEP both show weaker, but non-trivial, correlations. The CLS token is of note with a consistent rapid rise as layers progress, suggesting that it quickly takes on properties of the words of the phrase. For all models but DistilBERT, CLS token correlations peak in middle layers and then decline.

Model-wise, XLM-RoBERTa shows the weakest overall correlations, potentially due to the fact that it is trained to infer input language and to handle multiple languages. BERT retains fairly consistent correlations across layers, while RoBERTa and XLNet show rapid declines as layers progress, suggesting that these models increasingly incorporate information that deviates from human intuitions about phrase smilarity. DistilBERT, despite being of smaller size, demonstrates competitive correlation. The CLS token in DistilBERT is notable for its continuing rise in correlation strength across

[4] http://paraphrase.org

[5] Because context sentences are extracted based on source phrases, our use of the same context for source and target phrases can give rise to unnatural contextual fit for target phrases. We consider this acceptable for the sake of controlling sentence position—and if anything, differences in contextual fit may aid models in distinguishing more and less similar phrases. The slight boost observed on the full datasets (for Avg-Phrase) suggests that the sentence contexts do provide the intended benefit from using input of a more natural size.

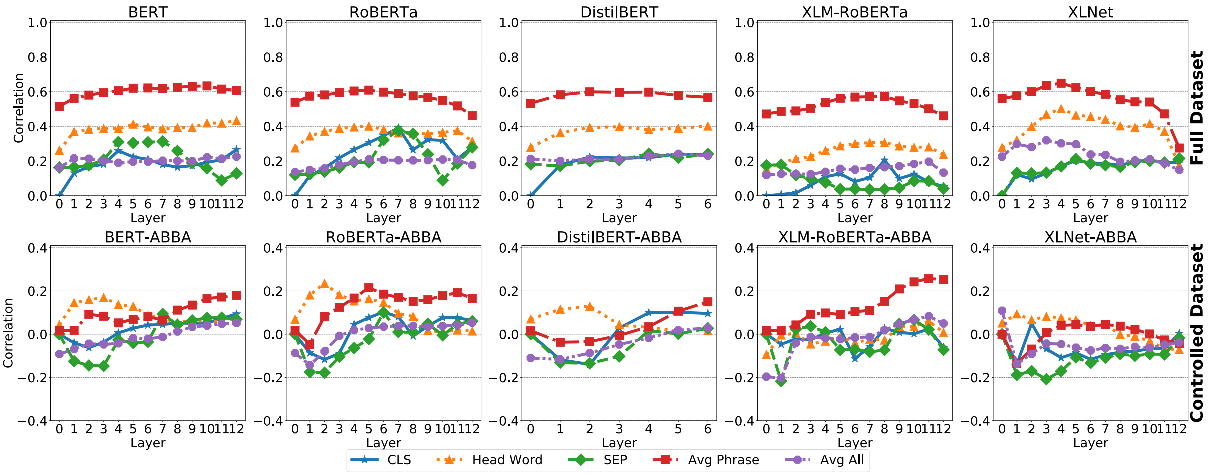

Figure 3: Correlation on BiRD dataset with phrases embedded in sentence context (context-available input setting).

layers. This suggests that DistilBERT in particular makes use of the CLS token to encode phrase information, and unlike other models, its representations retain the relevant properties to the final layer.

Controlled dataset Turning to our controlled AB-BA dataset, we examine the extent to which the above correlations indicate sophisticated phrasal composition versus effective encoding of information about phrases' component words. The bottom row of Figure 2 shows the correlations on this controlled subset. We see that performance of all models drops significantly, often with roughly zero correlation. Avg-All and Avg-Phrase no longer dominate the correlations, suggesting that these representations capture word information, but not higher-level compositional information. XLM-RoBERTa and XLNet show particularly low correlations, suggesting heavier reliance on word content. Notably, the CLS tokens in RoBERTa and DistilBERT stand out with comparatively strong correlations in later layers. This suggests that the rise that we see in CLS correlations for DistilBERT in particular may correspond to some real compositional signal in this token, and for this model the CLS token may in fact correspond to something more like a representation of the meaning of the full input sequence. The Avg-Phrase representation for RoBERTa also makes a comparatively strong showing.

Including sentence context Figure 3 shows the correlations when target phrases are embedded as part of a sentence context, rather than in isolation. As can be expected, Avg-Phrase is now consistently the highest in correlation on the full dataset—other tokens are presumably more impacted by the presence of additional words in the context. We also see that the Avg-Phrase correlations no longer drop so dramatically in later layers, suggesting that when given full sentence inputs, models retain more word properties in later layers than when given only phrases. This general trend holds also for Avg-All and Head-Word representations.

In the AB-BA setting, we see that presence of context does boost overall correlation with human judgment. Of note is XLM-RoBERTa's Avg-Phrase, which without sentence context has zero correlation in the AB-BA setting, but which with sentence context reaches our highest observed AB-BA correlations in its final layers. However, even with context, the strongest correlation across models is still less than 0.3. It is still the case, then, that correlation on the controlled data degrades significantly relative to the full dataset. This indicates that even when phrases are input within sentence contexts, phrase representations in transformers reflect heavy reliance on word content, largely missing additional nuances of compositional phrase meaning.

6.2 Paraphrase classification

Full dataset Results for our full paraphrase classification dataset, with phrase-only inputs, are shown in the top row of Figure 4. Accuracies are overall very high, and we see generally similar patterns to the correlation tasks. Best accuracy is achieved by using Avg-Phrase and Avg-All representations. RoBERTa, XLM-RoBERTa, and XLNet show decreasing correlations for top-performing representations in later layers, while BERT and DistilBERT remain more consistent across layers. Performance of CLS requires a few

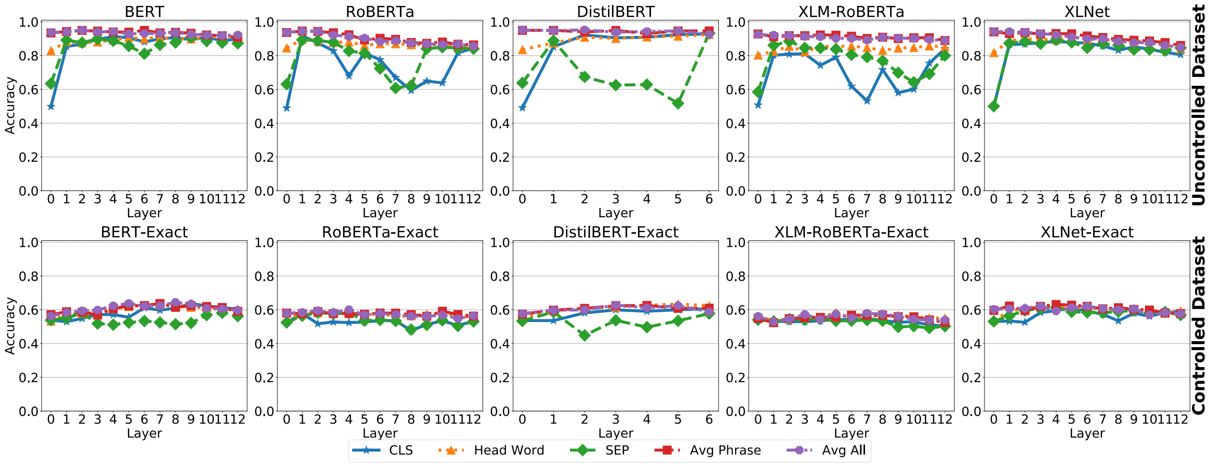

Figure 4: Classification accuracy on PPDB dataset (phrase-only input setting). First row shows classification accuracy on original dataset, and second row shows accuracy on controlled dataset.

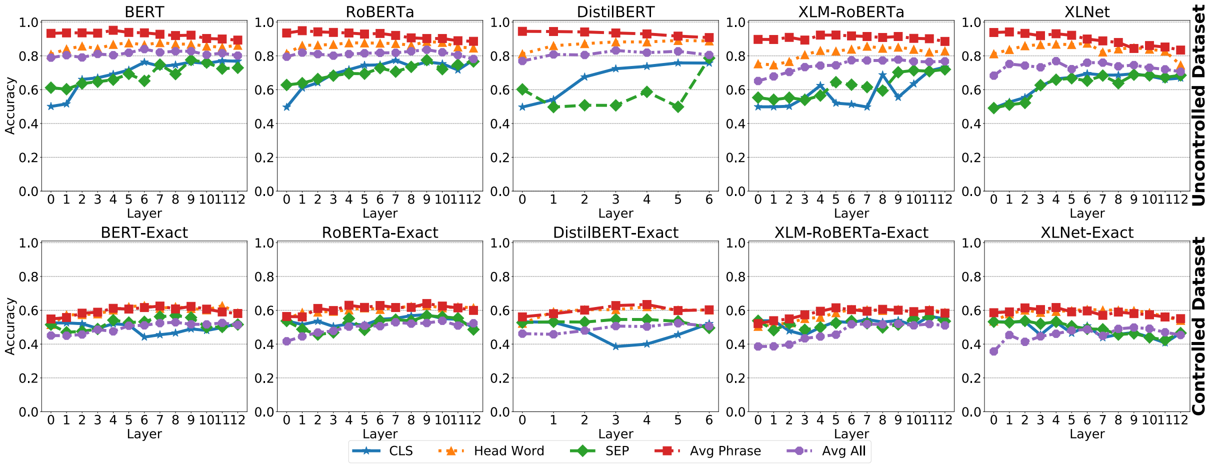

Figure 5: Classification accuracy on PPDB dataset with phrases embedded in sentence context. First row shows classification accuracy on original dataset, and second row shows accuracy on controlled dataset.

layers to peak, with top performance around middle layers, and in some models shows poor performance in later layers. SEP shows unstable performance compared to other representations, especially in DistilBERT and RoBERTa.

Controlled dataset The bottom row of Figure 4 shows classification accuracy when word overlap is held constant. Consistent with the drop in correlations on the controlled AB-BA experiments above, classification performance of all models drops down to only slightly above chance performance of 50%. This suggests that the high classification performance on the full dataset relies largely on word overlap information, and that there is little higher-level phrase meaning information to aid classification in the absence of the overlap cue. We see in some cases a very slight trend such that classification accuracy increases a bit toward middle layers—so to the extent that there is any compositional phrase information being captured, it may increase within representations in the middle layers. Overall, the consistency of these results with those of the correlation analysis suggests that the apparent lack of accurate compositional meaning information in our tested phrase representations is not simply a result of cosine correlations being inappropriate for picking up on correspondences.

Including sentence context Figure 5 shows the classification results for representations of phrases embedded in sentence contexts. The patterns largely align with our observations from the correlation task. Performance on the full dataset is still high, with Avg-Phrase now showing consistently highest performance, being least influenced by the presence of new context words. In the controlled setting, we see the same substantial drop in per-

	horse ran	*color ran*
gallop	POS	NEG
dissolve	NEG	POS

Table 3: An example of landmark experiment of verb "run". Representations are expected to have higher cosine similarities between phrase and landmark word that are marked "POS".

formance relative to the full dataset—there is very slight improvement over the phrase-only representations, but the highest accuracy among all models is still around 0.6. Thus, the inclusion of sentence context again does not provide any additional evidence for sophisticated compositional meaning information in the tested phrase representations.

7 Qualitative analysis: sense disambiguation

The above analyses rely on testing models' sensitivity to meaning similarity between two phrases. In this section we complement these analyses with another test aimed at assessing phrasal composition: testing models' ability to select the correct senses of polysemous words in a composed phrase, as proposed by Kintsch (2001). Each test item consists of a) a central verb, b) two subject-verb phrases that pick out different senses of the verb, and c) two *landmark* words, each associating with one of the target senses of the verb. Table 3 shows an example with central verb "ran" and phrases "horse ran"/ "color ran". The corresponding landmark words are "gallop", which associates with "horse ran", and "dissolve", which associates with "color ran". The reasoning is that composition should select the correct verb meaning, shifting representations of the central verbs—and of the phrase as a whole—toward landmarks with closer meaning. For this example, models should produce phrase embeddings such that "horse ran" is closer to "gallop" and "color ran" is closer to "dissolve". We use the items introduced in Kintsch (2001), which consist of a total of 4 sets of landmark tests. We feed landmarks and phrases respectively through each transformer, without context, to generate corresponding representations p^i_{rep} for each layer l_i and representation type rep. Cosine similarity between each phrase-landmark pair is computed and compared against expected similarities.

Figure 6 shows the percentage of phrases that fall closer to the correct landmark word than to the incorrect one, averaged over 16 phrase-landmark word pairs. We see strong overall performance across models, suggesting that the information needed for this task is successfully captured by these models' representations. Additionally, we see that the patterns largely mirror the results above for correlation and classification on uncontrolled datasets. Particularly, Avg-Phrase and Avg-All show comparatively strong performance across models. RoBERTa and XLNet show stronger performance in early layers, dropping off in later layers, while BERT and DistilBERT show more consistency across layers. XLM-RoBERTa and XLNet show lower performance overall.

For this verb sense disambiguation analysis, the Head-Word token is of note because it corresponds to the central verb of interest, so its sense can only be distinguished by its combination with the other word of the phrase. XLM-RoBERTa has the weakest performance with Head-Word, while BERT and DistilBERT demonstrate strong disambiguation with this token. As for the CLS token, RoBERTa produces the highest quality representation at layer 1, and BERT outperforms other models starting from layer 6, with DistilBERT also showing strong performance across layers.

Notably, the observed parallels to our correlation and classification results are in alignment with the uncontrolled rather than the controlled versions of those tests. So while these parallels lend further credence to the general observations that we make about phrase representation patterns across models, layers, and representation types, it is worth noting that these landmark composition tests may be susceptible to lexical effects similar to those controlled for above. Since these test items are too few to filter with the above methods, we leave in-depth investigation of this question to future work.

8 Discussion

The analyses reported above yield two primary takeaways. First, they shed light on the nature of these models' phrase representations, and the extent to which they reflect word content versus phrasal composition. At many points in these models there is non-trivial alignment with human judgments of phrase similarity, paraphrase classification, and verb sense selection. However, when we control our correlation and classification tests to remove the cue of word overlap, we see little evidence that the representations reflect sophisticated

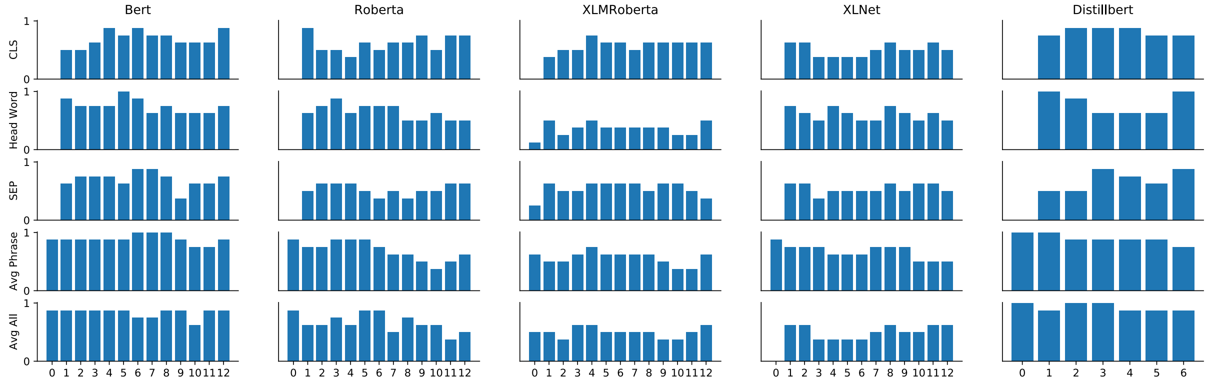

Figure 6: Landmark experiments. Y-axis denotes the percentage of samples that are shifted towards the correct landmark words in each layer. Missing bars occur when representations are independent of input at layer 0, such that cosine similarity between phrases and landmarks will always be 1.

phrase composition beyond what can be gleaned from word content. While we see strong performance on classic sense selection items designed to test phrase composition, the observed results largely parallel those from the uncontrolled versions of the correlation and classification analyses, suggesting that success on this landmark test may reflect lexical properties more than sophisticated composition. Given the importance of systematic meaning composition for robust and flexible language understanding, based on these results we predict that we will see corresponding weaknesses as more tests emerge for these models' handling of subtle meaning differences in downstream tasks.

Our systematic examination of models, layers and representation types yields a second takeaway in the form of practical implications for selecting and extracting representations from these models. For faithful representations of word content, Avg-Phrase is generally the strongest candidate. If only the phrase is embedded, drawing from earlier layers is best in RoBERTa, XLM-RoBERTa, and XLNet, while middle layers are better in BERT, and later layers in DistilBERT. If the phrase is input as part of a sentence, middle layers are generally best across models. Though the CLS token is often interpreted to represent a full input sequence, we find it to be a poor phrase representation even with phrase-only input, with the notable exception of the final layer of DistilBERT.

As for representations that reflect true phrase meaning composition, we have established that such representations may not currently be available in these models. However, to the extent that we do see weak evidence of potential compositional meaning sensitivity, this appears to be strongest in DistilBERT's CLS token in final layers, in RoBERTa's Avg-Phrase representation in later layers, and in XLM-RoBERTa's Avg-Phrase representation from later layers *only* when the phrase is contained within a sentence context.

9 Conclusions and future directions

We have systematically investigated the nature of phrase representations in state-of-the-art transformers. Teasing apart sensitivity to word content versus phrase meaning composition, we find strong sensitivity across models when it comes to word content encoding, but little evidence of sophisticated phrase composition. The observed sensitivity patterns across models, layers, and representation types shed light on practical considerations for extracting phrase representations from these models.

Future work can apply these tests to a broader range of models, and continue to develop controlled tests that target encoding of complex compositional meanings, both for two-word phrases and for larger meaning units. We hope that our findings will stimulate further work on leveraging the power of these generalized transformers while improving their capacity to capture compositional meaning.

Acknowledgments

We would like to thank three anonymous reviewers for valuable questions and suggestions for improving this paper. We also thank members of the University of Chicago CompLing Lab, and the Toyota Technological Institute at Chicago, for helpful comments and feedback on this work. Abstract

Transformer-based deep NLP models are trained using hundreds of millions of parameters, limiting their applicability in computationally constrained environments. In this paper, we study the cause of these limitations by defining a notion of *Redundancy*, which we categorize into two classes: *General Redundancy* and *Task-specific Redundancy*. We dissect two popular pretrained models, BERT and XLNet, studying how much redundancy they exhibit at a representation-level and at a more fine-grained neuron-level. Our analysis reveals interesting insights, such as: i) 85% of the neurons across the network are redundant and ii) at least 92% of them can be removed when optimizing towards a downstream task. Based on our analysis, we present an efficient feature-based transfer learning procedure, which maintains 97% performance while using at-most 10% of the original neurons.[1]

1 Introduction

Large pretrained models have improved the state-of-the-art in a variety of NLP tasks, with each new model introducing deeper and wider architectures causing a significant increase in the number of parameters. For example, BERT large (Devlin et al., 2019), NVIDIA's Megatron model, and Google's T5 model (Raffel et al., 2019) were trained using 340 million, 8.3 billion and 11 billion parameters respectively.

An emerging body of work shows that these models are over-parameterized and do not require all the representational power lent by the rich architectural choices during inference. For example, these models can be distilled (Sanh et al., 2019; Sun et al., 2019) or pruned (Voita et al., 2019; Sajjad et al., 2020), with a minor drop in performance. Recent research (Mu et al., 2018; Ethayarajh, 2019) analyzed contextualized embeddings in pretrained models and showed that the representations learned within these models are highly anisotropic. While these approaches successfully exploited over-parameterization and redundancy in pretrained models, the choice of what to prune is empirically motivated and the work does not directly explore the redundancy in the network. Identifying and analyzing redundant parts of the network is useful in: i) developing a better understanding of these models, ii) guiding research on compact and efficient models, and iii) leading towards better architectural choices.

In this paper, we analyze redundancy in pretrained models. We classify it into *general redundancy* and *task-specific redundancy*. The former is defined as the redundant information present in a pretrained model irrespective of any downstream task. This redundancy is an artifact of over-parameterization and other training choices that force various parts of the models to learn similar information. The latter is motivated by pretrained models being universal feature extractors. We hypothesize that several parts of the network are specifically redundant for a given downstream task.

We study both *general* and *task-specific* redundancies at the *representation-level* and at a more fine-grained *neuron-level*. Such an analysis allows us to answer the following questions: i) how redundant are the layers within a model? ii) do all the layers add significantly diverse information? iii) do the dimensions within a hidden layer represent different facets of knowledge, or are some neurons largely redundant? iv) how much information in a pretrained model is necessary for specific downstream tasks? and v) can we exploit redundancy to

enable efficiency?

We introduce several methods to analyze redundancy in the network. Specifically, for general redundancy, we use *Center Kernel Alignment* (Kornblith et al., 2019) for layer-level analysis, and *Correlation Clustering* for neuron-level analysis. For task-specific redundancy, we use *Linear Probing* (Shi et al., 2016a; Belinkov et al., 2017) to identify redundant layers, and *Linguistic Correlation Analysis* (Dalvi et al., 2019) to examine neuron-level redundancy.

We conduct our study on two pretrained language models, BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019). While these networks are similar in the number of parameters, they are trained using different training objectives, which accounts for interesting comparative analysis between these models. For task-specific analysis, we present our results across a wide suite of downstream tasks: four core NLP sequence labeling tasks and seven sequence classification tasks from the GLUE benchmark (Wang et al., 2018). Our analysis yields the following insights:

General Redundancy:

- Adjacent layers are most redundant in the network, with lower layers having greater redundancy with adjacent layers.
- Up to 85% of the neurons across the network are redundant in general, and can be pruned to substantially reduce the number of parameters.
- Up to 94% of neuron-level redundancy is exhibited within the same or neighbouring layers.

Task-specific Redundancy:

- Layers in a network are more redundant w.r.t. core language tasks such as learning morphology as compared to sequence-level tasks.
- At least 92% of the neurons are redundant with respect to a downstream task and can be pruned without any loss in task-specific performance.
- Comparing models, XLNet is more redundant than BERT.
- Our analysis guides research in model distillation and suggests preserving knowledge of lower layers and aggressive pruning of higher-layers.

Finally, motivated by our analysis, we present an **efficient feature-based transfer learning procedure** that exploits various types of redundancy present in the network. We first target layer-level task-specific redundancy using linear probes and reduce the number of layers required in a forward pass to extract the contextualized embeddings. We then filter out general redundant neurons present in the contextualized embeddings using Correlation Clustering. Lastly, we remove task-specific redundant neurons using Linguistic Correlation Analysis. We show that one can reduce the feature set to less than 100 neurons for several tasks while maintaining more than 97% of the performance. Our procedure achieves a speedup of up to 6.2x in computation time for sequence labeling tasks.

2 Related Work

A number of studies have analyzed representations at layer-level (Conneau et al., 2018; Liu et al., 2019; Tenney et al., 2019; Kim et al., 2020; Belinkov et al., 2020) and at neuron-level (Bau et al., 2019; Dalvi et al., 2019; Suau et al., 2020; Durrani et al., 2020). These studies aim at analyzing either the linguistic knowledge learned in representations and in neurons or the general importance of neurons in the model. The former is commonly done using a probing classifier (Shi et al., 2016a; Belinkov et al., 2017; Hupkes et al., 2018). Recently, Voita and Titov (2020); Pimentel et al. (2020) proposed probing methods based on information theoretic measures. The general importance of neurons is mainly captured using similarity and correlation-based methods (Raghu et al., 2017; Chrupała and Alishahi, 2019; Wu et al., 2020). Similar to the work on analyzing deep NLP models, we analyze pretrained models at representation-level and at neuron-level. Different from them, we analyze various forms of redundancy in these models. We draw upon various techniques from the literature and adapt them to perform a redundancy analysis.

While the work on pretrained model compression (Cao et al., 2020; Shen et al., 2020; Sanh et al., 2019; Turc et al., 2019; Gordon et al., 2020; Guyon and Elisseeff, 2003) indirectly shows that models exhibit redundancy, little has been done to explore the redundancy in the network. Recent studies (Voita et al., 2019; Michel et al., 2019; Sajjad et al., 2020; Fan et al., 2020) dropped attention heads and layers in the network with marginal degradation in performance. Their work is limited in the context of redundancy as none of the pruning choices are built upon the amount of redundancy present in different parts of the network. Our work identifies redundancy at various levels of the network and can guide the research in model compression.

3 Experimental Setup

3.1 Datasets and Tasks

To analyze the general redundancy in pre-trained models, we use the Penn Treebank development set (Marcus et al., 1993), which consists of roughly 44,000 tokens. For task-specific analysis, we use two broad categories of downstream tasks – *Sequence Labeling* and *Sequence Classification* tasks. For the sequence labeling tasks, we study core linguistic tasks, i) part-of-speech (POS) tagging using the Penn TreeBank, ii) CCG super tagging using CCGBank (Hockenmaier, 2006), iii) semantic tagging (SEM) using Parallel Meaning Bank data (Abzianidze and Bos, 2017) and iv) syntactic chunking using CoNLL 2000 shared task dataset (Sang and Buchholz, 2000).

For sequence classification, we study tasks from the GLUE benchmark (Wang et al., 2018), namely i) sentiment analysis (SST-2) (Socher et al., 2013), ii) semantic equivalence classification (MRPC) (Dolan and Brockett, 2005), iii) natural language inference (MNLI) (Williams et al., 2018), iv) question-answering NLI (QNLI) (Rajpurkar et al., 2016), iv) question pair similarity[2] (QQP), v) textual entailment (RTE) (Bentivogli et al., 2009), and vi) semantic textual similarity (Cer et al., 2017).[3] Complete statistics for all datasets is provided in Appendix A.1.

Other Settings The neuron activations for each word in our dataset are extracted from the pre-trained model for sequence labeling while the `[CLS]` token's representation (from a fine-tuned model) is used for sequence classification. The fine-tuning step is essential to optimize the `[CLS]` token for sentence representation. In the case of sub-words, we pick the last sub-word's representation (Durrani et al., 2019; Liu et al., 2019). For sequence labeling tasks, we use training sets of 150K tokens, and standard development and test splits. For sequence classification tasks, we set aside 5% of the training data and use it to optimize all the parameters involved in the process and report results on development sets, since the test sets are not publicly available.

3.2 Models

We present our analysis on two transformer-based pretrained models, BERT-base (Devlin et al., 2019) and XLNet-base (Yang et al., 2019).[4] The former is a masked language model, while the latter is of an auto-regressive nature. We use the `transformers` library (Wolf et al., 2019) to fine-tune these models using default hyperparameters.

Classifier Settings For layer-level probing and neuron-level ranking, we use a logistic regression classifier with ElasticNet regularization. We train the classifier for 10 epochs with a learning rate of $1e^{-3}$, batch size of 128 and a value of $1e^{-5}$ for both $L1$ and $L2$ lambda regularization parameters.

4 Problem Definition

Consider a pretrained model $\mathbf{M}$ with L layers: $\{l_0, l_1, \ldots, l_L\}$, where l_0 is an embedding layer and each layer l_i is of size H. Given a dataset $\mathbb{D} = \{w_1, w_2, ..., w_T\}$ consisting of T words, the contextualized embedding of word w_j at layer l_i is $\boldsymbol{z}^i_j = l_i(w_j)$. A *neuron* consists of each individual unit of $\boldsymbol{z}^i_j$. For example, BERT-base has $L = 13$ layers, each of size 768 i.e. there are 768 individual neurons in each layer. The total number of neurons in the model are $13 \times 768 = 9984$.

We analyze redundancy in $\mathbf{M}$ at layer-level l_i: *how redundant is a layer?* and at neuron-level: *how redundant are the neurons?* We target these two questions in the context of general redundancy and task-specific redundancy.

Notion of redundancy: We broadly define redundancy to cover a range of observations. For example, we imply high similarity as a reflection of redundancy. Similarly, for task-specific neuron-level redundancy, we hypothesize that some neurons additionally might be irrelevant for the downstream task in hand. There, we consider irrelevancy as part of the redundancy analysis. Succinctly, two neurons are considered to be redundant if they serve the same purpose from the perspective of feature-based transfer learning for a downstream task.

5 General Redundancy

Neural networks are designed to be distributed in nature and are therefore innately redundant. Addi-

(a) BERT (b) XLNet

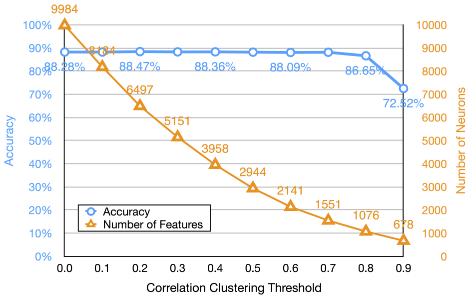
Figure 1: Pairwise Similarity between the layers. Brighter colors indicate higher similarity.

tionally, over-parameterization in pretrained models with a combination of various training and design choices causes further redundancy of information. In the following, we analyze general redundancy at layer-level and at neuron-level.

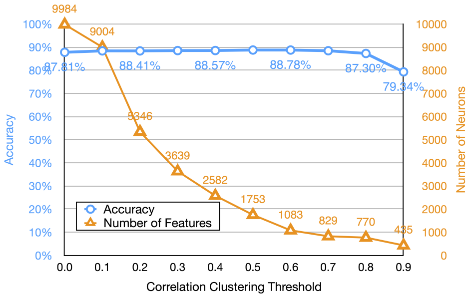
5.1 Layer-level Redundancy

We compute layer-level redundancy by comparing representations from different layers in a given model using linear Center Kernel Alignment (`cka` - Kornblith et al. (2019)). `cka` is invariant to isotropic similarity and orthogonal transformation. In other words, the similarity measure itself does not depend on the various representations having neurons or dimensions with exactly the same distributions, but rather assigns a high similarity if the two representations behave similarly over *all* the neurons. Moreover, `cka` is known to outperform other methods such as CCA (Andrew et al., 2013) and SVCCA (Raghu et al., 2017), in identifying relationships between different layers across different architectures. While there are several other methods proposed in literature to analyze and compare representations (Kriegeskorte et al., 2008; Bouchacourt and Baroni, 2018; Chrupała and Alishahi, 2019; Chrupała, 2019), we do not intend to compare them here and instead use `cka` to show redundancy in the network. The mathematical definition of `cka` is provided in Appendix A.6 for the reader.

We compute pairwise similarity between all L layers in the pretrained model and show the corresponding heatmaps in Figure 1. We hypothesize that a high similarity entails (general) redundancy. Overall the **similarity between adjacent layers is high**, indicating that the change of encoded knowledge from one layer to another takes place in small incremental steps as we move from a lower layer to a higher layer. An exception to this observation is the final pair of layers, l_{11} and l_{12}, whose similarity is much lower than other adjacent pairs of layers. We speculate that this is because the final layer is highly optimized for the objective at hand, while the lower layers try to encode as much general linguistic knowledge as possible. This has also been alluded to by others (Hao et al., 2019; Wu et al., 2020).



(a) BERT



(b) XLNet

Figure 2: General neuron-level redundancy in BERT and XLNet; comparing the average reduction of neurons for different CC thresholds and the average accuracy across all downstream tasks. See Appendix A.2 for detailed per-task results.

5.2 Neuron-level Redundancy

Assessing redundancy at the layer level may be too coarse grained. Even if a layer is not redundant with other layers, a subset of its neurons may still be redundant. We analyze neuron-level redundancy in a network using correlation clustering – `CC` (Bansal et al., 2004). We group neurons with highly correlated activation patterns over all of the words w_j. Specifically, every neuron in the vector $\boldsymbol{z}_j^i$ from some layer i can be represented as a T dimensional vector, where each index is the activation value $\boldsymbol{z}_j^i$ of that neuron for some word w_j, where j ranges from 1 to T. We calculate the Pearson product-moment correlation of every neuron vector $\boldsymbol{z}^i$ with every other neuron. This results in a $N \times N$ matrix $corr$, where N is the total number of neurons and $corr(x, y)$ represents the correlation

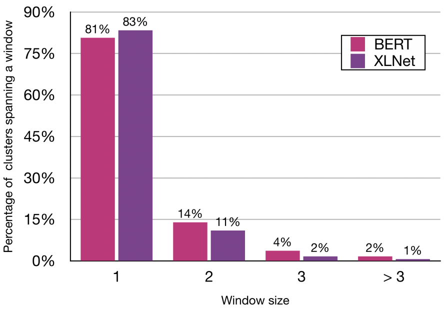


Figure 3: Percentage of clusters which contain neurons from the same layers, adjacent layers, within three neighboring layers and more than three layers apart.

between neurons x and y. The correlation value ranges from -1 to 1, giving us a relative scale to compare any two neurons. A high absolute correlation value between two neurons implies that they encode very similar information and therefore are redundant. We convert $corr$ into a distance matrix $cdist$ by applying $cdist(x, y) = 1 - |corr(x, y)|$ and cluster the distance matrix $cdist$ by using agglomerative hierarchical clustering with average linkage[5] to minimize the average distance of all data points in pairs of clusters. The maximum distance between any two points in a cluster is controlled by the hyperparameter c_t. It ranges from 0 to 1 where a high value results in large-sized clusters with a small number of total clusters.

Substantial amount of neurons are redundant In order to evaluate the effect of clustering in combining redundant neurons, we randomly pick a neuron from each cluster and form a reduced set of non-redundant neurons. Recall that the clustering is applied independently on the data without using any task-specific labels. We then build task-specific classifiers for each task on the reduced set and analyze the average accuracy. If the average accuracy of a reduced set is close to that of the full set of neurons, we conclude that the reduced set has filtered out redundant neurons. Figure 2 shows the effect of clustering on BERT and XLNet using different values of c_t with respect to average performance across all tasks. It is remarkable to observe that **85% of neurons can be removed without any loss in accuracy** ($c_t = 0.7$) in BERT, alluding to a high-level of neuron-level redundancy. We observe an even higher reduction in XLNet. At $c_t = 0.7$, 92% of XLNet neurons can be removed while maintaining oracle performance. We additionally visualize a few neurons within a cluster. The activation patterns are quite similar in their behavior, though not identical, highlighting the efficacy of `CC` in clustering neurons with analogous behavior. An activation heatmap for several neurons is provided in Appendix A.2.

Higher neuron redundancy within and among neighboring layers We analyze the general makeup of the clusters at $c_t = 0.3$.[6] Figure 3 shows the percentage of clusters that contain neurons from the same layer (window size 1), neighboring layers (window sizes 2 and 3) and from layers further apart. We can see that a vast majority of clusters ($\approx 95\%$) either contain neurons from the same layer or from adjacent layers. This reflects that the main source of redundancy is among the individual representation units in the same layer or neighboring layers of the network. The finding motivates pruning of models by compressing layers as oppose to reducing the overall depth in a distilled version of a model.

6 Task-specific Redundancy

While pretrained models have a high amount of general redundancy as shown in the previous section, they may additionally exhibit redundancies specific to a downstream task. Studying redundancy in relation to a specific task helps us understand pretrained models better. It further reflects on how much of the network, and which parts of the network, suffice to perform a task efficiently.

6.1 Layer-level Redundancy

To analyze layer-level task-specific redundancy, we train linear probing classifiers (Shi et al., 2016b; Belinkov et al., 2017) on each layer l_i (*layer-classifier*). We consider a classifier's performance as a proxy for the amount of task-specific knowledge learned by a layer. Linear classifiers are a popular choice in analyzing deep NLP models due to their better interpretability (Qian et al., 2016; Belinkov et al., 2020). Hewitt and Liang (2019) have shown linear probes to have higher *Selectivity*, a property deemed desirable for more interpretable probes.

We compare each *layer-classifier* with an oracle-classifier trained over concatenation of all layers

---

[5] We experimented with other clustering algorithms such as k-means and DBSCAN, and did not see any noticeable difference in the resulting clusters.

[6] The choice of 0.3 avoids aggressive clustering and enables the analysis of the most redundant neurons.

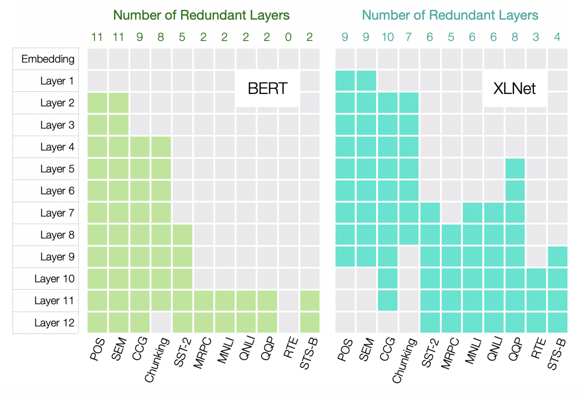

Figure 4: Task-specific layer-wise redundant layers represented by the colored blocks. Appendix A.3 presents fine-grained graphs for a few tasks.

of the network. For all individual layers that perform close to oracle (maintaining 99% of the performance in our results), we imply that they encode sufficient knowledge about the task and are therefore redundant in this context. Note that this does not necessarily imply that those layers are identical or that they represent the knowledge in a similar way – instead they have redundant overall knowledge specific to the task at hand.

High redundancy for core linguistic tasks Figure 4 shows the redundant layers that perform within a 1% performance threshold with respect to the oracle on each task. We found high layer-level redundancy for sequence labeling tasks. There are up to 11 redundant layers in BERT and up to 10 redundant layers in XLNet, across different tasks. This is expected, because the sequence labeling tasks considered here are core language tasks, and the information related to them is spread across the network. Comparing models, we found such core language information to be distributed amongst fewer layers in XLNet.

Substantially less amount of redundancy for higher-level tasks The amount of redundancy is substantially lower for sequence classification tasks, with *RTE* having the least number of redundant layers in both models. Especially in BERT, we did not find any layer that matched the oracle performance for RTE. It is interesting to observe that all the sequence classification tasks are learned at higher layers and none of the lower layers were found to be redundant. These results are intuitive given that the sequence classification tasks require complex linguistic knowledge, such as long range contextual dependencies, which are only learned at the higher-layers of the model. Lower layers do not have the sufficient sentence-level context to perform these tasks well.

XLNet is more redundant than BERT While XLNet has slightly fewer redundant layers for sequence labeling tasks, on average across all downstream tasks it shows high layer-level task-specific redundancy. Having high redundancy for sequence-level tasks reflects that XLNet learns the higher-level concepts much earlier in the network and this information is then passed to all the subsequent layers. This also showcases that XLNet is a much better candidate for model compression where several higher layers can be pruned with marginal loss in performance, as shown by Sajjad et al. (2020).

6.2 Neuron-level Redundancy

Pretrained models being a universal feature extractor contain redundant information with respect to a downstream task. We hypothesize that they may also contain information that is not necessary for the underlying task. In task-specific neuron analysis, we consider both redundant and irrelevant neurons as redundancy with respect to a task. Unlike layers, it is combinatorially intractable to exhaustively try all possible neuron permutations that can carry out a downstream task. We therefore aim at extracting only one minimal set of neurons that suffice the purpose, and consider the remaining neurons redundant or irrelevant for the task at hand.

Formally, given a task and a set of neurons from a model, we perform feature selection to identify a minimal set of neurons that match the oracle performance. To accomplish this, we use the Linguistic Correlation Analysis method (Dalvi et al., 2019) to ranks neurons with respect to a downstream task, referred as `FS` (feature selector) henceforth. For each downstream task, we concatenate representations from all layers L and use `FS` to extract a minimal set of top ranked neurons that maintain the oracle performance, within a defined threshold. Oracle is the task-specific classification performance obtained using all the neurons for training. The minimum set allows us to answer how many neurons are redundant and irrelevant to the given task. Tables 1 and 2 show the minimum set of top neurons for each task that maintains at least 97% of the oracle performance.

Complex core language tasks require more neurons CCG and Chunking are relatively complex tasks compared to POS and SEM. On average

Task	# Neurons
POS	290
SEM	330
CCG	330
Chunk.	750

(b) XLNet

Table 2: Task-specific neuron-level analysis for sequence classification tasks.

across both models, these complex tasks require more neurons than POS and SEM. It is interesting to see that the size of minimum neurons set is correlated with the complexity of the task.

Less task-specific redundancy for core linguistic tasks compared to higher-level tasks While the minimum set of neurons per task consist of a small percentage of total neurons in the network, the core linguistic tasks require substantially more neurons compared to higher-level tasks (comparing Tables 1 and 2). It is remarkable that some sequence-level tasks require as few as only 10 neurons to obtain desired performance. One reason for the large difference in the size of minimum set of neurons could be the nature of tasks, since core linguistic tasks are word-level tasks, a much higher capacity is required in the pretrained model to store the knowledge for all of the words. While in the case of sequence classification tasks, the network learns to filter and mold the features to form fewer "high-level" sentence features.

7 Efficient Transfer Learning

In this section, we build upon the redundancy analysis presented in the previous sections and propose a novel method for efficient feature-based transfer learning. In a typical feature-based transfer learning setup, contextualized embeddings are first extracted from a pretrained model, and then a classifier is trained on the embeddings towards the downstream NLP task. The bulk of the computational expense is incurred from the following sources:

- A full forward pass over the pretrained model to extract the contextualized vector, a costly affair given the large number of parameters.
- Classifiers with large contextualized vectors are: a) cumbersome to train, b) inefficient during inference, and c) may be sub-optimal when supervised data is insufficient (Hameed, 2018).

We propose a three step process to target these two sources of computation bottlenecks:

1. Use the task-specific layer-classifier (Section 6.1) to select the lowest layer that maintains oracle performance. Differently from the analysis, a concatenation of all layers until the selected layer is used instead of just the individual layers.
2. Given the contextualized embeddings extracted in the previous step, use `CC` (Section 5.2) to filter-out redundant neurons.
3. Apply `FS` (Section 6.2) to select a minimal set of neurons that are needed to achieve optimum performance on the task.

The three steps explicitly target task-specific layer redundancy, general neuron redundancy and task-specific neuron redundancy respectively. We refer to Step 1 as `LayerSelector` (`LS`) and Step 2 and 3 as `CCFS` (Correlation clustering + Feature selection) later on. For all experiments, we use a performance threshold of 1% for `LS` and `CCFS` each. It is worth mentioning that the tradeoff between loss in accuracy and efficiency can be controlled through these thresholds, which can be adjusted to serve faster turn-around or better performance.

7.1 Results

Table 3 presents the average results on all sequence labeling and sequence classification tasks. Detailed per-task results are provided in Appendix A.5.1. As expected from our analysis, a significant portion of the network can be pruned by `LS` for sequence labeling tasks, using less than 6 layers out of 13 (Embedding + 12 layers) for BERT and less than 3 layers for XLNet. Specifically, this reduces the parameters required for a forward pass for BERT

	Sequence Classification		Sequence Labeling	
	BERT	XLNet	BERT	XLNet
Oracle	93.0%	93.4%	85.5%	84.8%
Neurons	9984			
`LS`	92.3%	93.2%	85.0%	84.5%
Layers	5.3	2.5	11.6	8.1
`CCFS`	92.0%	92.2%	84.0%	84.0%
Neurons	425	400	90	150
% Reduct.	95.7%↓	96.0%↓	99.0%↓	98.5%↓

Table 3: Average results using `LS` and `CCFS` with performance thresholds of 1% for each. Oracle is using a concatenation of all layers. *Layers* shows the average number of selected layers. *Neurons* are the final number of neurons (features) used for classification. % *Reduct.* shows the percentage reduction in neurons compared to the full network.

by 65% for POS and SEM, and 33% for CCG and 39% for Chunking. On XLNet, `LS` led to even larger reduction in parameters; 70% for POS and SEM, and 65% for CCG and Chunking. The results were less pronounced for sequence classification tasks, with `LS` using 11.6 layers for BERT and 8.1 layers for XLNet on average, out of 13 layers.

Applying `CCFS` on top of the reduced layers led to another round of significant efficiency improvements. The number of neurons needed for the final classifier reducing to just 5% for sequence labeling tasks and 1.5% for sequence classification tasks. The final number of neurons is surprising low for some tasks compared to the initial 9984, with some tasks like QNLI using just 10 neurons.

More concretely, taking the POS task as an example: the pre-trained oracle BERT model has 9984 features and 110M parameters. `LS` reduced the feature set to 2304 (embedding + 2 layers) and the number of parameters used in the forward pass to 37M. `CCFS` further reduced the feature set to 300, maintaining a performance close to oracle BERT's performance on this task (95.2% vs. 93.9%).

An interesting observation in Table 3 is that the sequence labeling tasks require *fewer layers* but *a higher number of features*, while sequence classification tasks follow the opposite pattern. As we go deeper in the network, the neurons are much more richer and tuned for the task at hand, and only a few of them are required compared to the much more word-focused neurons in the lower layers. These observations suggest pyramid-shaped architectures that have wider lower layers and narrow higher layers. Such a design choice leads to significant savings of capacity in higher layers where a few, rich neurons are sufficient for good performance. In terms of neuron-based compression methods, these findings propose aggressive pruning of higher layers while preserving the lower layers in building smaller and accurate compressed models.

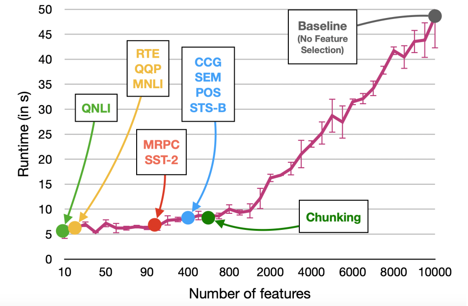

Figure 5: BERT: Runtime of the classifier w.r.t. number of neurons (features). The dots on the line mark the number of features selected by our method. Note that the X-axis is not linear, the lower half of the spectrum has been stretched for clarity.

7.2 Efficiency Analysis

While the algorithm boosts the theoretical efficiency in terms of the number of parameters reduced and the final number of features, it is important to analyze how this translates to real world performance. Using `LS` leads to an average speed up of 2.8x and 6.2x with BERT and XLNet respectively on sequence labeling tasks. On sequence classification tasks, the average speed ups are 1.1x and 1.6x with BERT and XLNet respectively. Detailed results are provided in Appendix A.5.2.

For the classifier built on the reduced set, we simulate a test scenario with 100,000 tokens and compute the total runtime for 10 iterations of training. The numbers were computed on a 6-core 2.8 GHz AMD Opteron Processor 4184, and were averaged across 3 runs. Figure 5 shows the runtime of each run (in seconds) against the number of features selected. The runtime of the classifier reduced from 50 to 10 seconds in the case of BERT. The 5x speedup can be very useful in a heavy-use scenarios where the classifier is queried a large number times in a short duration.

Training time efficiency: Although the focus of the current application is to improve inference-time efficiency, it is nevertheless important to understand how much computation complexity is added during training time. Let T be the total number of tokens in our training set, and N be the total number of neurons across all layers in a pre-trained model. The application presented in this section consists of 5 steps.

1. Feature extraction from pre-trained model: Extraction time scales linearly with the number of tokens T.
2. Training a classifier for every layer `LS`: With a constant number of neurons N, training time per layer scales linearly with the number of tokens T.
3. Correlation clustering `CC`: With a constant number of neurons N, running correlation clustering scales linearly with the number of tokens T.
4. Feature ranking: This step involves training a classifier with the reduced set of features, which scales linearly with the number of tokens T. Once the classifier is trained, the weights of the classifier are used to extract a feature ranking, with the number of weights scaling linearly with the number of selection neurons N.
5. Minimal feature set: Finding the minimal set of neurons is a brute-force search process, starting with a small number of neurons. For each set of neurons, a classifier is trained, the time for which scales linearly with the total number of tokens T. As the feature set size increases, the training time also goes up as described in Figure 5.

Appendix A.5.3 provides additional experiments and results used to analyze the training time complexity of our application.

8 Conclusion and Future Directions

We defined a notion of redundancy and analyzed pre-trained models for general redundancy and task-specific redundancy exhibited at layer-level and at individual neuron-level. Our analysis on general redundancy showed that i) adjacent layers are most redundant in the network with an exception of final layers which are close to the objective function, and ii) up to 85% and 92% neurons are redundant in BERT and XLNet respectively. We further showed that networks exhibit varying amount of task-specific redundancy; higher layer-level redundancy for core language tasks compared to sequence-level tasks. We found that at least 92% of the neurons are redundant with respect to a downstream task. Based on our analysis, we proposed an efficient transfer learning procedure that directly targets layer-level and neuron-level redundancy to achieve efficiency in feature-based transfer learning.

While our analysis is helpful in understanding pretrained models, it suggests interesting research directions towards building compact models and models with better architectural choices. For example, a high amount of neuron-level redundancy in the same layer suggests that layer-size compression might be more effective in reducing the pretrained model size while preserving oracle performance. Similarly, our finding that core-linguistic tasks are learned at lower-layers and require a higher number of neurons, while sequence-level tasks are learned at higher-layers and require fewer neurons, suggests pyramid-style architectures that have wide lower layers and compact higher layers and may result in smaller models with performance competitive with large models.

A Appendices

A.1 Data

For Sequence labeling tasks, we use the first 150,000 tokens for training, and standard development and test data for all of the four tasks (POS, SEM, CCG super tagging and Chunking). The links to all datasets is provided in the code README instructions. The statistics for the datasets are provided in Table 4.

Task	Train	Dev	Test	Tags
POS	149973	44320	47344	44
SEM	149986	112537	226426	73
Chunking	150000	44346	47372	22
CCG	149990	45396	55353	1272

Table 4: Data statistics (number of tokens) on training, development and test sets used in the experiments and the number of tags to be predicted

For the sequence classification tasks, we study tasks from the GLUE benchmark (Wang et al., 2018), namely i) sentiment analysis (SST-2) using the Stanford sentiment treebank (Socher et al., 2013), ii) semantic equivalence classification using the Microsoft Research paraphrase corpus (MRPC) (Dolan and Brockett, 2005), iii) natural language inference corpus (MNLI) (Williams et al., 2018), iv) question-answering NLI (QNLI) using the SQUAD dataset (Rajpurkar et al., 2016), iv) question pair similarity using the Quora Question Pairs[7] dataset (QQP), v) textual entailment using recognizing textual entailment dataset(RTE) (Bentivogli et al., 2009), and vi) semantic textual similarity using the STS-B dataset (Cer et al., 2017). The statistics for the datasets are provided in Table 5.

A.2 General Neuron-level Redundancy

Table 6 presents the detailed results for the illustration in Figures 2a and 2b. As a concrete example, 6 out of 12 tasks (POS, SEM, CCG, Chunking, SST-2, STS-B) can do away with more than 85% reduction in the number of neurons (threshold=0.7) with very little loss in performance.

Figure 6 visualizes heatmaps of a few neurons that belong to the same cluster built using `CC` at $c_t = 0.3$ as a qualitative example of a cluster.

Task	Train	Dev
SST-2	67349	872
MRPC	3668	408
MNLI	392702	9815
QNLI	104743	5463
QQP	363846	40430
RTE	2490	277
STS-B	5749	1500

Table 5: Data statistics (number of sequences) on the official training and development sets used in the experiments. All tasks are binary classification tasks, except for STS-B which is a regression task. Recall that the test sets are not publicly available, and hence we use 10% of the official train as development, and the official development set as our test set. Exact split information is provided in the code README.

A.3 Task-Specific Layer-wise redundancy

Tables 7a and 7a provide detailed results used to produce the illustrations in Figure 4.

Figures 7, 8 and 9 show the layer-wise task-specific redundancy for individual classes within POS, SEM and Chunking respectively. We do not present these fine-grained plots for CCG (over 1000 classes) or sequence classification tasks (binary classification only).

A.4 Task-Specific Neuron-level Redundancy

Tables 8a and 8b provide the per-task detailed results along with reduced accuracies after running task-specific neuron-level redundancy analysis.

A.5 Application: Efficient Feature Selection

A.5.1 Transfer Learning Detailed Results

Tables 9 and 10 show the detailed per-task results for our proposed feature selection algorithm.

A.5.2 Pretrained model timing analysis

The average runtime per instance was computed by dividing the total number of seconds taken to run the forward pass for all batches by the total number of sentences. All computation was done on an NVidia GeForce GTX TITAN X, and the numbers are averaged across 3 runs. Figures 10 and 11 shows the results of various number of layers (with the selected layer highlighted for each task).

A.5.3 Training time analysis

Figures 12, 13 and 14 show the runtimes of the various steps of the proposed efficient feature se-

lection for transfer learning application. Extraction of features and correlation clustering both scale linearly as the number of input tokens increases, while ranking the various features scales linearly with the number of total features.

A.6 Center Kernel Alignment

For layer-level redundancy, we compare representations from various layers using linear Center Kernel Alignment (`cka` - Kornblith et al. (2019)). Here, we briefly present the mathematical definitions behind `cka`. Let $\mathbf{Z}$ denote a column centering transformation. As denoted in the paper, $\boldsymbol{z}_j^i$ represents the contextualized embedding for some word w_j at some layer l_i. Let $\boldsymbol{z}^i$ represent the contextual embeddings over all T words, i.e. it is of size $T \times N$ (where N is the total number of neurons). Given two layers x and y,

$$\mathbf{X}, \mathbf{Y} = \mathbf{Z}\boldsymbol{z}^x, \mathbf{Z}\boldsymbol{z}^y$$

the CKA similarity is

$$\texttt{cka}(\boldsymbol{z}^x, \boldsymbol{z}^y) := \frac{\|\mathbf{X}^T\mathbf{Y}\|^2}{\|\mathbf{X}^T\mathbf{X}\|\|\mathbf{Y}^T\mathbf{Y}\|}$$

where $\|\cdot\|$ is the Frobenius norm.

Abstract

Text classification is a critical research topic with broad applications in natural language processing. Recently, graph neural networks (GNNs) have received increasing attention in the research community and demonstrated their promising results on this canonical task. Despite the success, their performance could be largely jeopardized in practice since they are: (1) unable to capture high-order interaction between words; (2) inefficient to handle large datasets and new documents. To address those issues, in this paper, we propose a principled model – hypergraph attention networks (HyperGAT), which can obtain more expressive power with less computational consumption for text representation learning. Extensive experiments on various benchmark datasets demonstrate the efficacy of the proposed approach on the text classification task.

1 Introduction

Text classification, as one of the most fundamental tasks in the field of natural language processing, has received continuous endeavors from researchers due to its wide spectrum of applications, including sentiment analysis (Wang et al., 2016), topic labeling (Wang and Manning, 2012), and disease diagnosis (Miotto et al., 2016). Inspired by the success of deep learning techniques, methods based on representation learning such as convolutional neural networks (CNNs) (Kim, 2014) and recurrent neural networks (RNNs) (Liu et al., 2016) have been extensively explored in the past few years. In essence, the groundbreaking achievements of those methods can be attributed to their strong capability of capturing sequential context information from local consecutive word sequences.

More recently, graph neural networks (GNNs) (Kipf and Welling, 2017; Veličković et al., 201b; Hamilton et al., 2017) have drawn much attention and demonstrated their superior performance in the task of text classification (Yao et al., 2019; Wu et al., 2019a; Liu et al., 2020). This line of work leverages the knowledge from both training and test documents to construct a corpus-level graph with global word co-occurrence and document-word relations, and consider text classification as a semi-supervised node classification problem. Then with GNNs, long-distance interactions between words could be captured to improve the final text classification performance.

Despite their promising early results, the usability of existing efforts could be largely jeopardized in real-world scenarios, mainly owing to their limitations in the following two aspects: **(i)** *Expressive Power.* Existing GNN-based methods predominately focus on pairwise interactions (i.e., dyadic relations) between words. However, word interactions are not necessarily dyadic in natural language, but rather could be triadic, tetradic, or of a higher-order. For instance, consider the idiom "`eat humble pie`", whose definition is "admit that one was wrong" in common usage. If we adopt a simple graph to model the word interactions, GNNs may misinterpret the word `pie` as "a baked dish" based on its pairwise connections to other two words (`humble` – `pie` and `eat` – `pie`), then further misunderstand the actual meaning of the whole idiom. Hence, how to go beyond pairwise relations and further capture the high-order word interactions is vital for high-quality text representation learning, but still remains to be explored. **(ii)** *Computational Consumption.* On the one hand, most of the endeavors with GNN backbone tend to be memory-inefficient when the scale of data increases, due to the fact that constructing and learning on a global document-word graph consumes immense memory (Huang et al., 2019). On the other hand, the mandatory access to test documents during training renders those methods inherently *trans-*

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4927–4936,
November 16–20, 2020.

ductive. It means that when new data arrives, we have to retrain the model from scratch for handling newly added documents. Therefore, it is necessary to design a computationally efficient approach for solving graph-based text classification.

Upon the discussions above, one critical research question to ask is "*Is it feasible to acquire more expressive power with less computational consumption?*". To achieve this goal, we propose to adopt document-level hypergraph (hypergraph is a generalization of simple graph, in which a hyperedge can connect *arbitrary number of nodes*) for modeling each text document. The use of document-level hypergraphs potentially enables a learning model not only to alleviate the computational inefficiency issue, but more remarkably, to capture heterogeneous (e.g., sequential and semantic) high-order contextual information of each word. Therefore, more expressive power could be obtained with less computational consumption during the text representation learning process. As conventional GNN models are infeasible to be used on hypergraphs, to bridge this gap, we propose a new model named HyperGAT, which is able to capture the encoded high-order word interactions within each hypergraph. In the meantime, its internal dual attention mechanism highlights key contextual information for learning highly expressive text representations. To summarize, our contributions are in three-fold:

- We propose to model text documents with document-level hypergraphs, which improves the model expressive power and reduces computational consumption.
- A principled model HyperGAT based on a dual attention mechanism is proposed to support representation learning on text hypergraphs.
- We conduct extensive experiments on multiple benchmark datasets to illustrate the superiority of HyperGAT over other state-of-the-art methods on the text classification task.

2 Related Work

2.1 Graph Neural Networks

Graph neural networks (GNNs) – a family of neural models for learning latent node representations in a graph, have achieved remarkable success in different graph learning tasks (Defferrard et al., 2016; Kipf and Welling, 2017; Veličković et al., 201b; Ding et al., 2019a, 2020). Most of the prevailing GNN models follow the paradigm of neighborhood aggregation, aiming to learn latent node representations via message passing among local neighbors in the graph. With deep roots in graph spectral theory, the learning process of graph convolutional networks (GCNs) (Kipf and Welling, 2017) can be considered as a mean-pooling neighborhood aggregation. Later on, GraphSAGE (Hamilton et al., 2017) was developed to concatenate the node's feature with mean/max/LSTM pooled neighborhood information, which enables inductive representation learning on large graphs. Graph attention networks (GATs) (Veličković et al., 201b) incorporate trainable attention weights to specify fine-grained weights on neighbors when aggregating neighborhood information of a node. Recent research further extend GNN models to consider global graph information (Battaglia et al., 2018) and edge information (Gilmer et al., 2017) during aggregation. More recently, hypergraph neural networks (Feng et al., 2019; Bai et al., 2020; Wang et al., 2020) are proposed to capture high-order dependency between nodes. Our model HyperGAT is the first attempt to shift the power of hypergraph to the canonical text classification task.

2.2 Deep Text Classification

Grounded on the fast development of deep learning techniques, various neural models that automatically represent texts as embeddings have been developed for text classification. Two representative deep neural models, CNNs (Kim, 2014; Zhang et al., 2015) and RNNs (Tai et al., 2015; Liu et al., 2016) have shown their superior power in the text classification task. To further improve the model expressiveness, a series of attentional models have been developed, including hierarchical attention networks (Yang et al., 2016), attention over attention (Cui et al., 2017), etc. More recently, graph neural networks have shown to be a powerful tool for solving the problem of text classification by considering the long-distance dependency between words. Specifically, TextGCN (Yao et al., 2019) applies the graph convolutional networks (GCNs) (Kipf and Welling, 2017) on a single large graph built from the whole corpus, which achieves state-of-the-art performance on text classification. Later on, SGC (Wu et al., 2019a) is proposed to reduce the unnecessary complexity and redundant computation of GCNs, and shows competitive results with superior time efficiency. TensorGCN (Liu et al., 2020) proposes a text graph tensor to learn word and document embeddings by incorporating more context information. (Huang et al., 2019) propose to learn text representations on document-level graphs. However, those transductive methods are computationally inefficient and cannot capture the high-order interactions between words for improving model expressive power.

3 Methodology

In this section, we introduce a new family of GNN models developed for inductive text classification. By reviewing the existing GNN-based endeavors, we first summarize their main limitations that need to be addressed. Then we illustrate how we use hypergraphs to model text documents for achieving the goals. Finally, we propose the model HyperGAT based on a new dual attention mechanism and model training for inductive text classification.

3.1 GNNs for Text Classification

With the booming development of deep learning techniques, graph neural networks (GNNs) have achieved great success in representation learning on graph-structured data (Zhou et al., 2018; Ding et al., 2019b). In general, most of the prevailing GNN models follow the neighborhood aggregation strategy, and a GNN layer can be defined as:

$$\mathbf{h}_i^l = \textsc{Aggr}^l\Big(\mathbf{h}_i^{l-1}, \{\mathbf{h}_j^{l-1} | \forall j \in \mathcal{N}_i\}\Big), \qquad (1)$$

where $\mathbf{h}_i^l$ is the node representation of node i at layer l (we use $\mathbf{x}_i$ as $\mathbf{h}_i^0$) and $\mathcal{N}_i$ is the local neighbor set of node i. AGGR is the aggregation function of GNNs and has a series of possible implementations (Kipf and Welling, 2017; Hamilton et al., 2017; Veličković et al., 201b).

Given the capability of capturing long-distance interactions between entities, GNNs also have demonstrated promising performance on text classification (Yao et al., 2019; Wu et al., 2019b; Liu et al., 2020). The prevailing approach is to build a corpus-level document-word graph and try to classify documents through semi-supervised node classification. Despite their success, most of the existing efforts suffer from the computational inefficiency issue, not only because of the mandatory access of test documents, but also the construction of corpus-level document-word graphs. In the meantime, those methods are largely limited by the expressibility of using simple graphs to model word interactions. Therefore, how to improve model expressive power with less computational consumption is a challenging and imperative task to solve.

3.2 Documents as Text Hypergraphs

To address the aforementioned challenges, in this study, we alternatively propose to model text documents with document-level hypergraphs. Formally, hypergraphs can be defined as follows:

Definition 3.1 ***Hypergraphs**: A hypergraph is defined as a graph $G = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = \{v_1, \dots, v_n\}$ represents the set of nodes in the graph, and $\mathcal{E} = \{e_1, \dots, e_m\}$ represents the set of hyperedges. Note that for any hyperedge e, it can connect two or more nodes (i.e., $\sigma(e) \geq 2$).*

Notably, the topological structure of a hypergraph G can also be represented by an incidence matrix $\mathbf{A} \in \mathbb{R}^{n \times m}$, with entries defined as:

$$\mathbf{A}_{ij} = \begin{cases} 1, \text{if } v_i \in e_j, \\ 0, \text{if } v_i \notin e_j. \end{cases} \qquad (2)$$

In the general case, each node in hypergraphs could come with a d-dimensional attribute vector. Therefore, all the node attributes can be denoted as $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n]^{\mathrm{T}} \in \mathbb{R}^{n \times d}$, and we can further use $G = (\mathbf{A}, \mathbf{X})$ to represent the whole hypergraph for simplicity.

For a text hypergraph, nodes represent words in the document and node attributes could be either one-hot vector or the pre-trained word embeddings (e.g., word2vec, GloVe). In order to model heterogeneous high-order context information within each document, we include multi-relational hyperedges as follows:

Sequential Hyperedges. Sequential context depicts the language property of local co-occurrence between words, which has demonstrated its effectiveness for text representation learning (Yao et al., 2019). To leverage the sequential context information of each word, we first construct sequential hyperedges for each document in the corpus. One natural way is to adopt a fixed-size sliding window to obtain global word co-occurrence as the sequential context. Inspired by the success of hierarchical attention networks (Yang et al., 2016), here we consider each sentence as a hyperedge and it connects all the words in this sentence. As another benefit, using sentences as sequential hyperedges enables our model to capture the document structural information at the same time.

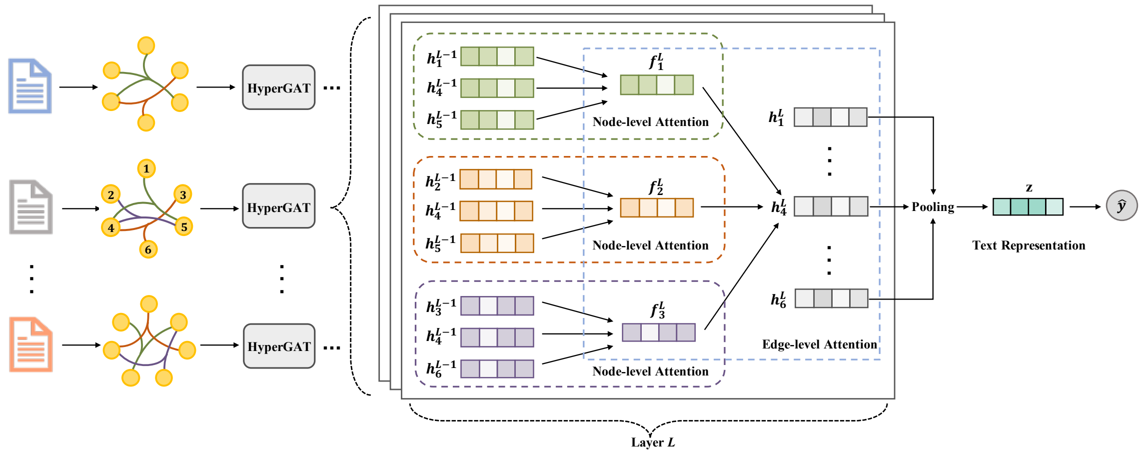

Figure 1: Illustration of the proposed hypergraph attention networks (HyperGAT) for inductive text classification. We construct a hypergraph for each text document and feed it into HyperGAT. Based on the node and edge-level attention, text representations that capture high-order word interactions can be derived. Figure best viewed in color.

Semantic Hyperedges. Furthermore, in order to enrich the semantic context for each word, we build semantic hyperedges to capture topic-related high-order correlations between words (Linmei et al., 2019). Specifically, we first mine the latent topics T from the text documents using LDA (Blei et al., 2003) and each topic $t_i = (\boldsymbol{\theta}_1, ..., \boldsymbol{\theta}_w)$ (w denotes the vocabulary size) can be represented by a probability distribution over the words. Then for each topic, we consider it as a semantic hyperedge that connects the top K words with the largest probabilities in the document. With those topic-related hyperedges, we are able to enrich the high-order semantic context of words in each document.

It is worth mentioning that though we only discuss sequential and semantic hyperedges in this study, other meaningful hyperedges (e.g., syntactic-related) could also be integrated into the proposed model for further improving the model expressiveness and we leave this for future work.

3.3 Hypergraph Attention Networks

To support text representation learning on the constructed text hypergraphs, we then propose a new model called HyperGAT (as shown in Figure 1) in this section. Apart from conventional GNN models, HyperGAT learns node representations with two different aggregation functions, allowing to capture heterogeneous high-order context information of words on text hypergraphs. In general, a HyperGAT layer can be defined as:

$$\begin{aligned} \mathbf{h}_i^l &= \textsc{Aggr}_{edge}^l\Big(\mathbf{h}_i^{l-1}, \{\mathbf{f}_j^l | \forall e_j \in \mathcal{E}_i\}\Big), \\ \mathbf{f}_j^l &= \textsc{Aggr}_{node}^l\Big(\{\mathbf{h}_k^{l-1} | \forall v_k \in e_j\}\Big), \end{aligned} \tag{3}$$

where $\mathcal{E}_i$ denotes the set of hyperedges connected to node v_i and $\mathbf{f}_j^l$ is the representation of hyperedge e_j in layer l. $\textsc{Aggr}_{edge}$ is an aggregation function that aggregates features of hyperedges to nodes and $\textsc{Aggr}_{node}$ is another aggregation function that aggregates features of nodes to hyperedges. In this work, we propose to implement those two functions based on a dual attention mechanism. We will start by describing a single layer l for building arbitrary HyperGAT architectures as follows:

Node-level Attention. Given a specific node v_i, our HyperGAT layer first learns the representations of all its connected hyperedges $\mathcal{E}_i$. As not all the nodes in a hyperedge $e_j \in \mathcal{E}_i$ contribute equally to the hyperedge meaning, we introduce attention mechanism (i.e., node-level attention) to highlight those nodes that are important to the meaning of the hyperedge and then aggregate them to compute the hyperedge representation $\mathbf{f}_j^l$. Formally:

$$\mathbf{f}_j^l = \sigma\Bigg(\sum_{v_k \in e_j} \alpha_{jk} \mathbf{W}_1 \mathbf{h}_k^{l-1}\Bigg), \tag{4}$$

where σ is the nonlinearity such as ReLU and $\mathbf{W}_1$ is a trainable weight matrix. α_{jk} denotes the attention coefficient of node v_k in the hyperedge e_j, which can be computed by:

$$\begin{aligned} \alpha_{jk} &= \frac{\exp(\mathbf{a}_1^{\mathrm{T}} \mathbf{u}_k)}{\sum_{v_p \in e_j} \exp(\mathbf{a}_1^{\mathrm{T}} \mathbf{u}_p)}, \\ \mathbf{u}_k &= \mathrm{LeakyReLU}(\mathbf{W}_1 \mathbf{h}_k^{l-1}), \end{aligned} \tag{5}$$

where $\mathbf{a}_1^{\mathrm{T}}$ is a weight vector (a.k.a, context vector).

Edge-level Attention. With all the hyperedges representations $\{\mathbf{f}_j^l | \forall e_j \in \mathcal{E}_i\}$, we again apply an edge-level attention mechanism to highlight the informative hyperedges for learning the next-layer representation of node v_i. This process can be formally expressed as:

$$\mathbf{h}_i^l = \sigma\left(\sum_{e_j \in \mathcal{E}_i} \beta_{ij} \mathbf{W}_2 \mathbf{f}_j^l\right), \tag{6}$$

where $\mathbf{h}_i^l$ is the output representation of node v_i and $\mathbf{W}_2$ is a weight matrix. β_{ij} denotes the attention coefficient of hyperedge e_j on node v_i, which can be computed by:

$$\begin{aligned} \beta_{ij} &= \frac{\exp(\mathbf{a}_2^{\mathrm{T}} \mathbf{v}_j)}{\sum_{e_p \in \mathcal{E}_i} \exp(\mathbf{a}_2^{\mathrm{T}} \mathbf{v}_p)}, \\ \mathbf{v}_j &= \mathrm{LeakyReLU}([\mathbf{W}_2 \mathbf{f}_j^l || \mathbf{W}_1 \mathbf{h}_i^{l-1}]), \end{aligned} \tag{7}$$

where $\mathbf{a}_2^{\mathrm{T}}$ is another weight (context) vector for measuring the importance of the hyperedges and $||$ is the concatenation operation.

The proposed dual attention mechanism enables a HyperGAT layer not only to capture the high-order word interactions, but also to highlight the key information at different granularities during the node representation learning process.

3.4 Inductive Text Classification

For each document, after going through L HyperGAT layers, we are able to compute all the node representations on the constructed text hypergraph. Then we apply the *mean-pooling* operation on the learned node representations $\mathbf{H}^L$ to obtain the document representation $\mathbf{z}$, and feed it to a softmax layer for text classification. Formally:

$$\hat{\mathbf{y}} = \mathrm{softmax}\big(\mathbf{W}_c \mathbf{z} + \mathbf{b}_c\big), \tag{8}$$

where $\mathbf{W}_c$ is a parameter matrix mapping the document representation into an output space and $\mathbf{b}_c$ is the bias. $\hat{\mathbf{y}}$ denotes the predicted label scores. Specifically, the loss function of text classification is defined as the cross-entropy loss:

$$\mathcal{L} = -\sum_d \log(\hat{\mathbf{y}}_j^d), \tag{9}$$

where j is the ground truth label of document d. Thus HyperGAT can be learned by minimizing the above loss function over all the labeled documents.

Note that HyperGAT eliminates the mandatory access of test documents during training, making the model different from existing GNN-based methods. For unseen documents, we can directly feed their corresponding text hypergraphs to the previously learned model and compute their labels. Hence, we can handle the newly added data in an inductive way instead of retraining the model.

4 Experiments

4.1 Experimental Setting

Evaluation Datasets. To conduct a fair and comprehensive evaluation, we adopt five benchmark datasets from different domains in our experiments: 20-Newsgroups (20NG), Reuters (R8 and R52), Ohsumed, and Movie Review (MR). Those datasets have been widely used for evaluating graph-based text classification performance (Yao et al., 2019; Huang et al., 2019; Liu et al., 2020). Specifically, the 20-Newsgroups dataset and two Reuters datasets are used for news classification. The Ohsumed dataset is medical literature. The Movie Review dataset is collected for binary sentiment classification. A summary statistics of the benchmark datasets is presented in table 1 and more detailed descriptions can be found in (Yao et al., 2019). For quantitative evaluation, we follow the same train/test splits and data preprocessing procedure in (Yao et al., 2019) in our experiments. In each run, we randomly sample 90% of the training samples to train the model and use the left 10% data for validation. More details can be found in Appendix A.1.

Compared Methods. In our experiments, the baselines compared with our model HyperGAT can be generally categorized into three classes: (i) *word embedding-based* methods that classify documents based on pre-trained word embeddings, including fastText (Joulin et al., 2016), and more advanced methods SWEM (Shen et al., 2018) and LEAM (Wang et al., 2018); (ii) *sequence-based* methods which capture text fea-

tures from local consecutive word sequences, including CNNs (Kim, 2014), LSTMs (Liu et al., 2016), and Bi-LSTM (Huang et al., 2015); (iii) *graph-based* methods that aim to capture interactions between words, including Graph-CNN (Defferrard et al., 2016), two versions of TextGCN (Yao et al., 2019) and Text-level GNN (Huang et al., 2019). Note that TextGCN (transductive) is the model proposed in the original paper and TextGCN (inductive) is the inductive version implemented by the same authors. Text-level GNN is a state-of-the-art baseline which performs text representation learning on document-level graphs. More details of baselines can be found in (Yao et al., 2019).

Implementation Details. HyperGAT is implemented by PyTorch and optimized with the Adam optimizer. We train and test the model on a 12 GB Titan Xp GPU. Specifically, our HyperGAT model consists of two layers with 300 and 100 embedding dimensions, respectively. We use one-hot vectors as the node attributes and the batch size is set to 8 for all the datasets. The optimal values of hyperparameters are selected when the model achieves the highest accuracy for the validation samples. The optimized learning rate α is set to 0.0005 for MR and 0.001 for the other datasets. L2 regularization is 10^{-6} and dropout rate is 0.3 for the best performance. For learning HyperGAT, we train the model for 100 epochs with early-stopping strategy. To construct the semantic hyperedges, we train an LDA model for each dataset using the training documents and select the Top-10 words from each topic. The topic number is set to the same number of classes. For baseline models, we either show the results reported in previous research (Yao et al., 2019) or run the codes provided by the authors using the parameters described in the original papers. *More details can be found in the Appendix A.2.* Our data and source code is available at `https://github.com/kaize0409/HyperGAT`.

4.2 Experimental Results

Classification Performance. We first conduct comprehensive experiments to evaluate model performance on text classification and present the results in Table 2. Overall, our model HyperGAT outperforms all the baselines on the five evaluation datasets, which demonstrates its superior capability in text classification. In addition, we can make the following in-depth observations and analysis:

- *Graph-based* methods, especially GNN-based models are able to achieve superior performance over the other two categories of baselines on the first four datasets. This observation indicates that text classification performance can be directly improved by capturing long-distance word interactions. While for the MR dataset, *sequence-based* methods (CNNs and LSTMs) show stronger classification capability than most of the *graph-based* baselines. One potential reason is that sequential context information plays a critical role in sentiment classification, which cannot be explicitly captured by the majority of existing *graph-based* methods.

- Not surprisingly, without the additional knowledge on test documents, the performance of

Model	TextGCN (transductive)	HyperGAT
20NG	1,4479.36MB	180.33MB
R8	931.58MB	41.75MB
R52	1289.48MB	46.85MB
Ohsumed	1822.71MB	63.17MB
MR	3338.24MB	80.99MB

Table 3: GPU memory consumption of different methods. The batch size for HyperGAT is set to 8.

TextGCN (inductive) largely falls behind its original transductive version. Though Text-level GNN is able to achieve performance improvements by adding trainable edge weights between word, its performance is still limited by the information loss of using pairwise simple graph. In particular, our model HyperGAT achieves considerable improvements over other GNN-based models, demonstrating the importance of high-order context information for learning word representations.

Computational Efficiency. Table 3 presents the computational cost comparison between the most representative transductive baseline TextGCN and our approach. Form the reported results, we can clearly find that HyperGAT has a significant computational advantage in terms of memory consumption. The main reason is that HyperGAT conducts text representation learning at the document-level and it only needs to store a batch of small text hypergraphs during training. On the contrary, TextGCN requires constructing a large document-word graph using both training and test documents, which inevitably consumes a great amount of memory. Another computational advantage of our model is that HyperGAT is an inductive model that can generalize to unseen documents. Thus we do not have to retrain the whole model for newly added documents like transductive methods.

Model Sensitivity. The model performance on 20NG and Ohsumed with different first-layer embedding dimensions is reported in Figure 2, and we omit the results on other datasets since similar results can be observed. Notably, the best performance of HyperGAT is achieved when the first-layer embedding size is set to 300. It indicates that small embedding size may render the model less expressive, while the model may encounter overfitting if the embedding size is too large. In the meantime, to evaluate the effect of the size of labeled training data, we compare several best performing models with different proportions of the training data and report the results on Ohsumed and MR in Figure 3. In general, with the growth of labeled training data, all the evaluated methods can achieve performance improvements. More remarkably, HyperGAT can significantly outperform other baselines with limited labeled data, showing its effectiveness in real-world scenarios.

4.3 Ablation Analysis

To investigate the contribution of each module in HyperGAT, we conduct an ablation analysis and report the results in Table 4. Specifically, *w/o attention* is a variant of HyperGAT that replaces the dual attention with convolution. *w/o sequential* and *w/o semantic* are another two variants by excluding sequential, semantic hyperedges, respectively. From the reported results we can learn that HyperGAT can achieve better performance by stacking more layers. This observation can verify the usefulness of long-distance word interactions for text representation learning. Moreover, the performance gap between *w/o attention* and HyperGAT shows the effectiveness of the dual attention mechanism for learning more expressive word representations. By comparing the results of *w/o sequential* and *w/o semantic*, we can learn that the context informa-

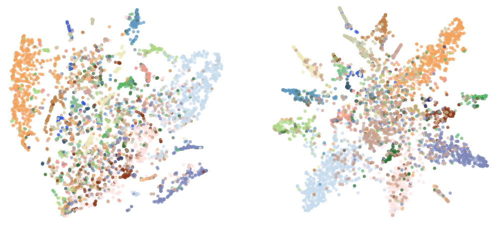
tion encoded by the sequential hyperedges is more important, but adding semantic hyperedges can enhance the model expressiveness. It also indicates that heterogeneous high-order context information can complement each other and we could investigate more meaningful hyperedges to further improve the performance of our approach.

4.4 Case Study

Embedding Visualization. In order to show the superior embedding quality of HyperGAT over other methods, we use t-SNE (Maaten and Hinton, 2008) to visualize the learned representations of documents for comparison. Specifically, Figure 4 shows the visualization results of the best performing baseline Text-level GNN and HyperGAT on the test documents of Ohsumed. Note that the node's color corresponds to its label, which is used to verify the model's expressive power on 23 document classes. From the embedding visualization, we are able to observe that HyperGAT can learn more expressive document representations over the state-of-the-art method Text-level GNN.

Attention Visualization. To better illustrate the learning process of the proposed dual attention mechanism, we take a text document from 20NG (labeled as *sport.baseball* correctly) and visualize the attention weights computed for the word `player`. As shown in Figure 5, `player` is connected to four hyperedges within the constructed document-level hypergraph. The first three lines ended with periods represent sequential hyperedges, while the last one without a period is a semantic hyperedge. Note that we use orange to denote the node-level attention weight and blue to denote the edge-level attention weight. Darker color represents larger attention weight.



(a) **Text-level GNN** (b) **HyperGAT**

player

we cannot isolate the total contribution that any player at any position .

they can always find a player a little bit better than one on they already have .

the best player is the one who does the most things to help his team win .

player team baseball win

Figure 5: Visualization of the dual attention mechanism in HyperGAT. Figure best viewed in color.

On the one hand, node-level attention is able to select those nodes (words) carrying informative context on the same hyperedge. For example, `win` and `team` in the third hyperedge gain larger attention weights since they are more expressive compared to other words in the same sentence. On the other hand, edge-level attention can also assign fine-grained weights to highlight meaningful hyperedges. As we can see, the last hyperedge that connects `player` with `baseball` and `win` receives higher attention weight since it can better characterize the meaning of `player` in the document. To summarize, this case study shows that our proposed dual attention can capture key information at different granularities for learning expressive text representations.

5 Conclusion

In this study, we propose a new graph-based method for solving the problem of inductive text classification. Apart from the existing efforts, we propose to model text documents with document-level hypergraphs and further develop a new family of GNN model named HyperGAT for learning discriminative text representations. Specifically, our method is able to acquire more expressive power with less computational consumption for text representation learning. By conducting extensive experiments, the results demonstrate the superiority of the proposed model over the state-of-the-art methods.

A Appendix

A.1 Implementation Details

As the supplement to Section 4, in the following, we explain the implementation of HyperGAT.

LDA Model Training. We use the implementation provided in scikit-learn to train the LDA model. We only use the documents in the training set to train the LDA model for each dataset. We select to use the Online Variational Bayes method for model learning. We set the random state is set to be 0 and the learning offset to be 50. As for the other parameters, we follow the default setting provided by scikit-learn. The topic number is set to be the same as the number of classes for each of the datasets. And we select the Top-10 keywords of each topic to construct the semantic hyperedges.

Implementation of HyperGAT. The proposed HyperGAT model is implemented in PyTorch and optimized with the Adam optimizer (Kingma and Ba, 2014). It is trained and tested on a 12 GB Titan Xp GPU. Specifically, the hypergraph attention network consists of two layers with 300 and 100 embedding dimensions, respectively. We use one-hot vectors as the node attributes. The batch size is set to be 8 for all the datasets. We grid search for the learning rate in $\{0.0001, 0.0005, 0.001, 0.005, 0.01, 0.05, 0.1\}$, L2 regularization in $\{10^{-6}, 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ and the dropout rate in $\{0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7\}$. The optimal values are selected when the model achieves the highest accuracy for the validation samples. The optimized learning rate α for MR is 0.0005 while that for the other datasets is 0.001. We select the L2 regularization to be 10^{-6} and the dropout rate to be 0.3 for the best performance. For each dataset, we train the model for 100 epochs or stop if the performance for the validation doesn't increase for 5 consecutive epochs as an early-stopping strategy. Under the optimized setup, the model can converge in 587s, 145s, 156s, 97s and 78s on average for 20NG, R8, R52, Ohsumed and MR, respectively.

Validation Performance. As supplement to the test results in Table 2, we also report the corresponding validation performance of the proposed HyperGAT. The validation accuracy is 0.9355 ± 0.0011, 0.9755 ± 0.0019, 0.9375 ± 0.0023, 0.6964 ± 0.0024 and 0.7779 ± 0.0015 for 20NG, R8, R52, Ohsumed and MR, respectively.

A.2 Space Complexity Analysis

Theoretically, the main difference of memory usage between HyperGAT and other methods lies in the size of the adjacency matrix. Formally, let N denote vocabulary size and M denote document size. Take TextGCN as an example, the size of the adjacency matrix is $(N + M)^2$. As HyperGAT adopts document-level hypergraphs, for each hypergraph, the adjacency matrix size is $n \times m$, where n is the number of words and m is the number of hyperedges in a document. Based on mini-batch training, the memory consumption for each mini-batch is about $n \times m \times bsz$. Since N and M are way larger than n and m, the memory consumption of HyperGAT can be largely reduced in practice.

Entities as Experts: Sparse Memory Access with Entity Supervision

Abstract

We focus on the problem of capturing declarative knowledge about entities in the learned parameters of a language model. We introduce a new model—Entities as Experts (EAE)—that can access distinct memories of the entities mentioned in a piece of text. Unlike previous efforts to integrate entity knowledge into sequence models, EAE's entity representations are learned directly from text. We show that EAE's learned representations capture sufficient knowledge to answer TriviaQA questions such as *"Which Dr. Who villain has been played by Roger Delgado, Anthony Ainley, Eric Roberts?"*, outperforming an encoder-generator Transformer model with 10× the parameters. According to the LAMA knowledge probes, EAE contains more factual knowledge than a similarly sized BERT, as well as previous approaches that integrate external sources of entity knowledge. Because EAE associates parameters with specific entities, it only needs to access a fraction of its parameters at inference time, and we show that the correct identification and representation of entities is essential to EAE's performance.

1 Introduction

Neural network sequence models, pre-trained as language models, have recently revolutionized text understanding (Dai and Le, 2015; Peters et al., 2018; Howard and Ruder, 2018; Devlin et al., 2018), and recent work has suggested that they could take the place of curated knowledge bases or textual corpora for tasks such as question answering (Petroni et al., 2019; Roberts et al., 2020).

In this paper, we focus on developing neural sequence models that capture the knowledge required to answer questions about real world entities. To this end, we introduce a new model architecture that can access distinct and independent representations of the entities mentioned in text. Unlike other efforts to inject entity specific knowledge into sequence models (Peters et al., 2019; Zhang et al., 2019; Poerner et al., 2019) our model learns entity representations from text along with all the other model parameters. We call our model Entities as Experts (EAE), since it divides the parameter space according to entity identity. This name also reflects EAE's similarities with the Massive Mixture of Experts (Shazeer et al., 2017), as well as other work that integrates learned memory stores into sequence models (Weston et al., 2014; Lample et al., 2019).

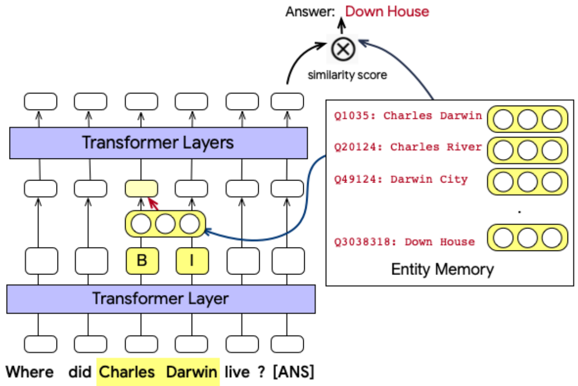

Figure 1: Our model with an entity memory, applied to the open domain QA task. The red arrows shows the integration of the entity and token representations.

To understand the motivation for distinct and independent entity representations, consider Figure 1. A traditional Transformer (Vaswani et al., 2017) needs to build an internal representation of Charles Darwin from the words "Charles" and "Darwin", both of which can also refer to different entities such as the Charles River, or Darwin City. Conversely, EAE can access a dedicated representation of "Charles Darwin", which is a memory of all of the contexts in which this entity has previously been mentioned. This memory can also be accessed for other mentions of Darwin, such as "Charles

November 16–20, 2020. ©2020 Association for Computational Linguistics

Robert Darwin" or "the father of natural selection". Retrieving and re-integrating this memory makes it easier for EAE to find the answer.

We train EAE to predict masked-out spans in English Wikipedia text (Devlin et al., 2018); to only access memories for entity mention spans; and to access the correct memory for each entity mention. Mention span supervision comes from an existing mention detector, and entity identity supervision comes from Wikipedia hyperlinks. By associating memories with specific entities, EAE can learn to access them sparsely. The memory is only accessed for spans that mention entities, and only the mentioned memories need to be retrieved.

We evaluate EAE's ability to capture declarative knowledge using the LAMA knowledge probes introduced by Petroni et al. (2019), as well as the open-domain variants of the TriviaQA and WebQuestions question answering tasks (Joshi et al., 2017; Berant et al., 2013). On both tasks, EAE outperforms related approaches with many more parameters. An in-depth analysis of EAE's predictions on TriviaQA shows that the correct identification and reintegration of entity representations is essential for EAE's performance.

We further demonstrate that EAE's learned entity representations are better than the pre-trained embeddings used by Zhang et al. (2019); Peters et al. (2019) at knowledge probing tasks and the TACRED relation extraction task (Zhang et al., 2017; Alt et al., 2020). We show that training EAE to focus on entities is better than imbuing a similar-sized network with an unconstrained memory store, and explain how EAE can outperform much larger sequence models while only accessing a small proportion of its parameters at inference time.

2 Approach

Let $\mathcal{E} = \{e_1 \dots e_N\}$ be a predefined set of entities, and let $\mathcal{V} = \{[\text{MASK}], w_1 \dots w_M\}$ be a vocabulary of tokens. A *context* $\mathbf{x} = [x_0 \dots x_L]$ is a sequence of tokens $x_i \in \mathcal{V}$. Each context comes with the list of the *mentions* it contains, $\mathbf{m} = [m_0 \dots m_M]$, where each mention $m_i = (e_{m_i}, s_{m_i}, t_{m_i})$ is defined by its linked entity e_{m_i}, start token index s_{m_i} and end token index t_{m_i}. Entity mentions might not be linked to a specific entity in $\mathcal{E}$, thus $e_{m_i} \in \mathcal{E} \cup e_\varnothing$, where $e_\varnothing$ refers to the null entity.

2.1 Model Architecture

The basic model architecture follows the Transformer (Vaswani et al., 2017), interleaved with our entity memory layer. Our model has two embedding matrices – token and entity embeddings. Figure 2 illustrates our model. Our model is:

$$\begin{aligned}
\mathbf{X}^0 &= \texttt{TokenEmbed}(\mathbf{x}) \\
\mathbf{X}^1 &= \texttt{Transformer}(\mathbf{X}^0, \texttt{num\_layers} = l_0) \\
\mathbf{X}^2 &= \texttt{EntityMemory}(\mathbf{X}^1) \\
\mathbf{X}^3 &= \texttt{LayerNorm}(\mathbf{X}^2 + \mathbf{X}^1) \\
\mathbf{X}^4 &= \texttt{Transformer}(\mathbf{X}^3, \texttt{num\_layers} = l_1) \\
\mathbf{X}^5 &= \texttt{TaskSpecificHeads}(\mathbf{X}^4)
\end{aligned}$$

The entity memory layer constructs an entity embedding E_{m_i} for each mention m_i. The output of the entity memory layer and preceding transformer layer are summed, normalized, then processed by additional transformer layers. Throughout this work we use $l_0 = 4$ and $l_1 = 8$.

Entity Memory Layer Let $\mathbf{E}$ be a matrix of learned entity embeddings of shape (N, d_{ent}). $\texttt{EntEmbed}(e_i)$ maps an entity e_i to its row in $\mathbf{E}$. The entity memory layer takes the output sequence from the preceding transformer layer ($\mathbf{X}^l$) and outputs a new sequence ($\mathbf{X}^{l+1}$), sparsely populated with entity representations. For each entity mention m_i, the output sequence has an entity representation, a projection of the weighted sum of entity embeddings in $\mathbf{E}$, at position s_{m_i}.

$$x_i^{l+1} = \mathbf{W}_b E_{m_k} \quad \texttt{if} \quad i = s_{m_k} \tag{1}$$

where $\mathbf{W}_b$ maps the entity representation E_{m_k} to the dimension of x_i^l.

We now describe how to generate E_{m_i} for each mention m_i. First, we generate a pseudo entity embedding h_{m_i} based on the mention's span representation $[x^l_{s_{m_i}} || x^l_{t_{m_i}}]$, a concatenation of its start and tail representations.

$$h_{m_i} = \mathbf{W_f}[x^l_{s_{m_i}} || x^l_{t_{m_i}}] \tag{2}$$

where $\mathbf{W_f}$ is of shape $(d_{ent}, 2 \cdot d_{emb})$, where d_{emb} is the dimension of $\mathbf{X^1}$.

We find the k nearest entity embeddings of h_{m_i} from $\mathbf{E}$ by computing the dot product, and E_{m_i} is a weighted sum of them. More formally:

$$E_{m_i} = \sum_{e_j \in \texttt{topK}(\mathcal{E}, h_{m_i}, k)} \alpha_j \cdot (\texttt{EntEmbed}(e_j))$$

$$\alpha_j = \frac{\exp(\texttt{EntEmbed}(e_j) \cdot h_{m_i})}{\sum_{e \in \texttt{topK}(\mathcal{E}, h_{m_i}, k)} \exp(\texttt{EntEmbed}(e) \cdot h_{m_i})}$$

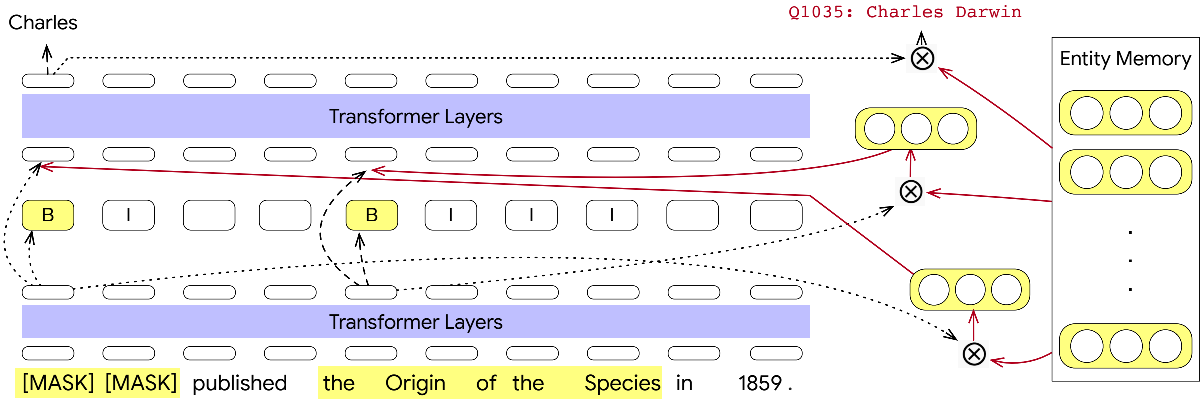

Figure 2: The **E**ntities **as** **E**xperts model: the initial transformer layer output is used (i) to predict mention boundaries, (ii) to retrieve entity embeddings from entity memory, and (iii) to construct input to the next transformer layer, augmented with the retrieved entity embeddings of (ii). The final transformer block output is connected to task specific heads: token prediction and entity prediction. The entity retrieval after the first transformer layer (ii) is also supervised with an entity linking objective during pre-training.

Where $\mathtt{topK}(\mathcal{E}, h_{m_i}, k)$ returns the k entities that yield the highest score $\mathtt{EntEmbed}(e_j) \cdot h_{m_i}$. We use $k = N$ to train and use $k = 100$ at inference (see Section 4.1 and 6.3).

The entity memory layer can be applied to any sequence output without loss of generality. We apply it to the output of the first Transformer.

Task-Specific Heads The final transformer layer can be connected to multiple task specific heads. In our experiments, we introduce two heads: `TokenPred` and `EntityPred`.

The `TokenPred` head predicts masked tokens for a cloze task. Each masked token's final representation x_i^4 is fed to an output softmax over the token vocabulary, as in BERT.

The `EntityPred` head predicts entity ids for each entity mention span (i.e., entity linking). We build the pseudo entity embedding (h_{m_i}) from the last sequence output (X^4). Then, the model predicts the entity whose embedding in $\mathbf{E}$ is the closest to the pseudo entity embedding.

Inference-time Mention Detection We introduce a mention detection layer to avoid dependence at inference on an external mention detector. The mention detection layer applies a BIO[1] classifier to the first transformer block's output. We decode the entire BIO sequence, ensuring that inconsistent sequences are disallowed. We use inferred mention spans at inference for all our experiments.

2.2 Training

2.2.1 Data and Preprocessing

We assume access to a corpus $\mathcal{D} = \{(\mathbf{x_i}, \mathbf{m_i})\}$, where all entity mentions are detected but not necessarily all linked to entities. We use English Wikipedia as our corpus, with a vocabulary of 1m entities. Entity links come from hyperlinks, leading to 32m 128 byte contexts containing 17m entity links. Non-overlapping entity mention boundaries come from hyperlinks and the Google Cloud Natural Language API[2] leading to 140m mentions.

We remove 20% of randomly chosen entity mentions (all tokens in the mention boundaries are replaced with [MASK]) to support a masked language modeling objective. See Appendix B for full details of our pre-processing and pre-training hyperparameters.

2.2.2 Learning Objective

The pre-training objective is the sum of (1) a mention boundary detection loss, (2) an entity linking loss, and (3) a masked language modeling loss.

Mention Detection The BIO classification of tokens is supervised with a cross-entropy loss over the labels. Assuming the mention boundaries are complete, we apply this supervision to all tokens.

Entity Linking We use the hyperlinked entities e_{m_i} to supervise entity memory assess. For each hyperlinked mention $m_i = (e_{m_i}, s_{m_i}, t_{m_i})$, where

---

[1] In a BIO encoding, each token is classified as being the Beginning, Inside, or Outside of a mention.

[2] https://cloud.google.com/natural-language/docs/basics#entity_analysis

$e_i \neq e_\varnothing$, the pseudo embedding h_{m_i} (Equation 2) should be close to the entity embedding of the annotated entity, $\texttt{EntEmbed}(e_{m_i})$.

$$\texttt{ELLoss} = \sum_{m_i} \alpha_i \cdot \mathbb{1}_{e_{m_i} \neq e_\varnothing}$$
$$\alpha_i = \frac{\exp(\texttt{EntEmbed}(e_{m_i}) \cdot h_{m_i})}{\sum_{e \in \mathcal{E}} \exp(\texttt{EntEmbed}(e) \cdot h_{m_i})}$$

Note that this loss is not applied to 88% of mentions, which do not have hyperlinks. Memory access for those mentions is unsupervised. The same loss is used for the `EntityPred` head.

Masked Language Modelling We follow BERT, and train the `TokenPred` head to independently predict each of the masked out tokens in an input context, using a cross-entropy loss over $\mathcal{V}$.

3 Related Work

Knowledge-augmented language models Our work shares inspiration with other approaches seeking to inject knowledge into language models (Ahn et al., 2016; Yang et al., 2016; Logan et al., 2019; Zhang et al., 2019; Levine et al., 2019; Xiong et al., 2019a; Peters et al., 2019; Poerner et al., 2019; Wang et al., 2020). These have used a variety of knowledge sources (WikiData, WordNet relations, outputs from dependency parsers) and additional training objectives (synonym and hyponym-hypernym prediction, word-supersense prediction, replaced entity detection, predication prediction, dependency relation prediction, entity linking).[3] Our focus is on adding knowledge about entities, so our work is closer to Zhang et al. (2019); Peters et al. (2019); Xiong et al. (2019b); Wang et al. (2020); Poerner et al. (2019) than to the linguistically-augmented approaches of Levine et al. (2019); Lauscher et al. (2019). Closest to our work, KNOWBERT (Peters et al., 2019) introduce an entity memory layer that is similar to the one in EAE. In contrast with our work, KNOWBERT starts from the BERT checkpoint, does not train with a knowledge-focused objective such as our mention-masking input function and uses pre-computed entity representations when integrating the information from knowledge bases. In addition, KNOWBERT relies on a fixed, pre-existing candidate detector (alias table) to identify potential candidates and entities for a span while our model learns to detect mentions. We compare to their approach in Section 7.

Memory Augmented Neural Networks Our entity memory layer is closely tied to memory-based neural layers (Weston et al., 2014; Sukhbaatar et al., 2015). In particular, it can be seen as a memory network where memory access is supervised through entity linking, and memory slots each correspond to a learned entity representation. When unconstrained, these memory networks can be computationally expensive and supervising access through entity linking limits this issue. Another approach to scale memory networks is given by Lample et al. (2019) who introduce product-key memories to efficiently index a large store of values.

Conditional Computation Conditional computation models seek to increase model capacity without a proportional increase in computational complexity. This is usually done through routing, where only a subset of the network is used to process each input. To facilitate such routing, approaches such as large mixture of experts (Shazeer et al., 2017) or gating (Eigen et al., 2013; Cho and Bengio, 2014) have been used. Our method proposes entities as experts, which allows us to supervise memory access at two levels. We only access memories for entity mentions, and we only need to access memories for the entities that were mentioned.

4 Models Evaluated

We evaluate EAE on cloze knowledge probes, open-domain question answering and relation extraction. Here, we describe baselines from previous work and ablations.

4.1 The Entities as Experts models

Our primary model, **E**ntities **A**s **E**xperts embeds the input using the token embedding layer, then passes it through 4 transformer layers. This output is used for the entity memory layer, which uses embeddings of size 256, then passed through an additional 8 transformer layers. Finally, the model has a `TokenPred` head and an `EntityPred` head. In EAE, hyper-parameters for the transformer layers are identical to those in BERT-base (Devlin et al., 2018).

Sparse Activation in EaE EAE only accesses the entity embedding matrix for mention spans, and we only retrieve $k = 100$ entity memories for each mention (see Appendix 6.3 for analysis of this

---

[3] See also Table 1 of Wang et al. (2020) for a useful review of such approaches.

choice). This type of conditional computation can facilitate massive model scaling with fixed computational resources (Shazeer et al., 2017; Lample et al., 2019) and, while our current implementation does not yet include an efficient implementation of top-k routing (Section 2), we note that it is possible with fast maximum inner product search (Ram and Gray, 2012; Shen et al., 2015; Shrivastava and Li, 2014; Johnson et al., 2017). We leave the implementation and investigation of this to future work.

4.2 Ablations

EaE-unsup In EAE-unsup, the entity memory is not supervised to isolate the usefulness of supervising memory slots with entity linking. We use full attention at inference when doing memory access.

No-EaE This ablation seeks to isolate the impact of the entity-memory layer. No EAE has a token embedding layer, twelve transformer layers, and an `EntityPred` and a `TokenPred` head. This approach has similar number of parameters as EAE,[4] but only uses the entity embedding matrix at the `EntityPred` head. In contrast with EAE, this baseline cannot model interactions between the entity representations in the entity embedding matrix. Also, the entity embeddings cannot be directly used to inform masked language modelling predictions.

BERT / MM We compare to the BERT model. To ascertain which changes are due to EAE's data and masking function (Section 2.2.2), and which are due to the entity-specific modeling, we report performance for BERT-MM which uses BERT's architecture with EAE's masking function and data. We present results for Base and Large model sizes.

4.3 Question Answering Models

RELIC learns entity embeddings that match BERT's encoding of the contexts in which those entities were mentioned (Ling et al., 2020). T5 is an encoder-decoder trained on an enormous web corpus. We compare to the version fine-tuned for open-domain question answering (Roberts et al., 2020). We also compare to the nearest neighbour baselines introduced by Lewis et al. 2020; and we compare to three recent QA models that use a retriever and a reader to extract answers: BM25+BERT and ORQA from Lee et al. 2019 and GraphRetriever (GR) is introduced by Min et al. 2019b. All are described fully in Appendix A.

5 Knowledge Probing Tasks

We follow previous work in using cloze tests and question answering tasks to quantify the declarative knowledge captured in the parameters of our model (Petroni et al., 2019; Roberts et al., 2020).

5.1 Predicting Wikipedia Hyperlinks

We explore the ability of our model to predict masked out hyperlink mentions from Wikipedia, similar to the pre-training task[5] (Section 2.2). We calculate accuracy on a 32k test examples separate from the training data (Appendix B).

Table 1 shows the results for all our models. The MM-base and No-EAE models perform similarly on the token prediction task. These two models have the same architecture up until the point of token prediction. This indicates that the signal coming from the entity linking loss (Section 2.2.2) does not benefit language modeling when it is applied at the top of the transformer stack only.

Introducing the entity memory layer in the middle of the transformer stack (EAE) improves performance on both language modeling and entity linking, compared to the No-EAE model. This indicates that the entity representations are being used effectively, and that the model is learning inter-entity relations, using the output from the entity memory layer to improve predictions at the downstream entity and token prediction layers.

If the memory layer is not supervised (EAE-unsup), performance on token prediction accuracy and perplexity is significantly worse than for EAE. This underlines the importance of entity linking supervision in teaching EAE how to best allocate the parameters in the entity memory layer.

Finally, EAE performs better at predicting mention tokens than the 24-layer MM-large, but does marginally worse in terms of perplexity. We believe that EAE is overconfident in its token predictions when wrong, and we leave investigation of this phenomenon to future work.

5.2 LAMA

LAMA (Petroni et al., 2019) contains cloze tasks from three different knowledge base sources, and one QA dataset. LAMA aims to probe the knowledge contained in a language model, with a focus on the type of knowledge that has traditionally been manually encoded in knowledge bases. As a zero-shot probing task, it does not involve any

---

[4] With the exception of projection matrices totalling less than one million parameters.

[5] In pre-training, we also mask non-hyperlinked mentions.

Model	Params	Entity Acc	Token Acc	Token PPL
MM-base	110m	-	45.0	19.6
MM-large	340m	-	53.4	**10.3**
EaE-unsup	366m	-	46.9	16.9
No EaE	366m	58.6	45.0	19.3
EaE	367m	**61.8**	**56.9**	11.0

Table 1: Results on cloze-style entity prediction accuracy, token prediction accuracy and perplexity on the test set of our masked hyperlink data.

Model	Concept Net	RE	SQuAD	T -REx	Avg.
BERT-base	15.6	9.8	14.1	31.1	17.7
BERT-large	**19.2**	**10.5**	17.4	32.3	19.9
MM-base	10.4	9.2	16.0	29.7	16.3
MM-large	12.4	6.5	**24.4**	31.4	18.7
EaE-unsup	10.6	8.4	23.1	30.0	18.0
No EaE	10.3	9.2	18.5	31.8	17.4
EaE	10.7	9.4	22.4	**37.4**	**20.0**

Table 2: Results on the LAMA probe. Adding entity memory improves performance for the probes that focus on entities. Mention masking reduces performance on ConceptNet sub-task which requires prediction of non-mention terms such as "happy".

task specific model training, and we do not apply any LAMA-specific modeling. Table 2 shows that adding the entity memory layer to the MM-base model improves performance across the board on this task. Not supervising this layer with entity linking (EaE-unsup) is worse overall.

EaE's average accuracy is similar to BERT-large. However, the LAMA sub-task accuracies show that the two models are complementary. Mention focused approaches are much better than the BERT baselines at predicting the mention like words in the SQuAD and T-REx probes, but they are marginally worse for the RE probe and very significantly worse for the ConceptNet probe. This is because the ConceptNet sub-task mostly includes non-entity answers such as "fly", "cry", and "happy", and a third of the answers in the Google-RE sub-task are dates. We leave modeling of non-entity concepts and dates to future work. Finally, the entity specific memory in EaE is most beneficial for T-Rex, which focuses on common entities that are likely in our 1m entity vocabulary.

5.3 Open domain Question Answering

Setup TriviaQA and WebQuestions were introduced as reading comprehension and semantic parsing tasks, respectively (Joshi et al., 2017; Berant et al., 2013). More recently, these datasets have been used to assess the performance of QA systems in the open domain setting where no evidence documents or database is given. In this setup, TriviaQA contains 79k train examples and WebQuestions 3.1k. Most approaches rely on a text corpus at test time, extracting answers from evidence passages returned by a retrieval system. However, T5 and RELIC used neural networks to answer questions directly. We follow Roberts et al. 2020 in describing approaches as open-book (test time access to corpus) and closed-book (no test time access to corpus), and we report the nearest neighbour results from Lewis et al. 2020.

We follow RELIC and resolve answer strings to Wikipedia entity identifiers.[6] We follow the training procedure from Section 2.2, with a round of task specific training that applies the entity linking and mention detection losses to the question answering data. Each question is appended with a special 'answer position' token and EaE is trained to predict the correct answer entity in this position, using the entity linking loss from Section 2.2.2. Mention spans are identified within the question (Section 2.2.1) and the mention detection loss from Section 2.2.2 is applied to encourage EaE to access the entity memory for entities in the question. See Appendix C for additional information on task setup and fine-tuning hyper-parameters.

Results Table 3 shows results on two open domain QA datasets. Entity prediction methods, RELIC and EaE, significantly outperform nearest neighbor baselines, showing that model generalizes beyond train / development overlap and entity representations contains information about answer entities. No-EaE and RELIC both encode text with a transformer and retrieve answer entities. Compared to RELIC, No-EaE is trained to identify all entities in a piece of text, instead of just one. This leads to small but significant gains on TriviaQA. A much larger gain (almost 6 points on both datasets) comes from adding an entity memory inside the transformer encoder (EaE). We also show that it is possible to improve performance on TriviaQA by doubling the size of the entity embeddings to 512d (EaE-emb-512). While this almost doubles the model size, it does not significantly increase

---

[6] We resolve 77% of TriviaQA train; 84% of TriviaQA dev; 84% of WebQuestions train; 95% of WebQuestions dev; 91% of WebQuestions test. See Appendix C for full details. Answering with free-form text is out of this paper's scope

	# Params	TQA Dev	TQA Wiki Test	Web Q
Open-Book: Span Selection - Oracle 100%				
BM25+BERT	110m	47.1	-	17.7

Closed-Book: Entity Prediction				
Oracle	-	85.0	-	91.0
Relic	3B	35.7	-	-
No EaE	366m	37.7	-	33.4
EaE	367m	43.2	53.4	39.0
EaE, emb 512	623m	45.7	-	38.7

Table 3: Exact Match accuracy on TriviaQA and WebQuestions. Open-book approaches reserve 10% of the training data for development; entity prediction approaches only train on linked entity answers; and T5 merges Unfiltered-Dev into training for Wiki-Test. For more description of these choices, see Appendix E.

the number of parameters that need to be accessed at inference time. See Section 4.1 for a discussion of how this could be beneficial, and Appendix 6.3 for a preliminary investigation of conditional activation in EaE.

Even though entity prediction approach cannot answer 15% of the data with unlinked answers for TriviaQA, and 9% for WebQuestions, it outperforms all of the standard T5 models including one that has 30× the parameters. This indicates that the entity specific model architecture is more efficient in capturing the sort of information required for this knowledge probing task than the general encoder-decoder architecture used by T5. However, when T5 is enhanced with an extra pre-training steps focusing on likely answer spans from Wikipedia (T5-11B + SSM) its performance leapfrogs that of EaE. We note that the 'salient spans' included in the SSM objective are likely to be entities (Guu et al., 2020), and believe that there is significant future work to be done in combining methods of entity prediction and text generation.

Though closed-book approaches are still behind open-book approaches on TriviaQA, we believe even higher performances could be attained by ensembling diverse approaches and a preliminary study (Appendix F), indicates that ensembling open-book with closed-book approaches is preferable to ensembling within a single paradigm.

6 Analysis of TriviaQA Results

6.1 Entity-Based Analysis

We compare the performances of retrieval-based GR, generation-based T5-11B, and our EaE model on the TriviaQA Unfiltered-dev set. Figure 3 (a) shows that all models perform better on frequent entities. EaE's performance is much lower for entities seen fewer than one hundred times, likely because their entity embedding do not contain enough information. Figure 3 (b) shows that as the number of named entity mentions grows in the question, T5 performance decreases whereas EaE and GR performance increases. We presume more entity mentions makes it easier to retrieve relevant documents, thus contributing to better performance for GR. For EaE, having more entity mentions allows the model to access more entity knowledge. We conduct further qualitative analysis below. Figure 3 (c) shows that closed-book models under-perform on long questions. The trend disappears for open-book models.

6.2 Manual Analysis

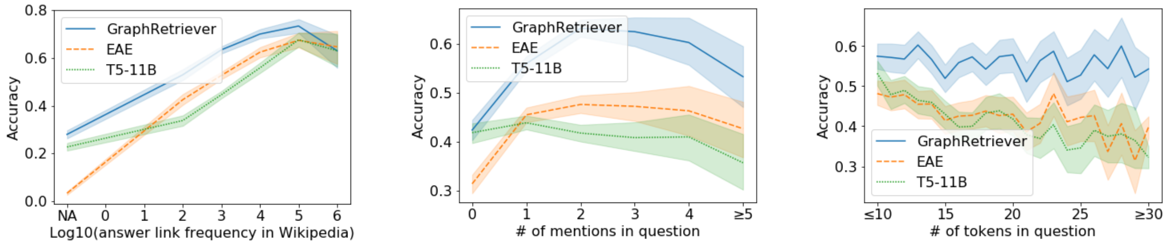
We randomly sampled 100 examples from unfiltered-dev set, and analysed the ability of EaE's to correctly identify and link the question's entities. We find that 87% of questions do not have any incorrectly predicted entities.[7]

We find that when there is at least one incorrectly linked entity, the performance of EaE is considerably reduced. On this small sample, the performance is even lower than for examples in which there are no named entities in the question.

Table 4 illustrates three representative examples from EaE and T5. In the first example, the question contains a date but no proper names. Since EaE does not have a representation for dates in the entity memory, this question is challenging and the model predicts an incorrect answer of the correct type (annual event). The second example demonstrates EaE's ability to model connections between entities. In this case, 'The Master' only occurs 38

---

[7] We do not define a strict bracketing to decide which entities in nested phrases like [[1966 [FIFA World Cup]] Final] should be predicted.



(a) (b) (c)

Figure 3: Performance on TriviaQA by: answer frequency in our Wikipedia training corpus (NA if not linked); proper names in the question; tokens in the question. Standard deviations obtained through bootstrapping.

Question	**Answer**	**T5 Prediction**	**EaE Prediction**
Next Sunday, Sept 19, is International what day?	Talk like a pirate day	talk like a pirate day	Pearl Harbor Remembrance Day
Which **[Dr. Who]** villain has been played by **[Roger Delgado]**, **[Anthony Ainley]**, **[Eric Roberts]**, etc?	The Master	mr. daleks	The Master
Which early aviator flew in a plane christened **{Jason}**?	Amy Johnston	jean batten	Icarus
Jason → Jason (Greek Mythology) Q176758			

Table 4: Illustrative examples of predictions for the TriviaQA dev set. Questions are annotated with **[correct]** and **{incorrect}** entity predictions from EAE, which is most successful when question entities are linked successfully.

K	Entity acc	Tok acc	Tok PPL	TQA
1	59.2	56.7	18.0	40.1
10	61.7	57.2	11.1	43.1
100	61.8	57.1	11.0	43.2
Full (10^6)	61.8	56.9	11.0	43.4

Table 5: Impact of varying the number of retrieved entity embeddings (K) in the Entity Memory layer at inference on the entity prediction and TriviaQA tasks.

times in our training data, but in each of those occurrences it is likely that at least one of the relevant actors is also mentioned. EAE learns the character-actor relationship, while T5 makes up an incorrect character name based on a common category of Dr. Who villain. The final example highlights the sensitivity of EAE to incorrectly linked question entities. Here, the name ‘Jason’ has been incorrectly linked to the Greek mythological with that name, which causes EAE to predict another Greek mythological figure, Icarus, as the answer. This is particularly interesting because Icarus is strongly associated with human flight—EAE is still trying to find an aviator, albeit one from Greek mythology. Additional examples can be found in Appendix G.

6.3 Top-K over Entity Embeddings

As described in Section 2, EAE uses the top 100 entity memories during retrieval for each mention. Here, we empirically analyse the influence of this choice. Table 5 shows how varying the number of retrieved entity embeddings in the entity memory layer at inference time impacts accuracy of entity prediction and TrviaQA. Even for $K = 10$, performance does not deteriorate meaningfully.

This is a key advantage of our modular approach, where entity information is organized in the Entity Memory layer. Despite only accessing as many parameters as BERT Base, our model outperforms BERT Large on token prediction. Similarly in TriviaQA, we outperform T5-3B model, while accessing about 3% of the parameters. While naive implementation would not bring significant computational gain, fast nearest neighbor methods methods on entity embeddings enable retrieving the top K entities in sub-linear time and storage, enabling efficient model deployment.

7 Comparison to Alternative Entity Representations

EAE is novel in learning entity representations along with the parameters of a Transformer model. Here, we provide a direct comparison between EAE’s learned representations and the externally trained, fixed representations used by ERNIE (Zhang et al., 2019) and KNOWBERT (Peters et al., 2019). Table 6 presents results for the EAE architecture trained with entity memories initialized

Initialization	Dim	Learned	Typing	PPL	Entity Acc.	LAMA-SquAD	T-REx	TQA
Random	100	✓	74.5	10.6	63.0	17.7	32.4	30.9
TransE	100	✗	74.1	14.7	49.7	12.8	30.8	24.2
TransE	100	✓	**75.1**	10.5	63.1	16.3	31.9	30.6
Random	300	✓	74.2	9.4	64.5	**19.3**	31.7	33.2
Deep-Ed	300	✗	73.0	12.6	57.4	17.0	29.8	30.1
Deep-Ed	300	✓	74.2	**8.9**	**65.1**	15.7	**33.5**	**33.9**

Table 6: Comparison of learned representations to knowledge graph embeddings (TransE) and pre-trained representations of entity descriptions and contexts (Deep-Ed). All experiments use same 200k entities.

from three different sources and two different training scenarios. The initial embeddings are either the TransE-Wikidata embeddings used by ERNIE (Bordes et al., 2013); the Deep-Ed embeddings used by KNOWBERT (Ganea and Hofmann, 2017); or the random embeddings used by EAE. The embeddings are either frozen, following ERNIE and KNOWBERT, or trained along with all other network parameters.[8] Along with the knowledge probing tasks from Section 5, we report performance on the on the 9-way entity typing task from Choi et al. 2018 (Appendix D).

It is clear that learning entity representations is beneficial. However, initializing the entity memory with Deep-Ed embeddings leads to gains on most of the knowledge probing tasks, suggesting that there are potential benefits from combining training regimens. Meanwhile, the best entity typing results come from initializing with Wikidata embeddings, possibly because Wikidata has high quality coverage of the types ('person', 'organization', 'location', etc.) used. Finally, we point out that both ERNIE and KNOWBERT differ from EAE in other ways (see Appendix A). KNOWBERT in particular incorporates WordNet synset embeddings as well as entity embeddings, leading to entity typing accuracy of 76.1. Future work will explore different ways of combining learned embeddings with knowledge from diverse external sources.

As discussed in Section 3, there are significant differences between EAE and KNOWBERT other than the choice of entity representation. In particular, KNOWBERT has an explicit entity-entity attention mechanism. To determine whether this has a significant effect on a model's ability to model entity-entity relations, we evaluate EAE on TACRED (Zhang et al., 2017) using the cleaned dataset introduced by (Alt et al., 2020).[9] Table 7 shows that EAE outperforms KNOWBERT on the revised and weighted splits introduced by (Alt et al., 2020), although it slightly under-performs on the original setting.[10] This result indicates that EAE, without explicitly entity-entity attention, can capture relations between entities effectively.

Model	# Params	Original	Revised	Weighted
KNOWBERT	523m	**71.5**	79.3	58.4
EAE	366m	70.2	**80.6**	**61.3**

Table 7: F_1 scores on original and revisited versions of TACRED test sets. KNOWBERT scores are reported as in Alt et al. (2020), corresponding to the best performing variant (`KnowBert-W+W`).

8 Conclusion

We introduced a new transformer architecture, EAE, which learns entity representations from text along with other model parameters. Our evaluation shows that EAE is effective at capturing declarative knowledge and can be used for a wide variety of tasks – including open domain question answering, relation extraction, entity typing and knowledge probing tasks. Our entity representations influence the answer predictions for open-domain question answering system and are of high quality, compared to prior work such as KNOWBERT.

Our model learns representations for a pre-fixed vocabulary of entities, and cannot handle unseen entities. Future work can explore representations for rare or unseen entities, as well as developing less memory-intensive ways to learn and integrate entity representations. Furthermore, integrating information from knowledge-bases can further improve the quality of entity representation.

---

[8] All experiments use the same 200k entities, at the intersection of the sets used by ERNIE and KNOWBERT For efficiency, these three comparison systems are trained for 500k steps, rather than the full 1m steps used in Section 5.

[9] Our method follows (Baldini Soares et al., 2019) in using special tokens to mark subject and object, and concatenating their representations to model the relation.

[10] The weighted split weights examples by its difficulty, focusing on correctly predicting difficult examples.

Acknowledgments

We thank many members of Google Research for helpful feedback and discussions, especially Kenton Lee, Dipanjan Das, Pat Verga and William Cohen. We also thank Adam Roberts and Sewon Min for sharing their system outputs.

A Other Models Evaluated

In this section we describe the models mentioned in Section 4.3 and compared to in Section sections 5 and 7.

A.1 Open-Book Question Answering Systems

Open-Book Open Domain Question Answering Systems are usually comprised of two components: a retriever and a reader. The retriever reads a set of documents from a corpus or facts from a knowledge base. Top retrievals are then fed to the reader which predicts an answer, often through span selection.

BM25+BERT (Lee et al., 2019) uses the non-parametric BM25 as its retriever and a BERT-base reader to predict an answer through span selection.

ORQA (Lee et al., 2019) uses two BERT-base models to retrieve relevant passages and a BERT-base reader to predict the answer span.

Graph Retriever (Min et al., 2019b)'s retriever can perform Graph-based, Entity-based and Text-match retrieval. These different retrieval modalities are then fused in representations that serve as input to a span-selection reader.

A.2 Other Models

BERT (Devlin et al., 2018) is a transformer, pre-trained using masked language modelling. We report results for BERT-base, which has 110m parameters, and BERT-large, which has 340m parameters. The transformer architecture used by BERT-base is identical to the 12 transformer layers in EAE. BERT-large uses a much larger transformer, and has a similar number of parameters overall to EAE.

RELIC (Ling et al., 2020) is a dual encoder with a BERT-base architecture that compares a representation of a mention to an entity representation. It is similar to our No-EAE architecture. Its training is however different, as only linked mentions are masked and only one mention is masked at a time. In addition, RELIC does not have mention detection or masked language modelling losses. Finally, it is also initialized with the BERT checkpoint whereas we train our models from scratch.

T5 T5 is an encoder-decoder transformer introduced in Raffel et al. (2019). It has been fine-tuned for open domain question answering in Roberts et al. (2020). In that setup, the model is trained to generate the answer to a question without any context. T5 does not explicitly model entities or have any form of memory. We compare to models of different sizes, from 220m parameters to 11B. 'SSM' refers to salient span masking, indicating that prior to fine-tuning on open domain question answering the model was fine-tuned using salient span masking, which bears resemblances to our mention masking.

KnowBERT (Peters et al., 2019) KNOWBERT is a BERT-base transformer that embeds multiple knowledge bases to improve performance in a variety of tasks. The integration of this information is done through a Knowledge Attention and Recontextualization component, which can be seen as a small transformer that is run on the pooled mention representations of potential entities. KNOWBERT uses this layer to embed entity representations from Wikipedia as well as Wordnet graph information. In contrast with our work, KNOWBERT starts from the BERTcheckpoint, does not train with a knowledge-focused objective such as our mention-masking input function and uses pre-existing representations when integrating the information from knowledge bases. In addition, KNOWBERT relies on a fixed, pre-existing candidate detector (alias table) to identify potential candidates and entities for a span while our model learns mention detection.

ERNIE (Zhang et al., 2019) ERNIE is a BERT-base transformer that takes as additional input the list of entities in the sentence. Multi-head attention is performed on those entities before they are introduced in they are aggregated with the token representations. In addition to BERT's pre-training objective, ERNIE also masks entities and trains the model to predict them. In contrast with both KNOWBERT and EAE, ERNIE takes entity linking as an input rather than learning to do it inside the model. In contrast with our approach, ERNIE uses pre-existing entity representations that are fixed during training.

B Wikipedia Pre-training

Wikipedia Processing We build our training corpus of contexts paired with entity mention labels from the 2019-04-14 dump of English Wikipedia. We first divide each article into chunks of 500 bytes, resulting in a corpus of 32 million contexts with over 17 million entity mentions. We restrict ourselves to the one million most frequent entities

(86% of the linked mentions). These are processed with the BERT tokenizer using the lowercase vocabulary, limited to 128 word-piece tokens. In addition to the Wikipedia links, we annotate each sentence with unlinked mention spans using the mention detector from Section 2.2. These are used as additional signal for our mention detection component and allow the model to perform retrieval even for mentions that are not linked in Wikipedia. We set aside 0.2% of the data for development and 0.2% for test and use the rest to pre-train our model.

Pre-training hyper-parameters We pre-train our model from scratch. We use ADAM (Kingma and Ba, 2014) with a learning rate of 1e-4. We apply warmup for the first 5% of training, decaying the learning rate afterwards. We also apply gradient clipping with a norm of 1.0. We train for one million steps using a large batch size of 4096. We use a `TokenPrediction` head for all our models and an `EntityPrediction` head for the EAE and No-EAE models. We did not run extensive hyper-parameter tuning for pre-training due to computational cost. We train on 64 Google Cloud TPUs for all our pre-training experiments. All pre-training experiments took between 2 days and a week to complete.

C Open Domain Question Answering

Open Domain QA Preprocessing We annotate each question with proper-name mentions[11] using the mention detector from Section 2.2.

When the answer is an entity, in our entity vocabulary, we link the answer string to an entity ID using the SLING phrase table[12] (Ringgaard et al., 2017). If the answer is not an entity in our vocabulary, we discard the question from the training set, though we keep it in the development and test set to ensure fair comparisons with prior work. Table 8 shows the share of answers that were linked using our procedure. This means that Oracle performance for our model on the TriviaQA development set is only 85%, which is due to non entity-answers and entities not in our vocabulary.

Dataset	Train	Development	Test
TriviaQA	77%	84%	-
WebQuestions	84%	95%	91%

Table 8: Share of the answers that are linked by our linking procedure for the TriviaQA and WebQuestion datasets. The test set for TriviaQA is not public, hence the missing number.

Hyper-parameters For TriviaQA, we fine-tune the entire model using a learning rate of 5e-6, a batch size of 64 and performing 50,000 training steps. For WebQuestions, we set the learning rate to 3e-5, the batch size to 32 and train for 700 steps. Fine-tuning was done on 4 Google Cloud TPUs. In both cases, we searched the learning rate over $\{5 \times 10^{-5}, 3 \times 10^{-5}, 10^{-5}, 5 \times 10^{-6}, 3 \times 10^{-6}\}$ and the batch size in $\{32, 64, 128\}$ and selected the model based on validation performance.

D Entity Typing

We describe the procedure to obtain the Typing results of Table 6.

Open Entity Processing We use the Ultra-fine entity typing dataset introduced in (Choi et al., 2018). As is done in Zhang et al. (2019); Peters et al. (2019) we limit the task to the 9 generic types ('person', 'group', 'organization', 'location', 'entity', 'time', 'object', 'event' and 'place') and use the Micro-F1 metric. The dataset is comprised of 5994 examples, equally divided between train, development and test. We pass the sentences to our model without extra annotations for mention annotations or entity linking, relying instead on the model's own predictions. To predict a type for the span, we take the span representation and project it to the 9 classes.

Hyper-parameters Since we have no mention boundary or linking information, we freeze the entity embeddings and the mention detection parameters in fine-tuning. We used a learning rate of 3e-5, a batch size of 32 and trained for 700 steps. We also used label smoothing with a value of 0.1. We searched the learning rate and the batch size between the same bounds as for the open-domain question answering tasks. For every model, we ran with five different seeds and selected the best model based on validation performance before running on test. We selected the threshold to compute F1 based on validation scores.

---

[11] Nominal mentions in questions typically refer to the answer entity. This is unlike Wikipedia text, where nominal mentions refer to entities that have previously been named. We only link proper name mentions in questions so that the model is not forced to hallucinate links for entities that have not been properly introduced to the discourse.

[12] `https://github.com/google/sling`

Systems	Oracle Acc.	Pred Overlap (%)
T5 & EaE	55.9	29.3
T5 & GR	**66.4**	30.1
EaE & GR	64.6	33.6
ORQA & GR	63.8	**39.6**

Table 9: Comparing prediction overlap and oracle accuracy on TriviaQA. Oracle accuracy considers a prediction correct if at least one of the model prediction is correct. While ORQA and GR outperform EAE and T5, their predictions overlap more with GR and offer less complementary value.

E TriviaQA Evaluation Data Configuration

As the TriviaQA dataset was originally introduced for reading comprehension task, prior work adapted the initial splits and evaluation to reflect the open domain setting. We describe the setup used by prior approaches and introduce ours, to enable fair comparison. The dataset comes in two blends, Wikipedia and Web documents. While TriviaQA's official web evaluation uses (question, document, answer) triplets, all open domain approaches average over (question, answer) pairs when using the Web data.

Open-book Approaches: Lee et al. (2019); Min et al. (2019a,b) use only the web splits. They use 90% of the original train data for training, performing model selection on the remaining 10% and reporting test numbers on the original development set since the original test set is hidden.

Previous Closed-book Approaches: Roberts et al. (2020) also use the web data to train and validate their model. However, they use the Wikipedia[13] test split as a test set. After hyper-parameter tuning, they re-train a model on both the training and development sets of the web data. Ling et al. (2020) uses the original web splits and reports performance on the development set.

Our approach: To compare our approach more closely to T5, we follow their setup, with the exception that we do not re-train a model on both the train and development splits after hyper-parameter selection.

F Comparing QA paradigms

We compare the performance of four systems (ORQA, GraphRetriever (GR), T5, EAE) on the TriviaQA Unfiltered-Dev set. GR achieves an accuracy of 55.4, ORQA 45.1, EAE 43.2 and T5 42.3. As the open-book paradigm differs significantly from the closed-book one, we intuit they might complement each other.

To test this hypothesis, we measure prediction overlap and oracle accuracy. Oracle accuracy considers a prediction correct if either system is correct (see Table 9). Unsurprisingly, the two open book approaches show the most similar predictions, overlapping in nearly 40% of examples. While ORQA outperforms T5 and EAE, the oracle accuracy of ORQA & GR is lower than ORQA & T5 or ORQA & EAE. This suggests some questions might be better suited to the closed book paradigm. In addition, the oracle accuracy of the two closed book systems is higher than that of the best performing open book system. We leave designing approaches that better combine these paradigms to future work.

G Additional Examples of TriviaQA Predictions

Table 10 illustrates additional representative sample of questions and predictions from EAE and T5. We break this sample down into questions that contain no named entities, questions that contain only correctly linked named entities, and questions that contain incorrectly linked named entities.

Example (i) shows another case where our model fails to handle dates. While T5 also has no distinct representation for dates, its 11B parameters managed to memorize the esoteric connection between the phrases 'Sept 19' and 'talk like a pirate day'. In the second example without named entities, the answer entity is sufficiently frequent in Wikipedia (top 50k entities), and EAE seems to have learned its connection with the specific categorical information in the question.

Example (iii) shows another case where the correctly linked entities enable EAE to correctly answer the prompt while T5 predicts a different director's name. Example (vi) shows how EAE fails at predicting date answers, even when there is abundant information in the question, predicting the entity representing the 1990's.

---

[13] `https://competitions.codalab.org/competitions/17208`

	Questions with no proper name mentions	**Answer**	**T5 Prediction**	**EaE Prediction**
i	What links 1st January 1660 and 31st May 1669?	First and last entries in Samuel Pepys's diaries	they were the dates of the henry viii's last bath	Anglo-Dutch Wars
ii	Which radioactive substance sometimes occurs naturally in spring water?	radon	radon	radon
	Questions with only [correctly] linked entities			
iii	Who directed the 2011 [Palme d'Or] winning film '[The Tree Of Life]'?	Terence Malick	ang lee	Terrence Malick
iv	Name the year: [Hirohito] dies; The [Exxon Valdez] runs aground; [San Francisco] suffers its worst earthquake since 1906.	1989	1989	1990s
	Questions with {incorrectly} linked entities			
v	Which car manufacturer produces the **{Jimmy}** model?	Suzuki	suzuki	Brixham
	Jimmy → Marcos Engineering Q1637323			
vi	Where do you find the **{Bridal Veil}**, **[American]**, and **[Horseshoe Falls]**?	Niagara falls	niagra Falls	Niagara Falls
	Bridal Veil → Veil (Garment) Q6497446			

Table 10: Additional examples of question, answer and model predictions for the TriviaQA Unfiltered dev set.

Examples (v) and (vi) shows other failure modes when EaE fails to correctly predict the entities in the question. In example (vi) the entity is not available, though this not cause the model to err, likely thanks to the two other correctly predicted question entities. Example's (vi) typo (from 'Jimny' to 'Jimmy') is particularly interesting: when fixed, EaE links 'Jimny' correctly and predicts the right answer.

H^{2}KGAT: Hierarchical Hyperbolic Knowledge Graph Attention Network

Abstract

Knowledge Graphs encode rich relationships among large number of entities. Embedding entities and relations in low-dimensional space has shed light on representing knowledge graphs and reasoning over them, e.g., predicting missing relations between pairs of entities. Existing knowledge graph embedding approaches concentrate on modeling symmetry/asymmetry, inversion, and composition typed relations but overlook the hierarchical nature of relations. Recent studies have observed that there exist rich semantic hierarchical relations in knowledge graphs such as WordNet, where synsets are linked together in a hierarchy. To fill this gap, in this paper, we propose Hierarchical Hyperbolic Knowledge Graph Attention Network (**H^{2}KGAT**), a novel knowledge graph embedding framework, which is able to better model and infer hierarchical relation patterns. Specifically, **H^{2}KGAT** defines each entity in a hyperbolic polar embedding space. In addition, we propose an attentional neural context aggregator to enhance embedding learning, which can adaptively integrate the relational context. Our empirical study offers insights into the efficacy of modeling the semantic hierarchies in knowledge graphs, and we achieve significant performance gains compared to existing state-of-the-art methods on benchmark datasets for link prediction task, particularly at low dimensionality.

1 Introduction

Knowledge graphs (KGs) are popular data structures for representing and reasoning over knowledge bases (KBs) containing factual knowledge of the type (head entity, relation, tail entity). KGs are queried and used in various downstream tasks, such as semantic search (Berant et al., 2013; Berant and Liang, 2014), dialogue generation (He et al., 2017; Keizer et al., 2017), and question answering (Diefenbach et al., 2018; Keizer et al., 2017). However, KGs usually suffer from incompleteness problem, where a large number of valid relations are missing. This problem naturally gives rise to the task of knowledge-base completion, which predicts whether a given triple is valid or not.

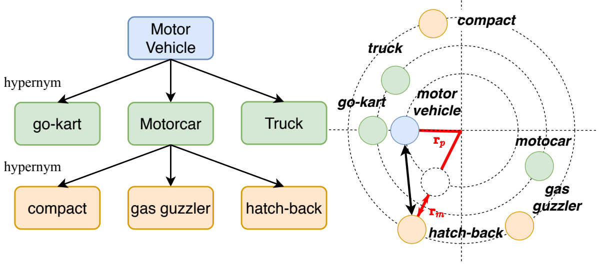

Figure 1: A subgraph from WordNet KG, where entities are linked together in a hierarchy. Their hierarchical relations can be described in a polar embedding space. Transformation from *motor_vehicle* to *hatch-back* is via a modulus change $\mathbf{r}_m$ and a phase change $\mathbf{r}_p$.

Embedding methods have shown effectiveness and scalability for knowledge graph representation. The basic idea is to map the knowledge graph entities and relations to a low dimensional vector space, where the semantics and inherent structures of entities/relations are preserved. The relation patterns in KGs can exhibit multiple properties, such as symmetry (e,g, *marriage*), anti-symmetry (e.g., *affiliation*), inversions (e.g., *hypernym* and *hyponym*), compositions (e.g., *my mother's sister is my aunt*). Many existing approaches have tried to either implicitly or explicitly model one or a few of these relation patterns (Bordes et al., 2013; Trouillon et al., 2016; Yang et al., 2017; Dettmers et al., 2018; Sun et al., 2019). However, these methods fail to adequately model semantic hierarchical relations in knowledge graphs. Instead, they attempt to

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4952–4962,
November 16–20, 2020.

capture various properties by providing additional flexibility to the model through increased dimensionality of the embeddings, which results in high memory usage. Therefore, an approach that is able to explicitly model and infer semantic hierarchical relations is needed.

Recent studies (Xie et al., 2016; Zhang et al., 2018; Balazevic et al., 2019) have shown that semantic hierarchical relations widely exist in knowledge graphs. For example, Figure 1 shows a subgraph from WordNet (Miller, 1995), where entities are linked together in a hierarchical (tree-like) structure. In this subgraph, we can obtain the triple *[truck, hypernym, motor_vehicle]*, where *motor_vehicle* is more general (i.e., at a higher level in the hierarchy) while *truck* is more specific. Similarly, Freebase (Bollacker et al., 2008) and YAGO (Mahdisoltani et al., 2013) also have rich hierarchical relations. Therefore, modeling the hierarchical relations is meaningful and important to ensure high quality embedding of knowledge graphs.

Recently, some works (Xie et al., 2016; Zhang et al., 2018; Gu et al., 2020) take the hierarchical relations into consideration and model the semantic hierarchy in KGs. However, they require additional data or process and cannot capture the hierarchy automatically. On the other hand, modeling hierarchical data in hyperbolic space has attracted considerable research interest, due to its ability of naturally capturing semantic hierarchies (Sarkar, 2011; Nickel and Kiela, 2017, 2018; Ganea et al., 2018; Tifrea et al., 2018; Balazevic et al., 2019). By considering the surface area of a hypersphere of increasing radius centered at a particular point, Euclidean space can be seen to "grow" polynomially, whereas in hyperbolic space the equivalent growth is exponential (De Sa et al., 2018). This provides more room to separate leaf nodes in a tree-like hierarchical structure. Balazevic et al. (2019) have shown that the translational KG embeddings can benefit from hyperbolic geometry, especially in low dimensions. However, the optimization in hyperbolic space is challenging and usually results in a suboptimal solution. Therefore, it requires an effective end-to-end approach to represent and reason the hierarchical relations.

In this paper, we propose a novel knowledge graph embedding approach, called Hierarchical Hyperbolic Knowledge Graph Attention Network (**H^{2}KGAT**), which maps the knowledge graph entities and relations into an hyperbolic polar embedding space. Specially, we explicitly model two types of hierarchical relations (inter-hierarchical and intra-hierarchical relations) by the radial coordinate (modulus) and the angular coordinate (phase) in the hyperbolic space, which can automatically preserve the hierarchical structure. In addition, we propose an attentional neural context aggregator – a graph neural network module to enhance embedding learning. By adaptively integrating the relational context, the learned embeddings can further preserve the hierarchical relations by capturing multi-hop relational contexts, encapsulating the diversity of roles played by an entity in various relations, and consolidating the existing knowledge present in semantically similar relation clusters. Experimental results show that the proposed H^{2}KGAT can more effectively model the hierarchical relations and significantly outperform several state-of-the-art methods on benchmark datasets, especially in low-dimensional space.

2 Methodology

We begin this section by introducing the KG embedding problem setting, followed by some necessary background on hyperbolic geometry. Then we provide a detailed description of our proposed H^{2}KGAT.

2.1 Background and Preliminaries

2.1.1 Knowledge Graph Embedding

A knowledge graph is a graph denoted by $\mathcal{G} = (\mathcal{E}, \mathcal{R})$, where $\mathcal{E}$ and $\mathcal{R}$ represent the set of entities (nodes) and relations (edges), respectively. A triple $(e_h, r, e_t) \in \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ is represented as an edge r between head entity e_h and tail entity e_t in $\mathcal{G}$. The objective is to map entities $e \in \mathcal{E}$ and relations $r \in \mathcal{R}$ to their corresponding embeddings $\mathbf{e}^{(\mathcal{U})} \in \mathcal{U}^{d_\mathcal{E}}$ and $\mathbf{r}^{(\mathcal{U})} \in \mathcal{U}^{d_\mathcal{R}}$ respectively, with $\mathcal{U}$ indicating the target space (e.g. $\mathbb{R}$), such that the KG structure is well preserved, especially the semantic hierarchical relations. In particular, the learned KG embeddings are used to predict the target entity of a given query with head entity and relation, $q := (e_h, r, ?)$–such that the predicted tuple doesn't exist in $\mathcal{G}$.

2.1.2 Hyperbolic geometry

Hyperbolic geometry is a non-Euclidean geometry with a constant negative curvature. Specifically, we employ the d-dimensional Poincaré ball model with negative curvature $-c$ $(c > 0)$: $\mathbb{B}_c^d = \mathbf{x} \in \mathbb{R}^d : ||x||^2 < \frac{1}{c}$ with $||\cdot||$ denotes the L_2 norm.

For each point $\mathbf{x} \in \mathbb{B}_c^d$, we define the tangent space $\mathcal{T}_x^c$ (the corresponding Euclidean space), which is a d-dimensional vector space containing all possible directions of paths in $\mathbb{B}_c^d$ leaving from $\mathbf{x}$. Let $\mathbf{v} \in \mathcal{T}_x^c$ be the corresponding point in the tangent space. To find the mapping between the tangent space $\mathcal{T}_x^c$ and hyperbolic $\mathbb{B}_c^d$, we define an exponential function for mapping and a logarithmic function for inverse-map. Specifically, the closed-form expressions for these maps at the origin are defined as follows:

$$\exp_o^c(\mathbf{v}) = \tanh(\sqrt{c}||\mathbf{v}||)\frac{\mathbf{v}}{\sqrt{c}||\mathbf{v}||} \tag{1}$$

$$\log_o^c(\mathbf{x}) = \tanh^{-1}(\sqrt{c}||\mathbf{x}||)\frac{\mathbf{x}}{\sqrt{c}||\mathbf{x}||} \tag{2}$$

As vector operation is not well-defined in the hyperbolic space, we adopt Möbius operations (Ungar, 2001; Ganea et al., 2018) to provides an analogue to Euclidean operation. In particular, we provide definitions of five Möbius operations used in the paper, including addition $\oplus_c$, scalar multiplication $\otimes_c$, element-wise multiplication $\odot_c$, matrix multiplication $\otimes_c$ and activation σ_c as follows:

$$\mathbf{x}\oplus_c\mathbf{y} = \frac{(1+2c\mathbf{x}^T\mathbf{y}+c||\mathbf{y}||^2)\mathbf{x}+(1-c||\mathbf{x}||^2)\mathbf{y}}{1+2c\mathbf{x}^T\mathbf{y}+c^2||\mathbf{x}||^2||\mathbf{y}||^2} \tag{3}$$

$$r \otimes_c \mathbf{x} = \exp_o^c(r \log_o^c(\mathbf{x})) \tag{4}$$

$$\mathbf{x} \odot_c \mathbf{y} = \exp_o^c(\mathbf{x} \circ \log_o^c(\mathbf{y})) \tag{5}$$

$$\mathbf{M} \otimes_c \mathbf{x} = \exp_o^c(\mathbf{M} \log_o^c(\mathbf{x})) \tag{6}$$

$$\sigma_c(\mathbf{x}) = \exp_o^c(\sigma(\log_o^c(\mathbf{x}))) \tag{7}$$

where $\circ$ denotes the element-wise multiplication. The hyperbolic distance on $\mathbb{B}_c^d$ is measured along a geodesic (i.e. shortest path between two points) and is given by:

$$d^{(\mathbb{B}_c^d)}(\mathbf{x},\mathbf{y}) = \frac{2}{\sqrt{c}}\tanh^{-1}(\sqrt{c}||-\mathbf{x}\oplus_c\mathbf{y}||) \tag{8}$$

2.2 The Proposed H^{2}KGAT

In this section, we first provide an overview of our proposed method H^{2}KGAT. Then we introduce the proposed hyperbolic polar embedding, which explicitly models the semantic hierarchies by mapping each entity and relation into a hyperbolic polar embedding space. Finally we describe the proposed attentional neural context aggregator, which updates the entity embedding and relation embedding by adaptively integrating the relational context.

2.3 Overview

The proposed proposed H^{2}KGAT consists of two key modules: Hyperbolic Polar Embedding and Attentional Neural Context Aggregator. Given a triple $(e_h, r, e_t) \in \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, H^{2}KGAT first performs the hyperbolic polar embedding to obtain the embeddings of the head entity, relation and tail entity. Then an attentional neural context aggregator is applied to update these embedding by adaptively fusing the relational context.

2.3.1 Hyperbolic Polar Embedding

In this part, we first introduce the polar embedding space modeling and then extend it to hyperbolic space. As observed by recent studies (Xie et al., 2016; Zhang et al., 2018; Balazevic et al., 2019), hierarchical relations exist widely in knowledge graphs. Specifically, these hierarchies among entities can be categorized in two categories: (a) Inter-level hierarchy: hierarchical relations among entities in different levels (e.g. *motor vehicle* vs *truck*, *person* vs *singer*). (b) Intra-level hierarchy: hierarchical relations among entities in the same level (e.g. *truck* vs *motorcar*, *singer* vs *writer*).

To model both inter-level and intra-level hierarchies, we propose a polar embedding space, which models the entities and relations using dual-embeddings: modulus and phase embeddings. Similar to complex space modeling methods, which contain a real part embedding and a image part embedding, our method can capture and reason symmetry/asymmetric, inversion, and composition typed relations. Specifically, we define an entity embedding $\mathbf{e}$ in two parts: modulus part $\mathbf{e}^m$ and phase part $\mathbf{e}^p$. Similarly, the relation embedding $\mathbf{r}$ is also defined in two parts: modulus part $\mathbf{r}^m$ and phase part $\mathbf{r}^p$.

The modulus embedding aims to model the inter-level hierarchy. As entities that exhibit hierarchical structure can be viewed as a tree, we use depth of an entity's modulus embedding to model different levels of hierarchy. In this way, each entry of entity corresponds to a modulus and each entry of relation corresponds to a scaling transformation between two moduli. Formally, we describe the modulus embedding as follows:

$$\begin{aligned}&\mathbf{e}_h^m \circ \mathbf{r}^m = \mathbf{e}_t^m \\ &\text{where } \mathbf{e}_h^m, \mathbf{e}_t^m \in \mathbb{R}^{d_\mathcal{E}}, \text{and } \mathbf{r}^m \in \mathbb{R}^{d_\mathcal{R}}\end{aligned} \tag{9}$$

where $\circ$ denotes the Hadamard product. We define the modulus distance function as follows:

$$d^m(e_h, e_t) = d(\mathbf{e}_h^m \circ \mathbf{r}^m, \mathbf{e}_t^m) \tag{10}$$

where $d(\cdot,\cdot)$ is the L2 distance in the Euclidean space.

The phase embedding aims to model intra-level hierarchy. As different entities with the same modulus should be different and need to be distinguished. Motivated by the fact that points on a circle can have different phases, we use phase to model the entities within an intra-level hierarchy. Specifically, each entry of entity corresponds to a phase and each entry of relation corresponds to a phase transformation between two phases. Formally, we describe the phase embedding as follows:

$$\begin{aligned}&(\mathbf{e}_h^p + \mathbf{r}^p) \bmod 2\pi = \mathbf{e}_t^p \\ &\text{where } \mathbf{e}_h^m, \mathbf{e}_t^m, \mathbf{r}^m \in [0, 2\pi)^{d_\mathcal{E}}\end{aligned} \tag{11}$$

The distance function is defined as follows:

$$d^p(e_h, e_t) = \sin(d(\mathbf{e}_h^p + \mathbf{r}^p, \mathbf{e}_t^p)/2) \tag{12}$$

where $\sin(\cdot)$ indicates an operation that applies the sine function to each element of the input. Combining the modulus embedding and the phase embedding, the KG entities and relations are mapped into the polar embedding space in an dual-embedding style. The overall distance function can be formulated as follows:

$$d(e_h, e_t) = d^m(e_h^m, e_t^m) + \lambda d^p(e_h^p, e_t^p) \tag{13}$$

where λ is a parameter learned by the model. The corresponding scoring function[1] can be formulated as follows:

$$\begin{aligned}\phi(e_h, e_t) &= -d^m(e_h, e_t) - \lambda d^p(e_h, e_t) \\ &= -d(\mathbf{e}_h^m \circ \mathbf{r}^m, \mathbf{e}_t^m) \\ &\quad - \lambda \sin(d(\mathbf{e}_h^p + \mathbf{r}^p, \mathbf{e}_t^p)/2)\end{aligned} \tag{14}$$

With the help of polar embeddings, two types of semantic hierarchies can be modeled explicitly. Moreover, benefiting from dual-embedding design, the other complex relations can also be well modeled. However, polar embeddings have a number of limitations: (1) the entity embeddings, relation embeddings and corresponding distance function are still defined in the euclidean space, which have limited modeling power, (2) the polar embedding is closely related to Poincaré disk with fixed curvature, which may lead to insufficient precision, and (3) the polar embedding is a dual-embedding model, which may result in high memory costs.

To overcome these limitations and further enhance the model's ability of modeling and reasoning the hierarchical relations, we extend the polar embeddings into the hyperbolic space. Specifically, we take the hyperbolic analogue of Equation 14 and define the scoring function for hyperbolic polar embedding as follows:

$$\begin{aligned}\phi^{(\mathbb{B}_c^d)}(e_h, e_t) &= -d^{(\mathbb{B}_c^d)m}(e_h, e_t) - \lambda d^{(\mathbb{B}_c^d)p}(e_h, e_t) \\ &= -d^{(\mathbb{B}_c^d)}(\mathbf{e}_h^{(\mathbb{B}_c^d)m} \odot_c \mathbf{r}^{(\mathbb{B}_c^d)m}, \mathbf{e}_t^{(\mathbb{B}_c^d)} m) \\ &\quad -\lambda \sin(d^{(\mathbb{B}_c^d)}(\mathbf{e}_h^{(\mathbb{B}_c^d)p} \oplus_c \mathbf{r}^{(\mathbb{B}_c^d)p}, \mathbf{e}_t^{(\mathbb{B}_c^d)p})/2)\end{aligned} \tag{15}$$

where $\mathbf{e}_h^{(\mathbb{B}_c^d)m}, \mathbf{e}_t^{(\mathbb{B}_c^d)m}, \mathbf{e}_h^{(\mathbb{B}_c^d)p}, \mathbf{e}_t^{(\mathbb{B}_c^d)p}$ are hyperbolic embedding of the head and tail entities e_h and e_t in modulus and phase part respectively and $\mathbf{r}^{(\mathbb{B}_c^d)m}, \mathbf{r}^{(\mathbb{B}_c^d)p}$ are hyperbolic translation vectors of relation r in modulus and phase part respectively. $\odot_c$ denotes the Möbius element-wise multiplication, $\oplus_c$ denotes the Möbius addition and $d^{(\mathbb{B}_c^d)}(\cdot,\cdot)$ denotes the hyperbolic distance. In this way, polar embedding and hyperbolic embedding can mutually enhance the ability to model hierarchical relations. However, it is challenging to perform polar embedding and hyperbolic embedding jointly since hyperbolic embedding presents challenges in optimization. It normally requires Riemannian Stochastic Gradient Descent as was used in MuRP. Applying hyperbolic modeling to complex models such as polar embedding increases the optimization difficulty. To overcome this challenge, we use tangent space at the origin to define all the model parameters and optimize embeddings using standard Euclidean techniques. As the tangent space optimization is an exact procedure, there is no loss in representation power.

2.3.2 Attentional Neural Context Aggregator

Recent work (Schlichtkrull et al., 2018; Vashishth et al., 2019; Bansal et al., 2019; Nathani et al., 2019) on graph neural networks has demonstrated

---

[1] In this subsection, we remove the relations as arguments in the score function for simplicity.

improved KG embedding quality by leveraging relational context. The context can help model and reason hierarchical relations with good explainability. For example, entities are more similar if they have deeper least common ancestors. Furthermore a triple may have multiple contexts, but not all the contexts are helpful. For example, to determine if two entities are more similar, the higher hierarchical-level common contexts are more useful. Motivated by these ideas, we propose attentional neural context aggregator, a graph-neural-network-based embedding updating module to update the representations of entities and relations by selectively aggregating the contextual information. Formally, it is defined as follows[2]:

$$\mathbf{e}_i^{(\mathbb{B}_c^d)'} = \mathrm{GNN}(\mathbf{e}_j^{(\mathbb{B}_c^d)}, \mathbf{r}_k^{(\mathbb{B}_c^d)} | j \in \mathcal{N}_i, k \in \mathcal{R}_{ij}) \tag{16}$$

where $\mathbf{e}_i^{(\mathbb{B}_c^d)'}$ denotes the updated embedding of the target entity, $\mathbf{e}_j^{(\mathbb{B}_c^d)}$ denotes the embedding of a tail entity e_j corresponding to the target entity e_i with the embedding $\mathbf{e}_i^{(\mathbb{B}_c^d)}$, $\mathcal{N}_i$ denotes the neighborhood of entity e_i and $\mathcal{R}_{ij}$ denotes the set of relations connecting entities e_i and e_j. We describe the relational context of an entity via the message vector $\mathbf{m}_{ijk}$, which is a linear transformation over the concatenation of entity and relation embeddings for a particular triple (e_i, r_k, e_j). Formally, it is defined as follows:

$$\mathbf{m}_{ijk} = \mathbf{W}_1 \otimes_c [\mathbf{e}_i^{(\mathbb{B}_c^d)} || \mathbf{e}_j^{(\mathbb{B}_c^d)} || \mathbf{r}_k^{(\mathbb{B}_c^d)}] \tag{17}$$

where $\mathbf{W}_1$ denotes the linear transformation matrix and $\otimes_c$ indicates the Möbius matrix multiplication. $[\,||\,||\,]$ represents the concatenation operation. We learn the importance of each message vector. In particular, a linear transformation parameterized by a weight matrix $\mathbf{W}_2$ is performed followed by application of the LeakyRelu activation function to get the absolute attention value of the triple. Since this transformation is defined in hyperbolic space, it is defined as follows:

$$b_{ijk} = \exp_o^c(\mathrm{LeakyReLU}(\log_o^c(\mathbf{W}_2 \otimes_c \mathbf{m}_{ijk})) \tag{18}$$

Next, we compute the attention value of each message vector by employing the softmax over b_{ijk} as follows:

$$\begin{aligned} \alpha_{ijk} &= \mathrm{softmax}_{jk}(b_{ijk}) \\ &= \frac{\exp(b_{ijk})}{\sum_{o \in \mathcal{N}_i} \sum_{q \in \mathcal{R}_{io}} \exp(b_{ioq})} \end{aligned} \tag{19}$$

Then we update the entity embedding. As suggested in (Veličković et al., 2017), we propose to utilize the multi-head attention to stabilize the learning process and encapsulate more information about the neighborhood. Then the new representation with N-head attention is defined as follows:

$$\mathbf{e}_i^{(\mathbb{B}_c^d)'} = ||_{n=1}^{N} \, \sigma\left(\sum_{j \in \mathcal{N}_i} \sum_{k \in \mathcal{R}_{ij}} \alpha_{ijk}^n \otimes_c \mathbf{m}_{ijk}^n\right) \tag{20}$$

To obtain the new representation of the relation, a linear transformation is employed as follows:

$$\mathbf{r}_k^{(\mathbb{B}_c^d)'} = \mathbf{W}_{rel} \otimes_c \mathbf{r}_k^{(\mathbb{B}_c^d)} \tag{21}$$

where $\mathbf{W}_{rel}$ denotes the linear transformation matrix for the relation embedding.

In particular, in this work we perform two iterations of embedding update to capture two-hop relational context. In the second iteration, we obtain the updated entity embedding by averaging (instead of concatenation) the embeddings from multiple heads by:

$$\mathbf{e}_i^{(\mathbb{B}_c^d)'} = \sigma\left(\frac{1}{N} \sum_{n=1}^{N} \sum_{j \in \mathcal{N}_i} \sum_{k \in \mathcal{R}_{ij}} \alpha_{ijk}^n \otimes_c \mathbf{m}_{ijk}^n\right) \tag{22}$$

To get the updated embedding while keeping the initial embedding information, we further employ a linear transformation layer to fuse the initial representation and the new representation:

$$\mathbf{e}_i^{(\mathbb{B}_c^d)''} = (\mathbf{W}_3 \otimes_c \mathbf{e}_i^{(\mathbb{B}_c^d)}) \oplus_c \mathbf{e}_i^{(\mathbb{B}_c^d)'} \tag{23}$$

where $\mathbf{W}_3$ is a weight matrix to trade-off the old and new representations. With the help of the graph attentional neural context aggregator, we can selectively gather the multi-hop context information to capture the semantic hierarchy.

3 Experiments and Results

3.1 Experimental Setup

Datasets We evaluated the proposed model on the link prediction task using three commonly used

---

[2] In this subsection, we remove the subscripts of modulus/phase indicator for all embedding related symbols for simplicity.

Dataset	#Entity	#Relations	#Train	#Valid	#Test	ξ_G
WN18RR	40,493	11	86,835	86,835	3,034	-2.54
FB15-237	14,541	237	237,115	272,115	17,535	-0.65
YAGO3-10	123,182	37	1,079,040	5000	5000	-0.54

Table 1: Dataset statistics. The lower the metric ξ_G, the more tree-like structure the knowledge graph has.

knowledge graph benchmark datasets, including WN18RR (Toutanova and Chen, 2015), FB15k-237 (Dettmers et al., 2018) and YAGO3-10 (Mahdisoltani et al., 2013). WN18RR is a subset of WordNet, which contains 11 lexical relationships between 40,943 word senses and has a natural hierarchical structure, e.g., *[motor_vehicle, hypernym of, truck]*. FB15k-237 is a subset of Freebase, a collaborative KB of general world knowledge. FB15k-237 has 14,541 entities and 237 relationships, most of which are non-hierarchical, e.g., *born-in or nationality*, while still having some hierarchical relations, e.g., *part-of*). YAGO3-10 is a subset of YAGO3, containing 123,182 entities and 37 relations, where most relations are hierarchical, e.g., *playsFor, actedIn*. Since each KG contains different numbers of hierarchical relations, we estimate the global graph curvature ξ_G (Gu et al., 2018) for all the datasets, which is a distance-based measure of whether the given knowledge graph has rich tree-like structure. The data statistics are summarized in Table 1.

Baselines We compare the proposed method to state-of-the-art methods, including Euclidean embedding models (RESCAL (Nickel et al., 2011), TransE (Bordes et al., 2013), DisMult (Yang et al., 2014), and MuRE (Balazevic et al., 2019)), Complex embedding models (complEx (Trouillon et al., 2016) and RotatE (Sun et al., 2019)), Neural Network based methods (Conve (Dettmers et al., 2018), CompGCN (Vashishth et al., 2019) and A2N (Bansal et al., 2019) and Hyperbolic model (MuRP (Balazevic et al., 2019)). Baseline results in the overall results subsection are taken from the original papers. The rest of baseline results are obtained by open-source implementations of each model. Specifically, we perform hyper-parameter search over the same parameters as indicated in the original papers to get these baseline results.

Ablations To analyze the advantage of hyperbolic geometry, we consider the variant of the proposed method, HKGAT – polar embedding only with attentional GNN updater. To analyze the advantage of graph neural network, we consider the variants of the proposed methods, including: (1) PE – polar embedding only without GNN updater. (2) HKGCN – polar embedding only with GCN updater. (3) HKGAT-khead – polar embedding only with k-head-attentional GNN updater.

Evaluation Protocol During the test stage, we evaluate each triple from the test set by generating n_e evaluation triples, including the test entity-relation pair with all possible entities. In particular we adopt the scoring function in Equation 15 to rank the correct tail or head entity against all possible entities, and use inverse relations for head prediction. We follow the standard evaluation protocol in the filtered setting: all true triples are removed from the evaluation triples apart from the current test triple. Similar to previous works, we compute two ranking-based metrics: (1) mean reciprocal rank (MRR), which measures the mean of inverse ranks assigned to correct entities, and (2) hits at $K(H@K, K \in 1, 3, 10)$, which measures the proportion of correct triples among the top K predicted triples.

Training Protocol We train the proposed method by minimizing the full cross-entropy loss with uniform negative sampling, where negative examples for a triple (e_h, r, e_t) are sampled uniformly from all possible triples obtained by perturbing the tail entity:

$$\mathcal{L} = -\sum_{e'_t \sim \mathcal{U}(\mathcal{V})} log(1+\exp(y_{e'_t} s(e_h, r, e'_t))) \quad (24)$$

where $y_{e'_t} = -1$ if $e'_t = e_t$, otherwise $y_{e'_t} = 1$. As optimization in hyperbolic space is challenging, we follow (Balazevic et al., 2019) and define all parameters in the tangent space at the origin. The optimization can be conducted in Euclidean geometry with exponential map to recover the hyperbolic parameters.

Implementation Details We implement the proposed method in PyTorch and conduct the experiments on NVIDIA Tesla V100 GPU. we implemented the graph neural network module using Pytorch Geometric Library[3], which can perform

---

[3] https://github.com/rusty1s/pytorch_geometric

the node-level operations in an inductive way and is easy to perform the parallel training to scale to the large knowledge graph. We conduct a grid search to select the learning rate, optimizer negative sample size, and batch size, using the validation set to select the best hyper-parameters. We make our implementation publicly available[4].

3.2 Overall Results

In this subsection, we compare the proposed method with existing state-of-the-art methods. The experimental results are shown in Table 2, where results of the baseline methods are reported as indicated in the original paper with the best hyper-parameters. As we can see, the proposed HKGAT and H^{2}KGAT outperforms all the baseline on datasets with rich hierarchical structures (WN18RR and YAGO3-10) and achieves the second best results on FB15k-237, which verifies the effectiveness of the proposed methods in representing hierarchical relations in KG. H^{2}KGAT outperforms its variant HKGAT, which demonstrates the effectiveness of hyperbolic embeddings. Besides, we can see hyperbolic methods achieve top performance on WN18RR and YAGO3-10 and beat the non-hyperbolic methods. It is also worth of noticing that GNN-based methods achieve top performance on all the dataset, which indicates the usefulness of leveraging relational contexts.

3.3 Analysis on Dimensionality

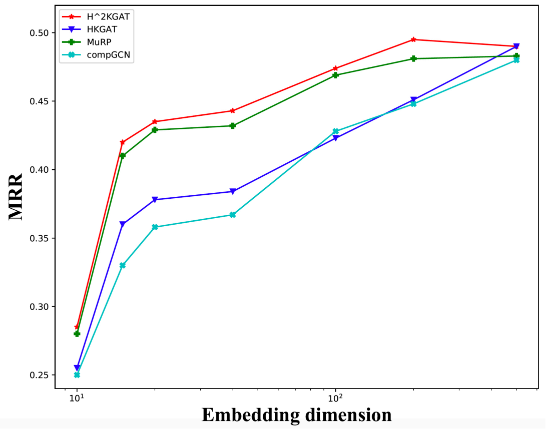

Figure 2: WN18RR MRR dimension for$d \in \{10, 15, 20, 40, 100, 200, 500\}$. Average and standard deviation computed over 10 runs.

In this subsection, we investigate the role of the dimensionality. We conduct experiments on WN18RR and report the MRR of HKGAT, H^{2}KGAT against state-of-the-art methods MuRP, compGCN at different dimensions $d \in \{10, 15, 20, 40, 100, 200, 500\}$. Fig. 2 shows the results, which are obtained by averaging over 10 runs. As expected, H^{2}KGAT achieves better performance across a broad range of dimensions, especially in lower dimensionality.

3.4 Analysis on Graph Neural Network

In this section, we study the effectiveness of the graph neural network module. The ablation results on WN18RR and FB15k-237 datasets are shown in Table 3. We can see that the model with graph neural network outperform the non-GNN model. The graph attention network with one head has similar performance compared with the graph convolutional variants. When the number of heads increases, the performance also increases.

Figure 3: Example of queries, their top prediction and the set of top 3, bottom 2 attention relational contexts as well as their attention probabilities for the H^{2}KGAT model.

To further study the effectiveness of the graph attention mechanism, we take some qualitative examples from FB15-k-237. The examples in Fig. 3 demonstrate how the model can benefit from the relational contexts. Specifically, the relation information within the relational contexts play a key role in identifying the correct prediction.

3.5 Analysis on Relation Type

In this subsection, we investigate how the performance of the proposed method is affected by relation types on WN18RR. We report a number of metrics to describe each relation, including the measures of hierarchy-level (global graph curvature ξ_G (Gu et al., 2018) and Krackhardt hierarchy score (Khs) (Krackhardt, 2014)), and maximum/average

shortest path between any two nodes in the KG for hierarchical relations. Specifically, we compare hits@10 for each relations of RotatE, MuRP, HKGAT and H^2KGAT for entity embeddings of low dimensionality (d= 20). From Table 4 we can see that all the models achieve comparable performance on non-hierarchical, symmetric relations with the low hierarchy-level, such as *verb_group*, whereas H^2KGAT generally outperforms the other models on hierarchical relations. We also observe that the performance gap between HKGAT and H^2KGAT is generally larger for relations that form deeper trees.

4 Related Works

In recent years, knowledge graph embedding models have been extensively investigated. Based on the defined embedding space, where the knowledge entities and relations are mapped to, we can divide knowledge graph embedding method into three categories–Euclidean embedding model, complex embedding model, neural networks embedding model.

Euclidean embedding model for KG representation has a long history. Rich approaches have been developed, including translational models (e.g., TransE (Bordes et al., 2013), TransD (Ji et al., 2015), TransH (Wang et al., 2014) and TransR (Lin et al., 2015)) and bilinear models (e.g., RESCAL (Nickel et al., 2011) and DistMult (Yang et al., 2014)). These methods simply consider Euclidean distance between the translated head-entity embedding and tail-entity embedding, which fail to capture the complex relations such as hierarchical relations.

Complex embedding model represent the knowledge graph embedding in complex space. Representative works include ComplEX (Trouillon et al., 2016), RotatE (Sun et al., 2019) and HAKGE (Gu et al., 2020). More recently, QuatE (Zhang et al., 2019) was proposed to learn KG embedding in quaternions. Complex embedding models are able to model complex relations, while the learned embeddings are usually in the high-dimensional space.

Neural network model have attracted considerable research interest in recent years, which map the entities and relations into the embedding space via neural network. NTN (Socher et al., 2013) and MLP (Dong et al., 2014) employ fully connected neural network to learn the entity embeddings and relation embeddings. ConvE (Dettmers et al., 2018) and ConvKB (Nguyen et al., 2017) leverage the convolutional neural networks. More

recently, graph neural networks are also applied to learn the KG embeddings. R-GCN (Schlichtkrull et al., 2018) and CompGCN (Vashishth et al., 2019) model the KG embedding via graph convolutional network. A2N (Bansal et al., 2019) and KBGAT (Nathani et al., 2019) employ the graph attention network. These methods can learn the KG embedding automatically in a data driven but they are not specifically designed to capture hierarchical relations.

A few recent works take hierarchical relations into consideration. (Xie et al., 2016; Zhang et al., 2018; Gu et al., 2020) explicitly model the semantic hierarchy. However, they require additional data or process and cannot capture the hierarchy automatically. On the other hand, embedding hierarchical data in hyperbolic space has attracted considerable research interest, due to its ability of naturally capturing the semantic hierarchies. (Balazevic et al., 2019) proposes MuRP to learn KG embeddings on hyperbolic space in order to capture the hierarchical structure automatically. However, MuRP has a number of limitations. First, it is a translation model, which can not encode complex relations. Second, it uses a fixed curvature, which may not adapt to the data. Third, it ignores the rich context information. Instead, our proposed method overcomes these limitations.

5 Conclusion

In this work, we propose H^{2}KGAT, a novel knowledge graph embedding framework to model and reason semantic hierarchies in the knowledge graph. H^{2}KGAT maps each entity and relation in a hyperbolic polar embedding space and further enhances the embedding learning via attentional neural context aggregator. With the help of the H^{2}KGAT, the semantic hierarchy can be modeled in an automatic and effective way. Experiments demonstrate that the proposed method significantly outperforms state-of-the-art methods on several benchmark datasets in terms of link prediction.

Does the Objective Matter?
Comparing Training Objectives for Pronoun Resolution

Abstract

Hard cases of pronoun resolution have been used as a long-standing benchmark for commonsense reasoning. In the recent literature, pre-trained language models have been used to obtain state-of-the-art results on pronoun resolution. Overall, four categories of training and evaluation objectives have been introduced. The variety of training datasets and pre-trained language models used in these works makes it unclear whether the choice of training objective is critical. In this work, we make a fair comparison of the performance and seed-wise stability of four models that represent the four categories of objectives. Our experiments show that the objective of sequence ranking performs the best in-domain, while the objective of semantic similarity between candidates and pronoun performs the best out-of-domain. We also observe a seed-wise instability of the model using sequence ranking, which is not the case when the other objectives are used.

1 Introduction

Hard cases of pronoun resolution have been a long-standing problem in natural language processing, which has served as a performance benchmark for the research community (Levesque et al., 2012; Wang et al., 2018, 2019a). For example, the WinoGrande dataset (Sakaguchi et al., 2019) consists of pronoun resolution schemas that are constructed so that resolving them requires background knowledge and commonsense reasoning. In WinoGrande, the pronoun is obscured by "___" to remove gender and number cues. The task is to find the correct candidate for "___" out of two given candidates. For example:

> *John moved the couch from the garage to the backyard to create space. The ___ is small.* Candidates: garage, backyard.

Recently, supervised learning on top of pre-trained language models has been established as the main approach for pronoun resolution (Kocijan et al., 2019b,a; Sakaguchi et al., 2019). Under this type of approach, we identify four categories of objectives commonly used for pronoun resolution:

1. comparing the language model probabilities for each candidate (Kocijan et al., 2019b,a; He et al., 2019),
2. using semantic similarity between the pronoun and the candidates (Wang et al., 2019b; He et al., 2019),
3. using sequence ranking among the possible substituted sentences (Opitz and Frank, 2018; Sakaguchi et al., 2019), and
4. selecting a candidate based on the attentions of the pronoun in a transformer model (Klein and Nabi, 2019).

We list one representative model from each category. For 1, Kocijan et al. (2019b) use the BERT masked language model (Devlin et al., 2018) to produce the probabilities of the pronoun to be replaced with each of the two candidates. For 2, the Unsupervised Deep Structured Semantic Model (UDSSM-I) (Wang et al., 2019b) uses contextualized word embeddings produced by a bidirectional recurrent neural network (BiRNN), and then compares the word embedding of each candidate with the word embedding of the pronoun. For 3, RoBERTa-WinoGrande (Sakaguchi et al., 2019) encodes a pair of sentences (one for each candidate substituted in the input) by using RoBERTa (Liu et al., 2019) to determine which substitution is the correct one. Finally, the zero-shot Maximum Attention Score (MAS) model (Klein and Nabi, 2019) selects a candidate based on how much the pronoun attends to each candidate internally in BERT.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4963–4969,
November 16–20, 2020.

The problem with all these objectives is that they have not been introduced under the same circumstances. They use different language models and word embeddings (e.g., BERT, RoBERTa, or BiRNN), and have been trained on different data (e.g., DPR (Rahman and Ng, 2012), WinoGrande, or no additional data). Therefore, it is unclear whether the choice of the objective function is essential for pronoun resolution tasks. Moreover, the seed-wise stability and the expected performance of these models have usually not been reported. However, seed-wise instability and performance variation are well-known problems when fine-tuning transformer-based models (Liu et al., 2020; Dodge et al., 2020).

In this work, we compare the performance and seed-wise stability of the four categories of training objectives for pronoun resolution on equal grounds. To do this, for category 4, we adapt to training the zero-shot MAS model. For category 2, we also introduce Coreference Semantic Similarity (CSS), which is a simplification and modification of UDSSM-I for transformer encoders. We select WinoGrande as our training and development dataset due to its large size (40,938 examples) and generalizability to other pronoun resolution tasks (Sakaguchi et al., 2019). We also use for testing the following well-established datasets: the Winograd Schema Challenge dataset (WSC) (Levesque et al., 2012) and the Definite Pronoun Resolution dataset (DPR) (Rahman and Ng, 2012). We choose as language model RoBERTa (Liu et al., 2019), as it significantly outperforms BERT on WinoGrande, WSC, and DPR (Sakaguchi et al., 2019).

Finally, our evaluations are done under an unprecedentedly large number of seeds (20).

2 Models

This section presents the four training objectives and the models[1] that represent each of them.

All four models share the RoBERTa[2] contextualized word embeddings. RoBERTa has an identical transformer architecture to BERT (Devlin et al., 2018), with the only difference being the training procedure. Hence, RoBERTa is a masked language model that outputs the probability distribution for filling a gap in the text (denoted by a "<mask>" token). Additionally, RoBERTa is a text encoder, with one output for each token of the input sentence. Three of the models (2.1, 2.3, and 2.4) use a multi-layer perceptron (MLP) classification "head", which takes some part of the encoder as input.

All four models use binary cross-entropy loss with a pair of probabilities as input, and the following target labels: sentence correctness for 2.1 and candidate correctness for 2.2, 2.3, and 2.4.

2.1 WinoGrande Sequence Ranking

We refer to the RoBERTa-WinoGrande model introduced by Sakaguchi et al. (2019) as WG-SR, since it has a sequence ranking objective. This model predicts which sentence of a pair of substituted sentences is more plausible. Each of the pair of sentences in the input of WG-SR is split in two before the substituted candidate. For example,

> <s> The city councilmen refused the demonstrators a permit because </s> </s> ___ feared violence. </s>,

where "___" is filled with each of the two candidates: "the city councilmen" or "the demonstrators".

The WG-SR code[3] is based on the RobertaForMultipleChoice model (Wolf et al., 2019), restricted to binary choice. This model consists of the pre-trained RoBERTa encoder and an MLP head based on the <s> (first) token of RoBERTa's output. The MLP has one hidden layer with tanh activation, hidden size matching that of the encoder, and one-dimensional output. The pair of input sentences $(\mathrm{S}_1, \mathrm{S}_2)$ thus produces a pair of values, which are then passed through a softmax to obtain the two sentence probabilities $P(\mathrm{S}_1)$ and $P(\mathrm{S}_2)$.

2.2 Binary Word Prediction

We denote by Binary Word Prediction (BWP) the model suggested by Liu et al. (2019) in their code repository[4] as a modification of the model from Kocijan et al. (2019b). Instead of using margin loss, BWP uses binary cross-entropy loss. We select this modified version, because it is claimed to be more robust by its authors, and it also has two fewer hyperparameters.

For a given (unsubstituted) input sentence, the BWP model estimates which of the two candidates is more likely to fill the gap "___". The input format is like in the following example, where "___" is

---

[1] The code is publicly available at: `https://github.com/YDYordanov/WS-training-objectives`.

[2] *roberta-large* from (Wolf et al., 2019)

[3] `https://github.com/allenai/winogrande`

[4] `https://github.com/pytorch/fairseq/tree/master/examples/roberta/wsc`

replaced by the "<mask>" token, to serve for the masked language model:

> <s> The city councilmen refused the demonstrators a permit because <mask> feared violence. </s>

With such an input, the RoBERTa masked language model returns the log-probability predictions at the "<mask>" token over the vocabulary. Of those predictions, only the ones corresponding to the two word candidates c_1 and c_2 are selected by BWP: $\log P_{\text{vocab}}(c_1)$ and $\log P_{\text{vocab}}(c_2)$. Here, the log-probability of each candidate is defined by averaging the log-probabilities of its tokens. Then, softmax is computed with inputs $\log P_{\text{vocab}}(c_1)$ and $\log P_{\text{vocab}}(c_2)$, which is how we define the pair of probabilities: $(P(c_1), P(c_2)) := (P_{\text{vocab}}(c_1)/(P_{\text{vocab}}(c_1) + P_{\text{vocab}}(c_2)), P_{\text{vocab}}(c_2)/(P_{\text{vocab}}(c_1) + P_{\text{vocab}}(c_2)))$.

2.3 Coreference Semantic Similarity

We propose Coreference Semantic Similarity (CSS), a modification of the training objective of the Unsupervised Deep Structured Semantic Model (UDSSM-I) (Wang et al., 2019b). Like UDSSM-I, the CSS objective works by comparison in the word embedding space, such that the candidate that is more similar to the embedding of the pronoun is selected. Unlike UDSSM-I, the CSS objective is simpler, with no attention weights on the tokens of the candidates. It also uses a transformer encoder instead of a recurrent neural network, which enables it to take advantage of state-of-the-art pretrained language models.

The input format for this model is the same as for BWP (2.2). This input is used by RoBERTa to produce contextualized word embeddings. For each candidate c, we define its contextualized word embedding $\text{emb}(c)$ by averaging the contextualized word embeddings of its tokens.

For classification, we compare the similarity scores of the embeddings of the <mask> token with each of the two candidates c_1 and c_2, i.e., we compare $\text{sim}(\text{emb}(c_1), \text{emb}(\text{<mask>}))$ and $\text{sim}(\text{emb}(c_2), \text{emb}(\text{<mask>}))$ and select the candidate with greater similarity.

For the similarity score function, we use *additive alignment* (Bahdanau et al., 2014), i.e., $\text{sim}(x, y) := v^{\top}\tanh(Wx + Uy)$, with the trainable parameters: vector v, and matrices W and U, with hidden size equal to that of RoBERTa and output size of one.

During training, $\text{sim}(\text{emb}(c_1), \text{emb}(\text{<mask>}))$ and $\text{sim}(\text{emb}(c_2), \text{emb}(\text{<mask>}))$ are fed to a binary softmax function to obtain $P(c_1)$ and $P(c_2)$.

2.4 Maximum Attention Score

The Maximum Attention Score (MAS) model was originally developed for zero-shot evaluation of transformer models on pronoun disambiguation (Klein and Nabi, 2019). It uses the attentions of all layers of a transformer model to produce a maximum attention score for each candidate that summarizes how much the pronoun attends to a candidate. The candidate that is most attended is selected. We adapt this objective to be trainable by replacing the summary of attentions with an MLP over the concatenated masked attention tensors, followed by a binary classifier.

The input of MAS is the same as for BWP (2.2). Then, similarly to Klein and Nabi (2019), we extract the two attention tensors A_{c_1} and A_{c_2} given by the multi-layer RoBERTa attentions of the "<mask>" token to each of the two candidates c_1 and c_2, respectively. For each candidate c, the attention tensor A_c is defined as the average of the attention tensors of all tokens that form c. The two corresponding max-masking tensors M_{c_1} and M_{c_2} are then derived as follows: for $i = 1, 2$ and for each multi-index j of the tensor A_{c_i}, we set $M_{c_i}(j) = 1$, if $A_{c_i}(j) \geq A_{c_{3-i}}(j)$, and $M_{c_i}(j) = 0$, otherwise. We obtain the two corresponding max-masked tensors by the element-wise products: $B_{c_1} = A_{c_1} \circ M_{c_1}$ and $B_{c_2} = A_{c_2} \circ M_{c_2}$.

Unlike Klein and Nabi (2019), we introduce an MLP on top of the concatenated tensor $B = [B_{c_1}, B_{c_2}]$ for binary classification. The MLP has two hidden layers, tanh activation, hidden size the same as its input, and two-dimensional output. It is followed by a binary softmax function to produce the two candidate probabilities $P(c_1)$ and $P(c_2)$.

3 Experiments

For all four models, we select the best hyperparameters via grid search using 3 seeds, and then train the models with the best hyperparameters on 20 additional seeds. For WinoGrande, we use WG-dev (1,267 examples) for selecting the hyperparameters, and WG-train-XL as our training dataset. Due to the submission limitation (maximum one per week) of the WinoGrande leaderboard,[5] we are unable to

Model	WG-dev	WSC	DPR
WG-SR	**78.2** (1.00)	89.2 (1.12)	92.2 (0.61)
BWP	76.3 (0.5)	89.6 (0.80)	91.8 (0.55)
CSS	77.4 (0.78)	**90.2** (0.90)	**92.7** (0.66)
MAS	76.6 (0.77)	89.0 (1.51)	92.3 (0.71)

Table 1: Seed-wise aggregated performance of models on WG-dev, WSC, and DPR. The number format is: average accuracy in %, and standard deviation (in parentheses). Out of the 20 seeds, only the converging ones are included. The best performance is marked in bold.

Model	Maximum	Average	Standard deviation	Number of converged
WG-SR	**80.0**	**76.8**	2.28	49 out of 96
BWP	77.6	75.4	1.45	54 out of 96
CSS	78.9	76.2	1.13	56 out of 96
MAS	77.7	74.5	2.50	69 out of 96

Table 2: Performance of all four models on WG-dev aggregated across all 96 hyperparameter combinations (including the three seeds). The numbers in the first three columns are: maximum accuracy in %, average accuracy in %, standard deviation. Only the converging models (with at least 60% accuracy) are reported, and their number is in the last column. The best performance is marked in bold.

report all 80 trained models on WG-test, and instead we report them on WG-dev. For additional verification, we include results over the hyperparameter space, where WG-dev is a true test set. We also report all models on the out-of-domain pronoun resolution datasets WSC (273 examples) and DPR (564 examples). The candidates provided in WSC were treated differently for the CSS and MAS models, as these models require precise candidate localization (see Appendix B).

For all four models, we do a grid search over the learning rate $\{5e-6, 1e-5, 3e-5, 5e-5\}$, the number of training epochs $\{3, 4, 5, 8\}$, and the batch-size $\{8, 16\}$, and we run each model with three different random seeds. This hyperparameter space is selected based on the union of the grid search by the original WG-SR work (Sakaguchi et al., 2019) and our observations on the other three models. The best hyperparameters (in Appendix A) are selected based on the maximum WG-dev accuracy across the three seeds.

For all experiments, we use linear learning rate decay with warm-up over 10% of the training data, and the AdamW optimizer (Wolf et al., 2019), for which we only alter the learning rate.

4 Results

Table 1 shows the final seed-wise results for all four objectives. We see that the semantic similarity objective (CSS) outperforms the other three objectives on out-of-domain testing, with 90.2% average accuracy on WSC and 92.7% average accuracy on DPR. On the other hand, the sentence ranking objective used by WG-SR clearly outperforms the other three objectives on in-domain testing, with 78.2% average accuracy on WG-dev. This is confirmed by the contents of Table 2, where we see that WG-SR has a better mean and max accuracy on WG-dev over the entire hyperparameter space compared to the other three models. For these cases, WG-dev is a true test set, since early stopping was not used, and all tested setups are reported; hence, WG-dev has not influenced the models reported in Table 2.

In order to verify the statistical significance of our main results, we used the t-test for similar variances and different sample sizes to compare the distributions of accuracy on the converging seeds. Comparing the accuracies of CSS and WG-SR on WG-dev, WSC, and DPR, respectively, we get the following two-tailed p-values: 0.008249, 0.003026, and 0.017441. All results are significant with $p < 0.05$.

We also observe that, even with the best hyperparameter combination, WG-SR exhibits seed-wise instability, as it fails to converge on 2 out of 20 seeds. This does not happen to the other three models. After considering 10 additional seeds, we obtained that WG-SR fails to converge on 10% of the seeds (3 out of 30).

Moreover, during the hyperparameter search, we observed that all models were prone to not converge for certain combinations of hyperparameters. The convergence threshold that we used was selected as having $\leq 60\%$ accuracy on WG-dev, and its value was selected based on the performance distribution of all models. We observed that all models either perform around 50% accuracy or 70% accuracy or more on WG-dev. 60% in this context is a good middle ground threshold. Table 2 shows that MAS converged most often; however, it also had the highest performance variation with a standard deviation of 2.5. Out of the four models, WG-SR converged least often, for only 49 out of all 96 hyperparameter combinations.

WG-SR likely performs better in-domain than CSS, MAS, and BWP, since those three use existing properties of RoBERTa (such as the possibility to compare contextualized embeddings, the attention structure of the model, and its pre-trained LM prediction head, respectively) for a task that they were not originally designed for (pronoun resolution). WG-SR, on the other hand, only uses the output of RoBERTa at the 0-th token, which is not pre-trained.

We identify two possible reasons why WG-SR performs worse than CSS on out-of-domain examples. The first reason is the one mentioned above, namely, not explicitly exploiting the listed properties of the pre-trained model would lead to a better fit on a specific dataset, but worse "general knowledge". This reason is not completely warranted, since WG-SR has similar out-of-domain performance to BWP and MAS. The second possible reason is that CSS uses an explicit candidate localization and candidate-pronoun matching (by comparing the embedding of the candidate and the pronoun), whereas in WG-SR these are achieved implicitly by feeding a pair of sentences to the model, one with the correct and one with the incorrect substitution. Again, this reason is not completely warranted, since MAS also uses explicit candidate localization and candidate-pronoun matching, but has a similar out-of-domain performance to WG-SR. Further investigation on the reasons why CSS outperforms WG-SR on the out-of-domain examples is left for future work.

5 Summary and Outlook

In this work, we categorized four existing objectives for pronoun resolution, and compared their performance and seed-wise stability on equal grounds. Our experiments showed that, on in-domain testing, the objective of sequence ranking based on the first token in RoBERTa outperforms the other three objectives, but can exhibit convergence problems. On out-of-domain testing, the objective of semantic similarity between the pronoun and each candidate outperforms the other three objectives.

Future work may investigate whether these results translate to other language models besides RoBERTa as well as other training datasets besides WinoGrande. Also, one could analyze the strengths and weaknesses of each objective, and evaluate other variations of these objectives.

A Best Hyperparameters

See Table 3 for the best hyperparameters for each model.

B WSC Preprocessing

When evaluating the CSS and the MAS model on the WSC dataset, we noticed a problem with the dataset, which interfered with locating the candidates in the text. The problem is that, in some WSC examples, the given candidate options do not match word-by-word the candidates as they appear in the text. For example,

> *Madonna fired her trainer because ___ couldn't stand her boyfriend.*
>
> Candidates: Madonna, The trainer.

In this example, we resolve this problem by manually replacing the candidate option "the trainer" with "her trainer", to match exactly the candidate as it appears in the text. By following this procedure, we manually modified all 88 problematic examples in WSC (out of 273 examples in total). Note that this problem does not exist for WinoGrande and DPR. Furthermore, in real-world applications, such a problem does not exist, since the candidates are not provided and have to be extracted automatically from the text. Detected candidates thus match the spans in the text.

We use this modified version of WSC only for the CSS and MAS models, because they require precise candidate localization. For WG-SR and BWP, we use the unmodified WSC version. The edited dataset can be found in the code repository[6].

Abstract

BERT set many state-of-the-art results over varied NLU benchmarks by pre-training over two tasks: masked language modelling (MLM) and next sentence prediction (NSP), the latter of which has been highly criticized. In this paper, we 1) clarify NSP's effect on BERT pre-training, 2) explore fourteen possible auxiliary pre-training tasks, of which seven are novel to modern language models, and 3) investigate different ways to include multiple tasks into pre-training. We show that NSP is detrimental to training due to its context splitting and shallow semantic signal. We also identify six auxiliary pre-training tasks – sentence ordering, adjacent sentence prediction, TF prediction, TF-IDF prediction, a FastSent variant, and a Quick Thoughts variant – that outperform a pure MLM baseline. Finally, we demonstrate that using multiple tasks in a multi-task pre-training framework provides better results than using any single auxiliary task. Using these methods, we outperform $\text{BERT}_{\text{Base}}$ on the GLUE benchmark using fewer than a quarter of the training tokens.

1 Introduction

When Devlin et al. (2018) released BERT, a transformer network (Vaswani et al., 2017) trained using a 'masked language model' (MLM) task and a 'next sentence prediction' (NSP), it redefined the NLP landscape, establishing itself as the state-of-the-art (SoTA) on many natural language understanding (NLU) benchmarks including the GLUE (Wang et al., 2018), SQuAD (Rajpurkar et al., 2016), and SWAG (Zellers et al., 2018) benchmarks.

Many models inspired by BERT have since surpassed its performance. However, in contrast to the original BERT paper, many obtained better results by excluding the NSP task. Some, such as XLNET (Yang et al., 2019) and RoBERTa (Liu et al., 2019), rely solely on a MLM variant, while others (Wang et al., 2020; Joshi et al., 2019; Cheng et al., 2019; Sun et al., 2019b) incorporate one or more different auxiliary loss functions. To our knowledge, there is no published work comparing or fully exploring auxiliary tasks for modern language models.

With multi-task learning's long history in transfer learning (Caruana, 1997; Parisotto et al., 2015; Ren et al., 2018), its use in language understanding models deserves further exploration. In this paper, we study existing and novel auxiliary tasks in a BERT paradigm to guide future research in an informed manner. Specifically, we test and provide insight on: 1) NSP's effect on BERT pre-training; 2) the result of 14 other auxiliary tasks on BERT pre-training; 3) how to combine multiple tasks in BERT pre-training; and 4) the advantages of multi-task learning in BERT pre-training. Although all experiments in this paper are conducted using BERT, we believe the results are applicable to BERT's successors (e.g. XLNET, RoBERTa, ERNIE...) and future models. The code is available at `https://github.com/StephAO/olfmlm`.

2 Related work

As with most deep learning, language representations require large datasets. While there exists corpora of labelled text, the vast majority of language data exists as raw, unlabelled text. Accordingly, many language embedding methods, and all those described below, rely solely on unsupervised or self-supervised tasks.

2.1 Pre-transformer sentence embeddings

Skip-Thoughts (Kiros et al., 2015) was the first deep learning sentence embedding model. Its training objective, inspired by word2vec (Mikolov et al., 2013), used RNNs to reconstruct the previous and next sentence from a given sentence. Like word2vec, similar sentences shared similar embeddings, and while it exhibited promising results, it

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4970–4981,
November 16–20, 2020.

was slow to train due to its encoding and double decoding of sentences through RNNs. Hill et al. (2016)'s FastSent tried to follow the same sequential sentence paradigm at a reduced training cost by encoding a sentence using a bag-of-words approach and maximizing the probability of words in adjacent sentences. Later, Quick Thoughts (Logeswaran and Lee, 2018) managed to maintain the sequential sentences objective while supporting ordered words. Using two RNN models, $f(s)$ and $g(s)$, they embedded a first set of sentences using $f(s)$ and a second set consisting of the subsequent sentences using $g(s)$. They jointly train the two models to predict the consecutive sentences from a set of candidates by comparing inner products. This resembles a referential game (David, 1969) where $f(s)$ and $g(s)$ are the sender and receiver respectively.

The previous methods relied on the premise that adjacent text is semantically similar, but other sentence embedding methods have relied on other linguistic properties. The sequential denoising autoencoder (SDAE) (Hill et al., 2016) corrupts a sentence through deletion or word order swapping, encodes it, then attempts to decode the original uncorrupted sentence from the encoding. This shares the same underlying sequence-consistency concept as BERT's MLM. Brahma (2018) also focused on sequence consistency by predicting whether or not a sentence had been corrupted through deletion, insertion, replacement, or permutation. These methods only require individual sentences rather than a set of sequential sentences.

2.2 Transformer-based sentence embeddings

The development of the transformer network (Vaswani et al., 2017) overcame the sequential bottleneck of RNNs by fully utilizing the parallelization of modern processing units, and enabling language models to train on significantly more data in less time. GPT (Radford et al., 2018) and its successor GPT-2 (Radford et al., 2019) were the first models to fully leverage this breakthrough. Following traditional language modelling, their training objective is to maximize the probability of a sequence of tokens x using the products of their conditional probabilities $p(x) = \prod_{i=1}^{n}(t_n \mid t_{n-1}, ..., t_1)$.

Devlin et al. (2018) addressed the limitation of unidirectional context in traditional language modelling in their development of Bidirectional Encoder Representations from Transformers (BERT) – a transformer trained using a masked language modelling (MLM) task and next-sentence prediction (NSP) task on approximately 137 billion tokens from a 3.3 billion word corpus created from the concatenation the BooksCorpus (Zhu et al., 2015) and English Wikipedia datasets. The masked language model modifies the traditional language model to consider the bidirectional context in its prediction. For each sequence, 15% of tokens are replaced with a [MASK] token. The model is then trained to predict the masked words. The NSP task uses the output embedding of the [CLS] token that prepends the sequence to predict whether the second sentence follows the first or is from a different document. BERT's original paper claimed that this task improved performance on downstream natural language inference (NLI) tasks.

MASS (Song et al., 2019), ERNIE (Sun et al., 2019a), and SpanBERT (Joshi et al., 2019) extended the MLM task by masking a sequence of contiguous tokens instead of a single token. All three demonstrated the superiority of this approach. MASS used a seq2seq model (Sutskever et al., 2014) to decode the sequence of masked tokens. ERNIE used larger sequences of tokens over the course of three stages – first identical to BERT, then masking phrases, then masking full entities. They additionally added a dialogue language model task using the CLS token to classify between question-response pairs and random pairs. SpanBERT uses spans of sampled lengths and a 'span boundary objective' where the token embeddings adjacent to the span are used to predict the masked span. Each of their additions provided gains on a range of downstream tasks, with maximal gains using both. They additionally showed that NSP is detrimental to training, hypothesizing that the context splitting required for NSP is more detrimental than the advantages provided from the task. Cheng et al. (2019) argued that NSP is semantically shallow and does not leverage BERT'S bidirectional nature, and replaced NSP with a three-way classification task of identifying whether one sentence follows or precedes another, or is from a different document. Using this simple change, they achieved a modest improvement over the BERT baseline.

XLNET (Yang et al., 2019) used permuted sentences to combine the true language modelling objective of GPT-2 (Radford et al., 2019) and BERT's insight of bi-directional context. It included the advancements from transformer-XL (Dai et al., 2019) to increase the context length, and created a larger training dataset. It also ran a small ablation study and found that removing the NSP task improved overall results. XLNET beat BERT on 20 tasks, achieving SoTA on 18. Shortly thereafter, Liu et al. (2019) introduced RoBERTa, which followed the core concepts of BERT closely, but optimized design choices, such as dynamically masking tokens each epoch instead of pre-masking the entire dataset, increasing the batch size, using full sentences in each batch, and removing the NSP loss. With these changes, and an increased dataset, they matched XLNET's performance.

Sun et al. (2019b)'s ERNIE 2.0 made further gains in the GLUE leaderboard[*] by incrementally adding seven tasks in a "continual multi-task learning" framework. They trained on ERNIE's original token/phrase/entity masking, capitalization prediction, token-document prediction, sentence reordering, sentence distance prediction, discourse relations, and information retrieval (IR) relevance. They provided no information on the benefit from any of the individual tasks or the ordering of the tasks. Raffel et al. (2019)'s T5, also high on the leaderboard, achieved their results using an encoder-decoder variant of BERT. Through rigorous experimentation of implementation details, culminating in a gigantic 11 billion parameter model trained on more data, using spans, multi-task learning on the supervised downstream tasks, and using beam search, they achieved SoTA on a vast array of tasks. Wang et al. (2020)'s StructBERT used a word structural objective, where the model has to recover a shuffled tri-gram, and sentence structural objective – identical to Cheng et al. (2019)'s three-way classification task, to place high on the leaderboard as well.

3 Method

3.1 Baselines

Our primary motivation in this paper is to study and survey auxiliary pre-training tasks for multi-task learning for modern language understanding models. In this case, 'modern' is a transformer-based model pre-trained on a large unlabelled corpus using a form of masked language modelling. This definition captures the large majority of recently successful language models. For our baseline we choose BERT, as it is the basis for subsequent models, but only include the MLM task as the benefits of the NSP task are debated (Liu et al., 2019; Yang et al., 2019). For computational reasons we use $\text{BERT}_{\text{Base}}$ ($L = 12$, $H = 768$, $A = 12$, Total Parameters=110M), and use the uncased WordPiece tokenizer (Wu et al., 2016) with vocabulary size of 30522 provided by Google[†].

3.2 Auxiliary pre-training tasks

To provide a fair comparison and due to computational constraints, we limit the scope of our investigation to auxiliary tasks that can be directly used on any corpus of unlabelled data, do not require any language decoding, and require at most one additional classification layer. This excludes the discourse relation task, the IR relevance task (Sun et al., 2019b), and the dialogue language modelling task (Sun et al., 2019a) as they require datasets that violate these constraints. We also exclude a Skip-Thoughts approach as sequentially decoding outputs would require significantly more computational resources. Token level tasks only use token embeddings as input. Sentence-level tasks use the [CLS] token embedding as input. The FastSent variant uses both, but we label it as a sentence-level task as it does require the sentence embedding (from the [CLS] token). Tasks that have not previously been applied to modern language models are italicized. We investigate the following tasks:

Token level tasks

1. *Term Frequency prediction (TF)*: Regression predicting a token's frequency in the rest of the document. The frequency is re-scaled between 0 and 10 per document.
2. *Term Frequency-Inverse Document Frequency prediction (TF-IDF)*: Regression predicting a token's tf-idf that has been re-scaled between 0 and 10 per document.
3. Sentence Boundary Objective (SBO): Predict the masked token given the embeddings of the adjacent tokens.
4. Trigram-Shuffling (TGS): 6-way classification predicting the original order of shuffled tri-grams.
5. *Token Corruption Prediction (TCP)*: Binary

---

[*] `https://gluebenchmark.com/leaderboard`

[†] `https://github.com/google-research/bert`

classification of whether a token has been corrupted (inserted, replaced, permuted) or not.

6. Capitalization Prediction (Cap.): Binary, whether a token is capitalized or not.
7. *Token Length Prediction (TLP)*: Regression to predict the length of the WordPiece token.

Sentence level tasks

8. Next Sentence Prediction (NSP): Binary, whether the second sentence follows the first or comes from a separate document.
9. Adjacent Sentence Prediction (ASP): 3-way classification whether the second sentence proceeds the first, precedes the first, or they come from separate documents.
10. Sentence Ordering (SO): Binary, predicting if the two sentences are in or out of order.
11. Sentence Distance Prediction (SDP): 3-way classification of whether the second sentence proceeds, the two sentences are non-contiguous from the same document, or come from separate documents.
12. *Sentence Corruption Prediction (SCP)*: Binary classification of whether a tokens in a sentence have been corrupted (inserted, replaced, permuted) or not.
13. *Quick Thoughts variant (QT)*: Split each batch into two, where the second half contains the subsequent sentences of the first half (e.g. with batch size 32, sentence 17 follows sentence 1, sentence 18 follows sentence 2,...). We use an energy-based model to predict the correct continuation for each sentence in the first half where the energy between two sentences is defined by the negative cosine similarity of their [CLS] embeddings. We use one model to encode both halves concurrently. See Figure 1.
14. *FastSent variant (FS)*: Split each batch into two, where the second half contains the subsequent sentences of the first half (same as QT above). The loss is defined as cross-entropy between 1.0 and the cosine similarity of a sentence [CLS] embedding and the other sentence token embeddings ([CLS] embedding from the first half with token embeddings from the second half and [CLS] embeddings from second half with token embeddigns from the first half). We use one model to encode both halves concurrently.

3.3 Combining tasks

BERT originally proposed summing the MLM and NSP losses directly. ERNIE uses significantly more losses and proposes a continual multi-task learning framework to incorporate them, in which they incrementally add new tasks while sampling previously learnt tasks. To provide insight on how best to combine tasks, we investigate the six following ways of combining a set of tasks for BERT pre-training:

1. Sum losses from all tasks (sum.)
2. Incrementally add tasks, summing the losses from all added tasks (Inc.)
3. Alternating between tasks each iteration (Alt.)
4. Alternating between auxiliary tasks each iteration and summing it with MLM (Alt.+)
5. ERNIE's continual multi-task learning (CMTL), for more detail see Appendix A
6. ERNIE's continual multi-task learning on auxiliary tasks summed with MLM (CMTL+)

We note that both a direct summation and a simple incremental approach cannot accommodate tasks that require different input structures – for example sentence ordering, which requires that the two sentences are always adjacent, cannot be trained simultaneously with next sentence prediction, which requires sentences from different documents at times – or different corpora, such as ERNIE 2.0's IR relevance dataset.

3.4 Input Representation

To construct the input embedding to the transformer, we sum token embeddings, learned position embeddings, learned sentence type (sentence A or B) embeddings, and, to enable ERNIE's continual multi-task learning, a learned task id embeddings .

3.5 Dataset

We follow precedent in using the BookCorpus[‡] (Zhu et al., 2015) and Wikipedia dataset as our corpora. We filter the Wikipedia corpus in the same fashion as BERT, ignoring lists, tables, and headers. We additionally filter documents that have: fewer than 10 words or fewer than 4 sentences. This excludes small uninformative documents. We additionally segment long documents into documents of roughly 1024 tokens. This creates a corpus with 2.7 billion words (3.8 billion tokens) divided into 6.8 million documents.

[‡] Unfortunately, the BookCorpus is no longer publicly available.

3.6 Pre-Training Details

For all tests, we train on 10 billion tokens using an Adam optimizer (Kingma and Ba, 2014) with a learning rate of 1e-4 that warms-up over the first 1% of tokens and linearly decays after, batch size = 128, max sequence length = 128, β_1 = 0.9, β_2 = 0.999, L2 weight decay of 0.01, and a dropout probability of 0.1. In accordance with other papers, we use a gelu activation (Hendrycks and Gimpel, 2016). Using four p100 GPUs, it takes between 13 and 15 hours to train a model for each one billion token epoch depending on the tasks used.

3.7 Fine-Tuning Details

All models are tested on the GLUE (Wang et al., 2018) benchmark, as it has been accepted by the community as a benchmark for NLU. We also compare the final best model and our baseline on the SuperGLUE (Wang et al., 2019a) benchmark. Following Devlin et al. (2018); Cheng et al. (2019), we disregard GLUE's problematic WNLI task. Due to GLUE's private test set, and the number of experiments performed, the results are on the available development set except for the final results in Tables 3 and 4. To fine-tune the model on the GLUE dataset, we use Jiant's (Wang et al., 2019b) provided code[§]. We limit the maximum number of epochs to 3 and we run the fine-tuning procedure three times with learning rates = 5e-5, 3e-5, 2e-5 and take the best results for each task individually across these runs. This is done to reduce the variance in the results that comes from the low-resource tasks CoLA, RTE, and MRPC. For all other fine-tuning parameters, we use the default values provided by jiant unless otherwise stated.

3.8 Final Model

Our final CMLT+ model is shown in Figure 1 to help visualize the inputs to each task.

[§] https://github.com/nyu-mll/jiant

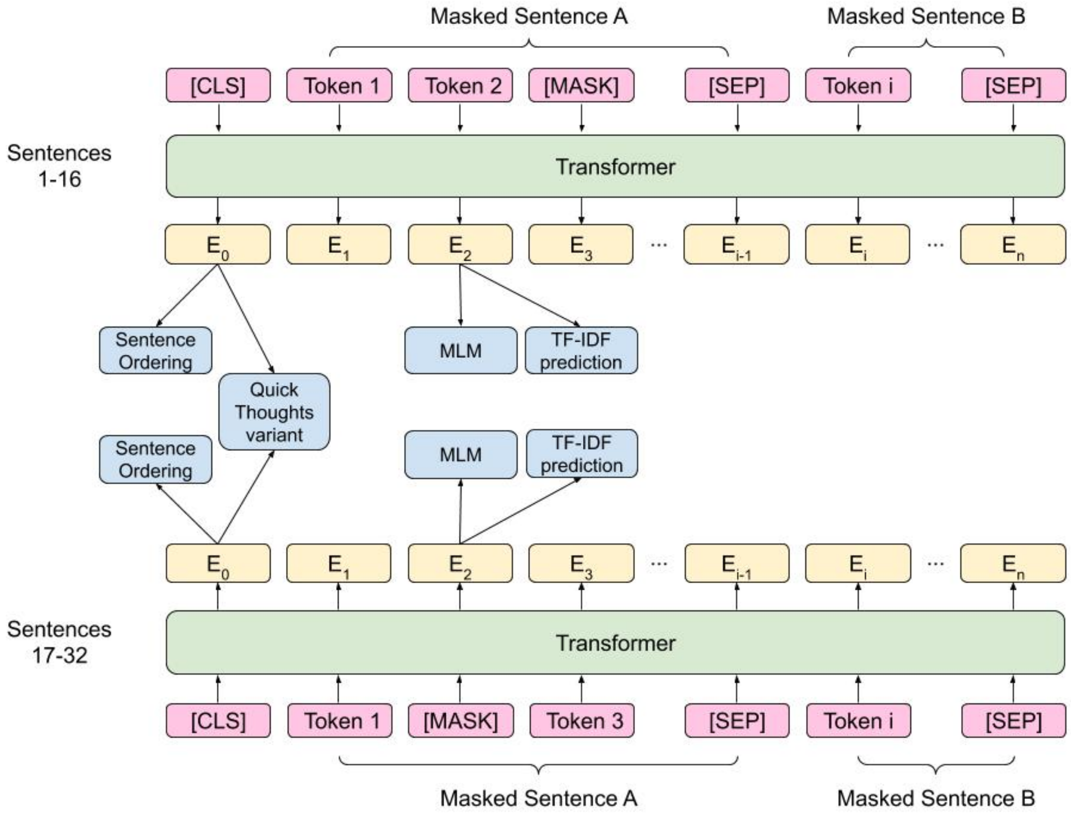

Figure 1: Architecture used for the combined tasks tests. Sentences 17-32 are the continuations of sentences 1-16 respectively (1-17, 2-18, 3-19...). The two halves of the batch are only split for clarity of the Quick Thoughts variant task; they are embedded at the same time by the same network. Though only depicted on only one token, the token level tasks (MLM, TF-IDF prediction) are trained across all token embeddings.

4 Results

In this section, we present the results from an array of different tests. Due to the stochastic nature of the training, we would ideally run each test numerous times. However, this is prohibitively expensive due to the computational costs. Building from Raffel et al. (2019)'s experimental approach, we instead calculate the standard deviation for 5 independent trainings of the baseline MLM-only model, the MLM + NSP model, and our CMTL+ model. We find $\sigma_{MLM} = 0.198$, $\sigma_{NSP} = 0.222$, $\sigma_{CMTL+} = 0.273$, and use the highest, $\sigma = 0.273$, as an estimate for the standard deviation across all experiments. See Appendix B for more detail. This is comparable to Raffel et al. (2019)'s estimated standard deviation of 0.235. In each table, we boldface all average GLUE scores that are two estimated standard deviations above the MLM baseline. For the average GLUE score, we follow Wang et al. (2018) and average the macro averages of each task. This is different than averaging the numbers in a row as we only report one metric per task.

4.1 Understanding NSP

To understand the role of NSP in BERT pre-training we compare the performance of three models: the first trained on MLM; the second trained on MLM and NSP; and the third trained on MLM with NSP's context split, but without NSP's loss, which we label split. Contrasting the MLM model to the split model explicates the impact of splitting the inputs context, while comparing the NSP model to the split model clarifies the benefits of the NSP loss. As expected, figure 2 a) demonstrates a clear performance drop when splitting contexts. From figure 2 b) and 2 c), we see the biggest drops are from inference tasks. We hypothesize that providing a model split contexts and no signal to differentiate it from contiguous text hinders it's ability to understand the logical flow of language. As we contrast the NSP model and the split model, we see that adding such a signal does indeed improve the results on inference tasks, especially in early stages of training. However, as training progresses, its benefit stagnate. This may be because, as other papers

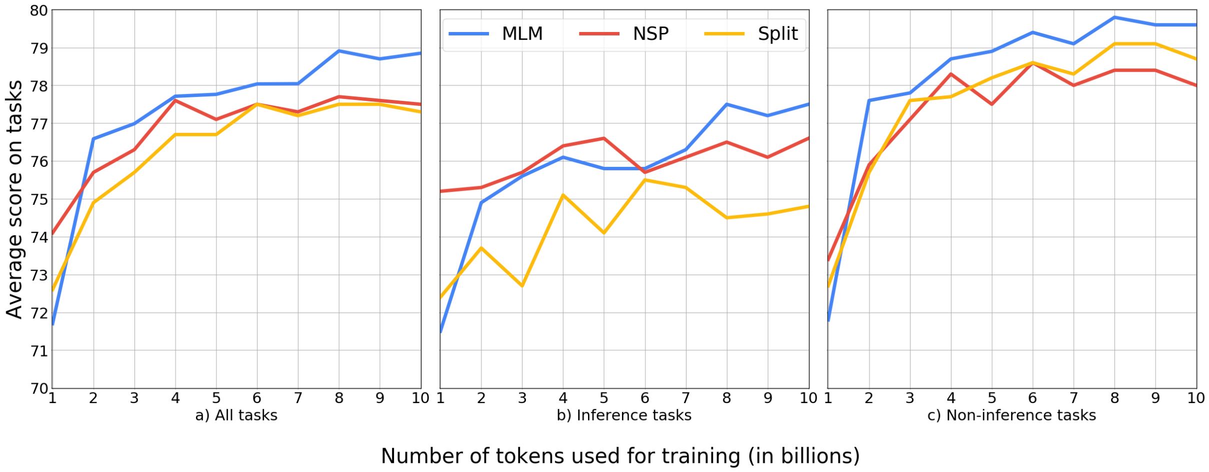

Figure 2: Average results on a) all GLUE tasks, b) only inference tasks (MNLI, QNLI, RTE), and c) non-inference tasks (QQP, SST-2, CoLA, STS-B, MRPC) for models trained on MLM, MLM + NSP, and MLM with NSP's split context but no NSP loss (Split) throughout training over 10 billion tokens.

have proposed, NSP is semantically shallow and can often be solved easily through lexical overlap. Interestingly, figure 2 c) shows that the NSP loss provides no benefits, and may indeed be detrimental towards non-inference tasks even when compared to the split model. Finally, we see that the MLM model continues to improve throughout each stage of training, whereas both the NSP model and the split model see have diminishing returns with more training, indicating that splitting the context imposes inherent limitations on language models.

4.2 Auxiliary Tasks

We first compare the 14 auxiliary tasks in Table 1 to a MLM baseline (No Aux.). As noted in the previous section, and supporting many recent papers (Liu et al., 2019; Yang et al., 2019; Joshi et al., 2019), NSP is detrimental to training. As discussed by Cheng et al. (2019) and reinforced by the results of (Wang et al., 2020), next sentence prediction provides a shallow supervision signal, and is often solvable through lexical overlap. Adjacent sentence prediction and sentence ordering on the other hand require deeper semantic understanding of the structure of language. Our results clearly support this claim, with SO and ASP outperforming MLM and NSP on all inference tasks and greatly outperforming all auxiliary tasks on RTE, the only low-resource inference task. Additionally, they are less penalized by context splitting, which we have shown to degrade performance; NSP and SDP cut the context in half 50% of the time, ASP cuts the context in half a third of the time, and sentence ordering preserves the full context in all cases, albeit shuffled. The model trained using the Quick Thoughts variant (QT) performs the best out of all the above models. We hypothesize that the loss, based on cosine similarity, provides a soft clustering around semantically similar topics, which produces more distinguishable embeddings. The FastSent variant (FS) provides a similar signal and performs the second best, suggesting that some form of soft clustering does provide substantial benefit to pre-training. TF-IDF, and to a lesser extent TF, prediction also improve performance on a range of downstram tasks. This aligns with Sun et al. (2019b)'s observations that identifying high value words (and discounting filler words) provides a useful signal for language models. All other tasks fail to provide any meaningful gains. Of these, the context distortion from the corruption prediction tasks (TC and SC) likely outweigh their benefit. Additionally, MLM is already a form of corruption, making TC and SC partially redundant. Our results did not find the Sentence Boundary Objective (SBO) to be beneficial. However, as it was originally implemented for spans, this does not discount the results of Joshi et al. (2019); in our context, which only masks a single word, it is likely redundant with MLM. The trigram shuffling (TGS) tasks similarly did not provide the value exhibited in Wang et al. (2020). However, due to a lack of details and code in the original paper, implementation details may be at fault. Token length and capitalization prediction, which were implemented as other proxies for word importance prediction, appear to be too noisy for their intended purpose.

	MNLI	QQP	QNLI	SST-2	CoLA	STS-B	MRPC	RTE	Avg.	Dev. Set Avg.
$\text{BERT}_{\text{Base}}$	84.6/83.4	71.2	90.5	93.5	52.1	85.8	88.9	66.4	79.6	-
MLM baseline	81.8/81.3	70.0	87.1	90.4	45.3	80.6	87.3	59.2	76.1	80.0
CMTL+	83.8/82.9	71.7	90.7	92.2	56.3	83.4	88.8	66.9	80.1	83.2
$\text{BERT}_{\text{Large}}$ (330M)	86.7/85.9	72.1	92.7	94.9	60.5	86.5	89.3	70.1	82.1	-
RoBERTa (355M)	90.8/90.2	74.3	95.4	96.7	67.8	91.9	92.3	88.2	87.88	-
T5 (11B)	92.2/91.9	75.1	96.9	97.5	71.6	92.8	92.8	92.8	89.78	-

Table 3: GLUE test results, scored by the evaluation server excluding the problematic WNLI task. Matched/mismatched accuracy are reported for MNLI, F1 scores are reported for QQP and MRPC, Spearman correlations are reported for STS-B, and accuracy scores are reported for the other tasks. The $\text{BERT}_{\text{Base}}$ results are from the original BERT paper (Devlin et al., 2018). The MLM baseline and CMTL+ models are our implementations. We include the performance of our models on the development set for reproducibility. Best results in each column for models of comparable size are underlined. For context, we additionally include results from the GLUE leaderboard for $\text{BERT}_{\text{Large}}$, RoBERTa, and T5, and their respective size measured by number of parameters. $\text{BERT}_{\text{Base}}$, MLM baseline, and CMTL+ all have a size of 110M parameters.

	BoolQ	CB	COPA	MultiRC	ReCoRD	RTE	WiC	WSC	Avg.
MLM baseline	69.2	67.8	59.0	30.7	33.0	59.4	61.0	65.1	55.7
CMTL+	72.0	72.9	62.8	34.9	33.0	64.0	64.9	65.1	58.7
$\text{Bert}_{\text{Large}}$ (330M)	77.4	79.5	70.6	47.1	71.7	71.7	69.6	65.1	69.0
T5 (11B)	91.2	95.4	94.8	75.7	93.8	92.5	76.9	93.8	89.3

Table 4: SuperGLUE test results, scored by the evaluation server. Both models use most common class prediction for ReCoRD and WSC. The MLM baseline also uses most common class prediction for MultiRC. Best results in each column for models of comparable size are underlined. For context, we additionally include results from the SuperGLUE leaderboard for $\text{BERT}_{\text{Large}}$ and T5, and their respective size measured by number of parameters. CMTL+ and MLM baseline both have sizes of 110M parameters.

4.3 Combining Tasks

To test combining multiple tasks, we use all auxiliary losses that substantially outperform a pure MLM baseline. For tasks that provide similar signals, we select the one that achieved a higher average on the previous test; QT is chosen over FS and TF-IDF is chosen over TF. Between ASP and SO, which have a statistically insignificant difference, we choose SO as it retains the full context, as any split context from ASP would likely be detrimental to the other tasks. This provides 4 tasks for the multi-task training: MLM, QT, SO, and TF-IDF.

Table 2 shows a stark contrast between incorporating an MLM loss term in each iteration compared to treating MLM equivalent to other tasks when switching between them; Alt.+ and CMTL+ both outperform their counterparts by 1.9 and 3.3 percent respectively. Our results indicate that multi-task training with MLM preserves the benefits of each individual task, with the combined models retaining QT's high CoLA score and SO's high RTE score. Further, these gains are additive in most cases: for QNLI, MNLI, and STS-B the combined models performs better than any single auxiliary task models. This leads to a model that vastly outperforms the baseline MLM model or using any singular auxiliary task.

Between combination methods that use MLM in every iteration, the incremental approach appears to be the worse, while summing everything, alternating auxiliary tasks (Alt.+), and continual multi-task learning on auxiliary tasks (CMTL+) all perform similarly, with CMTL+ slightly outperforming the other two, which supports Sun et al. (2019b)'s results. Interestingly, both approaches where tasks vary each iteration (Alt.+ and CMTL+) see a significant benefit on the CoLA task. While not beneficial in our framework, an alternating pattern or CMTL have the additional benefit of enabling different input structures or the use of different corpora (such as ERNIE 2.0's IR relevance corpora), which cannot be done using a direct summation.

4.4 Final Results

For our final test, we train our baseline MLM model and CMTL+ model on 32 billion tokens and present the results using the GLUE and SuperGLUE evaluation servers in Tables 3 and 4 respectively. When fine-tuning these models, we run an exhaustive hyper parameter search on learning rates = 1e-5, 2e-5, 3e-5, 5e-5, batch sizes = 16, 32, and number of epochs = 2, 3, 4. The results show that the CMTL+ model – trained on MLM, QT, SO, and TF-IDF in a continual multi-task learning framework – vastly outperforms the MLM baseline in every task. Further, our model trained on 32 billion tokens outperforms the original $\text{BERT}_{\text{Base}}$, which required 137 billion tokens. While we include larger models – $\text{BERT}_{\text{Large}}$, RoBERTa, and T5 – in the tables for context, we remind the readers that these results are not comparable to our results. First, they are larger, with sizes of 330 million, 335 million, and 11 billion parameters respectively, compared to our 110 million parameters. Second, RoBERTa and T5 are trained using a much larger dataset of 160 GB and 750 GB compared to our (and $\text{BERT}_{\text{Large}}$'s) 13 GB. Finally, $\text{BERT}_{\text{Large}}$, RoBERTa, and T5 are trained on more tokens, training on 137 billion, 2.2 trillion, and 1 trillion tokens respectively compared to our 32 billion tokens. While the results are not comparable, we hope that the tasks we used in our model can be utilized by newer and larger models to improve their understanding of language.

5 Discussion

Our results support several recent papers: we support Liu et al. (2019); Yang et al. (2019); Joshi et al. (2019)'s claim that NSP hinders BERT pre-training, especially for non-inference tasks, due to cutting context half the time; we reinforce Cheng et al. (2019); Wang et al. (2020)'s proposal that NSP prediction is a semantically shallow and often solvable through lexical overlap and that using a task that requires understanding the ordering of contiguous text provides a stronger semantic signal; and we uphold Sun et al. (2019a,b)'s idea that a language model should be trained in a multi-task setting. Further, we offer novel methods and insights. Providing a signal to reduce the embedding distance between semantically similar sentences, as in our FastSent or QuickThought variants do, produces a strong boosts to downstream tasks, with the hypothesis that they produce more distinguishable embeddings. Providing a signal that relays word importance, such as TF-IDF and TF, likewise produces substantial benefit to BERT pre-training. We show strong evidence that a MLM variant loss should always be included when multi-task learning. Finally, we demonstrate the value of multi-task learning for language model pre-training; combining multiple beneficial tasks leads to better results than using any of the individual tasks alone.

As our focus was a breadth-based search of possible auxiliary tasks, we believe that further gains are possible through a deeper exploration of each task. Using soft labels in ASP for sentences that are near (but not directly adjacent to) the other sentence has been shown to provide improvements (Cheng et al., 2019). (n!)-way classification with n sentence-pieces for sentence ordering is a more challenging task that could provide additional benefits. Other similarity metrics, such as dot product or Euclidean distance, may provide more useful for the FS or QT methods. Beyond using a loss based on a similarity metric, it is possible that other unsupervised clustering algorithms could be beneficial. Currently, each task has different loss ranges based on the nature, and not the inherent value, of the task. As some tasks may be more useful than others, it is likely that weighting each task based on some value metric could prove beneficial. Groups with sufficient computational resources may also be interested in exploring how the ordering in the continual multi-task learning framework affects downstream tasks. Lastly, we do not tune hyperparameters, using only the stated values from previous papers for all our experiments. We leave the above potential to future work.

6 Conclusion

We investigate and support several reasons why next-sentence prediction is ill-suited for BERT pre-training, we provide better inference-based alternatives, and we develop other novel auxiliary tasks based on word importance and soft clustering that provide substantial benefits to BERT pre-training. We also demonstrate the benefit of multi-task learning in BERT pre-training, and identify key factors on how to best combine tasks. We hope the insights provided here will help guide the development of better language models in the future.

A Continual Multi-Task Learning

Though no explicit details are provided for ERNIE 2.0's continual multi-task learning (CMTL), we infer the following algorithm from their description and example:

1. Split training into N stages where N is the number of non-jointly trained tasks (e.g. in our final model, only auxiliary tasks are counted, MLM is not counted). Each stage defines a number of tokens to be trained on for each task. When each task has been trained on for the specified number of tokens, the training moves to the next stage.
2. Calculate the token chunk size, $C = T/(N * (N+1))$, where T is the total number of training tokens.
3. Each stage, S_i, a new task is introduced. During that stage the new task is trained on $C*(i+1)$ tokens, previously introduced tasks are trained on C tokens, and yet to be introduced tasks are trained on 0 tokens.

The method can use iterations or tokens. The above method trains on each task using the same number of tokens/iterations, gradually incorporating more tasks, while still training on previous tasks. Below we provide two examples. The first from (Sun et al., 2019b) which uses four tasks and 200k iterations, the second from our final combined model which uses three tasks (MLM not included) and 10 billion tokens.

Task	Stage 1	Stage 2	Stage 3	Stage 4
1	20k	10k	10k	10k
2	0	30k	10k	10k
3	0	0	40k	10k
4	0	0	0	50k

Table 5: Training using CMTL with 4 tasks over 200k total iterations. Example from Sun et al. (2019b)

Task	Stage 1	Stage 2	Stage 3
1	1.67B	0.83B	0.83B
2	0	2.5B	0.83B
3	0	0	3.33B

Table 6: Training using CMTL with 3 tasks over 10B total iterations.

B Significance testing

To further solidify our claims, we perform significance testing on our results between NSP and the MLM baseline, as well as our CMTL+ model and the MLM baseline. For each NSP, MLM, and the CMTL+ model we evaluate 5 runs, found in table 7. We first run a Lilliefors test, and find that the p-values are large enough that we accept the null hypothesis that our the data follows a normal distribution for each of our sets of experiments. We then run an independent t-test between NSP and MLM, and between the our CMTL+ and MLM. We correct the p-values using Bonferroni correction and find a p-val of $2.547e-03$ between NSP and MLM and a p-val of $1.069e-06$ between CMTL+ and MLM. In both cases, the p-values are small enough that we reject the null hypothesis that the samples come from the same distribution, supporting our hypothesis that MLM is better than NSP, and CMTL+ is better than MLM.

Run	MLM	NSP	CMTL+
1	78.18	77.663	80.56
2	77.90	77.363	80.30
3	78.38	77.775	80.66
4	78.25	77.275	80.45
5	77.96	77.338	81.03
Mean:	78.13	77.483	80.60
Std. Dev.:	0.20	0.22	0.27
Lilliefors p-val	0.712	0.148	0.659

We Can Detect Your Bias:
Predicting the Political Ideology of News Articles

Abstract

We explore the task of predicting the leading political ideology or bias of news articles. First, we collect and release a large dataset of 34,737 articles that were manually annotated for political ideology –left, center, or right–, which is well-balanced across both topics and media. We further use a challenging experimental setup where the test examples come from media that were not seen during training, which prevents the model from learning to detect the source of the target news article instead of predicting its political ideology. From a modeling perspective, we propose an adversarial media adaptation, as well as a specially adapted triplet loss. We further add background information about the source, and we show that it is quite helpful for improving article-level prediction. Our experimental results show very sizable improvements over using state-of-the-art pre-trained Transformers in this challenging setup.

1 Introduction

In any piece of news, there is a chance that the viewpoint of its authors and of the media organization they work for, would be reflected in the way the story is being told. The emergence of the Web and of social media has lead to the proliferation of information sources, whose leading political ideology or bias may not be explicit. Yet, systematic exposure to such bias may foster intolerance as well as ideological segregation, and ultimately it could affect voting behavior, depending on the degree and the direction of the media bias, and on the voters' reliance on such media (DellaVigna and Kaplan, 2007; Iyengar and Hahn, 2009; Saez-Trumper et al., 2013; Graber and Dunaway, 2017). Thus, making the general public aware, e.g., by tracking and exposing bias in the news is important for a healthy public debate given the important role media play in a democratic society.

Media bias can come in many different forms, e.g., by omission, by over-reporting on a topic, by cherry-picking the facts, or by using propaganda techniques such as appealing to emotions, prejudices, fears, etc. (Da San Martino et al., 2019, 2020a,b) Bias can occur with respect to a specific topic, e.g., COVID-19, immigration, climate change, gun control, etc. (Darwish et al., 2020; Stefanov et al., 2020) It could also be more systematic, as part of a political ideology, which in the Western political system is typically defined as left vs. center vs. right political leaning.

Predicting the bias of individual news articles can be useful in a number of scenarios. For news media, it could be an important element of internal quality assurance as well as of internal or external monitoring for regulatory compliance. For news aggregator applications, such as Google News, it could enable balanced search, similarly to what is found on AllSides.[1] For journalists, it could enable news exploration from a left/center/right angle. It could also be an important building block in a system that detects bias at the level of entire news media (Baly et al., 2018, 2019, 2020), such as the need to offer explainability, i.e., if a website is classified as left-leaning, the system should be able to pinpoint specific articles that support this decision.

In this paper, we focus on predicting the bias of news articles as left-, center-, or right-leaning. Previous work has focused on doing so at the level of news media (Baly et al., 2020) or social media users (Darwish et al., 2020), but rarely at the article level (Kulkarni et al., 2018). The scarce article-level research has typically used distant supervision, assuming that all articles from a given medium should share its overall bias, which is not always the case. Here, we revisit this assumption.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4982–4991,
November 16–20, 2020.

Our contributions can be summarized as follows:

- We create a new dataset for predicting the political ideology of news articles. The dataset is annotated at the article level and covers a wide variety of topics, providing balanced left/center/right perspectives for each topic.
- We develop a framework that discourages the learning algorithm from modeling the source instead of focusing on detecting bias in the article. We validate this framework in an experimental setup where the test articles come from media that were not seen at training time. We show that adversarial media adaptation is quite helpful in that respect, and we further propose to use a triplet loss, which shows sizable improvements over state-of-the-art pretrained Transformers.
- We further incorporate media-level representation to provide background information about the source, and we show that this information is quite helpful for improving the article-level prediction even further.

The rest of this paper is organized as follows: We discuss related work in Section 2. Then, we introduce our dataset in Section 3, we describe our models for predicting the political ideology of a news article in Section 4, and we present our experiments and we discuss the results in Section 5. Finally, we conclude with possible directions for future work in Section 6.

2 Related Work

Most existing datasets for predicting the political ideology at the news article level were created by crawling the RSS feeds of news websites with known political bias (Kulkarni et al., 2018), and then projecting the bias label from a website to all articles crawled from it, which is a form of distant supervision. The crawling could be also done using text search APIs rather than RSS feeds (Horne et al., 2019; Gruppi et al., 2020).

The media-level annotation of political leaning is typically obtained from specialized online platforms, such as News Guard,[2] AllSides,[3] and Media Bias/Fact Check,[4] where highly qualified journalists use carefully designed guidelines to make the judgments.

As manual annotation at the article level is very time-consuming, requires domain expertise, and it could be also subjective, such annotations are rarely available at the article level. As a result, automating systems for political bias detection have opted for using distant supervision as an easy way to obtain large datasets, which are needed to train contemporary deep learning models.

Distant supervision is a popular technique for annotating datasets for related text classification tasks, such as detecting hyper-partisanship (Horne et al., 2018; Potthast et al., 2018) and propaganda/satire/hoaxes (Rashkin et al., 2017). For example, Kiesel et al. (2019) created a large corpus for detecting hyper-partisanship (i.e., articles with extreme left/right bias) consisting of 754,000 articles, annotated via distant supervision, and additional 1,273 manually annotated articles, part of which was used as a test set for the SemEval-2019 task 4 on Hyper-partisan News Detection. The winning system was an ensemble of character-level CNNs (Jiang et al., 2019). Interestingly, all top-performing systems in the task achieved their best results when training on the manually annotated articles only and ignoring the articles that were labeled using distant supervision, which illustrates the dangers of relying on distant supervision.

Barrón-Cedeno et al. (2019) extensively discussed the limitations of distant supervision in a text classification task about article-level propaganda detection, in a setup that is similar to what we deal with in this paper: the learning systems may learn to model the source of the article instead of solving the task they are actually trained for. Indeed, they have shown that the error rate may drastically increase if such systems are tested on articles from sources that were never seen during training, and that this effect is positively correlated with the representation power of the learning model. They analyzed a number of representations and machine learning models, showing which ones tend to overfit more, but, unlike our work here, they fell short of recommending a practical solution.

Budak et al. (2016) measured the bias at the article level using crowd-sourcing. This is risky as public awareness of media bias is limited (Elejalde et al., 2018). Moreover, the annotation setup does not scale. Finally, their dataset is not freely available, and their approach of randomly crawling articles does not ensure that topics and events are covered from different political perspectives.

---

[2] `http://www.newsguardtech.com`

[3] `http://allsides.com/`

[4] `http://mediabiasfactcheck.com`

Lin et al. (2006) built a dataset annotated with the ideology of 594 articles related to the Israeli-Palestinian conflict published on `bitterlemons.org`. The articles were written by two editors and 200 guests, which minimizes the risk of modeling the author style. However, the dataset is too small to train modern deep learning approaches.

Kulkarni et al. (2018) built a dataset using distant supervision and labels from AllSides. Distant supervision is fine for the purpose of training, but they also used it for testing, which can be problematic. Moreover, their training and test sets contain articles from the same media, and thus models could easily learn to predict the article's source rather than its bias. In their models, they used both the text and the URL contents of the articles.

Overall, political bias has been studied at the level of news outlet (Dinkov et al., 2019; Baly et al., 2018, 2020; Zhang et al., 2019), user (Darwish et al., 2020), article (Potthast et al., 2018; Saleh et al., 2019), and sentence (Sim et al., 2013; Saez-Trumper et al., 2013). In particular, Baly et al. (2018) developed a system to predict the political bias and the factuality of news media. In a follow-up work, Baly et al. (2019) showed that bias and factuality of reporting should be predicted jointly. A finer-grained analysis is performed in (Horne et al., 2018), where a model was trained on 10K sentences from a dataset of reviews (Pang and Lee, 2004), and used to discriminate objective versus non-objective sentences in news articles. Lin et al. (2006) presented a sentence-level classifier, where the labels were projected from the document level.

3 Dataset

In this section, we describe the dataset that we created and that we used in our experiments. While most of the platforms that analyze the political leaning of news media provide in-depth analysis of particular aspects of the media, AllSides stands out as it provides annotations of political ideology for individual articles, which ensures high-quality data for both training and testing, which is in contrast with distant supervision approaches used in most previous research, as we have seen above. In AllSides, these annotations are made as a result of a rigorous process that involves blind bias surveys, editorial reviews, third-party analysis, independent reviews, and community feedback.[5]

Furthermore, AllSides uses the annotated articles to enable its *Balanced Search*, which shows news coverage on a given topic from media with different political bias. In other words, for each trending event or topic (e.g., *impeachment* or *coronavirus pandemic*), the platform pushes news articles from all sides of the political spectrum, as shown in Figure 1. We took advantage of this and downloaded all articles along with their political ideology annotations (*left*, *center*, or *right*), their assigned topic(s), the media in which they were published, their author(s), and their publication date. Thus, our dataset contains articles that were manually selected and annotated, and that are representative of the real political scenery. Note that the *center* class covers articles that are biased towards a centrist political ideology, and not articles that lack political bias (e.g., *sports* and *technology*), which commonly exist in news corpora that were built by scraping RSS feeds.

We collected a total of 34,737 articles published by 73 news media and covering 109 topics.[6] In this dataset, a total of 1,080 individual articles (3.11%) have a political ideology label that is different from their source's. This suggests that, while the distant supervision assumption generally holds, we would still find many articles that defy it. Table 1 shows some statistics about the dataset.

Political Ideology	**Count**	**Percentage**
Left	12,003	34.6%
Center	9,743	28.1%
Right	12,991	37.3%

Table 1: Statistics about our dataset.

Figure 2 illustrates the distribution of the different political bias labels within each of the most frequent topics. We can see that our dataset is able to represent topics or events from different political perspectives. This is yet another advantage, as it enables a more challenging task for machine learning models to detect the linguistic and the semantic nuances of different political ideologies in news articles, as opposed to cases where certain topics might be coincidentally collocated with certain labels, in which case the models would be actually learning to detect the topics instead of predicting the political ideology of the target news article.

---

Figure 1: AllSides: balanced search on the topic of *reopening after the coronavirus lockdown*.

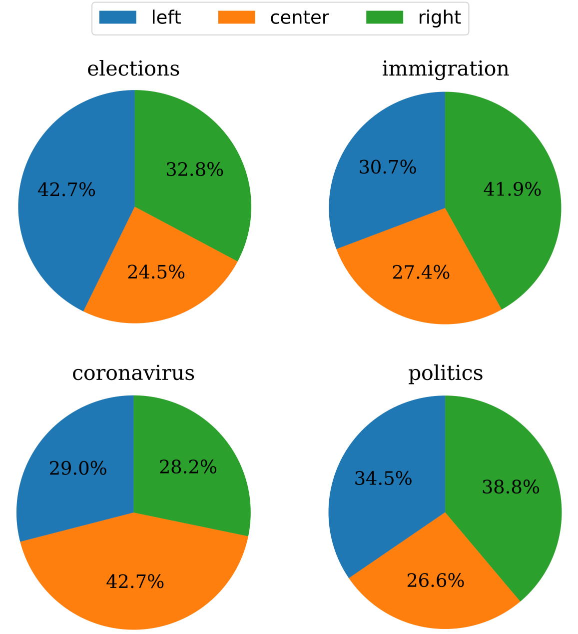

Figure 2: Political ideology for the most frequent topics: *elections*, *immigration*, *coronavirus*, and *politics*.

It is worth noting that since most article labels are aligned with their source labels, it is likely that machine learning classifiers would end up modeling the source instead of the political ideology of the individual articles. For example, a model would be learning the writing style of each medium, and then it would associate it with a particular ideology. Therefore, we pre-processed the articles in a way that eliminates explicit markers such as the name of the authors, or the name of the medium that usually appears as a preamble to the article's content, or in the content itself. Furthermore, in order to ensure that we are actually modeling the political ideology as it is expressed in the language of the news, we created evaluation splits in two different ways: (*i*) randomly, which is what is typically done (for comparison only), and (*ii*) based on media, where all articles by the same medium appear in either the training, the validation, or the testing dataset.

The latter form of splitting would help us indicate what a trained classifier has actually learned. For instance, if it modeled the source, then it would not be able to perform well on the test set, since all its articles would belong to sources that were never seen during training. In order to ensure fair one-to-one comparisons between experiments, we created these two different sets of splits, while making sure that they share the same test set, as follows:

- **Media-based Split:** We sampled 1,200 articles from 12 news media (100 per medium) and used them as the *test* set, and we excluded the remaining 5,470 articles from these media. Then, we used the articles from the remaining 61 media to create the *training* and the *validation* sets, where all articles from the same medium would appear in the same set: training, development, or testing. This ensures that the model is fine-tuned and tested on articles whose sources were not seen during training.

- **Random Split:** Here, the *test* set is the same as in the media-based split. The 5,470 articles that we excluded from the 12 media are now added to the articles from the 61 remaining media. Then, we split this collection of articles (using stratified random sampling) into *training* and *validation* sets. This ensures that the model is fine-tuned and evaluated only on articles whose sources were observed during training.

Table 2 shows statistics about both splits, including the size of each set and the number of media and topics they cover. We release the dataset, along with the evaluation splits, and the code,[7] which can be used to extend the dataset as more news articles are added to AllSides.

4 Methodology

4.1 Classifiers

The task of predicting the political ideology of news articles is typically formulated as a classification problem, where the textual content of the articles is encoded into a vector representation that is used to train a classifier to predict one of C classes (in our case, $C = 3$: *left*, *center*, and *right*). In our experiments, we use two deep learning architectures: (*i*) *Long Short-Term Memory networks* (LSTMs), which are Recurrent Neural Networks (RNNs), which use gating mechanisms to selectively pass information across time and to model long-term dependencies (Hochreiter and Schmidhuber, 1997), and (*ii*) *Bidirectional Encoder Representations from Transformers* (BERT), with a complex architecture yielding high-quality contextualized embeddings, which have been successful in several Natural Language Processing tasks (Devlin et al., 2019).

4.2 Removing Media Bias

Ultimately, our goal is to develop a model that can predict the political ideology of a news article. Our dataset, along with some others, has a special property that might stand in the way of achieving this goal. Most articles published by a given source have the same ideological leaning. This might confuse the model and cause it to erroneously associate the output classes with features that characterize entire media outlets (such as detecting specific writing patterns, or stylistic markers in text). Consequently, the model would fail when applied to articles that were published in media that were unseen during training. The experiments in Section 5 confirm this. Thus, we apply two techniques to *de-bias* the models, i.e., to prevent them from learning the style of a specific news medium rather than predicting the political ideology of the target news article.

4.2.1 Adversarial Adaptation (AA)

This model was originally proposed by Ganin et al. (2016) for unsupervised domain adaptation in image classification. Their objective was to adapt a model trained on labelled images from a *source* domain to a novel *target* domain, where the images have no labels for the task at hand. This is done by adding an adversarial *domain classifier* with a gradient reversal layer to predict the examples' domains. The *label predictor's* is minimized for the labelled examples (from the source domain), and the adversarial *domain classifier's* loss is maximized for all examples in the dataset. As a result, the encoder can extract representation that is (*i*) discriminative for the main task and also (*ii*) invariant across domains (due to the gradient reversal layer). The overall loss is minimized as follows:

$$\sum_{\substack{i=1:N \\ d_i=0}} \mathcal{L}_y^i(\theta_f, \theta_y) - \lambda \sum_{i=1:N} \mathcal{L}_d^i(\theta_f, \theta_d), \quad (1)$$

where N is the number of training examples, $\mathcal{L}_y^i(\cdot, \cdot)$ is the label predictor's loss, the condition $d_i = 0$ means that only examples from the source domain are used to calculate the label predictor's loss, $\mathcal{L}_d^i(\cdot, \cdot)$ is the domain classifier's loss, λ controls the trade-off between both losses, and $\{\theta_f, \theta_y, \theta_d\}$ are the parameters of the encoder, the label predictor, and the domain classifier, respectively. Further details about the formulation of this method is available in (Ganin et al., 2016).

We adapt this architecture as follows. Instead of a *domain classifier*, we implement a *media classifier*, which, given an article, tries to predict the medium it comes from. As a result, the encoder should extract representation that is discriminative for the main task of predicting political ideology, while being invariant for the different media. This approach was originally proposed as an unsupervised domain adaptation, since labelled examples were available for one domain only, whereas in our case, all articles from different media were labelled for their political ideology. Therefore, we jointly minimize the losses of both the *label predictor* and the *media classifier* over the entire dataset. The new objective function to minimize is as follows:

$$\sum_{i=1:N} \mathcal{L}_y^i(\theta_f, \theta_y) - \lambda \sum_{i=1:N} \mathcal{L}_m^i(\theta_f, \theta_m), \quad (2)$$

where $\mathcal{L}_m^i(\cdot, \cdot)$ is the loss of the *media classifier*, and θ_m is its set of parameters.

4.2.2 Triplet Loss Pre-training (TLP)

In this approach, we pre-train the encoder using a triplet loss (Schroff et al., 2015). The model is trained on a set of triplets, each composed of an anchor, a positive, and a negative example. The objective in Eq. 3 ensures that the positive example is always closer to the anchor than the negative example is, where $\boldsymbol{a}$, $\boldsymbol{p}$ and $\boldsymbol{n}$ are the encodings of the anchor, of the positive, and of the negative examples, respectively, and $D(\cdot,\cdot)$ is the Euclidean distance:

$$\mathcal{L} = \max\left(D\left(\boldsymbol{a},\boldsymbol{p}\right) - D\left(\boldsymbol{a},\boldsymbol{n}\right) + \epsilon, 0\right). \quad (3)$$

Figure 3 shows an example of such a triplet. The positive example shares the same ideology as the anchor's, but they are published by different media. The negative example has a different ideology than the anchor's, but they are published by the same medium. In this way, the encoder will be clustering examples with similar ideologies close to each other, regardless of their source. Once the encoder has been pre-trained, its parameters, along with the softmax classifier's, are fine-tuned on the main task by minimizing the cross-entropy loss when predicting the political ideology of articles.

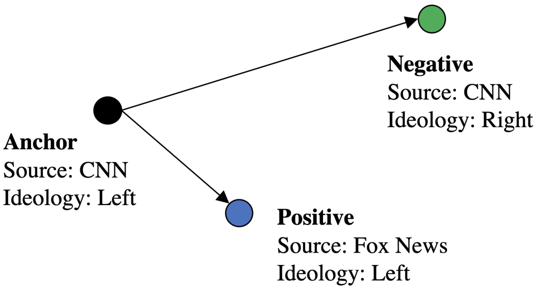

Figure 3: An example triplet used for de-biasing.

4.3 Media-level Representation

Finally, we explore the benefits of incorporating information describing the target medium, which can serve as a complementary representation for the article. While this seems to be counter-intuitive to what we have been proposing in Subsection 4.2, we believe that medium-level representation can be valuable when combined with an accurate representation of the article. Intuitively, having an accurate understanding of the natural language in the article, together with a glimpse into the medium it is published in, should provide a more complete picture of its underlying political ideology.

Baly et al. (2020) proposed a comprehensive set of representation to characterize news media from different angles: how a medium portrays itself, who is its audience, and what is written about it. Their results indicate that exploring the *Twitter bios* of a medium's followers offers a good insight into its political leaning. To a lesser extent, the content of a *Wikipedia* page describing a medium can also help unravel its political leaning. Therefore, we concatenated these representations to the encoded articles, at the output of the encoder and right before the SOFTMAX layer, so that both the article encoder and the classification layer that is based on the article and the external media representations are trained jointly and end-to-end.

Similarly to (Baly et al., 2020), we retrieved the profiles of up to a 1,000 Twitter followers for each medium, we encoded their bios using the Sentence-BERT model (Reimers and Gurevych, 2019), and we then averaged these encodings to obtain a single representation for that medium. As for the Wikipedia representation, we automatically retrieved the content of the page describing each medium, whenever applicable. Then, we used the pre-trained base BERT model to encode this content by averaging the word representations extracted from BERT's second-to-last layer, which is common practice, since the last layer may be biased towards the pre-training objectives of BERT.

5 Experiments and Results

We evaluated both the LSTM and the BERT models, assessing the impact of (*i*) de-biasing and (*ii*) incorporating media-level representation.

5.1 Experimental Setup

We fine-tuned the hyper-parameters of both models on the validation set using a guided grid search trial while fixing the seeds of the random weights initialization. For LSTM, we varied the length of the input (128–1,024 tokens), the number of layers (1–3), the size of the LSTM cell (200–400), the dropout rate (0–0.8), the learning rate ($1e{-3}$ to $1e{-5}$), the gradient clipping value (0–5), and the batch size (8–256). The best results were obtained with a 512-token input, a 2-layer LSTM of size 256, a dropout rate of 0.7, a learning rate of $1e{-3}$, gradient clipping at 0.5, and a batch size of 32. This model has around 1.1M trainable parameters, and was trained with 300-dimensional GloVe input word embeddings (Pennington et al., 2014).

For BERT, we varied the length of the input, the learning rate, and the gradient clipping value. The best results were obtained using a 512-token input, a learning rate of 2e−5, and gradient clipping at 1. This model has 110M trainable parameters.

We trained our models on 4 *Titan X Pascal* GPUs, and the runtime for each epoch was 25 seconds for the LSTM-based models and 22 minutes for the BERT-based models. For each experiment, the model was trained only once with fixed seeds used to initialize the models' weights.

For the Adversarial Adaptation (AA), we have an additional hyper-parameter λ (see Equation 2), which we varied from 0 to 1, where 0 means no adaptation at all. The best results were obtained with $\lambda = 0.7$, which means that we need to pay significant attention to the adversarial classifier's loss in order to mitigate the media bias.

For the Triplet Loss Pre-training (PLT), we sampled 35,017 triplets from the training set, such that the examples in each triplet discuss the same topic in order to ensure that the change in topic has minimal impact on the distance between the examples.

To evaluate our models, we use accuracy and macro-F_1 score (F_1 averaged across all classes), which we also used as an early stopping criterion, since the classes were slightly imbalanced. Moreover, given the ordinal nature of the labels, we report the Mean Absolute Error (MAE), shown in Equation (4), where N is the number of instances, and y_i and $\hat{y}_i$ are the number of correct and of predicted labels, respectively.

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^{N} |y_i - \hat{y}_i| \tag{4}$$

5.2 Results

Baseline Results The results in Table 3 show the performance for LSTM and for BERT at predicting the political ideology of news articles for both the *media-based* and the *random* splits. We observe sizable differences in performance between the two splits. In particular, both models perform much better when they are trained and evaluated on the *random* split, whereas they both fail on the *media-based* split, where they are tested on articles from media that were not seen during training. This observation confirms our initial concerns that the models would tend to learn general characteristics about news media, and then would face difficulties with articles coming from new unseen media.

Model	**Split**	**Macro F_1**	**Acc.**	**MAE**
Majority		19.61	41.67	0.92
LSTM	*Media-based*	31.51	32.30	0.97
	Random	65.50	66.17	0.52
BERT	*Media-based*	35.53	36.75	0.90
	Random	80.19	79.83	0.33

Table 3: Baseline experiments (without de-biasing or media-level representation) for the two splits.

Removing the Source Bias In order to further confirm the bias towards modeling the media, we ran a side experiment of fine-tuning BERT on the task of predicting the medium given the article's content, which is a 73-way classification problem. We used stratified random sampling to create the evaluation splits and to make sure each set contains all labels (media). The results in Table 4 confirm that BERT is much stronger than the majority class baseline, despite the high number of classes, which means that predicting the medium in which a target news article was published is a fairly easy task.

Model	**Macro F_1**	**Acc.**
Majority	0.25	10.21
BERT	59.72	80.12

Table 4: Predicting the medium in which a target news article was published.

In order to remove the bias towards modeling the medium, we evaluated the impact of the adversarial adaptation (AA) and the Triplet Loss Pre-training (TLP) with the media-based split. The results in Table 5 show sizeable improvements when either of these approaches is used, compared to the baseline (no de-biasing). In particular, TLP yields an improvement of 14.12 points absolute in terms of accuracy, and 12.73 points in terms of macro-F_1.

Model	**De-bias**	**Macro F_1**	**Acc.**	**MAE**
LSTM	*None*	31.51	32.30	0.97
	AA	40.33	40.57	0.69
	TLP	**45.44**	**46.42**	**0.62**
BERT	*None*	35.53	36.75	0.90
	AA	43.87	46.22	0.59
	TLP	**48.26**	**51.41**	**0.51**

Table 5: Impact of de-biasing (adversarial adaptation and triplet loss) on article-level bias detection.

#	Representation	LSTM			BERT		
		Macro F_1	**Acc.**	**MAE**	**Macro F_1**	**Acc.**	**MAE**
1	*Article (baseline)*	31.51	32.30	0.97	35.53	36.75	0.90
2	*Article with TLP*	45.44	46.42	0.62	48.26	51.41	0.51
3	*Wikipedia*	41.39	41.86	0.92	41.39	41.86	0.92
4	*Wikipedia + Article*	40.49	40.79	0.92	42.33	41.90	0.90
5	*Wikipedia + Article with TLP*	48.25	46.47	0.69	51.16	49.75	0.32
6	*Twitter bios*	60.30	62.69	0.42	60.30	62.69	0.42
7	*Twitter bios + Article*	60.30	62.69	0.42	60.42	63.12	0.40
8	*Twitter bios + Article with TLP*	**62.02**	**70.03**	**0.32**	**64.29**	**72.00**	**0.29**

Table 6: Impact of adding media-level representations to the article-level representations (with and without de-biasing). Note that the results in rows 3 and 6 are the same for both LSTM and BERT because no articles were involved, and the media-level representations were directly used to train the classifier.

Impact of Media-Level Representation Finally, we evaluated the impact of incorporating the media-level representation (Twitter followers' bios and Wikipedia content) in addition to teh article-level representation. Table 6 illustrates these results in an incremental way. First, we evaluated the performance of the media-level representation alone at predicting the political ideology of news articles (see rows 3 and 6). We should note that these results are identical for the LSTM and the BERT columns since no article was encoded in these experiments, and the media representation was used directly to train the logistic regression classifier. Then, adding the article representation from either model, without any de-biasing, had no or little impact on the performance (see rows 4 vs. 3, and 7 vs. 6). This is not surprising, since we have shown that, without de-biasing, both models learn more about the source than about the bias in the language used by the article. Therefore, the ill-encoded articles do not provide more information than what the medium representation already gives, which is why no or too little improvement was observed.

When we use the triplet loss to mitigate the source bias, the resulting article representation is more accurate and meaningful, and the medium representation does offer complementary information, and eventually contributes to sizeable performance gains (see rows 5 and 8 vs. 2). The Twitter bios representation appears to be much more important than the representation from Wikipedia, which shows the importance of inspecting the media followers' background and their point of views, which is also one of the observations in (Baly et al., 2020).

Overall, comparing the best results to the baseline (rows 8 vs. 1), we can see that (*i*) using the triplet loss to remove the source bias, and (*ii*) incorporating media-level representation from Twitter followers yields 30.51 and 28.76 absolute improvement in terms of macro $\boldsymbol{F_1}$ on the challenging *media-based* split.

6 Conclusion and Future Work

We have explored the task of predicting the leading political ideology of news articles. In particular, we created a new large dataset for this task, which features article-level annotations and is well-balanced across topics and media. We further proposed an adversarial media adaptation approach, as well as a special triplet loss in order to prevent modeling the source instead of the political bias in the news article, which is a common pitfall for approaches dealing with data that exhibit high correlation between the source of a news article and its class, as is the case with our task here. Finally, our experimental results have shown very sizable improvements over using state-of-the-art pre-trained Transformers.

In future work, we plan to explore topic-level bias prediction as well as going beyond left-center-right bias. We further want to develop models that would be able to detect specific fragments in an article where the bias occurs, thus enabling explainability. Last but not least, we plan to experiment with other languages, and to explore to what extent a model for one language is transferable to another one given that the left-center-right division is not universal and does not align perfectly across countries and cultures, even when staying within the Western political world.

Acknowledgments

This research is part of the Tanbih project[8], which aims to limit the effect of "fake news," propaganda and media bias by making users aware of what they are reading. The project is developed in collaboration between the Qatar Computing Research Institute, HBKU and the MIT Computer Science and Artificial Intelligence Laboratory.

Abstract

Label smoothing has been shown to be an effective regularization strategy in classification, that prevents overfitting and helps in label denoising. However, extending such methods directly to seq2seq settings, such as Machine Translation, is challenging: the large target output space of such problems makes it intractable to apply label smoothing over all possible outputs. Most existing approaches for seq2seq settings either do token level smoothing, or smooth over sequences generated by randomly substituting tokens in the target sequence. Unlike these works, in this paper, we propose a technique that smooths over *well formed* relevant sequences that not only have sufficient n-gram overlap with the target sequence, but are also *semantically similar*. Our method shows a consistent and significant improvement over the state-of-the-art techniques on different datasets.

1 Introduction

Label smoothing is a regularization technique commonly used in deep learning (Szegedy et al., 2016; Chorowski and Jaitly, 2017; Vaswani et al., 2017; Zoph et al., 2018; Real et al., 2018; Huang et al., 2019), that improves calibration (Müller et al., 2019) and helps in label de-noising (Lukasik et al., 2020a). Here, one *smooths* labels by introducing a prior in the label space (often just a uniform distribution) in order to prevent overly confident predictions and achieve better model calibration, both of which lead to better generalization.

Given these benefits, it is natural to consider whether label smoothing can be applied to *sequence-to-sequence* (seq2seq) prediction tasks in Natural Language Processing. Here, inducing a label prior involves smoothing in *sequence space*. However, this is a challenging task because the output space is exponentially large for sequences, unlike the label space in standard classification. Previous works approached this challenge either by smoothing over individual tokens of the target sequence, or by sampling a few nearby targets according to Hamming distance or BLEU score (Norouzi et al., 2016; Elbayad et al., 2018). These techniques however do *not* guarantee that the smoothed targets lie within the space of acceptable targets (i.e., the sampled new target may no longer be grammatically correct or even preserve semantic meaning).

In this work, we propose a label smoothing approach for seq2seq problems that overcomes this limitation. Given a large-scale corpus of valid sequences, our approach selects a subset of sequences that are not only semantically similar to the target sequence, but also *well formed*. We achieve this using a pre-trained model to find semantically similar sequences from the corpus, and then use BLEU scores to rerank the closest targets. We empirically show that this approach improves over competitive baselines on multiple machine translation tasks.

2 Related Works

Token-level smoothing A popular approach used in language tasks is so called token level smoothing, where for each position's classification loss, a prior distribution over the entire vocabulary (uniformly or with unigram probability estimates) is used for regularization (Pereyra et al., 2017; Edunov et al., 2017). This is similar to the classical label smoothing (e.g. (Szegedy et al., 2016)), as it smooths each token label independent of their context and position in the sequence. Such an approach is thus unlikely to result in semantically related targets.

Sequence-level smoothing Norouzi et al. (2016) augment the loss with a term rewarding predictions of sampled sequences. The sampling of sequences is based on their edit distance or Hamming

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4992–4998,
November 16–20, 2020.

distance to the target. This method thus smooths the loss over to similar sequences (in terms of the edit distance) with smoothing rewards. Elbayad et al. (2018) employ a similar technique, but with a new reward function based on BLEU (Papineni et al., 2002) or CIDEr (Vedantam et al., 2015) score. Specifically, Elbayad et al. (2018) generate a smoothed version of the target sequence, wherein one replaces a token with a random token (with up-sampling of rare words). Such newly generated sequences were given a partial reward based on the cosine similarity between the two tokens in a pre-trained word-embedding space. This differs from our approach because this context-independent perturbation is limited to generating the same structure for the new sequence as that of the original sequence.

Zheng et al. (2018), on the other hand, constructed grammatically correct and meaning preserving sequences. However, unlike our work, their approach relies on having multiple references (target sequences per input sequence) and might not be able to generate sequences where common words or synonyms do not appear in the same order, which is a strong limitation, precluding an augmentation like: *Yesterday, he scored a 94 on his final* (original sequence), *He had 94 points in the final test yesterday* (augmented sequence).

More broadly, an important shortcoming of such approaches is that sequences deemed close can actually lack important properties such as preserving the meaning of the original sequence. In particular, swapping even a single token in a sequence may cause a drastic shift in its meaning (e.g., turning a factually correct text into a false one) even though being close in the Hamming space. We address this shortcoming by restricting augmented target sequences to the training set, and selecting sequences based on similarity obtained from a pre-trained model.

Unlike other approaches, (Bengio et al., 2015) proposed a scheduled sampling technique that does not depend on any external data source. Instead, it utilizes the self-generated sequences from the current model. Both our approach and the scheduled sampling technique bear similarity in that they aim at improving model generalization, by either providing semantically similar candidates (ours) or self-generated sequences (theirs). Indeed, these two approaches could complement each other by providing various ways of related but not exact targets.

Hard negative mining Our work is also related to hard negative mining approaches that select a subset of confusing negatives for each input (Mikolov et al., 2013; Reddi et al., 2019; Guo et al., 2018). Different from the above, we add a soft objective function over the sampled (relevant) target sequences, rather than treating them as negatives in the classification sense.

3 Method

Sequence-to-sequence (seq2seq) learning involves learning a mapping from an input sequence $\mathbf{x}$ (e.g., a sentence in English) to an output sequence $\mathbf{y}$ (e.g., a sentence in French). Canonical applications include machine translation and question answering.

Formally, let $\mathcal{X}$ denote the space of input sequences (e.g., all possible English sentences), and $\mathcal{Y}$ the space of output sequences (e.g., all possible French sentences). We represent by $\mathbf{x} = [x_1, x_2, ...x_N]$ an input sequence consisting of N tokens, and similarly $\mathbf{y} = [y_1, y_2, ...y_{N'}]$ an output sequence with N' tokens. Our goal is to learn a function $f \colon \mathcal{X} \to \mathcal{Y}$ that, given an input sequence, generates a suitable target sequence.

To achieve this goal, we have a training set $\mathcal{S} \subseteq (\mathcal{X} \times \mathcal{Y})^n$ comprising pairs of input and output sequences. We then seek to minimise the objective

$$L(\theta) = \sum_{(\mathbf{x},\mathbf{y}) \in \mathcal{S}} - \log p_\theta(\mathbf{y} \mid \mathbf{x}), \qquad (1)$$

where $p_\theta(\cdot|\mathbf{x}; \theta)$ is a parametrized distribution over all possible output sequences. Given such a distribution, we choose $f(\mathbf{x}) = \mathrm{argmax}_{\mathbf{y} \in \mathcal{Y}}\, p_\theta(\mathbf{y} \mid \mathbf{x})$. Observe that one may implement (1) via a token-level decomposition,

$$L(\theta) = \sum_{(\mathbf{x},\mathbf{y}) \in \mathcal{S}} \sum_{i=1}^{N} - \log p_\theta(y_i \mid \mathbf{x}, y_1, \ldots, y_{i-1}).$$

This may be understood as a maximum likelihood objective, or equivalently the *cross-entropy* between $p_\theta(\cdot|\mathbf{x}; \theta)$ and a one-hot distribution concentrated on $\mathbf{y}$.

Label smoothing meets seq2seq. Intuitively, the cross-entropy objective encourages the model to score the *observed* sequence $\mathbf{y}$ higher than any "competing" sequence $\mathbf{y}' \neq \mathbf{y}$. While this is a sensible goal, one limitation observed from classification settings is that the loss may lead to models that are overly confident in their predictions, which can hamper generalisation (Guo et al., 2017).

Label smoothing (Szegedy et al., 2016; Pereyra et al., 2017; Müller et al., 2019) is a simple means of correcting this in classification settings. Smoothing involves simply adding a small reward to all possible *incorrect* labels, i.e., mixing the standard one-hot label with a uniform distribution over all labels. This regularizes the training and generally leads to better predictive performance as well as probabilistic calibration (Müller et al., 2019).

Given the success of label smoothing in classification settings, it is natural to explore its value in seq2seq problems. However, standard label smoothing is clearly inadmissible: it would require smoothing over all possible outputs $\mathbf{y}' \in \mathcal{Y}$, which is typically an intractably large set. Nonetheless, we may follow the basic intuition of smoothing by adding a subset of *related* targets to the observed sequence $\mathbf{y}$, yielding a *smoothed loss*

$$-\log p_\theta(\mathbf{y} \mid \mathbf{x}) + \frac{\alpha}{|\mathcal{R}(\mathbf{y})|} \cdot \sum_{\mathbf{y}' \in \mathcal{R}(\mathbf{y})} -\log p_\theta(\mathbf{y}' \mid \mathbf{x}). \quad (2)$$

Here, $\mathcal{R}(\mathbf{y})$ is a set of *related sequences* that are similar to the ground truth $\mathbf{y}$, and $\alpha > 0$ is a tuning parameter that controls how much we rely on the observed versus related sequences.

The quality of $\mathcal{R}(\mathbf{y})$ is important for our task. Ideally, we would like an $\mathcal{R}(\mathbf{y})$ that: (i) is efficient to compute, and (ii) comprises sequences which meaningfully align with $\mathbf{x}$ (e.g., are plausible alternate translations). We now assess several options for constructing $\mathcal{R}(\mathbf{y})$ in light of the above.

Random sequences. One simple choice is to choose a random subset of output sequences from the training set. In the common setting where f is learned by minibatch SGD on randomly drawn minbatches $\mathcal{B} = \{(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})\}$, one may simply pick $\mathcal{R}(\mathbf{y})$ to be all output sequences in $\mathcal{B}$.

Such random sequences contain general target language understanding (e.g., French grammar for an English to French translation task). However, these sequences are unlikely to have any semantic correlation with the true label.

Token-level smoothing. To ensure greater semantic correlation between the selected sequences and the original $\mathbf{y}$, one idea is to perform *token-level smoothing*. For example, Vaswani et al. (2017) proposed to smooth uniformly over all tokens from the vocabulary. Elbayad et al. (2018) proposed to construct sequences $\mathbf{y}' = [y'_1, y'_2, \ldots, y'_{N'}]$ where for a randomly selected subset of tokens $j \in [N']$, y'_i is some *related* token in the minibatch; for other tokens, $y'_i = y_i$. These related tokens are chosen so as to maximise the BLEU score between $\mathbf{y}$ and $\mathbf{y}'$.

Algorithm 1 Sampling of related sequences.

```
Input: example $(\mathbf{x}, \mathbf{y})$; sequences $\mathcal{Y}_{\mathrm{ref}}$
Output: related sequences $\mathcal{R}(\mathbf{y})$

2nd:	But the child just scored 9 points on the Apgar test.
Orig:	Exchange of experience and good practices.
1st:	Exchange of best practices.
2nd:	Exchange of information and best practices.
Orig:	Nothing else I can do?
1st:	Is there anything else I can do for you, sir?
2nd:	Can I do something for you?

Table 1: English translations of top two augmentations from BERT+BLEU4 on examples from EN-CS.

While this approach increases the semantic similarity to $\mathbf{y}$, operating on a token level is limiting. For example, one may change the meaning of a factual sentence by changing even a few words. Further, operating at a per-token level limits the *diversity* of $\mathcal{R}(\mathbf{y})$, since, e.g., all sequences have the same number of tokens and structure as $\mathbf{y}$.

Proposal: semantic smoothing. To overcome the limitations of token-level smoothing, we would ideally like to directly smooth over related *sequences*. Our basic idea is to seek sequences

$$\mathcal{R}(\mathbf{y}) = \{\mathbf{y}' \colon s_{\mathrm{sem}}(\mathbf{y}, \mathbf{y}') \wedge s_{\mathrm{bleu}}(\mathbf{y}, \mathbf{y}') > 1 - \epsilon\},$$

where s_{sem} is a score of semantic similarity, and s_{bleu} is the BLEU score. Intuitively, our relevant sequences comprise those that are both semantically similar to $\mathbf{y}$, *and* have sufficient unigram overlap.

A key challenge is efficiently identifying semantically similar sequences to $\mathbf{y}$. To achieve this in a tractable manner, we propose the following procedure (see Algorithm 1). First, we assume the existence of an *embedding space* for output sequences. For example, this could be the result of BERT (Devlin et al., 2019), which embeds each sequence into a fixed vector representation. Given such an embedding space and a corpus $\mathcal{Y}_{\mathrm{ref}}$ of reference sequences, we may now efficiently compute the neighbors of $\mathbf{y}$, $\mathcal{N}(\mathbf{y})$, comprising the top-k closest sequences in $\mathcal{Y}_{\text{ref}}$ for the given $\mathbf{y}$ (Indyk and Motwani, 1998).[1]

The elements of $\mathcal{N}(\mathbf{y})$ can be expected to have high semantic similarity with $\mathbf{y}$, which is desirable. However, such sequences may *not* meaningfully align with the original input $\mathbf{x}$ (e.g., may not be sufficiently close translations). To account for this, we prune the elements from $\mathcal{N}(\mathbf{y})$ based on the BLEU score. Intuitively, this pruning retains sequences that are both semantically similar *and* have non-trivial token overlap with $\mathbf{y}$.

We use $\mathcal{Y}_{\text{ref}}$ as all output sequences in the training set. In practice, one may however use any set of sequences that are valid for the domain in question. We find $k = 100$ closest sequences in this space, and smooth over $k' = 5$ pruned sequences with the highest BLEU score to $\mathbf{y}$. In Table 1 we show example augmentations. Notice both the diversity of augmentations, as well as relatedness to the original targets.

4 Experiments

Setup. We use the Transformer model for our experiments, and follow the experimental setup and hyperparameters from Vaswani et al. (2017). We experiment on three popular machine translation tasks: English-German (EN-DE), English-Czech (EN-CS) and English-French (EN-FR), using the WMT training datasets, and on the tensor2tensor framework (Vaswani et al., 2018).[2] We evaluate on the Newstest 2015 for EN-DE and EN-CS, and WMT 2014 for EN-FR.

Baselines. We use the seq2seq model results by Vaswani et al. (2017) as a baseline. We compare our approach with the following alternate smoothing methods: i) smoothing is done over all possible tokens from the vocabulary at each next token prediction (Szegedy et al., 2016), ii) smoothing is conducted over random targets from within batch (Guo et al., 2018), and iii) smoothing is done over artificially generated targets that are close to the actual target sequence according to BLEU score (Elbayad et al., 2018). For all these methods we experiment with values of α in $\{0.1, 0.001, 0.0001, 0.00001\}$, and report the best results in each case. For the (Elbayad et al., 2018) baseline, we follow the reported best performing variant, randomly swapping tokens with others from the target sequence.

Main results. In Table 2 we report results from our method (BERT+BLEU) and the different state-of-the-art methods mentioned above. Our most direct comparison is against (Elbayad et al., 2018), as both the methods smooth over sequences that have high BLEU score. However, instead of generating sequences by randomly replacing tokens, we retrieve them from a corpus of well formed text sequences. In particular, we use BERT-base multilingual model to embed all the training target sequences into 768 dim fixed vector representation (corresponding to CLS token) and then identify top-100 nearest neighbors for each of the target sequence. Consequently, our method outperforms (Elbayad et al., 2018) by a large margin on all three benchmarks. This demonstrates the importance of smoothing over sequences that not only have significant n-gram overlap with the ground truth target sequence but are also well formed and are semantically similar to the ground truth. In Table 3 we report the comparison between our model and the strongest baseline on EN-CS across multiple metrics, confirming the improvement we report in Table 2 for BLEU score.

Ablating BLEU pruning. Table 4 reveals it is useful to use a sufficiently restrictive criterion in BLEU pruning; however, excess pruning (BLEU5) is harmful. Thus, we seek to retrieve semantically related targets which do not necessarily have highest scoring n-gram overlap to the original target. This is intuitive: enforcing too high n-gram overlap may cause all augmented targets to be too lexically similar, limiting the benefit of seeing new targets in training. We also experimented with not reranking neighbors using BLEU pruning, which resulted in no improvement over the baseline. In other words, it was essential to use this kind of postprocessing for obtaining improvements.

Ablating the number of neighbors. We experimented with how the number of neighbors influences the results. For EN-CS, we obtained the following BLEU4 scores correspondingly for 10, 5 and 3 neighbors: 21.86, 22.82, 22.23. Overall, we find that too few or too many neighbors harm the performance compared to the 5 neighbors we used in other experiments. At the same time, the time complexity increases linearly as number of neighbors increases.

---

[1] Alternatively, one could consider selecting highest scoring augmentations based on a pre-trained seq2seq model. However, the resulting quadratic computational complexity renders such an approach impractical.

BERT+BLEU5	29.41	22.38	17.26

Table 4: Results on EN-CS from targets smoothing with varying n-gram overlap enforced for the final selection of top 5 augmented targets. Enforcing higher overlap to the original target worsens the performance.

5 Conclusion

We propose a novel label smoothing approach for sequence to sequence problems that selects a subset of sequences that are not only semantically similar to the target sequences, but are also *well formed*. We achieve this by using a pre-trained model to find semantically similar sequences from the training corpus, and then we use BLEU score to rerank the closest targets. Our method shows a consistent and significant improvement over state-of-the-art techniques across different datasets.

In future work, we plan to apply our semantic label smoothing technique to various sequence to sequence problems, including Text Summarization (Zhang et al., 2019) and Text Segmentation (Lukasik et al., 2020b). We also plan to study the relation between pretraining and data augmentation techniques.

Abstract

Most recent improvements in NLP come from changes to the neural network architectures modeling the text input. Yet, state-of-the-art models often rely on simple approaches to model the label space, e.g. bigram Conditional Random Fields (CRFs) in sequence tagging. More expressive graphical models are rarely used due to their prohibitive computational cost. In this work, we present an approach for efficiently training and decoding hybrids of graphical models and neural networks based on Gibbs sampling. Our approach is the natural adaptation of SampleRank (Wick et al., 2011) to neural models, and is widely applicable to tasks beyond sequence tagging. We apply our approach to named entity recognition and present a neural skip-chain CRF model, for which exact inference is impractical. The skip-chain model improves over a strong baseline on three languages from CoNLL-02/03. We obtain new state-of-the-art results on Dutch. [1]

1 Introduction

Complex probabilistic graphical models were widely adopted for NLP tasks before the prevalence of deep learning (e.g. the skip-chain CRF of Finkel et al. (2005) and Sutton and Mccallum (2004) for NER). Although modern neural architectures are able to learn much better feature representations (e.g. the contextualized word representations of Peters et al. (2018), Devlin et al. (2018), and Akbik et al. (2019)) than the hand-crafted features used classically in graphical model's log-linear potentials, these advances in feature learning do not negate the need for modeling the output label space.

Consider two contrasting approaches to structured prediction: transition-based models and graphical models. Transition-based models (e.g. the sequence-to-sequence models of Sutskever et al. (2014)) have enjoyed recent success thanks to their ability to have unbounded memory of past transitions when predicting subsequent ones; yet because no conditional independence assumptions are made, inference is typically restricted to (heuristic) greedy search and its variants. By contrast, graphical models make strong conditional independence assumptions, but enjoy a wealth of inference algorithms, both exact and approximate, as a result. Moreover, graphical models readily admit the incorporation of domain knowledge about interactions between the output variables. In this paper, we focus on this latter approach to modeling.

Specifically, we explore conditional random fields (CRFs) (Lafferty et al., 2001) with neural potential functions. Prior state-of-the-art approaches utilizing such models (e.g. CRF-LSTMs) for sequence tagging tasks like named entity recognition (NER) have focused on simple linear-chain CRFs, which only model bi-gram dependencies of adjacent labels (Lample et al., 2016; Peters et al., 2017), and the exact inference can be done in polynomial time with dynamic programming. By contrast, we are motivated by CRFs that do not admit exact inference.

We propose Neural SampleRank, a novel algorithm that is computationally efficient for approximate inference and training of complex CRFs (where exact inference is impractical) with neural factors. The main inspiration of our work is SampleRank (Wick et al., 2011; Zhang et al., 2014), a training algorithm for complex graphical models based on Gibbs sampling, that has been shown to work well with linear factors. We extend SampleRank to work with neural scoring factors. Neural SampleRank enables us to use CRFs that are far more expressive than the linear-chain structures seen in NER models. The loss does *not* require full

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4999–5011,
November 16–20, 2020.

inference to compute the gradient in training, which makes it more computationally efficient. Comparing with message-passing based algorithms like loopy belief propagation (LBP), Neural SampleRank is conceptually simpler and easier to implement with modern deep learning tools like PyTorch (Paszke et al., 2019). We empirically evaluate Neural SampleRank on the CoNLL-02 and CoNLL-03 NER task on English, German and Dutch (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003). We show that for linear-chain BiLSTM-CRF model (Lample et al., 2016), training with Neural SampleRank achieves competitive F1 score compared with MLE and exact inference. With a new neural skip-chain CRF model trained with Neural SampleRank, we achieve higher F1 on English and German than all existing models that do not use contextualized word embeddings or external labeled data. With contextualized word embeddings, our skip-chain model obtains new state-of-the-art results on Dutch.

2 Related Work

Various approaches have been taken in NLP to combine graphical models and neural architectures. For sequence tagging tasks like NER, it is common to use a linear-chain CRF model (Huang et al., 2015; Lample et al., 2016), for which exact inference can be done in polynomial time with forward-backward. Malaviya et al. (2018) adopt a factorized CRF to model the output space of morphological tagging, and the exact inference is tractable with belief propagation. Ganea and Hofmann (2017) propose a fully connected binary CRF to model mention sequence for entity linking task, and they use loopy belief propagation for approximate inference.

Other approaches have been proposed to adopt expressive graphical models while keeping the inference computationally feasible, but have not been applied to deep neural networks. Steinhardt and Liang (2015) propose to select non-local contexts while keeping the model feasible for exact inference. Finkel et al. (2005) use Gibbs Sampling with simulated annealing for fast approximate inference for models with non-local factors. Sutton and Mccallum (2004) propose a skip-chain CRF for NER learned with loopy belief propagation. SampleRank (Wick et al., 2011; Zhang et al., 2014) propose a new training objective targeted for sampling-based inference which is efficient both in terms of computation cost and task performance. In prior work, Gibbs sampling has been used with deep neural networks for Bayesian posterior inference (Shi et al., 2017; Tran et al., 2016), and sampling from conditional sequence models (Lin and Eisner, 2018). Gibbs sampling was only widely applied to discriminative models before the prevalence of deep learning, and restricted to generative models when used with neural models (Das et al., 2015; Nguyen et al., 2015; Xun et al., 2017). To the best of knowledge, we are the first to use Gibbs sampling to obtain point estimation for neural network graphical model hybrids, for the task of structured prediction.

State-of-the-art approaches for NER all use a simple linear-chain CRF model to model the label space. Neural architectures to learn a better representation of the text input include bi-directional LSTM (Huang et al., 2015; Lample et al., 2016), GRU (Yang et al., 2017) and character CNN (Yang et al., 2017; Peters et al., 2017). A major recent step in the field is contextualized word embedding like ELMo (Peters et al., 2018) , BERT (Devlin et al., 2018) and the character-based Flair (Akbik et al., 2019). However, none of these approaches model longer range context dependencies in the document, limited by the linear-chain structure of the CRF.

3 Neural SampleRank

3.1 CRF with Neural Factors

We use x to denote an input sentence and $y \in \mathcal{Y}(x)$ to denote a structured output for the sentence. $\mathcal{Y}(x)$ is the valid output space for input x. We denote the ground truth output as y^*. The neural CRF can be interpreted as a factor graph that defines the following conditional distribution:

$$p(y|x;\Theta) = \frac{\exp(s(x,y;\Theta))}{\sum_{y' \in \mathcal{Y}(x)} \exp(s(x,y';\Theta))} \quad (1)$$

where $s(x,y;\Theta)$ is a differentiable scoring function parameterized by Θ, given by a factor graph with arbitrary structure and factors defined with neural networks. The goal of inference is to find the output $\hat{y}$ with the highest conditional probability defined in Eq. 1, or equivalently with highest score:

$$\hat{y} = \operatorname*{arg\,max}_{y \in \mathcal{Y}(x)} s(x,y;\Theta) \quad (2)$$

For many NLP tasks the size of the output space $\mathcal{Y}(x)$ grows exponentially as the length of x increases, which makes computation of the partition function (i.e. the denominator in Eq. 1) and finding the maximum over $\mathcal{Y}(x)$ (i.e. Eq. 2) hard combinatorial problems. However, with Gibbs sampling, we are able to avoid computing the partition function altogether and make finding an (approximate) maximum feasible in practice.

To avoid repetitive computation for the neural networks, we decompose the scoring function s as:

$$s(x, y; \Theta) = s\big(x, y, f(x; \theta_N); \theta_G\big) \tag{3}$$

where we break down the learnable parameters as $\Theta = \{\theta_N, \theta_G\}$, where θ_N parameterizes the neural network f that constructs a representation of the input, and θ_G parameterizes the CRF that captures dependencies in the output label space. The neural function $f(x; \theta_N)$ is usually expensive to compute but only depends on the input x. On the other hand, after f is evaluated, the score $s(x, y, f; \theta_G)$ is usually very cheap to compute (e.g. look-ups in a factor table). We will leverage these properties to improve computational efficiency.

3.2 Decoding with Gibbs Sampling

To decode a neural CRF model, we find the output that maximizes the scoring function (as shown in Eq. 2) by sampling from the conditional distribution defined in Eq. 1 with Markov Chain Monte Carlo (MCMC). However, finding maximum by sampling from the original distribution is inefficient, and a common practice (Finkel et al., 2005) is to instead sample from this distribution:

$$p(y|x; \Theta, T) \propto \exp\big(\tfrac{1}{T} s(x, y; \Theta)\big) \tag{4}$$

where we introduce a temperature $T \leq 1$ to sharpen the distribution around the region with highest probability density (a smaller T will lead to a sharper peak). In practice we typically design an annealing schedule to gradually decrease T, so that we allow more exploration in the beginning of the Markov Chain, and gradually converge to the region with the highest probability density.

The decoding algorithm is shown in Alg. 1. We conduct decoding with Gibbs sampling, where the proposal distribution q is the conditional distribution of one variable (or a subset of variables) in y^t conditioned on all other variables according to p (defined in Eq. 4).

When decoding with MCMC, the output y may be stuck at a local maxima due to the annealing process, and for each run of MCMC we may end up in a different local maxima. Therefore, we run MCMC decoding for multiple times, then conduct a majority vote for each label. This simple ensemble approach is able to reduce the variance of MCMC decoding and improve prediction accuracy.

Algorithm 1: Decoding with Gibbs Sampling.

```
Input: $x$, $\Theta = \{\theta_N, \theta_G\}$
Output: $\hat{y}$
Initialize temperature $T$;
$z \leftarrow f(x; \theta_N)$;
Randomly initialize output $y^0$;
for $t = 0, \dots, M-1$ do
    $y^{t+1} \leftarrow q(\cdot|x, y^t, z, \theta_G, T)$;
    if $s(x, y^{t+1}, z; \theta_G) > s(x, \hat{y}, z; \theta_G)$ then
        $\hat{y} \leftarrow y^{t+1}$
    $T \leftarrow$ anneal$(T)$;
```

3.3 Training with Neural SampleRank

The training algorithm of Neural SampleRank is largely inspired by the SampleRank algorithm proposed by Wick et al. (2011). We adopt a max-margin loss to train the neural CRF scoring function, so that the score of a favorable output is higher than an unfavorable output by a margin. Assume $\omega(y)$ is a metric to measure the quality of a tag sequence y according to the ground truth y^* (e.g. F1 score, or negative Hamming distance). If $\omega(y) > \omega(y')$ then y is considered to have higher quality, and the ground truth $y^* = \arg\max_{y \in \mathcal{Y}} \omega(y)$. Then the margin $\Delta_\omega(y_i, y_j)$ is defined as:

$$\Delta_\omega(y_i, y_j) = \omega(y^+) - \omega(y^-) \tag{5}$$

where $y^+ = \arg\max_{y \in \{y_i, y_j\}} \omega(y)$ and $y^- = \arg\min_{y \in \{y_i, y_j\}} \omega(y)$, thus $\Delta_\omega(y_i, y_j) \geq 0$.

The SampleRank loss is incurred by a pair of outputs y_i, y_j when $\Delta_\omega(y_i, y_j) > 0$, defined as:

$$\begin{aligned} \ell(y_i, y_j) = [&\Delta_\omega(y_i, y_j) - \\ &\big(s(y^+, x; \theta) - s(y^-, x; \theta)\big)]_+ \end{aligned} \tag{6}$$

The training procedure for Neural SampleRank is shown in Alg. 2. The loss $\ell(\cdot, \cdot)$ is defined in Eq. 6, and $q(\cdot)$ is the proposal distribution for Gibbs sampling.

Computing the loss for Neural SampleRank does not require running full inference of the CRF model, and is instead accumulated over M Gibbs sampling steps. There are two types of loss terms: pairwise loss $\ell(y^t, y^{t-1})$, which is the max-margin loss computed with two consecutive samples y^{t-1}

Algorithm 2: Neural SampleRank Training.

```
Input: $D = \{(x_1, y_1^*), \ldots, (x_n, y_n^*)\}$
Output: $\Theta = \{\theta_N, \theta_G\}$
Initialize $\Theta = \{\theta_N, \theta_G\}$ ;
while not converged do
    foreach $x_i, y_i^* \in D$ do
        loss_total $\leftarrow 0$;
        $z \leftarrow f(x_i; \theta_N)$ ;
        $y^0 \leftarrow$ random_initialize($y_i^*$);
        for $t = 1, \ldots, M$ do
            $y^t \leftarrow q(\cdot|x_i, y^{t-1}, z, \theta_G)$ ;
            if $\Delta_\omega(y^t, y^{t-1}) > 0$ then
                loss_total += $\ell(y^t, y^{t-1})$;
            if $\Delta_\omega(y^t, y_i^*) > 0$ then
                loss_total += $\ell(y^t, y_i^*)$;
        $\Theta \leftarrow$ update($\Theta$, $\nabla_\Theta$loss_total) ;
```

and y^t; and gold loss $\ell(y^t, y_i^*)$, which is computed with the ground truth output y_i^* and a sample y^t. Intuitively, while gold loss helps the model to rank ground truth higher than all incorrect outputs, the pairwise loss ensures the model can correctly rank between two similar outputs. This property is helpful during the sampling based decoding: the predicted output is able to take "guided" steps to gradually move to better quality outputs, even though the initial output might be far from ground truth.

During training, for each example, the initial sample y^0 is taken from random_initialize($\cdot$) in Alg. 2, which randomly copies from the ground truth output y^*. We first uniformly randomly sample a probability u between 0 and 1, then for each label value $y^0[j]$, we copy from $y^*[j]$ with probability u, and take random value with probability $1-u$. This is to simulate different stages of MCMC decoding, in which the samples converge to a high probability density region, i.e. get closer and closer to ground truth.

In Alg. 2, the model is only updated after sampling (not during), and we reinitialize the sample after each model update, therefore we are not breaking detailed balance and the sampler is still proper MCMC. However, since full inference is not needed for training, the Markov Chains in Alg. 2 only have a small number of samples, and do not necessarily converge.

3.4 Comparison with Linear SampleRank

Comparing with the SampleRank algorithm proposed in previous work (Wick et al., 2011; Zhang et al., 2014), Neural SampleRank uses the same pairwise training objective defined on two consecutive examples on the Markov chain. Unlike Wick et al. (2011), we also adopt the gold loss term defined on the ground truth and one sample as done in Zhang et al. (2014), which has empirically shown to be important for model performance.

The key difference between Neural SampleRank and the SampleRank algorithm for CRFs with linear factors is the optimization algorithm. Wick et al. (2011) frames the optimization problem as a saddle point optimization problem and solves it with a stochastic approximation saddle point (SASP) algorithm. On the other hand, Zhang et al. (2014) frames the learning objective as a constrained optimization problem, and solves it with the MIRA algorithm (Crammer and Singer, 2003). Both algorithms rely on the fact that the scoring factors are linear functions, to derive a closed form update for each iteration in training, so neither optimization algorithm works with neural scoring factors. In Neural SampleRank, we reframe the optimization objective as a structured hinge loss (Eq. 6) without constraints, so that we are able to train the neural scoring factors with back-propagation based gradient updates.

3.5 Computational Efficiency

After the decomposition of scoring function in Eq. 3, we take a two-step approach to evaluate the scoring function. As shown in Alg. 1 and Alg. 2, for each input x, we first compute its neural representation $z = f(x; \theta_N)$ before we take any samples. Once the sampling starts, only the output y could change, leaving z, the neural representation of x, unchanged. Therefore, when we take new samples, we only need to recompute the scoring function defined by the non-neural factors of the CRF (parameterized by θ_G). In this way, for each input x, we only need to evaluate the expensive deep neural networks once, and for each additional sample we only need to evaluate the cheap non-neural factors.

In pairwise SampleRank loss $\ell(y^t, y^{t-1})$, the two consecutive Gibbs samples usually only differ in a small subset of the variables in the CRF. We can leverage this fact to sparsify the computation of the score difference between y^t and y^{t-1} (Eq. 6) and its gradient w.r.t the factor scores, by only considering the factors in the CRF that involve the small label subset that has been re-sampled (Wick et al., 2011). This sparse property makes Neural

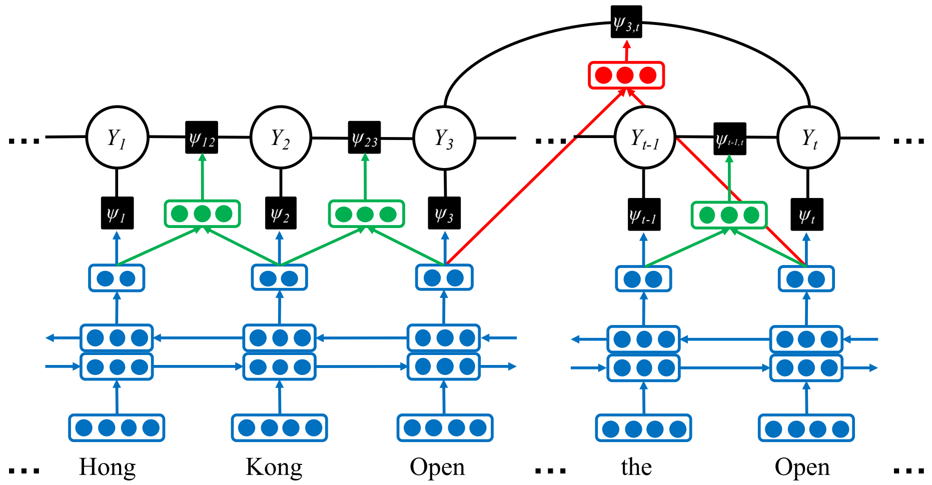

Figure 1: Neural skip-chain CRF. The BiLSTM (shown in blue) computes a vector representation for each input token. These vectors are fed into transition (green) and skip-chain (red) MLPs (i.e. feed-forward layers). The outputs of these neural scoring functions are used to compute unary, transition, and skip-chain factors (black squares). The factors provide a score for each assignment of their neighboring variables (white circles).

SampleRank efficient for complex CRFs when the degree of each node is bounded by a small constant. CRFs can usually satisfy this sparsity condition as they introduce inductive bias by making (conditional) independence assumptions. On the other hand, the gold loss $\ell(y^t, y^*)$ may require evaluating the full CRF as the sample y^t could be far from the ground truth y^*. However, as training progresses, y^t will get sufficiently close to y^* with fewer and fewer samples, resulting in fewer number of factors that need re-evaluation, thus lead to a speed-up for gold loss computation.

4 Neural Skip-Chain CRF for NER

4.1 Base Model

The base model we adopt for NER is a BiLSTM-CRF (Lample et al., 2016), which adopts a multi-layer BiLSTM to learn a representation of the text input, then use a linear-chain CRF to model the dependencies in the output label space. For token inputs of BiLSTM, we use either concatenation of pretrained word embedding and character-CNN word embedding, or contextualized word embedding.

The linear-chain CRF scoring function is:

$$\begin{aligned} s(y, x; \Theta) = &\sum_{1 \le i \le d} \Psi_i(y_i, x; \Theta) + \\ &\sum_{1 \le i \le d-1} \Psi_{i,i+1}(y_i, y_{i+1}, x; \Theta) \end{aligned} \tag{7}$$

where d is the length of the text input. The model consists of emission factors $\Psi_i(y_i, x; \Theta)$ for each token label y_i, and transition factors $\Psi_{i,i+1}(y_i, y_{i+1}, x; \Theta)$ for each pair of adjacent token labels (i.e. a bi-gram).

The hidden states of the token BiLSTM are treated as a context-aware representation for each token, and are used to parameterize the emission factors in the linear chain CRF. In previous works, the transition factors are learnable scalars shared across all bi-grams, and they do not have any dependencies on the context. In our model, we modify the transition factors to be context dependent: we use feed-forward layers to compute the transition factors with the BiLSTM hidden states of the two tokens in the bi-gram. The parameters of the feed-forward layers are shared among all bi-grams.

4.2 Skip-Chain CRF

Besides bi-gram level label dependencies modeled by the transition factors in linear-chain CRF, we introduce longer range factors that model global dependencies in a sequence tagging task. The design of global factors may be different for each task in order to model the task-specific dependency patterns. In this section we present one approach to design global factors for NER. The resulting neural skip-chain CRF is depicted in Figure 1.

We adopt the same consistency assumption and inductive bias proposed by Finkel et al. (2005) and Sutton and Mccallum (2004): different occurrences of the same token are likely to be labeled in the same way (e.g. they could be recurring references to the same named entity). However, this assumption is not always true, as the labels of a token sequence are context dependent, so we introduce factors to model this uncertainty. On top of the linear-chain CRF, we introduce a skip-chain connection between every pair of recurring capitalized tokens in the same document—named entities are usually capitalized. We denote the set of skip-chain connections that satisfy these conditions as S, then the scoring function for the skip-chain CRF is:

$$\begin{aligned} s(y, x; \Theta) = & \sum_{1 \le i \le d} \Psi_i(y_i, x; \Theta) + \\ & \sum_{1 \le i \le d-1} \Psi_{i,i+1}(y_i, y_{i+1}, x; \Theta) + \\ & \sum_{(i,j) \in S} \Psi_{i,j}(y_i, y_j, x; \Theta) \end{aligned} \tag{8}$$

A skip-chain factor scores all possible labels of the token pair with feed forward layers on token representations constructed by the token BiLSTM. Although the skip-chain factors $\Psi_{i,j}(y_i, y_j, x; \Theta)$ are still second order factors like the transition factors, the token labels y_i, y_j are usually not adjacent, and in most cases are far apart in the document. We can no longer use forward-backward for exact inference. Instead, we use Gibbs sampling to do efficient approximate inference for each document. In our experiments, we employ block Gibbs sampling for token pairs that have a skip-chain connection, so that the model can better leverage long-range context dependency.

5 Experiments

5.1 Dataset and Model Configuration

We evaluate Neural SampleRank for sequence tagging models on CoNLL-02 Dutch (Tjong Kim Sang, 2002), and CoNLL-03 English and German NER datasets (Tjong Kim Sang and De Meulder, 2003). [2] Summary statistics of the training set for each language is shown in Table 1. We are unable to evaluate our skip-chain CRF model on CoNLL-02 Spanish due to lack of labels for document boundaries. We use the BIOES tagging scheme, and report the F1 score in its standard definition for NER.

	English	German	Dutch
#document	946	553	287
#sentence	14,987	12,705	15,806
#token	204,567	207,484	202,931
#skip-chain	29,309	31,683	44,309

Table 1: Training sets statistics of CoNLL-03 English and German, and CoNLL-02 Dutch.

For pretrained word embeddings, we use GLoVE (Pennington et al., 2014) for English, and Fasttext (Bojanowski et al., 2017) for German and Dutch. For contextualized word embedding, we use Flair (Akbik et al., 2019) in its recommended settings for each language. For training, we use negative Hamming distance for the metric in the SampleRank loss and Adam optimizer (Kingma and Ba, 2014). For Gibbs sampling, at training time we take 10 cycles of samples for each update. (We resample the full label sequence in each cycle.) At decoding time, we set the initial temperature to 10, the annealing rate to 0.95 and take 120 cycles of samples. We ensemble model predictions over 3 runs with majority vote. Additional hyperparameter settings can be found in Appendix A.

Following the convention for NER tasks (Peters et al., 2017; Akbik et al., 2019), we train the model using both training and development sets when reporting test set results. For analysis, we train the model with training set only and report on development set. We use paired permutation test (Yeh, 2000) for significance testing in result comparisons.

5.2 NER Results

We present the NER results of our neural skip-chain CRF model with Flair embedding in Table 2. The skip-chain CRF has context dependent transition and skip-chain factors, and is trained with Neural SampleRank (NSR), while all other models are trained with standard MLE. On English, we are able to achieve comparable F1 scores as other contextualized embedding models, yet unable to match Akbik et al. (2019). When trained with Flair embedding, our neural skip-chain CRF model does not improve over baseline for English and German. The F1 score difference between baseline and neural skip-chain CRF on German is not statistically significant. Our skip-chain neural CRF model sig-

---

[2] Following Akbik et al. (2019), we use the 2006 revised ground truth labels for German NER. Clarifications from the author can be found at `https://github.com/flairNLP/flair/issues/1102`. In our paper, we use † to denote results for which we are not sure about the label version, so they may or may not be comparable to our results. In Appendix C, we discuss more about the label version change, and show results of our models with the original 2003 ground truth labels. In general, models trained and evaluated on the 2006 label set get higher F1 scores than the 2003 label set. The magnitudes of improvements brought by our skip-chain model are comparable on the two label set versions.

Model	Learning	English F1	German F1	Dutch F1
ELMo (Peters et al., 2018)	MLE	92.22	—	—
BERT (Devlin et al., 2018)	MLE	92.80	—	—

+ context transition + skip-chain	NSR	**84.50***

Table 4: NER F1 score comparison for German, without contextualized word embeddings.

nificantly improves the Flair model's performance on Dutch ($p < 0.01$), achieving new state-of-the-art. According to Table 1, the Dutch dataset has significantly longer documents compared with the other languages, and significantly more skip-chain connections, which could explain why the skip-chain model performs exceptionally well on Dutch.

We further evaluate our neural skip-chain model trained without contextualized word embedding on English and German NER. As shown in Table 3 and Table 4, we are able to significantly improve F1 over baseline on both languages ($p < 0.05$). On English, we also present results when the context dependent transition factors and skip-chain factors are separately added to baseline. We show that the context-dependent transition factors and skip-chain factors can separately improve on NER performance of the base model, and some synergy exists between the two types of factors when used together. Compared with previous approaches that do not use contextualized word embedding or external labeled data, our neural skip-chain CRF model trained with Neural SampleRank achieves the highest F1 on both CoNLL-03 English and German.

5.3 Qualitative Analysis

For all analysis, we investigate the neural skip-chain CRF model without Flair embedding for English, trained without development set. In Figure 2, we show an example of improvements on NER brought by skip-chain factors, from a document in the English development set. We look at two mentions of the English cricketer Peter Such: while the first mention uses his full name, the second mention only uses his last name. From the emission factors, we can see that the local context for the first mention is clear enough for the model to give a high score to label it as a Person type. However, since the last name "Such" is also a common stopword, the model confuses the second mention as a non-entity context. The skip-chain factors are especially helpful in this case, in which long-range contexts can help with disambiguation. From the skip-chain factor, we can see that when looking at both contexts, the model is confident that both mentions are referring to a Person type entity.

5.4 Ablation Study

To compare Neural SampleRank and MLE with exact inference for training, we train the base BiLSTM-CRF model with Neural SampleRank as well. At evaluation time we still use Viterbi decoding for a fair comparison of the training algorithm. As shown in Table 5, the F1 score regressed after switching from exact inference to approximate inference with Neural SampleRank. However, the performance is still comparable.

We conduct ablation study on the neural skip-chain CRF model to see the effectiveness of each component. Results reported in Table 5 are best of

w/o context transition	94.89

Table 5: Ablation results on the development set for English. Each row changes one component while keeping all of the others.

5 training runs with different random seeds. The mean and standard deviation for the base model setting is 94.67 ± 0.12, while our best skip-chain model setting is 94.96 ± 0.16. This shows that Neural SampleRank does not bring much additional variance in the training process. As for the variance in MCMC decoding, in Figure 3 we show how various initial temperatures affect decoding results. We can see that as long as the initial temperature is high enough for exploration in the beginning, and the temperature anneals sufficiently close to 0 in the end, the decoding achieves optimal performance, with a lower standard deviation compared with training variations.

From Table 5, We can see that among the two types of SampleRank loss, the pairwise loss has a much bigger impact on the F1 score than the gold loss. This shows that the training signal introduced by pairwise loss is necessary for efficient Gibbs sampling. The pairwise loss pushes the model locally to a better output structure even when it is far from the gold output. Over time this should push the model towards faster convergence. We also observe that block Gibbs sampling can improve the performance of the skip-chain model, which effectively leverages long-range context dependencies.

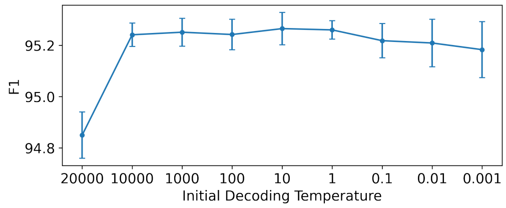

Figure 3: Decoding results with different initial temperature (mean and standard deviation over 10 runs).

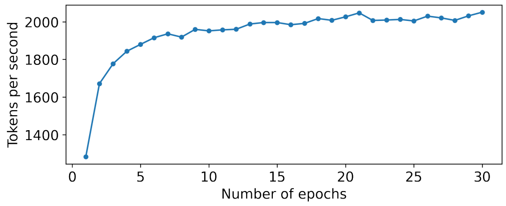

Figure 4: Training speed (tokens per second) for the first 30 epochs of one run.

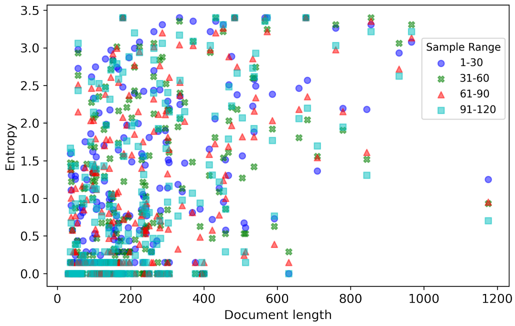
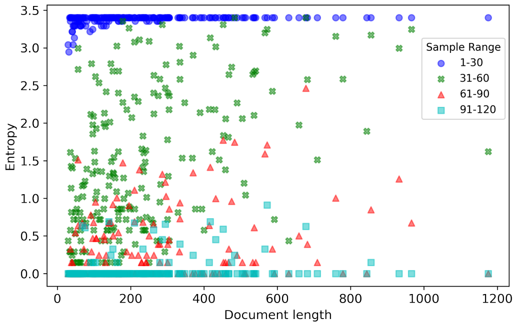
5.5 Training speed

As discussed in Section 3.5, the gold loss term can be very dense at the beginning of training, but will become sparse as we train the model and get samples closer to the gold label. The increase in training speed brought by this sparsity is shown in Figure 4. While the first epoch runs at 1283 tokens



(a) MCMC without annealing.



(b) MCMC decoding with annealing.

Figure 5: Entropy of samples against document length, at different stages of MCMC, measured on 30-sample ranges.

per second on average, the first 3 update steps runs at 367 tokens per second. After 30 epochs, the training speed stabilizes at 2,000 tokens per second. As a comparison, the linear-chain model runs at 8,000 tokens per second for training with MLE. See Appendix D for details about the profiling environment.

5.6 Mixing of MCMC

In order to evaluate the mixing of the Markov chain defined by the neural skip-chain CRF, we measure the entropy of samples for each document at different stages of MCMC. Following Keith et al. (2018), we approximate the probability of each sample (i.e. tag sequence) with its frequency when calculating the entropy, then plot this empirical entropy against the length of document. We take 120 samples, by collecting the sample at the end of each cycle (i.e. resampling of the full tag sequence), then split the 120 samples into four 30-sample stages. In Figure 5, we compare the sample entropy of standard MCMC (i.e. without annealing), and MCMC decoding with annealing. From Figure 5a, we observe that the entropy distributions at different stages stay roughly the same, which suggests that the Markov chain is well-mixed, even after a small number of samples. Figure 5b shows how annealing affects sample mixing: Initially, the high temperature leads to samples with high entropy and better exploration. Then, annealing of the temperature drives down the entropy, such that the chain gradually converges to a high probability density region.

6 Conclusion

In this work, we have proposed Neural SampleRank (NSR), an efficient algorithm for approximate inference and training for CRF models with neural network factors. With a novel skip-chain CRF model that models long range context dependencies, NSR can significantly improve NER performance over the linear-chain CRF on multiple datasets. NSR is computationally efficient for arbitrarily complex graphical models, thus applicable to a wide range of structured prediction tasks. Graphical models with task specific inductive bias have been successful for tasks like NER, coreference resolution, relation extraction, and parsing. Our proposed method paves the way for new neural graphical models to be designed for these tasks.

Appendices

A Model Hyperparameters

For our base BiLSTM-CRF model, we use a two-layer BiLSTM with hidden state dimension set to 200. For each token, we train a character CNN with 25-dimensional dense character embedding input and 100 filters with size 3, then concatenate with pretrained word embeddings. For English we use the 100 dimensional GLoVE embedding (Pennington et al., 2014). For Dutch and German we use the 300 dimensional Fasttext embedding trained on Wikipedia (Bojanowski et al., 2017). Alternatively, we use Flair embedding (Akbik et al., 2019) in its recommended setup for each language to represent tokens. The emission factors of the CRF are computed by a feed-forward network with a 200 dimensional hidden layer. The transition and skip-chain factors use feed-forward networks with a hidden layer of 500 dimensions, which takes the concatenation, element-wise sum and maximum of the token hidden states as input.

For training, we use negative Hamming distance for the metric in the SampleRank loss. We use Adam optimizer (Kingma and Ba, 2014) with 0.001 initial learning rate, and an annealing rate of 0.5 and patience of 3. We clip the gradients at 1.0, and apply dropout to BiLSTM outputs and feed-forward layers with 0.5 dropout rate. Each mini batch contains 2 documents. For Gibbs sampling, at training time we take 10 cycles of samples for each update. (We resample the full label sequence in each cycle.) At decoding time, we set the initial temperature to 10, the annealing rate to 0.95 and take 120 cycles of samples. We ensemble model predictions over 3 runs with majority vote. Following the convention for NER tasks (Peters et al., 2017; Akbik et al., 2019), we train the model using both training and development sets when reporting test set results. For analysis we train the model with training set only and report on development set. We use paired permutation test (Yeh, 2000) for significance testing in result comparisons.

When training with both train and development sets, the early stopping is determined by the progress of learning rate annealing. The optimal point of learning rate value is determined by our experiments that only use train set for training.

B Evaluation Metrics

For all NER results we report the F1 score in its standard definition for the task. To compute the F1 scores, we directly reuse the perl script released alongside the CoNLL-02/03 shared task [3] .

C CoNLL-03 German Results

For the CoNLL-03 German NER task, there seems to be some discrepancy in the NLP community about the version of ground truth labels being used. Besides the original 2003 ground truth labels, a revised set of labels was released in 2006, with updated annotation guidelines that should lead to higher label quality [4]. The most prominent difference between the two label versions is MISC type entity, where the 2006 version has significantly fewer mentions than the 2003 version, as a result of major changes in the annotation guideline. Statistics of each entity type, in each of the training, development and test sets, is shown in Table 6.

Among the models that we compare our methods against, only Akbik et al. (2019) made clarifications on the label version in an issue in their Github repository for Flair embedding [5]. We are not sure about the label version used in Lample et al. (2016) or Riedl and Padó (2018), thus their results may or may not be comparable to ours. For our models we report results on both label versions in Table 7. We can see that the F1 scores are significantly lower on 2003 labels than on 2006 labels. However, for both versions of data, we get similar trends in the results: while our neural skip-chain CRF model trained with Neural SampleRank is not able to improve over the Flair baseline, it brings statistically significant improvements ($p < 0.05$) for models trained without contextualized word embedding.

We note that our baseline Flair results on 2003 labels match the results reported by Flair users in the Github issue (one user reported 83.22, another reported 83.78). While we can not be certain about the label version used in other works, we speculate that Lample et al. (2016) used the 2003 label version, while Riedl and Padó (2018) used the 2006 version. This speculation is made solely based on

comparisons with our baseline results, as our model settings are otherwise very similar to theirs.

D Profiling Configurations

Our model is implemented with PyTorch (Paszke et al., 2019), and the Neural SampleRank loss is implemented as a PyTorch C++ extension. The profiling is run with an NVIDIA RTX 2080 Ti GPU, and an Intel Core i9-9900K CPU (8 core 16 threads, 3.6 GHz).

Multilevel Text Alignment with Cross-Document Attention

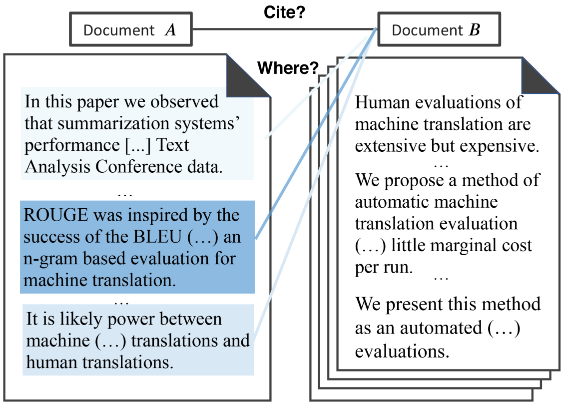
Abstract

Text alignment finds application in tasks such as citation recommendation and plagiarism detection. Existing alignment methods operate at a single, predefined level and cannot learn to align texts at, for example, sentence *and* document levels. We propose a new learning approach that equips previously established hierarchical attention encoders for representing documents with a cross-document attention component, enabling structural comparisons across different levels (document-to-document and sentence-to-document). Our component is weakly supervised from document pairs and can align at multiple levels. Our evaluation on predicting document-to-document relationships and sentence-to-document relationships on the tasks of citation recommendation and plagiarism detection shows that our approach outperforms previously established hierarchical, attention encoders based on recurrent and transformer contextualization that are unaware of structural correspondence between documents.

1 Introduction

Aligning texts and understanding their relationships is a common problem for NLP tasks such as citation recommendation (Bhagavatula et al., 2018; Jiang et al., 2019), comparable document mining (He et al., 2010; Peng et al., 2016; Bhagavatula et al., 2018; Guo et al., 2019), parallel sentence mining (Shi et al., 2006; Ture and Lin, 2012; Guo et al., 2018), plagiarism detection (Barrón-Cedeño et al., 2010; Forner et al., 2013; Ferrero et al., 2017), paraphrase identification (Wan et al., 2006; Das and Smith, 2009; Wang et al., 2016), and textual entailment (Dagan and Glickman, 2004; Androutsopoulos and Malakasiotis, 2010; Zhao et al., 2016). Longer texts make the problem more challenging due to the potential complexity of the underlying correspondence. Here, we develop a model to address this problem and demonstrate its applicability on three different tasks which require such understanding, namely on citation recommendation, citation localization, and plagiarism detection for general web documents.



In this paper we observed that summarization systems' performance [...] Text Analysis Conference data.

Figure 1: A motivating example of aligning scientific documents at different levels. We consider citation recommendation (whether A cites B) and citation localization (which sentence in A cites) at the same time. The confidence of our model for citation localization is represented by the degree of blueness.

One key component of an NLP system for aligning documents is the encoding process. Present approaches for comparing documents rely on hierarchically structured document encoders such as hierarchical attention networks (HANs; Yang et al., 2016), which independently represent the two documents as fixed-length vectors. The vectors are fed to a classifier which makes a decision on the relation between them (Jiang et al., 2019; Guo et al., 2019). However, such methods do not provide insights about or leverage the underlying relationships across documents and are applicable only to a single, predefined level (Jiang et al., 2019; Yang et al., 2020). Importantly, when comparing documents, those methods ignore the structural cor-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5012–5025,
November 16–20, 2020. ©2020 Association for Computational Linguistics

respondence between parts.

Figure 1 shows an example of predicting and localizing citations in scientific documents. To solve this problem in a cost-effective way, models need to be able to make joint predictions about these different tasks without relying on fine-grained annotations which are typically more expensive to obtain. In this paper, we propose a new approach for encoding documents that aligns document parts during the encoding process and is able to make predictions about their relationships across different levels (specifically, document-to-document and sentence-to-document). In particular, we equip a powerful class of models, namely hierarchical attention encoders (Yang et al., 2016; Liu and Lapata, 2019; Guo et al., 2019) with a cross-document attention component that "attends" to the structure of documents, enabling inferences about alignment of their parts (Section 3).

We introduce new benchmarks for joint document-to-document prediction and sentence-to-document localization of document relationships for citation recommendation and plagiarism detection (Section 4). Our experiments with variations find that cross-document attention is beneficial to strong baseline hierarchical encoders (Section 5) on these challenging tasks.

2 Comparing Documents

Many potential applications of natural language processing involve a comparative analysis of two (or more) documents. Examples include:

- recommending existing documents to be cited in a new document (Jiang et al., 2019; Yang et al., 2020);
- inferring whether one document plagiarizes another (Foltýnek et al., 2019);
- inferring whether one document is a translation of another (Guo et al., 2019); and
- multi-document summarization (Liu and Lapata, 2019) and coreference resolution (Lee et al., 2012).

Our experiments in Section 5 will consider tasks inspired by the first two applications.

Note that, in each of these examples, the most useful analysis of the document-to-document relationship will include a more fine-grained analysis: which *parts* of the source document correspond to which parts of the target document? Figure 1 illustrates an example for citation recommendation, in which the main relationship (does/should document A cite document B?) is actually composed of a number of more localized relationships between sentences in document A that contain citations and document B (or, perhaps, parts of document B). In general, whenever we seek to model relationships between documents, we believe that these relationships can be *localized* in one or both documents. We believe that automatic identification of these local correspondences is useful, both directly (e.g., mining parallel sentences for use in training a machine translation system), and for providing explanations (e.g., in plagiarism detection).

Of course, these fine-grained, localized correspondences are not typically directly observable in realistic datasets. Here, we consider scenarios where positive and negative examples of document-level relationships are available for supervision, but fine-grained correspondences between their parts are not. We exploit simple decompositions of documents (into sentences and words) but follow earlier work (Yang et al., 2016) in offering a general hierarchical model that could be extended to allow for additional levels in future work.

The problem we aim to solve is: (i) given two documents (each decomposed, e.g., into sentences and words), automatically categorize whether a particular relationship holds between them, and (ii) which parts between them should be "aligned" in support of the relationship in (i). We will refer to these tasks respectively as document-to-document alignment (D2D) and sentence-to-document alignment (S2D), and will conduct experiments on tasks of both kinds in Section 5.

3 Approach

We next describe our solution to this problem, starting with a high-level overview (Section 3.1). We build on a family of widely used models for document representation, known as hierarchical attention networks (HANs; Section 3.2), which is sensitive to predefined notions of hierarchy (here, sentences; Yang et al., 2016). We augment the HAN with cross-document attention (Section 3.3).

3.1 Overview

The training data assumed in our setup is a collection of labeled document pairs. In this work, the labels are binary (either the relationship of interest exists or does not). Let $\langle A, B, y \rangle$ denote a training tuple of two documents with their label y. We apply a familiar "Siamese" architecture (Mueller and Thyagarajan, 2016; Jiang et al., 2019): A and B are encoded using the same function (which we call the "document encoder"), the outputs are concatenated, and then passed through a fully-connected relu layer and a sigmoid function to yield a score. The network is trained to minimize cross-entropy.

This model relies heavily on the document encoder to learn representations relevant to the relationship of interest. As discussed in Section 2, we desire an encoder that can align parts of either or both texts, localizing the relationship to particular sentences, but any encoding function for a document can be used. Our baselines, based on the encoder we present next, do not have any notion of alignment, while our new model does (Section 3.3).

3.2 Hierarchical Attention Networks

Yang et al. (2016) introduced a family of document encoding models that are based on a word/sentence/document hierarchy, known as hierarchical attention networks (HANs). They have been shown superior to earlier hierarchical encoding models based on convolutional networks (Collobert et al., 2011; Kim, 2014; Zhang et al., 2016), they are competitive for tasks involving long documents (Choi et al., 2016; Pappas and Popescu-Belis, 2017; Sun et al., 2018; Miculicich et al., 2018; Liu and Lapata, 2019; Guo et al., 2019),[1] and they can be used orthogonally to other design decisions (e.g., word embeddings and the use of pretraining).

For document X, a HAN builds a vector representation $\mathbf{d}_X$ using the (given) structure of X: typically, the document vector is derived from sentence vectors, which are derived from (contextualized) word vectors. Working in the order that the computation proceeds, the encoding procedure is:

1. Each word in the document is mapped (by lookup) to its type embedding.[2]

2. Each word's vector is contextualized, i.e., a new word *token* vector is derived from the word and the other words in the sentence. In this work, we consider two contextualizers: pretrained BERT (Devlin et al., 2019) and a GRU (Cho et al., 2014) whose parameters are trained only for the end task.

3. Each sentence in the document is encoded by aggregating the contextualized word vectors. Letting $\mathbf{x}_i$ denote the ith word vector and $\mathbf{y}$ denote the sentence vector, the layer that performs this aggregation has the form:

$$\mathbf{y} = \sum_i \overbrace{\frac{\exp\left[\mathbf{u}^\top \tanh\left(\mathrm{affine}(\mathbf{x}_i)\right)\right]}{\sum_j \exp\left[\mathbf{u}^\top \tanh\left(\mathrm{affine}(\mathbf{x}_j)\right)\right]}}^{\text{attention}_i} \mathbf{x}_i, \tag{1}$$

   where i and j range over the words within the sentence. We suppress the parameters of the affine transformation but not the attention parameters $\mathbf{u}$. Note that, when using pretrained BERT, we instead take the average of word token vectors to obtain sentence vectors, following Reimers and Gurevych (2019).

4. Analogous to the two steps above, the sentence vectors are contextualized using a bidirectional GRU for both word-level contextualizers (the default encoder for HAN at the sentence level; Yang et al., 2016) and then aggregated. Aggregation is exactly as in Equation 1, but $\mathbf{x}_i$ now denotes a contextualized sentence vector and $\mathbf{y}$ is the document vector $\mathbf{d}$. A separate set of parameters is used at this level of the hierarchical model. Note that the contextualization can be done with transformers too as by Pappagari et al. (2019); we leave this alternative option as future work.

HANs handle long documents by imposing a simple notion of hierarchy and compositionality; they restrict the dependence of one part's representation on the representations of its neighbors. They have been used effectively for semantic comparison tasks between documents (Jiang et al., 2019), but they do not offer a way to localize correspondences between parts of the two documents.

3.3 Cross-Document Attention

We augment HANs with a cross-document attention (CDA) mechanism that attends to their document parts, allowing them to reason over structural correspondences between documents. Illustrated

---

[1] Transformers have emerged as a successful tool across NLP (Vaswani et al., 2017), but they are not yet well suited for long sequences without an hierarchical configuration because their costs scale quadratically with sequence length. When more efficient variants of transformers become available, they will be an appealing option to consider in this setting as well.

[2] "Type embedding" refers to traditional word (subword) vectors; we use the term to contrast with contextualized embeddings associated with specific tokens.

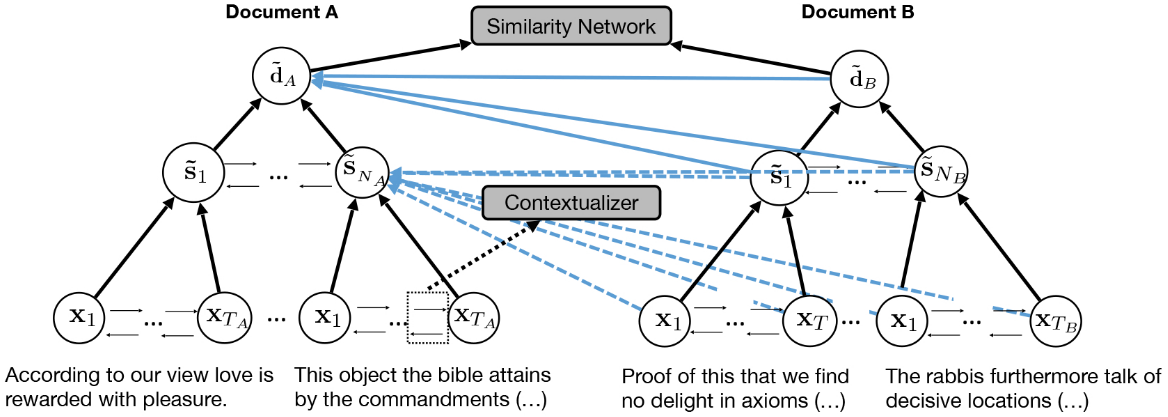

Figure 2: Illustration of our models. In the exposition, SHALLOW considers cross-document attention without the dashed line, while DEEP considers all levels' cross-document attention. Only part of attention is shown in the figure for clarity. The similarity network is for predicting the binary label. The blue arrows indicate the cross-document attention for two example nodes, namely $\tilde{\mathbf{d}}_A$ and $\tilde{\mathbf{s}}_N$.

in Figure 2, the main idea is to allow the representation of a sentence or word in document A to be influenced by the representations of sentences and words in document B, and vice versa.

Consider the document vector $\mathbf{d}_A$ for document A. In the HAN, the aggregation function considered only the (contextualized) vectors for sentences within the document (Equation 1). We inject another layer that "attends" to document B and its sentences. Let $\mathcal{B}$ denote the set containing all contextualized sentence vectors[3] from B and B's document vector. We have:

$$\tilde{\mathbf{d}}_A = \text{affine}\left(\left[\mathbf{d}_A; \sum_{\mathbf{v}\in\mathcal{B}} \frac{\exp \mathbf{v}^\top \mathbf{d}_A}{\sum_{\mathbf{v}'\in\mathcal{B}} \exp \mathbf{v}'^\top \mathbf{d}_A}\mathbf{v}\right]\right) \tag{2}$$

Again, we suppress the parameters of the affine transformation for clarity. The new vector $\tilde{\mathbf{d}}_A$ is now used as the document representation for A. The same process is repeated in the other direction for obtaining the document vector $\tilde{\mathbf{d}}_B$ which is used as the document representation for the candidate document B.

The modification above is a variant of our model we call SHALLOW; it modifies only the final layer of the encoding so that A's document vector depends on B's document and sentence vectors, and vice versa. A similar layer can optionally be added to update each *sentence* vector in A, using attention over the sentence and word vectors in B; this is illustrated in Figure 2, and we refer to it as the DEEP variant of our model, because CDA is used to modify both sentence and document vectors.

More generally, CDA could be applied with additional levels in a HAN's hierarchy (e.g., paragraphs) and with different design choices about attention across levels.

Relation to previous models. Our idea is related to prior work which has encoded shorter texts such as sentences using attention over their syntactic structures (Liu et al., 2018) to better align texts at the sentence-level. We go beyond sentences by encoding longer texts such as documents at multiple levels using attention over their document structures. An approach similar to ours is due to Li et al. (2019), who used cross-graph attention to compute alignment between computer programs. However, they only evaluated document-to-document alignment (not other levels). They also rely on a graph representation of the documents, which may be costly both in terms of annotation and in computational cost for the required graph-based encoder; semantic and discourse graph structures for natural language are an interesting opportunity to explore in future work.

4 A Benchmark for Document Relation Prediction and Localization

While many tasks and datasets focus on understanding the relationships between sentences or documents separately, to the best of our knowledge, there are no joint publicly available English benchmark for both D2D and S2D tasks. Annotating document correspondences is expensive and time-

---

[3] Note that we have different strategies for different models here. Details are included in Appendix A.4.2.

	Pairs	**Docs**	**Words**		**Sentences**	
Dataset	count	count	avg	std	avg	std
AAN	132K	13K	122.7	11.2	4.9	2.7
OC	300K	567K	190.4	16.3	7.0	3.5
S2ORC	190K	270K	263.7	19.2	9.3	5.9
PAN	34K	23K	1569.7	90.4	47.4	66.1

Table 1: Dataset statistics, namely the number of unique documents (count), average (avg) number of words per sentence and sentences per document along with their standard deviations (std).

consuming, especially at a fine-grained level like sentences. Therefore, we introduce a new benchmark consisting of six tasks (four D2D and two S2D). This benchmark is shared publicly to encourage continued research.[4]

Datasets. Our data resources of citation recommendation come from the ACL Anthology Network Corpus (AAN; Radev et al., 2009), the Semantic Scholar Open Corpus (OC; Bhagavatula et al., 2018), and the Semantic Scholar Open Research Corpus (S2ORC; Lo et al., 2020). For plagiarism detection, we use the PAN plagiarism alignment task (Potthast et al., 2013). We downsample OC and S2ORC, which are very large. All of our datasets are preprossessed similarly: we filter out characters that are not digits, letters, punctuation, or white space in the texts.

AAN. Contains computational linguistics papers published on ACL Anthology from 2001 to 2014, along with their metadata. For each paper, we extract its abstract and the abstracts of its citations and treat them as positive pairs without including full texts. For each positive pair's source paper, an (uncited, presumed irrelevant) negative paper is sampled at random to create a negative instance. Since the dataset is not complete, we filter out pairs where either document lacks an abstract, but otherwise include all positive citation pairs.

OC. Contains about 7.1M papers in computer science and neuroscience. We follow a similar procedure to that for AAN. Here we only select one citation per source paper, for wider coverage.

S2ORC. A large contextual citation graph of 8.1M open access papers across broad domains of science. The papers in S2ORC are divided into sections and linked by citation edges. We select one section with at least one citation edge provided and the abstract of the cited paper to obtain a positive pair. To obtain a negative pair, we randomly select a paper from S2ORC which is not cited by the source section. Pairs with incomplete abstract or text are filtered out. To obtain the S2D groundtruth for a positive pair (which we will use only in evaluation, not as supervision), we use the citation span stored in the citation edge to identify where the citation appears in the citing document. Specifically, the information implied by the edges (that a paper cites another) for any pair is used to localize the ground-truth sentences which contain the citation. That citation in the sentence is removed from the text to prevent leakage, and the citing sentence is recorded. Note that not every pair has a citation edge that contains relevant sentence-level information, in which case the pair is discarded.

Note that for all the citation-related datasets above, the examples are counted as "negative" as long as they are uncited by the relevant paper. It is possible to use a heuristic approach to avoid treating similar documents as negative examples but we chose not to because the constraint is already largely satisfied with the random sampling procedure and the hypothesis that a paper should be cited by another one when they have high lexical overlap which may not always be true.

PAN. A collection of web documents which contain several kinds of plagiarism phenomena. Human annotations show the segments of texts that are relevant to the plagiarism both in the source and suspicious documents. We construct a positive pair by extracting the relevant segment in the source document and a span (continuous) of text containing the relevant segment in the suspicious document. A negative pair is subsequently constructed by replacing the source segment in the afore-created positive pair with a segment from the corresponding source document which is not annotated as being plagiarised. For the S2D task, the sentences on the suspicious side that are not relevant to the plagiarism are treated as negative candidates in the positive pair. Note that the mapping between sentences is missing from the annotation, which prevents us from creating a sentence-to-sentence task.

---

[4] Relevant details such as train/dev./test splits are included in Appendix A.1.

Evaluation scores. For D2D tasks, we report accuracy and F_1 score. For S2D tasks, we report the mean reciprocal rank (MRR) and precision-at-N (P@N). In the plagiarism case, multiple sentences can be seen as positive instances; MRR only considers the rank of the first relevant sentence, while P@N reports the number of relevant sentences in the top N.

5 Experiments

Our experiments are performed on the above benchmark to test the benefit of cross-document attention. We first evaluate our model on scientific document citation recommendation (Section 5.2) followed by citation localization (Section 5.3). Then, we evaluate our model on web document plagiarism detection and localization (Section 5.4).

5.1 Settings

Baselines. We compare our method with previous established hierarchical document methods adapted for the task of similarity learning described in Section 3.2. For baseline selection, we considered only methods that could deal with documents of arbitrary length on all of the examined datasets. In particular, we focus on two types of hierarchical attention networks (HANs), namely the first is using pretrained transformer representations from BERT and the other bidirectional GRU trained end-to-end:

- **BERT-AVG**: represents each sentence with the average embedding of its tokens from BERT (Devlin et al., 2019). The representation of the document is computed as the average of the sentence representations.

- **BERT-HAN**: uses BERT to represent sentences with the average embedding. Following Pappagari et al. (2019), the representation of the document is computed by the HAN network starting from the sentence-level representations. The model does not have direct access to word-level representations.

- **GRU-HAN**: encodes documents with a hierarchical attention network with word-level and sentence-level abstractions based on GRU (Yang et al., 2016; Jiang et al., 2019).

For our augmentation, we equip both types of hierarchical encoders with a SHALLOW or a DEEP CDA component, keeping the base setup exactly the same. GRU and BERT are widely used contextualizers in NLP, while each can be viewed as a strong representative of the family of recurrent neural networks and transformers respectively. Note that BERT-HAN only trains a model over sentence-level representations, thus DEEP does not apply to BERT-HAN. For the S2D task, we extract sentence representations from the candidate document $\mathbf{v} \in \mathcal{B}$ per model and rank them according to their similarity with the the target document vector $\mathbf{d}_A$ using an attention function:

$$\text{AttScore} = \frac{\exp \mathbf{v}^\top \mathbf{d}_A}{\sum_{\mathbf{v}' \in \mathcal{B}} \exp \mathbf{v}'^\top \mathbf{d}_A}, \tag{3}$$

or a cosine similarity function:

$$\text{CosScore} = \frac{\mathbf{v}^\top \mathbf{d}_A}{\|\mathbf{v}\| \|\mathbf{d}_A\|}. \tag{4}$$

We will refer to them as *attention alignment* and *cosine alignment* respectively. The best scores for each metric and encoder type are marked in **bold**.

Note that the goal of our experiments was not to compare to state-of-the-art document models but to make a controlled experiment using various hierarchical configurations and provide some initial estimates of the difficulty of our benchmark for multilevel document alignment.

Configuration. All the models are implemented in PyTorch. Our code is available on Github.[5] We use Adam to optimize the parameters with an initial learning rate of 10^{-5}. The dimensions of hidden state vectors in GRUs and other hidden layers are set to 50 as in the original HAN (Yang et al., 2016). For word embeddings, we use 50-dimensional GloVe embeddings, which are updated during the training phase.

For pretrained contextualized embeddings, we use BERT-large implemented by HuggingFace.[6] Note that, due to budget constraints, we keep BERT frozen in all experiments except for the finetuning experiment in Section 5.2. Unless otherwise noted, we perform early stopping based on the validation loss if there is no improvement for 5 consecutive epochs. The size of parameters of HAN models with GRU and BERT (kept frozen) are 20M and 1M respectively. Our corresponding models with

a cross-document alignment component increase the number of parameters marginally, namely by 20K parameters. The networks with hierarchical configuration have $\mathcal{O}(T \log D)$ complexity with GRU and $\mathcal{O}(T^2 \log D)$ with BERT (T: sequence length, D: number of layers). SHALLOW (DEEP) adds one (two) more linear and quadratic terms respectively to these complexities, hence the asymptotic complexity remains the same. In practice, adding CDA negligibly impacts decoding speed.[7] For more training details, see Appendix A.2.

5.2 Citation Recommendation

We evaluate the ability of our models to predict whether one document cites another, given citing signal at the document level, and specifically to quantify the effect of augmenting a model with CDA. From the results shown in Table 2 (left), we see a consistent benefit from CDA across AAN, OC, and S2ORC, on accuracy and F_1. Further, the DEEP version of our model consistently outperforms the SHALLOW one on these tasks.

Finetuning BERT. To further evaluate our method, we finetune the BERT- HAN and SHALLOW with BERT models, on the AAN dataset (where GRU models show an advantage).[8] Table 2 shows that finetuning improves both models' performance, and the benefit of CDA is still present.

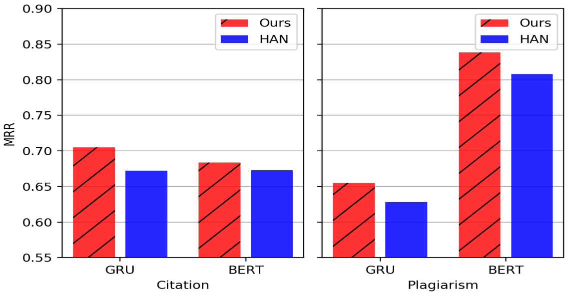

Figure 3: Citation localization results in terms of MRR given oracle document-to-document alignments. *Left*: S2ORC. *Right*: plagiarism detection. For GRU and BERT, "ours" refers to adding a DEEP and SHALLOW CDA component, respectively.

Comparison to state-of-the-art models. The performance of our finetuned BERT-HAN with CDA (SHALLOW) is stronger than the SMASH model of Jiang et al. (2019), which achieves 80.68% accuracy and 80.84% F_1 on AAN. Yang et al. (2020) introduce a method similar to our BERT-HAN baseline and achieve 85.36% accuracy and 85.43% F_1. Note that both models carried out training on full texts; we only use abstracts, using a much smaller computational budget. As reported in Jiang et al. (2019), the baseline HAN trained on full texts achieves 78.13% accuracy, while HAN only achieves 68.01% accuracy on our AAN task.

5.3 Citation Localization

The same models as those in the D2D experiments above can be used to extract S2D alignments for evaluation on the second S2ORC task. If a model fails to predict the document alignment, the

Table 4: Comparison of baselines and our models at the sentence-level S2ORC task. The *Random* baseline assigns a random alignment score between 0 and 1 for each sentence.

sentence-level alignment is counted as incorrect.

As shown in Table 3, the deep variant of CDA here shows a consistent advantage over the shallow one, suggesting that explicitly modeling word-level correspondences helps localize citations. We also find that *attention alignment* is consistently better than *cosine alignment* in S2D tasks.

We also consider an oracle evaluation, where the trained models are given the correct D2D prediction (recall that above, the D2D and S2D alignments are jointly predicted). Figure 3 (left) illustrates that CDA is beneficial in this setting as well, for both encoders. The other evaluation metrics show similar trends.

5.4 Plagiarism Detection

For plagiarism detection, the input consists of a source document and a suspicious document; the D2D task is to predict whether the suspicious document plagiarizes the source document, and the S2D (localization) task is to identify which sentences in the suspicious document plagiarize. The dataset here (PAN) is considerably smaller than those we explored for citations (Table 1).

D2D results are shown in Table 2 (right). CDA is not helpful to the BERT-HAN model and only SHALLOW CDA helps the HAN GRU model on the D2D task, which could be attributed to the small size of the plagiarism dataset.

S2D performance is shown in Table 5 with *attention alignment*; here we see a consistent benefit from CDA across encoders and evaluation scores.

Enc	**CDA**	MRR	P@10	P@5

6 Other Related Work

Latent Alignment. Attention has been previously used to align word sequences based on their intermediate hidden states for summarization (Rush et al., 2015) and machine translation (Bahdanau et al., 2015). The alignment is typically softly learned and does not consider alternative alignments in a probabilistic sense. Hard attention (Luong et al., 2015) is an alternative approach which selects only one word at a time but it is non-differentiable and requires more complicated techniques such as reinforcement learning to train. Deng et al. (2018) considered an alternative attention network for learning latent variable alignment models based on amortized variational inference. Others modified attention to attend to partial segmentations and subtrees (Kim et al., 2017) or trees (Liu et al., 2018), while Yang et al. (2018) cast the problem as latent graph learning to capture dependencies between pairs of words from unlabeled data. Orthogonal to these studies, we use attention to compare documents represented by hierarchical document encoders at multiple levels.

Similarity Learning. There are three types of similarity learning in NLP. The supervised paradigm differs from typical supervised learning in that training examples are cast into pairwise constraints (Yang and Jin, 2006), as in cross-lingual word embedding learning based on word-level alignments (Faruqui and Dyer, 2014) and zero-shot utterance/document classification (Yazdani and Henderson, 2015; Nam et al., 2016; Pappas and Henderson, 2019) based on utterance/document-level annotations. The unsupervised paradigm aims to learn an underlying low-dimensional space where the relationships between most of the observed data are preserved, as in word embedding learning (Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014). The weakly supervised paradigm is the middle ground between the two, as in cross-lingual word embedding learning based on sentence-level alignments (Hermann and Blunsom, 2014; Gouws et al., 2015). Our approach is weakly supervised and operates at the document-level, making use of structural correspondence between documents.

7 Conclusion

We augment hierarchical attention networks with cross-document attention, allowing their use in document-to-document and sentence-to-document alignment tasks. We introduce benchmarks, based on existing datasets, to evaluate model performance on such tasks. In controlled experiments, we observe a benefit from cross-document attention on three out of the four document-to-document tasks and two out of two sentence-to-document tasks.

A Supplementary Material for "Multilevel Text Alignment with Cross-Document Attention"

We provide more details about the datasets in the new benchmark, experimental setup, choices of hyperparameters, model design choices, and validation performances corresponding to the ones reported in the main paper. Moreover, we provide qualitative examples that visualize the cross-document attention component.

A.1 Benchmark Details

In Table 6, we list the statistics about training, development and test splits of the four datasets that are part of our benchmark. The exact splits used in our experiments are released along with the datasets of the benchmark.[9] A sample of our datasets are attached along with our submission. Note that we have not included the whole benchmark because its size exceeds the limit allowed in the submission portal.

Dataset	**Training**	**Validation**	**Test**
AAN	106,592	13,324	13,324
OC	240,000	30,000	30,000
S2ORC	152,000	19000	19000
PAN	17,968	2,908	2,906

Table 6: Dataset statistics regarding the number of examples for the training/validation/test splits.

A.2 Experimental Setup Details

For our experiments, we used the following computing infrastructure: 1 GeForce 960, 1 GeForce 1080, and 1 Titan Xp for the model training. The batch size is set to 128 for GRU-HAN (including our augmentation) experiments on AAN task, and is set to 256 for all other experiments. The running time ranges from 36 hours to 48 hours for the GRU-based models, and from 1 to 2 hours for BERT-frozen models, and about 24 hours for BERT-finetuning models.

A.3 Development Scores

We report validation performance for all the reported test results for the document-to-document alignment tasks in Tables 8–9. Note that for the sentence-to-sentence alignment tasks there is no validation taking place, hence, there are no development scores to report here.

A.4 Model Design Choices

In this section, we describe the set of model design choices that were made based on development performance before running our main experiment.

A.4.1 Word Embedding Dimension

To decide what embedding size to use for our main experiments, we experimented with 50-dimensional and 200-dimensional GloVe embeddings by training the GRU-HAN model on the AAN task. When keeping other settings exactly the same as the aforementioned GRU-HAN models on the AAN task, the performance of GRU-HAN with a larger word embedding size is lower than the 50-dimensional model as shown in Table 7. Therefore, we stick with 50-dimensional GloVe embeddings for the other experiments.

Encoder	**Dim**	Acc	F_1
HAN	50	68.01	67.23
	200	66.94	66.24

Table 7: Influence of the dimensionality of word embeddings to the baseline model HAN.

A.4.2 Sentence Contextualization

Preliminary experiments show that one could obtain better performance on the AAN D2D task by using sentence vectors before contextualization in Equation 2 for GRU-based models. Therefore, the experiments for GRU-based models above use sentence vectors before contextualization for CDA. For BERT-based models, we use two GRU layers to contextualize sentence vectors, the sentence vectors after the first GRU layer are used in CDA. Practitioners can be flexible in deciding how CDA is used for different tasks and encoders.

Encoder	**CDA**	Acc	F_1
BERT-HAN	–	75.41	74.25
	SHALLOW	**83.72**	**82.57**

Table 8: Development set results corresponding to Table 3.

Encoder	CDA	AAN		OC		S2ORC		PAN	
		Acc	F_1	Acc	F_1	Acc	F_1	Acc	F_1
BERT-AVG	–	54.72	54.12	84.58	84.67	80.52	81.14	82.73	82.42
BERT-HAN	–	67.34	64.69	85.73	86.23	90.46	90.49	**88.85**	**88.77**
	SHALLOW	**73.20**	**70.80**	**87.73**	**87.91**	**91.66**	**91.54**	86.76	86.79
GRU-HAN	–	69.68	69.15	83.06	83.84	82.65	83.41	76.40	76.77
	SHALLOW	77.46	75.41	89.31	89.41	89.78	89.89	**77.02**	**78.15**
	DEEP	**78.17**	**75.94**	**91.10**	**91.11**	**92.01**	**92.02**	76.99	78.01

Table 9: Development set results corresponding to Table 2.

A.5 Integrating Cross-Document Attention

For the integration of the cross-document attention representations with the representations of the hierarchical attention network we experimented with two options, namely concatenation and addition of vectors. We found that our method is more competitive with concatenation. However, integrating with concatenation involves a linear projection to match the original hidden size of the network which increases slightly the number of parameters. Here, we evaluate the performance of our model when it uses addition, that is when the number of parameters remains exactly the same with that of the base network.

We evaluated the performance of our SHALLOW augmentation on BERT-HAN with finetuning BERT end-to-end. The results are displayed in Table 10. With SHALLOW (addition), BERT-HAN achieves 79.02% accuracy and 79.08% F_1, which still improves over the BERT-HAN baseline. Interestingly, using addition instead of concatenation performs quite well and its performance is still better than the hierarchical attention network baseline. Hence, we conclude that the additional number of parameters is not the only factor responsible for the superior performance of our model.

Encoder	CDA	Acc	F_1
BERT-HAN	–	73.36	73.51
	SHALLOW (concatenation)	**82.03**	**82.08**
	SHALLOW (addition)	79.02	79.08

Table 10: Comparison with BERT-HAN using finetuning on document-to-document alignment on AAN.

A.6 Qualitative Inspection

We select two examples from the test sets of GORC and PAN, where both HAN and HAN SHALLOW with BERT obtain correct D2D results. However, while HAN is confused of finding the sentence where citation or plagiarism happens, HAN SHALLOW is able to locate the relevant sentences in the document as shown in Figure 4.

We find that the document-to-document results in these two examples are heavily dependent on the localization of the sentences. While we have difficulty in interpreting HAN's decision for the two examples, it is not hard for us to see how HAN SHALLOW, as a unified model for D2D and S2D tasks, obtains its decision on whether this document cites or plagiarizes the other one. This property should be important for future models to pursue instead of simply producing a yes or no decision.

A.7 Computational Cost of CDA

In Table 11, We show the average inference time of each epoch (256 batch size) on GeForce 1080 for tasks S2ORC and PAN, which have longer texts among our tasks. In general, the extra computational cost for CDA is negligible (1–2% extra wall time), especially for SHALLOW. Note that BERT-based models share the same property.

Encoder	CDA	S2ORC	PAN
HAN	–	0.256	0.568
	SHALLOW	0.256	0.581
	DEEP	0.258	0.637

Table 11: Comparison of average inference time (s) of each epoch for S2ORC and PAN.

Abstract

The structured representation for semantic parsing in task-oriented assistant systems is geared towards simple understanding of one-turn queries. Due to the limitations of the representation, the session-based properties such as co-reference resolution and context carry-over are processed downstream in a pipelined system. In this paper, we propose a semantic representation for such task-oriented conversational systems that can represent concepts such as co-reference and context carryover, enabling comprehensive understanding of queries in a session. We release a new session-based, compositional task-oriented parsing dataset of 20k sessions consisting of 60k utterances. Unlike Dialog State Tracking Challenges, the queries in the dataset have compositional forms. We propose a new family of Seq2Seq models for the session-based parsing above, which achieve better or comparable performance to the current state-of-the-art on ATIS, SNIPS, TOP and DSTC2. Notably, we improve the best known results on DSTC2 by up to 5 points for slot-carryover.

1 Introduction

At the core of conversational assistants lies the semantic representation, which provides a structured description of tasks supported by the assistant. Traditional dialog systems operate through a flat representation, usually composed of a single intent and a list of slots with non-overlapping content from the utterance (Bapna et al., 2017; Gupta et al., 2018). Although flat representations are trivial to model with standard intent/slot tagging models, the semantic representation is fundamentally limiting. Gupta et al. (2018) explored the limitations of flat representations and proposed a compositional generalization which allowed slots to contain nested intents while allowing easy modeling through neural shift-reduce parsers such as RNNG (Dyer et al., 2016).

Our contributions are the following:

- We explore the limitations of this compositional form and propose an extension which overcomes these limitations that we call *decoupled representation*.
- To parse this more complicated representation, we propose a family of Seq2Seq models based off the Pointer-Generator architecture that set state of the art in multiple semantic parsing and dialog tasks (See et al., 2017).
- To further advance session based task oriented semantic parsing, we release a publicly available set with 60k utterances constituting roughly 20k sessions.

2 Semantic Representation

The compositional extension proposed by Gupta et al. (2018) overcame the limitation of classical intent-slot frameworks by allowing nested intents in slots. But to maintain an easily model-able structure the following constraint was introduced: *the in-order traversal*

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5026–5035,
November 16–20, 2020.

of the compositional semantic representation must reconstruct the utterance. Following this constraint it is possible to use discriminative neural shift reduce parsers such as RNNG to parse into this form (Dyer et al., 2016).

Although at face value this constraint seems reasonable, it has non-trivial implications for both the semantic parsing component (NLU) and downstream components in conversational assistants.

2.1 Surpassing Utterance Level Limitations with Decoupled Form

First we'll take a look at the space of utterances that can be covered by the compositional representation. One fundamental problem with the in-order constraint is that it disallows long-distance dependencies within the semantic representation. For example, the utterance *On Monday, set an alarm for 8am.* would optimally have a single date-time slot: `[SL_DATETIME 8am on Monday]`. But, because *8am* and *on Monday* are at opposite ends of the utterance, there is no way to construct a semantic parse tree with a single date-time slot. Gupta et al. (2018) mentioned this problem, but had some empirical data showing that utterances with long-distance dependencies are rare in English. Although this might be true, having fundamental limitations on what type of utterances can be supported even with a complete ontology is concerning.

In English, discontinuities are restricted in occurrence, despite emerging naturally within certain patterns, because English is a configurational language, which uses strongly marked word order to impart some level of semantic information (Chomsky, 1981). Beyond English, however, there are numerous world languages that are non-configurational and have much freer or potentially completely free word order. Non-configurational languages may often present the same semantic information through the use of Case Markers, Declensions, or other systems. The relatively free word order this allows creates much less emphasis on the collocation of a semantic unit's tokens. Therefore, as conversational assistants progress toward multiple languages it's important to consider that constraints that are acceptable if only English is considered will not analogously scale to other languages.

A simple solution is to convert a standard compositional intent-slot parse into a logical form containing two label types (slot and intent), with no constraints over intent spans. This is trivially accomplished by removing all text in the compositional semantic parse that does not appear in a leaf slot. We call this form of semantic parse the *decoupled* semantic representation, due to the semantic representation not being tightly coupled with the original utterance.

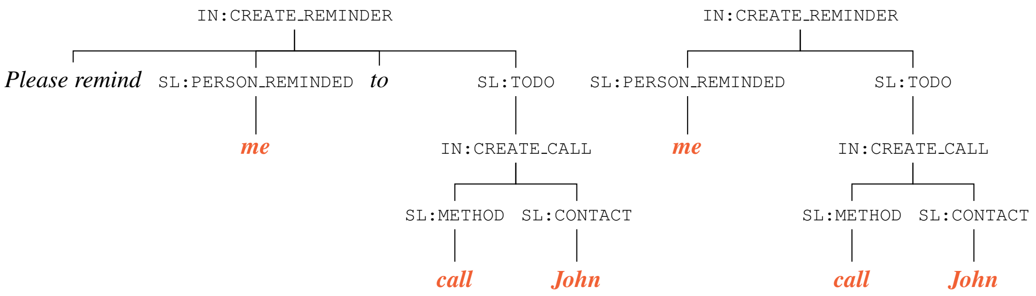
Figure 1 shows a side by side example of compositional and decoupled semantic representations for the utterance *Please remind me to call John*.

2.2 Session Based Limitations

Because traditional conversational systems historically have had a clear separation between utterance level semantic parsing and dialog systems (which stitch together utterance level information into sessions), semantic representations have not focused on session-based representations. Integrating session information into semantic parsers has been limited to refinement-based approaches.

Figure 2 shows an example of refinement and informationally complete based approaches to semantic parsing. The refinement approach delegates responsibility of session-based semantic parsing to a separate dialog component. Consequently, refinement approaches tend to have a very limited ontology due to the semantic parser operating over a fixed input (non-session utterances).

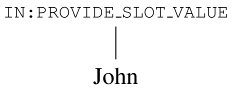
Predicting what slot to use for refining works for flat semantic representations, but it is non-trivial to extend to compositional or decoupled. The position of a slot in a flat semantic representation is not meaningful, thus it is sufficient to only predict the slot without specifying its position in the parse. But



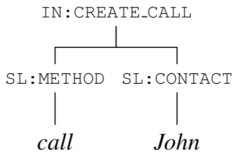
(a) Compositional form.

(b) Decoupled form.

Figure 1: Compositional and decoupled semantic representations for the single utterance "Please remind me to call John".



(a) Refinement



(b) Informationally Complete

Figure 2: **Refinement** and **Complete** session based semantic representations for the utterance "call".

both compositional and decoupled extensions to intent-slot parsing vary semantically by the position of the slot (or nested intent).

We present an example in Figure 3. Given the followup utterance *remind me to call*, a classical system would need to carry over the whole CONTACT slot, but the question is to where? The semantic parse is not flat. The slot could be carried over to the CREATE_REMINDER intent or the nested GET_CONTACT intent. So, if we were to extend classical slot carryover, we not only would need to predict what slot to carry over from the conversation, but what intent within the current semantic parse to place it under. We propose a new paradigm that does joint classical semantic parsing with co-reference resolution and slot-carryover.

2.3 Session Based Semantic Parsing

We present a simple extension to the decoupled paradigm of intent-slot semantic parsing by introduction of a new reference (REF) label type. The REF label type contains two elements in its set to represent co-references and slot-carryover as separate operations. Co-references can be seen as an explicit reference, namely a reference conditioned on an explicit word, while slot-carryover is treated as an implicit reference (conditioned by relevant contextual information).

As an example, refer to the sample session with decoupled semantic parses in Figure 4

3 Model

3.1 Sequence-to-Sequence Architecture

The decoupled semantic parsing model is an extension of the very common sequence-to-sequence learning approach (Sutskever et al., 2014), with the *source sequence* being the utterance and the *target sequence* being a linearized version of the target tree. Trees are linearized by bracketing them, using the same approach as Vinyals et al. (2015). The decoupled tree in Fig. 1b, for example, would be linearized to the following target sequence: [IN:CREATE_REMINDER, [SL:PERSON_REMINDED, me,], [SL:TODO, ...,]. After tokenization, an encoder processes the source tokens w_i and produces corresponding encoder hidden states:

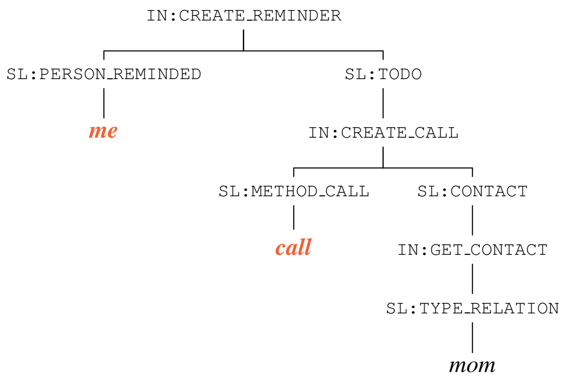


Figure 3: Sample session with complex slot-carryover: “Is mom available?” – “Remind me to call”

(a) “Weather in San Francisco”.
(b) “Traffic there”.
(c) “Any events going on?”

Figure 4: Decoupled semantic representations for a three-utterance session.

$$\boldsymbol{e}_1, ..., \boldsymbol{e}_T = \text{Encoder}(w_1, ..., w_T)$$

where the encoder, in our experiments, is either a standard bidirectional LSTM or a transformer.

In spite of its drawbacks, the rigid structure of the compositional semantic trees (Fig. 1a) has the advantage of readily mapping to the RNNG formalism and its inductive biases. The decoupled semantic representation, being more flexible, does not have such an easily exploitable form – but we can still exploit whatever structure exists. The tokens of the linearized decoupled representation (the *target sequence*) can always be divided into two classes: utterance tokens that are already present in the source sequence – which form the leaves of the tree – and ontology symbols. Taking again the example tree of Fig. 1b, *me*, *call*, and *John* are all tokens from the utterance, while `[IN:CREATE_REMINDER`, `[SL:PERSON_REMINDED`, `]`, etc., are ontology symbols. This partition is reflected in the structure of the decoder: at every decoding step, the model can either generate an element from the ontology, or copy a token from the source sequence via a mechanism analogous to the pointer-generator network of See et al. (2017). At decoding time step t, the decoder is fed with the encoder's outputs and produces a vector of features $\boldsymbol{x}_t$, which is used to compute an *ontology generation distribution* $\boldsymbol{p}_t^{\text{g}}$:

$$\begin{aligned}\boldsymbol{x}_t &= \text{Decoder}\left(\boldsymbol{e}_1, ..., \boldsymbol{e}_t; \boldsymbol{d}_{t-1}; \boldsymbol{s}_{t-1}\right), \\ \boldsymbol{p}_t^{\text{g}} &= \text{softmax}\left(\text{Linear}_{\text{g}}[\boldsymbol{x}_t]\right),\end{aligned}$$

where d_{t-1} is the previous output of the decoder, s_{t-1} is the decoder's incremental state, and $\text{Linear}_\theta[\boldsymbol{x}]$ is short-hand for an affine transformation with parameters θ, i.e. $\mathbf{W}^\theta \boldsymbol{x} + \boldsymbol{b}^\theta$. The decoder's features are also used to calculate the attention distribution – using multi-head attention (Vaswani et al., 2017) – which then serves to produce the *utterance copy distribution* $\boldsymbol{p}_t^{\text{c}}$:

$$\begin{aligned}\boldsymbol{p}_t^{\text{c}}, \boldsymbol{\omega}_t &= \text{MhAttention}\left(\boldsymbol{e}_1, ..., \boldsymbol{e}_t; \text{Linear}_{\text{c}}[\boldsymbol{x}_t]\right), \\ p_t^{\alpha} &= \sigma\left(\text{Linear}_{\alpha}\left[\boldsymbol{x}_t \| \boldsymbol{\omega}_t\right]\right),\end{aligned}$$

where $\sigma(x) = \frac{1}{1+e^{-x}}$ is the standard sigmoid function, $\|$ indicates concatenation, and $\mathrm{MhAttention}$ indicates multi-head attention which returns, respectively, the attention distribution and its weights. Finally, the extended probability distribution is computed as a mixture of the ontology generation and utterance copy distributions:

$$\boldsymbol{p}_t = p_t^{\alpha} \cdot \boldsymbol{p}_t^{\mathrm{g}} + (1 - p_t^{\alpha}) \cdot \boldsymbol{p}_t^{\mathrm{c}}.$$

3.2 Encoder and Decoder

We experiment with two main variants of the decoupled model: one based on recurrent neural networks, and one based on the transformer architecture (Vaswani et al., 2017).

RNN Our base model uses two distinct stacked bidirectional LSTMs as the encoder and stacked unidirectional LSTMs as the decoder. Both consist of two layers of size 512, with randomly initialized embeddings of size 300. The base model is optimized with LAMB while others are optimized with Adam, using parameters $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$, and L2 penalty 10^{-5} (Kingma and Ba, 2014). The learning rate is found separately for each experiment via hyperparameter search. We also use stochastic weight averaging (Izmailov et al., 2018), and exponential learning rate decay. For an extended version of this model, we also try incorporating contextualized word vectors, by augmenting the input with ELMo embeddings (Peters et al., 2018).

Transformer We also experiment with two further variants of the model, that replace encoder and decoder with transformers. In the first variant, the encoder is initialized with RoBERTa (Liu et al., 2019), a pretrained language model. The decoder is a randomly initialized 3-layer transformer, with hidden size 512 and 4 attention heads. In the second variant, we initialise both encoder and decoder with BART (Lewis et al., 2019), a sequence-to-sequence pretained model. Both encoder and decoder consist of 12 layers with hidden size 1024. We train these with stochastic weight averaging (Izmailov et al., 2018), and determine optimal hypermarameters on the validation sets.

4 Experiments

4.1 Session Based Task Oriented Parsing

To incentivize further research into session based semantic parsing through the decoupled intent-slot paradigm we are releasing 20 thousand annotated sessions in 4 domains: calling, weather, music and reminder. We also allow for mixtures of domains within a session.

The data was collected in two stages. First we asked crowdsourced workers to write sessions (both from the users perspective as well as the Assistant's output) tied to certain domains. Once we vetted the sessions, we asked a second group of annotators to annotate the user input per session. Each session was given to three separate annotators. We used majority voting to automatically resolve the correct parse when possible. In the cases where there was no agreement, we selected the maximum informative parse which abode by the labeling representations semantic constraints. The annotator agreement rate was 55%, while our final chosen semantic parses were correct 94% of the time. The large delta between the two numbers is due to multiple correct semantic parses existing for the same session.

We open source SB-TOP in the following link: `http://www.dl.fbaipublicfiles.com/sbtop/SBTOP.zip`. More information about the dataset can be found in the Table **??** in the Appendix.

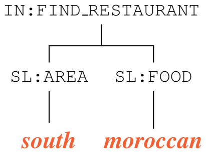
4.2 Semantic Parsing

We evaluate the decoupled model on five semantic parsing datasets, four public and one internal. All but two are annotated with compositional semantic representations and the other with the standard flat intent-slot representation. In order to apply the decoupled models to them, we follow a mechanical procedure to transform the annotations to decoupled representations: all utterance tokens which are not part of a slot are stripped. This procedure effectively turns the tree of Fig. 1a into the tree of Fig. 1b. We note that this procedure for all compositional and flat intent-slot data available is reversible, therefore we can convert from decoupled back to source representation.

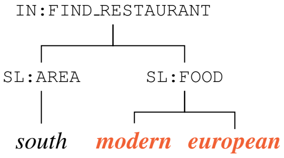
The first public dataset is TOP (Gupta et al., 2018), which consists of over 31k training utterances covering the navigation, events, and navigation to events domains. The first internal dataset we use contains over 170k training utterances annotated with flat representations, covering over 140 distinct intents from a variety of domains including weather, communication, music, weather, and device control. The second internal dataset contains over 67k training utterances with fully hierarchical representations, and covers over 60 intents all in the communication domain.

The second and third public datasets are SNIPS Natural Language Understanding benchmark1 (SNIPS-NLU) and the Airline Travel Information Systems (ATIS) dataset (Hemphill et al., 1990). We follow the same procedure that was mentioned above for preparing the decoupled data for both of these datasets.

As can be seen from Table 1b, our proposed approach outperforms the previous state-of-the-art results on the ATIS, comparable to state-of-the-art on SNIPS, and TOP semantic parsing task, which had been obtained with the Seq2SeqPtr model by Rongali et al. (2020). Comparing the decoupled model to RNNGs, we note that a single decoupled model, using either biLSTMs or transformers (with RoBERTa or BART pretraining) is able to outperform the RNNG. In fact, the decoupled model even outperforms an ensemble of seven RNNGs. The decoupled biLSTM extended with ELMo inputs is able to outperform the transformer model initialised with RoBERTa pretraining. However, the best performance is achieved by using the transformer model with BART-large pretraining, with the decoupled model fine-tuned jointly on top of it (Lewis et al., 2019). In order to understand how much of these gains are due to the semantic representation, we perform an ablation study by



(a) “i want a restaurant in the south part of town that serves moroccan food”.



(b) “how about modern european”

Figure 5: Example DSTC2 session, annotated for the decoupled model.

evaluating the biLSTM and RoBERTa-based models on TOP data using the standard logical form representation, and find a drop in frame accuracy of 0.32 and 0.55 respectively.

The TOP dataset contains to the order of 30k examples in its training set. In order to further tease out the differences between the biLSTM and transformer approaches, and to see how they compare when more training data is available, we also evaluate these models on our two larger internal datasets. Table 1c shows that the RoBERTa-based model does indeed benefit from the extra training data, being able to outperform the biLSTM-based model on the two datasets. In both cases, the decoupled model with BART pretraining achieves the top performance.

The same procedure was used over our SB-TOP dataset, with the only variant being we concatenated SB-TOP and TOP and jointly trained over both datasets. Table 2 shows the test results over

4.3 Slot carryover

To evaluate the ability of the decoupled models to work on session-based data, we evaluate them on a task which requires drawing information for multiple utterances. The DSTC2 dataset (Henderson et al., 2014) contains a number of dialogues annotated with dialogue state – slightly over 2k sessions in

Table 1: Frame accuracy of the decoupled models on semantic parsing tasks. † indicates results from Hakkani-Tür et al. (2016); ‡, from Goo et al. (2018); ∗, from Zhang et al. (2018); ×, from Chen et al. (2019a).

(a) Accuracy on TOP.

Model	Acc.
RNNG	80.86
RNNG + Ensembling	83.84
RNNG + ELMo	83.93
Decoupled biLSTM	79.51
Decoupled transformer	64.50
Decoupled ELMo	84.85
Decoupled RoBERTa	84.52
Decoupled BART	**87.10**
Best Seq2SeqPtr	86.67

(b) Accuracy on ATIS and SNIPS.

Model	ATIS	SNIPS
Joint biRNN†	80.7	73.2
Slot gated‡	82.2	75.5
CapsuleNLU*	83.4	80.9
Joint BERT$^{\times}$	88.2	**92.8**
Joint BERT CRF$^{\times}$	88.6	92.6
Decoupled BART	**89.25**	91.00
Best Seq2SeqPtr	87.12	87.14

(c) Accuracy on internal datasets.

Model	Acc.
Multi-domain (170k)	
Decoupled ELMo	86.03
Decoupled RoBERTa	87.32
Decoupled BART	**88.29**
Single-domain (67k)	
Decoupled ELMo	90.52
Decoupled RoBERTa	91.51
Decoupled BART	**92.16**

Table 2: Decoupled model architecture results over the SB-TOP dataset. FA is exact match between canonicalized predicted and tree structures. Ref Only FA does not distinguish between implicit/explicit references. Intent accuracy is accuracy over top level intents while Inner Parse Accuracy is FA not considering top level intent.

Model	Oracle@Beam	FA	Ref-only FA	Intent Acc.	Inner Parse Acc.
Humans	1	55.04	57.4	84.32	60.12
Decoupled biLSTM	1	48.48	49.19	78.60	52.74
	5	60.24	69.88	93.71	72.01
Decoupled ELMo	1	51.22	52.03	80.93	55.07
	5	62.58	70.08	94.73	72.11

	5	**65.19**	**72.78**	**96.67**	**76.45**

the training set. They involve users searching for restaurants, by specifying constraints such as cuisine type and price range. Given that users will often take multiple turns to specify all constraints, determining the correct dialogue state requires the model to consider all past turns too. Consider the example of the two-turn DSTC2 session shown in Figure 5: the `[SL:AREA south ]` slot, introduced in the first session, is said to *carry over* to the second session as it still applies to the dialogue state, despite not being explicitly mentioned.[1] To make previous utterances available to the model, we use a simple approach: all utterances are concatenated, with a separator token, and are fed to the encoder.

The decoupled models are evaluated on frame accuracy and slot carryover – the fraction of slots correctly carried over from one turn to the next. Carryover figures are split by slot distance: how many turns prior to the current one the slot under consideration first appeared. As shown in Table 3, the RoBERTa decoupled model outperforms the biLSTM model on frame accuracy, while the biLSTM model takes the lead in terms of raw slot carryover performance. BART outperforms both, achieving the best overall performance.

For informative purposes, we also include results from standard dialogue state tracking models. The results show that the decoupled models, despite not being specifically designed for the task of dialogue state tracking, compare favorably to other approaches in the literature. While our models outperform them on most metrics, it should be noted that they

[1] The image shows the tree form to which we converted the DSTC2 native state tracking annotations, to make them easily linearizable and thus treatable by the decoupled models.

Table 3: Performance of the decoupled models on a state tracking task (DSTC2).

Model	Accuracy	Slot distance			
		0	1	2	≥ 3
LSTM-based (Naik et al., 2018)	—	92.42	91.11	91.34	87.99
Pointer network decoder (Chen et al., 2019b)	—	92.70	92.04	92.90	91.39
Transformer decoder (Chen et al., 2019b)	—	93.00	92.69	92.80	89.49
GLAD (Zhong et al., 2018)	74.5	–	–	–	–
Decoupled biLSTM	88.3	93.34	94.73	95.28	95.73
Decoupled RoBERTa	89.8	91.98	92.94	93.58	94.28
Decoupled BART	**90.2**	94.21	95.47	95.90	97.05

are very different in nature: the decoupled models attend over all utterances leading up to and including the current turn, while state tracking models generally only have access to the current utterance and the previous system actions – in the case of Zhong et al. (2018) – or a fixed length dialogue representation. It is interesting to note that the decoupled models perform better on distant slots: this suggests that the models may be paying more attention to the beginning of the sentences, which may be an artifact of their pretraining.

5 Related Work

Traditional work on semantic parsing, either for the purposes of question answering or task-oriented request understanding, has focused on mapping utterances to logical form representations (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Kwiatkowksi et al., 2010; Liang, 2016; van Noord et al., 2018). Logical forms, while very expressive, are also complex. Highly trained annotators are required for the creation of training data, and as a result there is a lack of large scale datasets that make use of these formalisms.

Intent-slot representations such as those used for the ATIS dataset (Price, 1990) or the datasets released as part of the DSTC challenges (Henderson et al., 2014; Rastogi et al., 2019) have less expressive power, but have the major advantage of being simple enough to enable the creation of large-scale datasets. Gupta et al. (2018) introduce a hierarchical intent-slot representation, and show that it is expressive enough to capture the majority of user-generated queries in two domains.

Recent approaches to semantic parsing have focused on using techniques such as RNNGs (Gupta et al., 2018), RNNGs augmented with ensembling and re-ranking techniques or contextual embeddings (Einolghozati et al., 2018), sequence-to-sequence recurrent neural networks augmented with pointer mechanisms (Jia and Liang, 2016), capsule networks (Zhang et al., 2019), and Transformer-based architectures (Rongali et al., 2020).

6 Conclusions

We started this paper by exploring the limitations of compositional intent-slot representations for semantic parsing. Due to the constraints it imposes, it cannot represent certain utterances with long-term dependencies, and it is unsuitable for semantic parsing at the session (multi-utterance) level. To overcome these limitations we propose an extension of this representation, the *decoupled representation*. We propose a family of sequence-to-sequence models based on the pointer-generator architecture – using both recurrent neural network and transformer architectures – and show that they achieve top performance on several semantic parsing tasks. Further, to advance session-based task-oriented semantic parsing, we release to the public a new dataset of roughly 20k sessions (over 60k utterances).

Probing Task-Oriented Dialogue Representation from Language Models

Chien-Sheng Wu and Caiming Xiong
Salesforce Research
[wu.jason, cxiong]@salesforce.com

Abstract

This paper investigates pre-trained language models to find out which model intrinsically carries the most informative representation for task-oriented dialogue tasks. We approach the problem from two aspects: supervised classifier probe and unsupervised mutual information probe. We fine-tune a feed-forward layer as the classifier probe on top of a fixed pre-trained language model with annotated labels in a supervised way. Meanwhile, we propose an unsupervised mutual information probe to evaluate the mutual dependence between a real clustering and a representation clustering. The goals of this empirical paper are to 1) investigate probing techniques, especially from the unsupervised mutual information aspect, 2) provide guidelines of pre-trained language model selection for the dialogue research community, 3) find insights of pre-training factors for dialogue application that may be the key to success.

1 Introduction

Task-oriented dialogue systems achieve specific user goals within a limited number of dialogue turns via natural language. They have been used in a wide range of applications, such as booking restaurants (Wen et al., 2017), providing tourist information (Budzianowski et al., 2018), ordering tickets (Schulz et al., 2017), and healthcare consultation (Wei et al., 2018). They are also crucial components of intelligent virtual assistants like Siri, Alexa, and Google Assistant.

Most of the task-oriented dialogue systems nowadays, are benefited from transfer learning (Wu et al., 2019; Lin et al., 2020), especially pre-trained language models trained on general text, such as BERT (Devlin et al., 2018) and GPT2 (Radford et al., 2019). However, previous work claims that linguistic patterns could differ between writing text and human conversation, resulting in a large gap of data distributions (Bao et al., 2019; Wolf et al., 2019b). Recently, several approaches are leveraging open-domain data (Henderson et al., 2019; Zhang et al., 2019), or aggregating task-oriented data (Wu et al., 2020) to pre-train language models.

Model	Dial. Data	Parameters	Output Dim.
BERT-base	X	109.5M	768
AlBERT-base	X	11.7M	768
DistilBERT-base	X	66.4M	768

TOD-BERT-jnt	V	119.5M	768
TOD-GPT2	V	124.4M	768

Table 1: An overview of selected pre-trained language models (Details in Section 2).

In this paper, we are interested in answering these questions: which language model has the most informative representations that is better for what task-oriented dialogue task? Does pre-training with dialogue-specific data or different objectives make any difference? We investigate how good these pre-trained representations are for a task-oriented dialogue system, ignoring the model architectures and training strategies by only probing their final representations with fine-tuning models. A good representation implies better knowledge transferring and domain generalization ability, making downstream applications easier and cheaper to be improved.

We tackle this problem with two probing solutions: supervised classifier probe and unsupervised mutual information probe. Classifier probe is commonly used in different NLP tasks such as morphology (Belinkov et al., 2017), sentence length (Adi et al., 2016), or linguistic structure (Hewitt and

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5036–5051,
November 16–20, 2020.

Manning, 2019). In this setting, we fine-tune a simple classifier for a specific task (e.g., intent identification) on a fixed pre-trained language model. The probe uses supervision to find the best transformation for each sub-task.

In addition, we present mutual information probe to investigate these language models by directly clustering their output representations, as recent study (Pimentel et al., 2020) suggests that a simple classifier may not be able to achieve the best estimate of mutual information between features and the downstream task. We apply two clustering techniques, K-means (Lloyd, 1982) and Gaussian mixture model (Reynolds, 2009), to calculate its adjusted normalized mutual information (ANMI) (Vinh et al., 2010) between the predicted clustering and the true task-specific clustering.

We investigate 12 language models, as shown in Table 1, where five of them have been pre-trained with dialogue data. We evaluate four core task-oriented dialogue tasks, domain identification, intent detection, slot tagging, and dialogue act prediction. They correspond to the commonly defined natural language understanding, dialogue state tracking, and dialogue management modules (Wen et al., 2017). We hope our probing analysis can provide insights to facilitate future task-oriented dialogue research. Some of the key observations in this work are summarized here (More discussion in Section 4.4):

- No matter the open-domain or close-domain, pre-training with dialogue data helps learning better representations for task-oriented dialogue.
- Pre-trained language models intrinsically contain more information about intents and dialogue acts but less for slots.
- ConveRT (Henderson et al., 2019) and TOD-BERT-jnt (Wu et al., 2020) have the highest classification accuracy and mutual information score, suggesting that response selection is useful for dialogue pre-training, especially when we compare TOD-BERT-jnt to TOD-BERT-mlm.
- Top models also include TOD-GPT2 and DistilBERT (Sanh et al., 2019). The distilled version of BERT surprisingly outperforms BERT and other strong baselines such as RoBERTa (Liu et al., 2019).
- DialoGPT and GPT2 do not perform well on mutual information evaluation but have a middle-ranking classification accuracy, implying that their representations are informative but not suitable for unsupervised clustering.
- Models such as AlBERT (Lan et al., 2019) and ELECTRA (Clark et al., 2020) have low classification accuracy and mutual information, showing the least useful information on task-oriented dialogue tasks.

2 Pre-Trained Language Models

W can roughly divide pre-trained language models into two categories: uni-directional and bi-directional. BERT-based systems are bi-directional language models and usually trained with the masked language modeling (MLM) objective, i.e., given the left and right context to predict the current masked token. GPT-based models, on the other hand, are uni-directional language models trained always to predict the next token in an auto-regressive way.

For a BERT-based model, we use the final-layer hidden state of its first token, [CLS], to represent an input sequence. This built-in token is originally designed to aggregate the information. Since GPT-based models are uni-directional and do not have a similar design as the [CLS] token, we use the mean pooling of its output hidden states to represent the input sequence, which is better than only using the last hidden state in our experiments.

BERT-based BERT is a Transformer (Vaswani et al., 2017) encoder with a self-attention mechanism, which is trained on Wikipedia and BookCorpus using the MLM and next sentence prediction objectives. Liu et al. (2019) proposed a robustly optimized approach for BERT, call RoBERTa, where they improved it by training the model longer with bigger batches over more data and longer sequences, and removing the next sentence prediction objective. Lan et al. (2019) proposed a lite BERT (AlBERT) that trained with MLM and inter-sentence coherence losses, and aimed to lower memory consumption and increase the training speed. With similar motivation, Sanh et al. (2019) trained a DistilBERT that reduce 40% of parameters with a triple loss, including MLM, distillation, and cosine-distance losses. Clark et al. (2020) proposed ELECTRA using a sample-efficient pre-training task called replaced token detection. They used a generator network (ELECTRA-GEN) to replace tokens with plausible alternative tokens and trained a discriminative model (ELECTRA-DIS) to predict whether the generator replaced each token in the input.

Most of the pre-trained models above are trained on general text corpora with language modeling objectives. Henderson et al. (2019), on the other hand, used social media conversational data to train the ConveRT model. It is a Transformer-based dual-encoder model pre-trained on a dialogue response selection task using 727M Reddit (input, response) pairs. Very recently, Wu et al. (2020) proposed task-oriented dialogue BERT (TOD-BERT), which is initialized by BERT and further pre-trained on nine publicly available task-oriented dialogue corpora. They have one version with only MLM objective (TOD-BERT-mlm) and another with both MLM and contrastive learning objectives of response selection (TOD-BERT-jnt). TOD-BERT has shown good performance on several task-oriented downstream tasks, especially in the few-shot setting.

GPT-based GPT2 (Radford et al., 2019) is the representative of uni-directional language models using a Transformer decoder, where the objective is to maximize left-to-right generation likelihood. To ensure diverse and nearly unlimited text sources, they use Common Crawl to obtain 8M documents as its training data. Budzianowski and Vulić (2019) trained GPT2 on task-oriented response generation task, taking system belief, database result, and last dialogue turn as inputs. It only uses one dataset to train its model because few public datasets have database information available for pre-training. Zhang et al. (2019) pre-trained GPT2 on 147M open-domain Reddit data for response generation and called it DialoGPT. It aims to generate more relevant, contentful, and consistent responses for chit-chat dialogue systems. In this paper, following TOD-BERT's idea, we train a task-oriented GPT2 model (TOD-GPT2) built on the GPT2 model and further pre-trained with task-oriented datasets. We use the same dataset collection, which contains nine datasets in total, as shown in Wu et al. (2020), to pre-train the model as a reference.

3 Method

We define a dialogue corpus $D = \{D_1, \dots, D_M\}$ has M dialogue samples, and each dialogue sample D_m has T turns of conversational exchange $\{U_1, S_1 \dots, U_T, S_T\}$ between a user and a system. For every utterance U_t or S_t, we have human-annotated domain, user intent, slot, and dialogue act labels. We first feed all the utterances to a pre-trained model and obtain user and system representations. In this section, we first discuss how we design our classifier probe and then introduce our mutual information probe's background and usage.

3.1 Classifier Probe

We use a simple classifier to transform those representations for a specific task and optimize it with annotated data.

$$V_i = A(FFN(E_i)), \tag{1}$$

where $E_i \in \mathbb{R}^{d_B}$ is the output representation with dimension d_B from a pre-trained model, $FFN \in \mathbb{R}^{N \times d_B}$ is a feed-forward layer that maps from dimension d_B to a prediction with N classes, and A is an activation layer. For domain identification and intent detection, we use a Softmax layer and backpropagate with the cross-entropy loss. For dialogue slot and act prediction, we use a Sigmoid layer and the binary cross-entropy loss since they are multi-label classification tasks.

3.2 Mutual Information Probe

We first cluster utterances in an unsupervised fashion using either K-means (Lloyd, 1982) or Gaussian mixture model (GMM) (Reynolds, 2009) with K clusters. Then we compute the adjusted mutual information score (Vinh et al., 2010) between the predicted clustering and each of the true clusterings (e.g., domain and intent) for different hyper-parameters K. Note that the predicted clustering is not dependent on any particular labels.

3.2.1 Utterance Clustering

K-means is a common clustering algorithm that aims to partition N samples into K clusters $A = \{A_1, \dots, A_K\}$ in which each sample is assigned to a cluster centroid with the nearest mean.

$$\arg\max_{A} \sum_{i=1}^{K} \sum_{x \in A_i} \|x - \mu_i\|^2, \tag{2}$$

where μ_i is the centroid of the A_i cluster and the algorithm is updated in an iterative manner.

On the other hand, GMM assumes a certain number of Gaussian distributions (K mixture components). It takes both mean and variance of the data into account, while K-means only consider the data's mean. By the Expectation-Maximization algorithm, GMM first calculates each sample's probability belongs to a cluster A_i during the E-step, then updates its density function to compute new mean and variance during the M-step.

In our experiments, we cluster separately for user utterances U and system response S. Note that K is a hyper-parameter since we may not know the true distribution in a real scenario. To avoid the local minimum issue, we run multiple times (typically ten runs) and use the best clustering result for mutual information evaluation.

3.2.2 ANMI

To evaluate two clusterings' quality, we compute the ANMI score between a clustering and its ground-truth annotation. ANMI is adjusted for randomness, which accounts for the bias in mutual information, giving high values to the clustering with a larger number of clusters. ANMI has a value of 1 when two partitions are identical, and an expected value of 0 for random (independent) partitions.

More specifically, we assume two label clusterings, A and B, that have the same N objects. The mutual information (MI) between A and B is defined by

$$\mathrm{MI}(A,B) = \sum_{i=1}^{|A|}\sum_{j=1}^{|B|} P(i,j)\log\left(\frac{P(i,j)}{P(i)P(j)}\right), \quad (3)$$

where $P(i,j) = |A_i \cap B_j|/N$ is the probability that a randomly picked sample falls into both A_i and B_j classes. Similarly, $P(i) = |A_i|/N$ and $P(j) = |B_j|/N$ are the probabilities that the sample falls into either the A_i or B_j class.

The normalized mutual information (NMI) normalizes MI with the mean of entropy, which is defined as

$$\mathrm{NMI}(A,B) = \frac{\mathrm{MI}(A,B)}{mean(H(A),H(B))}, \quad (4)$$

where $H(A) = -\sum_{i=1}^{|A|} P(i)\log(P(i))$ is the entropy of the A clustering, which measures the amount of uncertainty for the partition set.

MI and NMI are not adjusted for chance and will tend to increase as the number of cluster increases, regardless of the actual amount of "mutual information" between the label assignments. Therefore, adjusted normalized mutual information (ANMI) is designed to modify NMI score with its expectation, which is defined by

$$\mathrm{ANMI} = \frac{\mathrm{MI} - \mathbb{E}[\mathrm{MI}]}{mean(H(A),H(B)) - \mathbb{E}[\mathrm{MI}]}, \quad (5)$$

where the expectation $\mathbb{E}[\mathrm{MI}]$ can be calculated using the equation in Vinh et al. (2010).

4 Experiments

4.1 Datasets

The multi-domain Wizard-of-Oz (MWOZ) dataset (Budzianowski et al., 2018) is one of the most common benchmark datasets for task-oriented dialogue systems. We use MWOZ to evaluate domain identification, dialogue slot tagging, and dialogue act prediction tasks. It contains 8420/1000/1000 dialogues for training, validation, and testing sets, respectively. There are seven domains in the training set and five domains in the others. There are 13 unique system dialogue acts and 18 unique slots as shown in Table 2.

Besides, we use the out-of-scope intent (OOS) dataset (Larson et al., 2019) for our intent detection experiment. The OOS dataset is one of the largest annotated intent datasets, including 15,100/3,100/5,500 samples for the train, validation, and test sets, respectively. It has 150 intent classes over ten domains and an additional out-of-scope intent class, a user utterance that does not fall into any of the predefined intents. The whole intent list is shown in the Appendix.

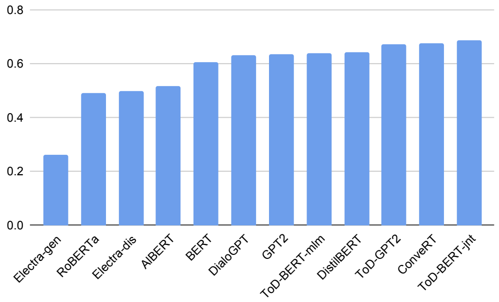
4.2 Training Details

We first process user utterance and system response using the tokenizer corresponding to each per-trained model. To obtain each representation, we run most of the pre-trained models using the

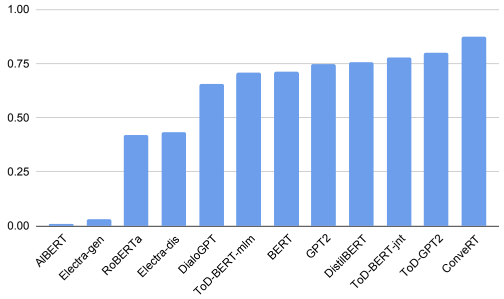
HuggingFace (Wolf et al., 2019a) library, except the ConveRT [1] and TOD-BERT [2]. We fine-tune GPT2 using its default hyper-parameters and the same nine datasets as shown in Wu et al. (2020) to train for TOD-GPT2 model. For classifier probing, we fine-tune the top layer with a consistent hyper-parameter setting. We apply AdamW (Loshchilov and Hutter, 2017) optimizer with a learning rate $5e^{-5}$ and gradient clipping 1.0. We use $K = 4, 8, 16, 32, 64, 128, 256$ with 50 iterations each, and report the moving trend for MI probing. We use GMM clustering from the scikit-learn library, and we adopt the K-means implementation from the faiss library (Johnson et al., 2017). Experiments were conducted on a single NVIDIA Tesla V100 GPU.

4.3 Evaluation

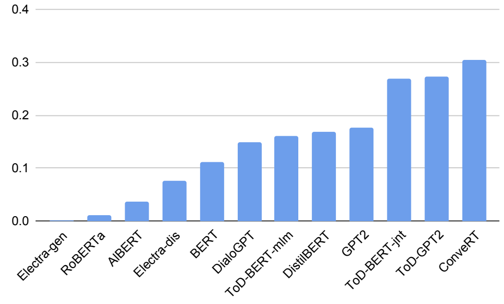
Domain identification and intent detection tasks are multi-class classification problems. Therefore, we can directly use their annotated domain and intent labels to compute the ANMI scores. Slot tagging and dialogue act prediction tasks, meanwhile, are multi-label classification problems. For example, each utterance can include multiple slots mentioned (<food> and <price> slots) and various actions triggered (<greeting> and <inform> acts). In our experiment, we use a naive way that is viewing a different set of slot or act combination as different labels, e.g., three slot sets <food>, <food, price>, and <price, location> belong to three different clusters.



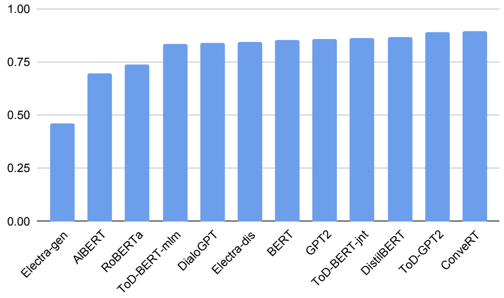
(a) MWOZ Domain (System)



(b) OOS Intent (User)



(c) MWOZ Slot (System)



(d) MWOZ Act (System)

Figure 1: The results of supervised classifier probe. The y-axis in (a) and (b) represents the accuracy. The y-axis in (c) and (d) represents the micro-F1 score.

4.4 Results

Classifier results are shown in Figure 1. We can observe that ConveRT, TOD-BERT-jnt, and TOD-GPT2 achieve the best performance, implying that pre-training with dialogue-related data captures better representations, at least in these sub-tasks. Moreover, the performance of ConveRT and TOD-BERT-jnt suggests that it is helpful to pre-train with a response selection contrastive objective, especially when comparing TOD-BERT-jnt to TOD-BERT-mlm. Moreover, most of the pre-trained models have a similar and high micro-F1 score in (d) system dialogue act prediction, as most of them are above 75% over 13 classes. Dialogue slot (c) information, meanwhile, is not well captured by these representations, resulting in a micro-F1 lower than 30%. On the other hand, ELECTRA-GEN, RoBERTa, and AlBERT show the worst classification results. Especially in (b) intent classification

and (c) dialogue slot tagging, some of them seem to have zero useful information to make a prediction.

Mutual information results using K-means clustering are shown in Figure 2. Due to the space limit, we report the results using GMM in the Appendix, as the two of them have similar trends. The x-axis is the number of clusters in each subplot, ranging from 4 to 256, and the y-axis is the ANMI score between a predicted clustering and its corresponding true clustering. In general, the mutual information probe results are similar to what we observe in the classifier probe. We can find that ToD-BERT-jnt and ConveRT are those with the highest mutual information, and they are usually followed by TOD-GPT2 and DistilBERT.

Another observation is that representations from those pre-trained language models, especially the top ones, seem to have more connection with user intent and system dialogue act labels than domain and slot labels. The average ANMI scores across 12 models and 7 different number of clusters for intent and dialogue act are 0.193 ± 0.169 and 0.226 ± 0.107, respectively. But domain and dialogue slot only have 0.086 ± 0.087 and 0.077 ± 0.057 AMNI scores in average. We discuss each subplot in detail in the following:

Figure 2 (a) and (b) show the mutual information between predicted clustering and the true domain labels on the MWOZ dataset. A user utterance seems to have higher domain mutual information than a system response. TOD-BERT-jnt, in this case, outperforms others by a large margin, achieving around 0.4 ANMI with 8 clusters. Figure 2 (c) is about user intent using user utterances. ConveRT surpasses others by far in the mutual information of intent, achieving over 0.7 ANMI at 128 clusters when the true number of classes equals to 151. Other than the top three models (ConveRT, TOD-BERT-jnt, and DistilBERT), the remaining pre-trained models have ANMI scores lower than 0.2.

Figure 2 (d) and (e) show the mutual information evaluation using the slot labels. When comparing (d) to (e), we can find that user utterances contain

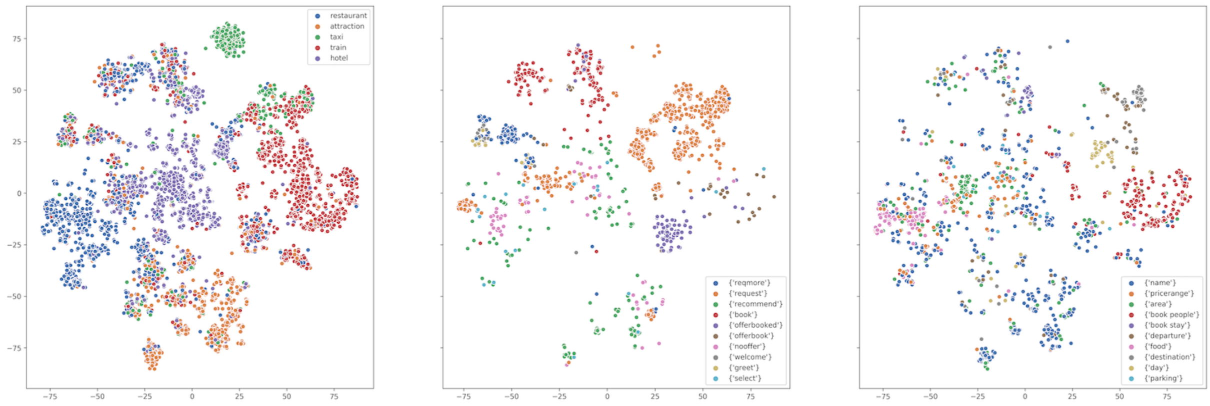

Figure 3: The tSNE visualization of dialogue representations from ToD-BERT-jnt. (Best view in color)

Figure 4: The tSNE visualization of dialogue representations from GPT2. (Best view in color)

more slot information than system responses (Max around 0.35 and 0.25). It is not surprising because a user in task-oriented dialogue is usually the slot information provider, informing what location or which cuisine s/he prefers. ToD-BERT and ConveRT perform similar in this case, still outperform others by a big margin.

Figure 2 (f) shows the mutual information for the predicted clustering of system dialogue acts. We can find that most of the pre-trained language models have shown a relatively high ANMI score (average 0.226) and closed the gap between their performance and the top model. ConveRT works the best, in this case, followed by TOD-BERT-jnt and TOD-GPT2, in which two of them seem to have similar ANMI scores.

5 More Analysis

Difference Between Probes Ideally, both probes should distinguish the goodness of different pre-trained language models, i.e., features that can be easily classified or features with high correlation with true distributions are preferred. However, we found that although, in general, the trends we observe from two probing methods are similar, they are not the same in terms of the ranking. When comparing the ranking of GPT2 and DialoGPT models in Figure 1 and Figure 2, we found that they obtain almost the worse ANMI scores but work quite good in classification accuracy. This observation means that their representations of different classes are "close" to each other as a low ANMI score suggesting a more noisy clustering. Still, at the same time, it is not hard to find a hyperplane that can well discriminate those features.

We discuss some possible reasons for this interesting observation in the following. The first guess is that these features may not follow a Gaussian distribution, as we assume during clustering, suggesting that more advanced clustering techniques can be investigated in future work. The second guess is that these features have an unavoidable clustering noise that can be denoised or debiased easily by a strong supervision signal. The third guess, which may be a possible reason, is that these features are clustered by some other factors that are

ConveRT	
Cluster 1 (Failed Booking)	i am sorry but dojo noodle bar is solidly booked at that time . i can try a different time or day for you .
	1 moment while i try to make the reservation of table for 8 , friday at 16:30 .
	booking was unsuccessful . can you try another time slot ?
	i am very sorry i was unable to book at acorn guest house for 5 nights , would you like to try for a shorter stay ?
	i am afraid that booking is unsuccessful . would you like a different day or amount of days ?
Cluster 2 (Train Time)	there are 5 trains available , may i book 1 for you that leaves at 7:40 and arrives at 10:23 ?
	tr0330 departs at 14:09 and arrives by 15:54 . would you like a ticket ?
	the tr2141 arrives by 15:27 . would you like me to reserve some seats for you ?
	i have train tr4283 that leaves cambridge at 5:29 and arrives in bishops stortford at 6:07 . would you like to make reservations ?
	i have a train that leaves cambridge 14:01 arriving in birmingham new street at 16:44 . would that work ?
Cluster 3 (Restaurant Request)	there are 21 restaurant -s available in the centre of town . how about a specific type of cuisine ?
	there are 9 indian restaurant -s in centre what price range do you want ?
	i am sorry , there are no catalan dining establishments in the city centre . would you like to look for a different cuisine or area ?
	i found 4 restaurant -s with the name tandoori that serve indian food on the south , west , and east . do you have a location preference ?
	there are no singaporean restaurant -s , but there are cheap ones offering several different cuisines .
Cluster 4 (Confirm Booking)	all set . your reference number is k2bo09vq .

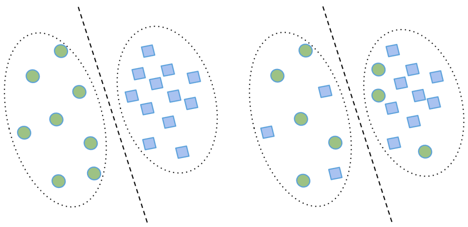
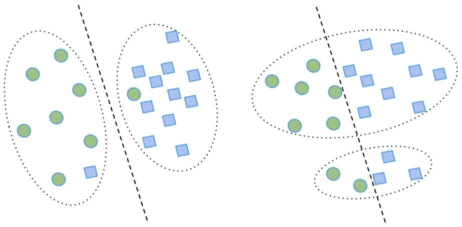
	your reservation was a success and the reference number is jtwxfm7m .
	i have got your booking set , the reference number is 9rmfgjma .
	i booked tr3932 , reference number is fiw5abo2 .
Cluster 5 (Hotel Request)	what part of town there are none in the west .
	i can help you with that . do you have any special area you would like to stay ? or possibly a star request ?
	there are no colleges close to the area you are requesting , would you like to chose another destination ?
	sure , what area are you thinking of staying ?
	i would be happy to help . may i ask what price range and area of town you are looking for ?

Table 3: Clustering results of the ConveRT model. The samples are picked from each randomly selected five clusters with K=32. We can roughly label a topic for each cluster.



(a) High MI High ACC (b) Low MI Low ACC



(c) High MI Low ACC (d) Low MI High ACC

Figure 5: Illustration of four different type of clusterings related to mutual information and accuracy.

not tested, and at the same time, the factors we are interested in are scattered in groups for different classes in a similar way. Intuitively, there are four clustering results shown in Figure 5, where GPT2 and DialoGPT may fall into the (d) clustering type, which has a lower mutual information score but higher classification accuracy.

As a result, we suggest a simple rule of thumb regarding which probing results. In short, the results of the classifier probe could be useful if a supervised approach for a downstream task is designed, e.g., user dialogue act prediction and dialogue state tracking. On the other hand, the mutual information probe is more effective for an unsupervised problem, e.g., utterance clustering and dialogue parsing tasks.

Visualization In Figure 3 and Figure 4, we visualize the embeddings of TOD-BERT-jnt and GPT2 given the same system responses from the MWOZ test set. Each point is reduced from its high-dimension features to a two-dimension point using the t-distributed stochastic neighbor embedding (tSNE). We use different colors to represent different domains (left), dialogue acts (middle), and turn slots (right). As one can observe, TOD-BERT-jnt has more clear group boundaries and better clustering results than GPT2. Visualization plots for other pre-trained models are shown in the Appendix.

What utterances are clustered together? In Table 3, we show the clustering examples of system responses from the top performance model ConveRT. We use $K = 32$ clustering and randomly select five clusters and five samples each. We found that most of the utterances are related to an unsuccessful booking in the cluster 1, containing "I am sorry," "solidly booked," or "booking was unsuccessful." We also found other clusters showing good clustering results, such as selecting departure or arrival time for a train ticket or requesting more user preference for a restaurant reservation. More clustering results are shown in the Appendix.

6 Conclusion

We investigate representations from pre-trained language models for task-oriented dialogue tasks, including domain identification, intent detection, slot tagging, and dialogue act prediction. We use a supervised classifier probe and a proposed unsupervised mutual information probe. From the ranking results of two different probings, we show a list of interesting observations to provide model selection guidelines and shed light on future research towards a more advanced language modeling learning for dialogue applications.

Abstract

Natural language understanding (NLU) in the context of goal-oriented dialog systems typically includes intent classification and slot labeling tasks. Existing methods to expand an NLU system to new languages use machine translation with slot label projection from source to the translated utterances, and thus are sensitive to projection errors. In this work, we propose a novel end-to-end model that learns to align and predict target slot labels jointly for cross-lingual transfer. We introduce MultiATIS++, a new multilingual NLU corpus that extends the Multilingual ATIS corpus to nine languages across four language families, and evaluate our method using the corpus. Results show that our method outperforms a simple label projection method using fast-align on most languages, and achieves competitive performance to the more complex, state-of-the-art projection method with only half of the training time. We release our MultiATIS++ corpus to the community to continue future research on cross-lingual NLU.

1 Introduction

As a crucial component of goal oriented dialogue systems, natural language understanding (NLU) is responsible for parsing an utterance into a semantic frame to identify the user's need. These semantic frames are structured by what the user intends to do (the *intent*) and the arguments of the intent (the *slots*) (Tur et al., 2010). Given the English example in Figure 1, we identify the intent of the utterance as "flight" and label the slots to extract the departure city and airline name. Intent detection can be modeled as a sentence classification task where each utterance is labeled with an intent y_I. Slot filling is typically modeled as a sequence labeling task where given the utterance $\boldsymbol{x}_{1 \ldots n}$, each word x_i is labeled with a slot y_i.

Despite the high accuracy achieved by neural models on intent detection and slot filling (Goo et al., 2018; Qin et al., 2019), training such models on a new language requires additional efforts to collect large amounts of training data. One would consider transfer learning from high-resource to low-resource languages to minimize the efforts of data collection and annotation. However, currently available multilingual NLU datasets (Upadhyay et al., 2018; Schuster et al., 2019) only support three languages distributed in two language families, which hinders the study of cross-lingual transfer across a broad spectrum of language distances. In this paper, we release a new multilingual NLU corpus that contains training, development, and test data for six new languages in addition to the three languages in the Multilingual ATIS corpus (Upadhyay et al., 2018). The resulting corpus, namely MultiATIS++, consists in total of 37,084 training examples and 7,859 test examples covering nine languages in four language families.

Using our corpus, we explore the use of multilingual BERT encoder (Devlin et al., 2019), machine translation (MT), and label projection methods for multilingual training and cross-lingual transfer. Furthermore, we propose an end-to-end model for joint slot label alignment and recognition, so that it no longer relies on slot label projections using external word alignment tools (Mayhew et al., 2017; Schuster et al., 2019) or engineered features (Ehrmann et al., 2011; Jain et al., 2019), which may not generalize well to low-resource languages. Our model performs soft label alignment using an attention module which is trained jointly with other model components on intent classification, slot filling, and an augmented reconstruction objective designed to improve the soft label alignment.

Experimental results show that our method uses the same amount of training time as a simple label projection approach using fast-align, while achiev-

ing significantly higher slot F1 on most languages. Furthermore, our method achieves competitive performance to the more complex, state-of-the-art label projection method that uses linguistic features to improve projection quality, while using half of the training time. Finally, our results show different trends when comparing various cross-lingual transfer methods on different languages, which emphasizes the need to evaluate cross-lingual transfer methods on a diverse set of languages to fully illustrate the strengths and weaknesses of each method.

2 Related Work

Cross-lingual transfer learning has been studied on a variety of sequence tagging tasks including part-of-speech tagging (Yarowsky et al., 2001; Täckström et al., 2013; Plank and Agić, 2018), named entity recognition (Zirikly and Hagiwara, 2015; Tsai et al., 2016; Xie et al., 2018), and natural language understanding (He et al., 2013; Upadhyay et al., 2018; Schuster et al., 2019). Existing methods can be roughly categorized into two categories: transfer through multilingual models and transfer through machine translation.

Transfer via Multilingual Models For closely related languages with similar alphabets, it is beneficial to train a multilingual model with shared character encoder to learn common character-based features (Yang et al., 2017; Lin et al., 2018). However, such techniques are less effective when applied to dissimilar languages that lack common lexical features. Chen et al. (2018, 2019) focus on the multi-source transfer scenario and apply adversarial training to extract language-invariant features shared by source languages. Recent advances on cross-lingual representations have enabled transfer between dissimilar languages. Representations from multilingual neural machine translation (NMT) encoders have been shown to be effective for cross-lingual text classification (Eriguchi et al., 2018; Yu et al., 2018; Singla et al., 2018). In this work, we use multilingual BERT (Devlin et al., 2019), an unsupervised cross-lingual language model trained on monolingual texts from a wide range of languages and has been shown to provide powerful sentence representations that lead to promising performance for zero-resource cross-lingual language understanding tasks (Pires et al., 2019). We leave the use of other recently proposed cross-lingual language models such as XLM-R (Conneau et al., 2020) to future work.

Transfer via Machine Translation requires translating the source language training data into the target language or translating the target language test data into the source language. Despite its empirical success on cross-lingual text classification tasks (Wan, 2009), it faces a challenging problem on the sequence tagging tasks: labels on the source language sentences need to be projected to the translated sentences. Most of the prior work relies on unsupervised word alignment from statistical MT (Yarowsky et al., 2001; Shah et al., 2010; Ni et al., 2017) or attention weights from NMT models (Schuster et al., 2019). Other heuristic approaches include matching tokens based on their surface forms (Feng et al., 2004; Samy et al., 2005; Ehrmann et al., 2011) and more complex projection approaches that combine linguistic features with information from the MT systems (Jain et al., 2019). By contrast, our method does not rely on external word alignment or linguistic features, but models label projection through an attention module that can be jointly trained with other model components on the machine translated data.

3 Data

One of the most popular datasets for multilingual NLU is the ATIS dataset (Price, 1990) and its multilingual extension (Upadhyay et al., 2018). The ATIS dataset is created by asking each participant to interact with an agent (who has access to a database) to solve a given air travel planning problem. Upadhyay et al. (2018) extend the English ATIS to Hindi and Turkish by manually translating and annotating a subset of the training and test data via crowdsourcing.[1]

To facilitate study on cross-lingual transfer across a broader spectrum of language distances, we create the MultiATIS++ corpus by extending both the training and test set of the English ATIS corpus to six additional languages.[2] The resulting corpus covers nine languages in four different language families including Indo-European (English, Spanish, German, French, Portuguese, and Hindi), Sino-Tibetan (Chinese), Japonic (Japanese), and Altaic (Turkish).

For each new language, we hire professional native translators to translate the English utterances and annotate the slots at the same time. When

Japanese	4488	490	893	133890	14416	25939	18	84
Hindi	1440	160	893	16422	1753	9755	17	75
Turkish	578	60	715	6132	686	7683	17	71

Table 1: Data statistics for the MultiATIS++ corpus. The number of *utterances* and *tokens* (characters for Chinese and Japanese) are provided for the training (train), development (dev), and test sets for each of the nine languages. The total number of *intents* and *slots* (before adding the BIO tags) are also given.

translating, we ask the translators to preserve the spoken modality phenomena (e.g. hesitations and word repetitions) and style (e.g. degree of formality) of the original English sentences, so that it is closer to the real scenaria. To get the slot labels for the translated utterances, we ask the translators to tag the segments in the translated utterances that are aligned to the corresponding English segments. Finally, we tokenize the translated utterances and BIO tag the tokens. For quality control, we ask a third-party to perform several rounds of qualification checks until no issues are reported.

We show an English training example and its translated versions in the other eight languages in Figure 1 and report the data statistics in Table 1. We split the English training and development sets randomly and keep the same split for all the other languages except for Hindi and Turkish from the Multilingual ATIS corpus. Note that the Hindi and Turkish portions of the data are smaller than the other languages, covering only a subset of the intent and slot types.

4 Cross-Lingual NLU

4.1 Joint Intent Detection and Slot Filling

Following Liu and Lane (2016), we model intent detection and slot filling jointly. We add a special classification token x_0 at the beginning of the input sequence $\boldsymbol{x} = (x_1, x_2, ..., x_T)$ of length T following Devlin et al. (2019). Next, an encoder Θ_{enc} is used to produce a sequence of contextualized representations $\boldsymbol{h}_{0...T}$ given the input sequence

$$\boldsymbol{h}_{0...T} = \Theta_{enc}(x_0, x_1, ..., x_T)$$

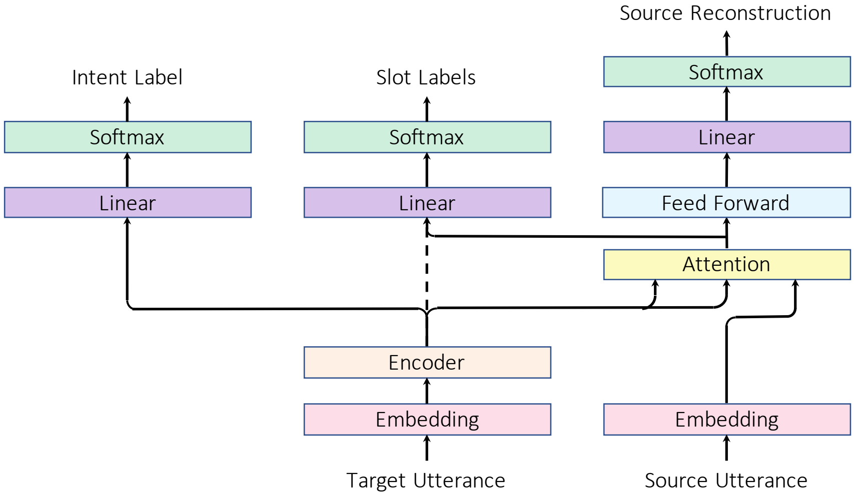

Figure 2: Architecture of our soft-alignment model for end-to-end slot alignment and recognition. The model is trained without external label projection: it learns to soft-align the representations of the target utterance to the source slot labels and predict the intent and slot labels jointly. The dotted line denotes the path during inference, where we directly connect the encoder module to the intent and slot classification layer to make predictions on the target utterance.

For intent detection, we take the representation $\boldsymbol{h}_0$ corresponding to x_0 as the sequence representation and apply a linear transformation and a softmax function to predict the intent probability

$$p_{\text{intent}}(\cdot|\boldsymbol{x}) = \text{softmax}(\boldsymbol{W}^I\boldsymbol{h}_0 + \boldsymbol{b}^I)$$

For slot filling, we compute the probability for each slot using the representations $\boldsymbol{h}_{1...T}$

$$p_{\text{slot}_i}(\cdot|\boldsymbol{x}) = \text{softmax}(\boldsymbol{W}^S\boldsymbol{h}_i + \boldsymbol{b}^S)$$

We explore two different encoder models:

- **LSTM:** We use the concatenation of the forward and backward hidden states of a bidirectional LSTM (Schuster and Paliwal, 1997) as the encoder representations. We initialize the encoder and embeddings randomly.
- **Multilingual BERT:** We use the multilingual BERT (Devlin et al., 2019) pre-trained in an unsupervised way on the concatenation of monolingual corpora from 104 languages. We take the hidden states from the top layer as the encoder representations and fine-tune the model on the NLU data.

4.2 Problems in Slot Label Projection

Past work has shown the effectiveness of using MT systems to boost the performance of cross-lingual NLU (Schuster et al., 2019). More specifically, one first translates the English training data to the target language using an MT system, and then projects the slot labels from English to the target language. Prior work projects the slot labels using word alignments from statistical MT models (Yarowsky et al., 2001) or attention weights from neural MT models (Schuster et al., 2019). The final performance on the target language highly depends on the quality of the slot projection. Jain et al. (2019) show that improving the quality of projection leads to significant improvements in the target performance on cross-lingual named entity recognition. However, the improvements come at the cost of much more complex and expensive projection process using engineered features.

To address the above issues, we propose a soft-alignment model that performs end-to-end slot alignment and recognition using an additional attention module (Figure 2), so that it requires no external slot projection process. Furthermore, we show that the soft slot alignment can be strengthened by building it on top of strong encoder representations from multilingual BERT.

4.3 End-to-End Slot Alignment and Recognition via Attention

Given a source utterance $\boldsymbol{s}_{1...S}$ of length S and its translation $\boldsymbol{t}_{1...T}$ of length T in the target language, the model learns to predict the target slot labels and soft-align it with the source labels via attention. First, it encodes the source utterance into a sequence of embeddings $\boldsymbol{e}^{(src)}_{1...S}$ and then encodes the translation $\boldsymbol{t}_{0\ldots T}$ (t_0 is inserted as the classification token) into a sequence of contextualized representations $\boldsymbol{h}^{(tgt)}_{0\ldots T} = \Theta_{enc}(\boldsymbol{t}_{0\ldots T})$, where Θ_{enc} represents the encoder. For intent classification, we assume that the translated utterance has the same intent as the source utterance. Thus we compute the intent probabilities using the representation $\boldsymbol{h}^{(tgt)}_0$

$$p_{\text{intent}}(\cdot|\boldsymbol{t}) = \text{softmax}(\boldsymbol{W}^I \boldsymbol{h}^{(tgt)}_0 + \boldsymbol{b}^I)$$

and the intent classification loss given the intent label $y^{(src)}_I$ on the source utterance

$$\mathcal{L}_{\text{intent}} = -\log p_{\text{intent}}(y^{(src)}_I|\boldsymbol{t})$$

For slot filling, we introduce an attention module to connect the source slot labels $\boldsymbol{y}^{(src)}_{1\ldots S}$ with the target sequence $\boldsymbol{t}_{1\ldots T}$. First, we compute the hidden state at each source position as a weighted average of the target representations

$$\boldsymbol{z}_i = \sum_{j=1}^{T} a_{ij} \boldsymbol{h}^{(tgt)}_j$$

where $\boldsymbol{z}_i$ is the hidden state at source position i, and a_{ij} is the attention weights between the source word s_i and translation word t_j. To compute the weights a_{ij}, we first linearly project the query vector $\boldsymbol{e}^{(src)}_i$ and the key vector $\boldsymbol{h}^{(tgt)}_j$ with learnable parameters to d dimensions. We then perform the scaled dot-product attention on the projected query and key vectors

$$\boldsymbol{a}_i = \text{softmax}\left(\frac{(\boldsymbol{e}^{(src)}_i \boldsymbol{W}^Q)(\boldsymbol{h}^{(tgt)} \boldsymbol{W}^K)^\intercal}{\sqrt{d}\tau}\right)$$

where the projections $\boldsymbol{W}^Q$ and $\boldsymbol{W}^K$ are parameter matrices, and τ is a hyperparameter that controls the temperature of the softmax function.

Next, we compute the slot probabilities at the source position i using the hidden state $\boldsymbol{z}_i$

$$p_{\text{slot}_i}(\cdot|s_i, \boldsymbol{t}) = \text{softmax}(\boldsymbol{W}^S \boldsymbol{z}_i + \boldsymbol{b}^S)$$

and the slot filling loss given the slot labels $y^{(src)}_{1\ldots S}$ on the source utterance

$$\mathcal{L}_{\text{slot}} = -\sum_{i=1}^{S} \log p_{\text{slot}_i}(y^{(src)}_i|s_i, \boldsymbol{t})$$

In addition, to improve the attention module to better align the source and target utterances, we add a reconstruction module consisting of a position-wise feed-forward and a linear output layer[3] to recover the source utterance using the attention outputs. We compute the probability distribution over the source vocabulary at position i as

$$\begin{aligned} p_{\text{rec}_i}(\cdot|s_i, \boldsymbol{t}) &= \text{softmax}(\boldsymbol{W}^R \tilde{\boldsymbol{z}}_i + \boldsymbol{b}^R) \\ \tilde{\boldsymbol{z}}_i &= \text{FeedForward}(\boldsymbol{z}_i) \end{aligned} \tag{1}$$

and the reconstruction loss as

$$\mathcal{L}_{\text{rec}} = -\sum_{i=1}^{S} \log p_{\text{rec}_i}(s_i|s_i, \boldsymbol{t}) \tag{2}$$

The final training loss is $\mathcal{L} = \mathcal{L}_{\text{intent}} + \mathcal{L}_{\text{slot}} + \mathcal{L}_{\text{rec}}$.

Empirically, we find it beneficial to train the model jointly on the machine translated target data using the objective $\mathcal{L}$ and the source data using the supervised objective.

The attention and reconstruction modules are only used during training. During inference, we directly feed the encoder representations $\boldsymbol{h}^{(tgt)}_{0\ldots T}$ of the target language utterance to the intent and slot classification layers

$$\begin{aligned} p_{\text{intent}}(\cdot|\boldsymbol{t}) &= \text{softmax}(\boldsymbol{W}^I \boldsymbol{h}^{(tgt)}_0 + \boldsymbol{b}^I) \\ p_{\text{slot}_i}(\cdot|\boldsymbol{t}) &= \text{softmax}(\boldsymbol{W}^S \boldsymbol{h}^{(tgt)}_i + \boldsymbol{b}^S) \end{aligned} \tag{3}$$

5 Multilingual NLU

In our first set of experiments, we explore using pre-trained multilingual BERT encoder for multilingual NLU. We compare the following training strategies to leverage the full supervised training data:

- **Target only:** Train each model on the target language training data using the standard supervised objective.
- **Multilingual:** Train a model on the concatenation of training data from all languages using the standard supervised objective.

Setup We train the models using the Adam optimizer (Kingma and Ba, 2015) for 20 epochs and select the model that performs the best on the development set (details in Appendix A). Following (Goo et al., 2018), we use intent accuracy and slot F1 as evaluation metrics.

---

[3] We tie the output weights $\boldsymbol{W}^R$ with BERT embeddings.

Table 2: Results on MultiATIS++ using full training data and the standard supervised objective averaged over 5 runs. The *Target only* models are trained only on the target language training data. The *Multilingual* models are trained on the concatenation of training data from all languages.

Results Table 2 shows the results using full training data and the supervised objective. First, we compare LSTM and BERT models trained on the target language data only. Multilingual BERT encoder brings significant[4] improvements of 1–6% on intent accuracy and 1–11% on slot F1. The largest improvements are on the two low-resource languages: Hindi and Turkish. Multilingual training on all languages brings further improvements on Hindi and Turkish: it improves intent accuracy by 2–5% and slot F1 by 4–11% for both LSTM and BERT models.

Comparison with SOTA On English ATIS, Qin et al. (2019) report 97.5% intent accuracy and 96.1% slot F1 when using BERT with their proposed stack-propagation architecture. This is comparable to our *target only with BERT* scores in Table 2. On multilingual ATIS, Upadhyay et al. (2018) report slot F1 of 80.6% on Hindi and 78.9% on Turkish using bilingual training. Our multilingual BERT model achieves higher F1 by +6.1% on Hindi and +7.1% on Turkish.

6 Cross-Lingual Transfer

In this section, we compare the following methods for cross-lingual transfer where we only use the English training data and a small amount (few-shot) or no (zero-shot) training data from the target language:

- **No MT:** Train the models only on the English training data without machine translating them to the target language.
- **MT+fast-align:** Use MT systems to translate the English data to the target language and project the slot labels using word alignment from *fast-align*.[5]
- **MT+TMP:** Use MT to translate the English data to the target language and the Translate-Match-Project method (Jain et al., 2019) to project the slot labels.
- **MT+soft-align:** Use MT to translate the English data to the target language and our soft-alignment method described in Section 4.3.

For all three MT-based approaches, we use AWS Translate for automatic translation and perform multilingual training on the English and machine translated data. We adopt the same setup as the previous section, except that we select the model at the last epoch as we assume no access to the development set from the target language in this setting. For the attention module in our soft-alignment model, we set the temperature $\tau = 0.1$.

6.1 Zero-Shot Results

Table 3 shows the results on zero-shot cross-lingual transfer. First, we study the impact of using multilingual BERT for MT-based transfer approaches. For *MT+fast-align*, BERT boosts the performance over LSTM by large margins: 14–32% on intent accuracy and 29–61% on slot F1 on all languages except for Turkish – a dissimilar language to English. For both LSTM and BERT models, using *MT+fast-align* brings significant improvements over their counterparts without MT on intent

Table 3: Zero-shot results on MultiATIS++ averaged over 5 runs. The *No MT* rows are models trained only on the English data. The *MT+fast-align* rows correspond to models trained on the English and machine translated data with automatically projected slot labels using *fast-align*, and *MT+TMP* correspond to Translate-Match-Project (Jain et al., 2019). The *MT+soft-align* row is the model trained on the English and machine translated data using our soft-alignment method.

		Time (mins)
No MT	LSTM	18
	BERT	65
MT+fast-align	LSTM	232
	BERT	317
MT+TMP	LSTM	626
	BERT	719
MT+soft-align	BERT	352

Table 4: Total training time of each method on all languages for the zero-shot transfer experiments (including the time for machine translation, label projection, and model training). *MT+TMP* requires a time-consuming label projection process and thus takes double the time as our soft-alignment method.

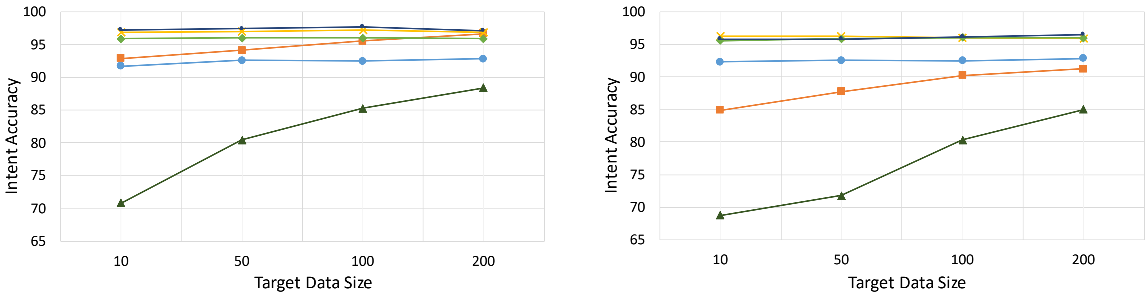
accuracy – improvements of 13–33% when using LSTM and 1–24% when using BERT. However, we observe different trends on slot F1 for different languages. For example, when using BERT, *MT+fast-align* improves slot F1 by 20–44% on Chinese, Japanese, and Hindi over BERT without MT, but hurts by around 6% on French.[6] This is possibly because that the mBERT representations of French are of high quality, which leads to relatively high slot F1 without MT, thus adding more noisy data via *MT+fast-align* does more harm than good. This indicates that, while training directly on the target language data is beneficial especially for languages dissimilar to English, the noisy projection of the slot labels could also bring harm to the model.

Next, we compare our soft-alignment method with other MT-based approaches. Our method outperforms *MT+fast-align* on five of the eight languages and is more robust across languages – it achieves consistent improvements over BERT fine-tuned without MT on both intent accuracy and slot F1, while *MT+fast-align* leads to a degradation on French and Turkish. Furthermore, we compare our method with *MT+TMP*, a strong label projection baseline that combines MT and linguistic features to improve the quality of label projection. Results show that our method uses only half the training time as *MT+TMP* (Table 4), while achieving competitive performance (Table 3): on intent accuracy, our method achieves on par or higher scores on all languages. On slot F1, our method performs on par or better than *MT+TMP* on four of the eight languages and achieves close performance on the remaining languages.

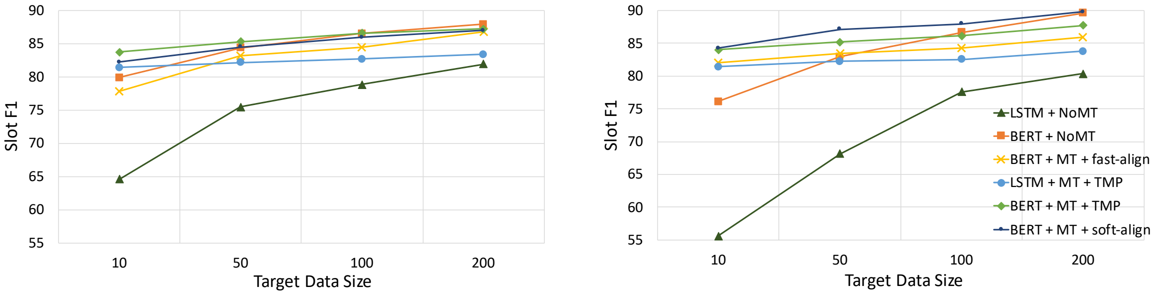
Finally, these results emphasize the need to evaluate cross-lingual transfer methods on a diverse set of languages to fully illustrate the strengths and

---

[6] The difference is significant with $p < 0.05$.



(a) Intent accuracy on French (b) Intent accuracy on Chinese



(c) Slot F1 on French (d) Slot F1 on Chinese

Figure 3: Results for cross-lingual transfer given various sizes of the labeled data from the target language in addition to the English and machine translated data used in zero-shot experiments. We report scores averaged over 5 runs using target training data selected with different random seeds. Results show the effectiveness of our soft-alignment method as compared to the best projection-based method (*BERT+MT+TMP*) in few-shot transfer where only a few hundred target examples are available.

weaknesses of each method and to avoid overly strong claims. In our experiments, we find that although *MT+TMP* achieves higher slot F1 than our method on some languages, our method is more robust across languages and outperforms *MT+TMP* by a large margin (+16.9%) on Turkish. To further explain the large gap, we measure the slot projection accuracy of *fast-align* and *TMP* compared against the annotated data. We find that *fast-align* obtains extremely low projection accuracy (20%) on Turkish, and *TMP* improves it to 39%, which is still low compared to that on other languages (above 70%). The low projection accuracy on Turkish can be attributed to the morphological difference between Turkish and English, which makes it difficult to hard-align each Turkish word to a single English word.

Intent acc.	average
MT+soft-align	94.87
w/o reconstruction loss	94.95
w/o joint training on source	94.64
Slot F1	average
MT+soft-align	80.00
w/o reconstruction loss	76.42
w/o joint training on source	71.62

Table 5: Ablation results for zero-shot transfer learning. Scores are averaged over Spanish, German, Chinese, Japanese, Portuguese, French, Hindi, and Turkish. Ablating the reconstruction loss or joint training on the source language data using supervised objective leads to a major drop on slot F1, while the impact on intent accuracy is small.

6.2 Learning Curves

Figure 3 shows the few-shot transfer results where we add a small amount of labeled data from the target language.[7] We select French as a similar language to English, and Chinese as a dissimilar language. We find that *BERT+NoMT* obtains promising results in the few-shot setting with only several hundred training examples in the target language – it achieves comparable or even higher scores than the best MT-based approach on French, but still lags behind on Chinese by around 5% on intent accuracy. In addition, results

---

[7] We apply only the standard supervised objective on the target language data.

show the effectiveness of our method in few-shot transfer: our method obtains comparable (on French) or higher (on Chinese) slot F1 than the best projection-based method (*BERT+MT+TMP*) given a few hundred target examples, which suggests that, even with a less noisy label projector, the projection errors may still hinder the model from best exploiting the small amount of target language data especially on languages dissimilar to English.

6.3 Ablation Study

We evaluate the impact of different components in our soft-alignment model. Table 5 shows that both the reconstruction loss and joint training on the source data using supervised objective are beneficial – slot F1 drops by 3.6% when ablating the reconstruction loss and by 8.4% when ablating joint training on the source, while both have little impact on intent accuracy.

7 Conclusion

We introduce MultiATIS++, a multilingual NLU corpus that extends the Multilingual ATIS corpus to nine languages across four language families. We use our corpus to evaluate various cross-lingual transfer methods including the use of multilingual BERT encoder, machine translation, and label projection. We further introduce a novel end-to-end model for joint slot label alignment and recognition that requires no external label projection. Experiments show that multilingual BERT brings substantial improvements on multilingual training and cross-lingual transfer tasks. Furthermore, our model outperforms the simple projection baseline using fast-align on most languages, and achieves competitive performance to the state-of-the-art label projection approach with only half of the training time. We release our MultiATIS++ corpus to facilitate future research on cross-lingual NLU to bridge the gap between cross-lingual transfer and supervised methods.

A Model and Training Details

We train all models on 4 NVIDIA V100 Tensor Core GPUs. For both the multilingual NLU and cross-lingual transfer experiments, we train the models using the Adam optimizer (Kingma and Ba, 2015) for 20 epochs. We set the initial learning rate to 10^{-3} for the LSTM model and 10^{-5} for the BERT model. The LSTM model has embeddings of size 256 and 128 hidden units. We add dropout of 0.1 to the embeddings and encoder hidden states. Both LSTM and BERT models use the WordPiece tokenization model from (Devlin et al., 2019). Table 6 shows the total number of parameters for each model, and Table 7 shows the training time used for each method in the multilingual NLU experiments.

	#params
LSTM	27,539,866
BERT	166,884,250
BERT+soft-align	169,944,625

Table 6: Total number of parameters for each model. Our model contains additional parameters for the attention module and linear output layer for the reconstruction loss.

		Time (mins)
Target only	LSTM	18
	BERT	65
Multilingual	LSTM	9
	BERT	51

Table 7: Total training time for all languages in the multilingual NLU experiments.

B Evaluation

We evaluate all NLU models using intent accuracy and slot F1. Before computing slot F1, we merge all slots that are segmented during preprocessing to match with the original slot segments. We use the script `conlleval.pl`[8] to compute slot F1.

C Validation Performance

We report the average intent accuracy and slot F1 on the development sets in the multilingual NLU experiments in Table 8. For zero-shot experiments, we select the model at the last epoch as we assume no access to the development sets from the target language in this setting.

Intent acc.		Average
Target only	LSTM	94.98
	BERT	97.12
Multilingual	LSTM	98.57
	BERT	98.37
Slot F1		Average
Target only	LSTM	89.41
	BERT	91.91
Multilingual	LSTM	97.64
	BERT	98.82

Table 8: Average intent accuracy and slot F1 on the development sets in the multilingual NLU experiments. For *targe only* models, we average the scores over all nine languages. For *multilingual* models, we only validate on the English development set.

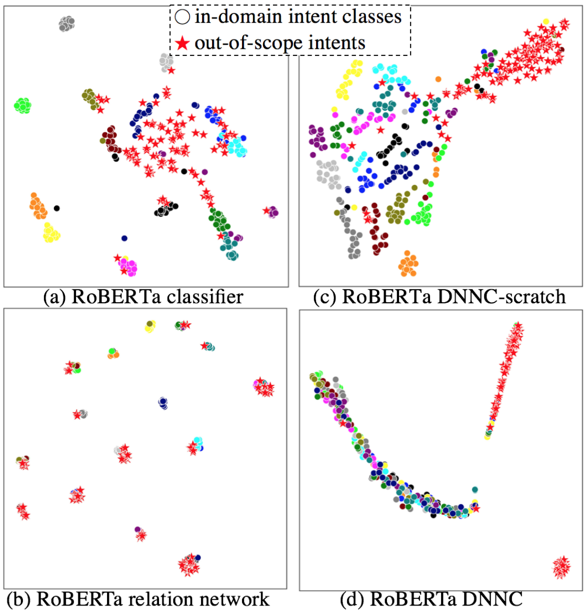
Abstract

Intent detection is one of the core components of goal-oriented dialog systems, and detecting out-of-scope (OOS) intents is also a practically important skill. Few-shot learning is attracting much attention to mitigate data scarcity, but OOS detection becomes even more challenging. In this paper, we present a simple yet effective approach, discriminative nearest neighbor classification with deep self-attention. Unlike softmax classifiers, we leverage BERT-style pairwise encoding to train a binary classifier that estimates the best matched training example for a user input. We propose to boost the discriminative ability by transferring a natural language inference (NLI) model. Our extensive experiments on a large-scale multi-domain intent detection task show that our method achieves more stable and accurate in-domain and OOS detection accuracy than RoBERTa-based classifiers and embedding-based nearest neighbor approaches. More notably, the NLI transfer enables our 10-shot model to perform competitively with 50-shot or even full-shot classifiers, while we can keep the inference time constant by leveraging a faster embedding retrieval model.

1 Introduction

Intent detection is one of the core components when building goal-oriented dialog systems. The goal is to achieve high intent classification accuracy, and another important skill is to accurately detect unconstrained user intents that are out-of-scope (OOS) in a system (Larson et al., 2019). A practical challenge is data scarcity because different systems define different sets of intents, and thus few-shot learning is attracting much attention. However, previous work has mainly focused on the few-shot intent classification without OOS (Luo et al., 2018; Casanueva et al., 2020).



(a) RoBERTa classifier (c) RoBERTa DNNC-scratch
(b) RoBERTa relation network (d) RoBERTa DNNC

Figure 1: tSNE visual comparison for OOS detection between existing methods ((a) and (b)) and our proposed method ((c) and (d)). Their embeddings before their classifier layers are used (best viewed in color).

OOS detection can be considered as out-of-distribution detection (Hendrycks and Gimpel, 2017; DeVries and Taylor, 2018). Recent work has shown that large-scale pre-trained models like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) still struggle with out-of-distribution detection, despite their strong in-domain performance (Hendrycks et al., 2020). Figure 1 (a) shows how unseen input text is mapped into a feature space, by a RoBERTa-based model for 15-way 5-shot intent classification. The separation between OOS and some in-domain intents is not clear, which presumably hinders the model's OOS detection ability. This observation calls for investigation into more sample-efficient approaches to handling

the in-domain and OOS examples accurately.

In this paper, we tackle the task from a different angle, and propose a discriminative nearest neighbor classification (DNNC) model. Instead of expecting the text encoders to be generalized enough to discriminate both the in-domain and OOS examples, we make full use of the limited training examples both in training and inference time as a nearest neighbor classification schema. We leverage the BERT-style paired text encoding with deep self-attention to directly model relations between pairs of user utterances. We then train a matching model as a pairwise binary classifier to estimate whether an input utterance belongs to the same class of a paired example. We expect this to free the model from having the OOS separation issue in Figure 1 (a) by avoiding explicit modeling of the intent classes. Unlike an embedding-based matching function as in relation networks (Sung et al., 2018) (Figure 1 (b)), the deep pairwise matching function produces clear separation between the in-domain and OOS examples (Figure 1 (c)). We further propose to seamlessly transfer a natural language inference (NLI) model to enhance this clear separation (Figure 1 (d)).

We verify our hypothesis by conducting extensive experiments on a large-scale multi-domain intent detection task with OOS (Larson et al., 2019) in various few-shot learning settings. Our experimental results show that, compared with RoBERTa classifiers and embedding nearest neighbor approaches, our DNNC attains more stable and accurate performance both in in-domain and OOS accuracy. Moreover, our 10-shot model can perform competitively with a 50-shot or even full-shot classifier, with the performance boost by the NLI transfer. We also show how to speedup our DNNC's inference time without sacrificing accuracy.

2 Background

2.1 Task: Few-Shot Intent Detection

Given a user utterance u at every turn in a goal-oriented dialog system, an intent detection model $I(u)$ aims at predicting the speaker's intent:

$$I(u) = c, \tag{1}$$

where c is one of pre-defined N intent classes $\mathbf{C} = \{C_1, C_2, \dots, C_N\}$, or is categorized as OOS. The OOS category corresponds to user utterances whose requests are not covered by the system. In other words, any utterance can be OOS as long as it does *not* fall into any of the N intent classes, so the definition of OOS is different depending on $\mathbf{C}$.

Balanced K-shot learning In a few-shot learning scenario, we have a limited number of training examples for each class, and we assume that we have K examples for each of the N classes in our training data. In other words, we have $N \cdot K$ training examples in total. We denote the i-th training example from the j-th class C_j as $e_{j,i} \in E$, where E is the set of the examples. K is typically 5 or 10.

2.2 Multi-Class Classification

The goal is to achieve high accuracy both for the intent classification and OOS detection. One common approach to this task is using a multi-class classification model. Specifically, to get a strong baseline for the few-shot learning use case, one can leverage a pre-trained model as transfer learning, which has been shown to achieve state-of-the-art results on numerous natural language processing tasks. We use BERT (Devlin et al., 2019; Liu et al., 2019) as a text encoder:

$$h = \mathrm{BERT}(u) \in \mathbb{R}^d, \tag{2}$$

where h is a d-dimensional output vector corresponding to the special token `[CLS]` as in the follwing input format: [`[CLS]`, u, `[SEP]`].[1]

To handle the intent classification and the OOS detection, we apply the threshold-based strategy in Larson et al. (2019), to the softmax output of the N-class classification model (Hendrycks and Gimpel, 2017):

$$p(c|u) = \mathrm{softmax}(Wh + b) \in \mathbb{R}^N, \tag{3}$$

where $W \in \mathbb{R}^{N \times d}$ and $b \in \mathbb{R}^N$ are the classifier's model parameters. The classification model is trained by cross-entropy loss with the ground-truth intent labels of the training examples. At inference time, we first take the class C_j with the largest value of $p(c = C_j|u)$, then output $I(u) = C_j$ if $p(c = C_j|u) > T$, where $T \in [0.0, 1.0]$ is a threshold to be tuned, and otherwise we output $I(u) = \mathrm{OOS}$.

2.3 Nearest Neighbor Classification

As the fundamental building block of our proposed method, we also review nearest neighbor classification (i.e., k-nearest neighbors (kNN) classification

---

[1] The format of these special tokens is different in RoBERTa, but we use the original BERT's notations.

	Input utterance	Utterance to be compared	Label
(a)	i need you to send 500 dollars from my high tier account to my regular checking	help me move my money please	pos.
(b)	i would like to know when the bill is due	i need to know the amounts due for my utilities and cable bills	neg.
(c)	And can you tell me any of the names and addresses? Annie considered.	Are you able to inform me of any name or address?	pos.
(d)	It's Sunday, what channel is this?	It's Sunday, can you change the channel?	neg.
(e)	I want to go back to Marguerite.	I never want to return to Marguerite.	neg.

Table 1: Training examples for our model. The first two examples ((a)–(b)) come from the CLINC150 dataset (Larson et al., 2019), and the other three examples ((c)–(e)) come from the MNLI dataset (Williams et al., 2018).

with $k = 1$), a simple and well-established concept for classification (Simard et al., 1993; Cunningham and Delany, 2007). The basic idea is to classify an input into the same class of the most relevant training example based on a certain metric.

In our task, we formulate a nearest neighbor classification model as the following:

$$I(u) = \text{class}\left(\underset{e_{j,i} \in E}{\arg\max}\ S(u, e_{j,i})\right), \quad (4)$$

where $\text{class}(e_{j,i})$ is a function returning the intent label (class) of the training example $e_{j,i}$, and S is a function that estimates some relevance score between u and $e_{j,i}$. To detect OOS, we can also use the uncertainty-based strategy in Section 2.2; that is, we take the output label from Equation (4) if the corresponding relevance score is greater than a threshold, and otherwise we output $I(u) = \text{OOS}$.

3 Proposed Method

This section first describes how to directly model inter-utterance relations in our nearest neighbor classification scenario. We then introduce a binary classification strategy by synthesizing pairwise examples, and propose a seamless transfer of NLI. Finally, we describe how to speedup our method's inference process.

3.1 Deep Pairwise Matching Function

The objective of $S(u, e_{j,i})$ in Equation (4) is to find the best matched utterance from the training set E, given the input utterance u. The typical methodology is to embed each data example into a vector space and (1) use an off-the-shelf distance metric to perform a similarity search (Cunningham and Delany, 2007) or (2) learn a distant metric between the embeddings (Sung et al., 2018). However, as shown in Figure 1, the text embedding methods do not discriminate the OOS examples well enough.

To model fine-grained relations of utterance pairs to distinguish in-domain and OOS intents, we propose to formulate $S(u, e_{j,i})$ as follows:

$$h = \text{BERT}(u, e_{j,i}) \in \mathbb{R}^d, \quad (5)$$

$$S(u, e_{j,i}) = \sigma(W \cdot h + b) \in \mathbb{R}, \quad (6)$$

where BERT is the same model in Equation (2), except that we follow a different input format to accommodate pairs of utterances: [`[CLS]`, u, `[SEP]`, $e_{j,i}$, `[SEP]`]. σ is the sigmoid function, and $W \in \mathbb{R}^{1\times d}$ and $b \in \mathbb{R}$ are the model parameters. We can interpret our method as wrapping both the embedding and matching functions into the paired encoding with the deep self-attention in BERT (Equation (5)) along with the discriminative model (Equation (6)). It has been shown that the paired text encoding is crucial in capturing complex relations between queries and documents in document retrieval (Watanabe et al., 2017; Nie et al., 2019; Asai et al., 2020).

3.2 Discriminative Training

We train the matching model $S(u, e_{j,i})$ as a binary classifier, such that $S(u, e_{j,i})$ is closed to 1.0 if u belongs to the same class of $e_{j,i}$, and otherwise closed to 0.0. The model is trained by a binary cross-entropy loss function.

Positive examples To create positive examples, we consider all the possible ordered pairs within the same intent class: $(e_{j,i}, e_{j,\ell})$ such that $i \neq \ell$. We thus have $N \times K \times (K-1)$ positive examples in total. Table 1 (a) shows a positive example created from an intent, "transfer," in a banking domain.

Negative examples For negative examples, we consider all the possible ordered pairs across any two different intent classes: $(e_{j,i}, e_{o,\ell})$ such that $j \neq o$. We thus have $K^2 \times N \times (N-1)$ negative examples in total, and this number is in general greater than that of the positive examples. Table 1 (b) shows a negative example, where the input utterance comes from the intent, "bill due", and the paired sentence from another intent, "bill balance".

3.3 Seamless Transfer from NLI

A key characteristic of our method is that we seek to model the relations between the utterance pairs, instead of explicitly modeling the intent classes. To mitigate the data scarcity setting in few-shot learning, we consider transferring another inter-sentence-relation task.

This work focuses on NLI; the task is to identify whether a hypothesis sentence can be entailed by a premise sentence (Bowman and Zhu, 2019). We treat the NLI task as a binary classification task: `entailment` (positive) or `non-entailment` (negative).[2] We first pre-train our model with the NLI task, where the premise sentence corresponds to the u-position, and the hypothesis sentence corresponds to the $e_{j,i}$-position in Equation (5). Note that it is not necessary to modify the model architecture since the task format is consistent, and we can train the NLI model solely based on existing NLI datasets. Once the NLI model pre-training is completed, we fine-tune the NLI model with the intent classification training examples described in Section 3.2. This allows us to transfer the NLI model to any intent detection datasets seamlessly.

Why NLI? The NLI task has been actively studied, especially since the emergence of large scale datasets (Bowman et al., 2015; Williams et al., 2018), and we can directly leverage the progress. Moreover, recent work is investigating cross-lingual NLI (Eriguchi et al., 2018; Conneau et al., 2018), and this is encouraging to consider multilinguality in future work. On the other hand, while we can find examples relevant to the intent detection task, as shown in Table 1 ((c), (d), and (e)), we still need the few-shot fine-tuning. This is because a domain mismatch still exists in general, and perhaps more importantly, our intent detection approach is not exactly modeling NLI.

Why not other tasks? There are other tasks modeling relationships between sentences. Paraphrase (Wieting and Gimpel, 2018) and semantic relatedness (Marelli et al., 2014) tasks are such examples. It is possible to automatically create large-scale paraphrase datasets by machine translation (Ganitkevitch et al., 2013). However, our task is not a paraphrasing task, and creating negative examples is crucial and non-trivial (Chambers and Jurafsky, 2010). In contrast, as described above, the NLI setting comes with negative examples by nature. The semantic relatedness (or textual similarity) task is considered as a coarse-grained task compared to NLI, as discussed in the previous work (Hashimoto et al., 2017), in that the task measures semantic or topical relatedness. This is not ideal for the intent detection task, because we need to discriminate between topically similar utterances of different intents. In summary, the NLI task well matches our objective, with access to the large datasets.

3.4 A Joint Approach with Fast Retrieval

The number of model parameters of the multi-class classification model in Section 2.2 and our model in Section 3 is almost the same when we use the same pre-trained models. However, our example-based method has an inference-time bottleneck in Equation (5), where we need to compute the BERT encoding for all $N \times K$ $(u, e_{j,i})$ pairs.

We follow common practice in document retrieval to reduce the inference-time bottleneck (Nie et al., 2019; Asai et al., 2020), by introducing a fast text retrieval model to select a set of top-k examples E_k from the training set E, based on its retrieval scores. We then replace E in Equation (4) with the shrunk set E_k. The cost of the paired BERT encoding is now constant, regardless the size of E. Either TF-IDF (Chen et al., 2017) or embedding-based retrieval (Johnson et al., 2017; Seo et al., 2019; Lee et al., 2019) can be used for the first step. We use the following fast kNN.

Faster kNN As a baseline and a way to instantiate our joint approach, we use Sentence-BERT (SBERT) (Reimers and Gurevych, 2019) to separately encode u and $e_{j,i}$ ($x \in \{u, e_{j,i}\}$) as follows:

$$v(x) = \mathrm{SBERT}(x) \in \mathbb{R}^d, \tag{7}$$

where the input text format is identical to that of BERT in Equation (2). SBERT is a BERT-based text embedding model, fine-tuned by siamese networks with NLI datasets. Thus both our method and SBERT transfer the NLI task in different ways.

Cosine similarity between $v(u)$ and $v(e_{j,i})$ then replaces $S(u, e_{j,i})$ in Equation (6). To get a fair comparison, instead of using the encoding vectors produced by the original SBERT, we fine-tune SBERT with our intent training examples described in Section 3.2. The cosine similarity is symmetric, so we have half the training examples. We use the

---

[2] A widely-used format is a three-way classification task with `entailment`, `neutral`, and `contradiction`, but we merge the latter two classes into a single `non-entailment` class.

	N	Train	Dev.	Test
All domains	150	15,000	3,000	4,500
Single domain	15	1,500	300	450
OOS	-	n/a	100	1,000

Table 2: Dataset statistics. The number of the examples is equally distributed across the intent classes.

pairwise cosine-based loss function in Reimers and Gurevych (2019). After the model training, we pre-compute $v(e_{j,i})$ for fast retrieval.

4 Experimental Settings

4.1 Dataset: Multi-Domain Intent Detection

We use a recently-released dataset, CLINC150,[3] for multi-domain intent detection (Larson et al., 2019). The CLINC150 dataset defines 150 types of intents in total (i.e., $N = 150$), where there are 10 different domains and 15 intents for each of them. Table 2 shows the dataset statistics.

OOS evaluation examples The dataset also provides OOS examples whose intents do not belong to any of the 150 intents. From the viewpoint of out-of-distribution detection (Hendrycks and Gimpel, 2017; Hendrycks et al., 2020), we do not use the OOS examples during the training stage; we only use the evaluation splits as in Table 2.

Single-domain experiments The task in the CLINC150 dataset is like handling many different services in a single system; that is, topically different intents are mixed (e.g., "alarm" in the "Utility" domain, and "pay bill" in the "Banking" domain). In contrast, it is also a reasonable setting to handle each domain (or service) separately as in Rastogi et al. (2019). In addition to the all-domain experiment, we conduct single-domain experiments, where we only focus on a specific domain with its 15 intents (i.e., $N = 15$). More specifically, we use four domains, "Banking," "Credit cards," "Work," and "Travel," among the ten domains. Note that the same OOS evaluation sets are used.

4.2 Evaluation Metrics

We follow Larson et al. (2019) to report in-domain accuracy, $\mathrm{Acc}_{\mathrm{in}}$, and OOS recall, R_{oos}. These two metrics are defined as follows:

$$\mathrm{Acc}_{\mathrm{in}} = C_{\mathrm{in}}/N_{\mathrm{in}}, \quad R_{\mathrm{oos}} = C_{\mathrm{oos}}/N_{\mathrm{oos}}, \qquad (8)$$

where C_{in} is the number of correctly predicted in-domain intent examples, and N_{in} is the total number of the examples evaluated. This is analogous to the calculation of the OOS recall.

Threshold selection We use the uncertainty-based OOS detection, and therefore we need a way to set the threshold T. For each T in $[0.0, 0.1, \ldots, 0.9, 1.0]$, we calculate a joint score $J_{\mathrm{in\_oos}}$ defined as follows:

$$J_{\mathrm{in\_oos}} = \mathrm{Acc}_{\mathrm{in}} + R_{\mathrm{oos}}, \qquad (9)$$

and select a threshold value to maximize the score on the development set. There is a trade-off to be noted; the larger the value of T is, the higher R_{oos} (and the lower $\mathrm{Acc}_{\mathrm{in}}$) we expect, because the models predict OOS more frequently.

Notes on $J_{\mathrm{in\_oos}}$ Our joint score $J_{\mathrm{in\_oos}}$ in Equation (9) gives the same weight to the two metrics, $\mathrm{Acc}_{\mathrm{in}}$ and R_{oos}, compared to other combined metrics. For example, Larson et al. (2019) and Wu et al. (2020) used a joint accuracy score:

$$\frac{C_{\mathrm{in}} + C_{\mathrm{oos}}}{N_{\mathrm{in}} + N_{\mathrm{oos}}} = \frac{\mathrm{Acc}_{\mathrm{in}} + rR_{\mathrm{oos}}}{1 + r}, \qquad (10)$$

where $r = N_{\mathrm{oos}}/N_{\mathrm{in}}$ depends on the balance between N_{in} and N_{oos}, and thus this combined metric can put much more weight on the in-domain accuracy when $N_{\mathrm{in}} \gg N_{\mathrm{oos}}$. Table 2 shows $r = 100/3000\ (= 0.0333)$ in the development set of the "all domains" setting, which underestimates the importance of R_{oos}. Actually, the OOS recall scores in Larson et al. (2019) and Wu et al. (2020) are much lower than those with our RoBERTa classifier, and the trade-off with respect to the tuning process was not discussed.[4]

We also report OOS precision and OOS F1 for more comprehensive evaluation:

$$P_{\mathrm{oos}} = C_{\mathrm{oos}}/N'_{\mathrm{oos}}, \quad F_1 = H(P_{\mathrm{oos}}, R_{\mathrm{oos}}), \quad (11)$$

where N'_{oos} is the number of examples predicted as OOS, and $H(\cdot,\cdot)$ is the harmonic mean.

4.3 Model Training and Configurations

We use RoBERTa (the `base` configuration with $d = 768$) as a BERT encoder for all the BERT/SBERT-based models in our experiments,[5]

---

[3] `https://github.com/clinc/oos-eval`.

[4] When we refer to our RoBERTa classifier's scores $(A_{\mathrm{in}}, R_{\mathrm{oos}}) = (92.9 \pm 0.2,\ 90.2 \pm 0.5)$ in Table 4, their corresponding scores are $(96.2,\ 52.3)$ and $(96.1,\ 46.3)$ in Larson et al. (2019) and Wu et al. (2020), respectively.

[5] We use `https://github.com/huggingface/transformers` and `https://github.com/UKPLab/sentence-transformers`.

because RoBERTa performed significantly better and more stably than the original BERT in our few-shot experiments. We combine three NLI datasets, SNLI (Bowman et al., 2015), MNLI (Williams et al., 2018), and WNLI (Levesque et al., 2011) from the GLUE benchmark (Wang et al., 2018) to pre-train our proposed model.

We apply label smoothing (Szegedy et al., 2016) to all the cross-entropy loss functions, which has been shown to improve the reliability of the model confidence (Müller et al., 2019). Experiments were conducted on single NVIDIA Tesla V100 GPU with 16GB memory.

Sampling training examples We conduct our experiments with $K = 5, 10$ following the task definition in Section 2.1. We randomly sample K examples from the entire training sets in Table 2, for each in-domain intent class 10 times unless otherwise stated. We train a model with a consistent hyper-parameter setting across the 10 different runs and follow the threshold selection process based on a mean score for each threshold. We also report a standard deviation for each result.

Using the development set We would not always have access to a large enough development set in the few-shot learning scenario. However, we still use the development set provided by the dataset to investigate the models' behaviors when changing hyper-parameters like the threshold.

Models compared We list the models used in our experiments:

- **Classifier baselines:** "Classifier" is the RoBERTa-based classification model described in Section 2.2. We further seek solid baselines by data augmentation. "Classifier-EDA" is the classifier trained with data augmentation techniques in Wei and Zou (2019). "Classifier-BT" is the classifier trained with back-translation data augmentation (Yu et al., 2018; Shleifer, 2019) by using a transformer-based English↔German translation system (Vaswani et al., 2017).

- **Non-BERT classifier:** We also test a state-of-the-art fast embedding-based classifier, "USE+ConveRT" (Henderson et al., 2019; Casanueva et al., 2020), in the "all domains" setting. Casanueva et al. (2020) showed that the "USE+ConveRT" outperformed a BERT classifier on the CLINC150 dataset, while it was not evaluated along with the OOS detection task. We modified their original code[6] to apply the uncertainty-based OOS detection.

- **kNN baselines:**[7] "Emb-kNN" is the kNN method with S(Ro)BERT(a) described in Section 3.4, and "Emb-kNN-vanilla" is *without* using our intent training examples for fine-tuning. "TF-IDF-kNN" is another kNN baseline using TF-IDF vectors, which tells us how well string matching performs on our task. We also implement a relation network (Sung et al., 2018), "RN-kNN," to learn a similarity metric between the SRoBERTa embeddings, instead of using the cosine similarity.

- **Proposed method:**[8] "DNNC" is our proposed method, and "DNNC-scratch" is *without* the NLI pre-training in Section 3.3. "DNNC-joint" is our joint approach on top of top-k retrieval by Emb-kNN (Section 3.4).

More details about the model training and the data augmentation configurations are described in Appendix A and Appendix B, respectively.

5 Experimental Results

This section shows our experimental results. Appendix C shows some additional figures.

5.1 Model Performance CLINC150 Dataset

Single domains We first show test set results of 5-shot and 10-shot in-domain classification and OOS detection accuracy in Table 3 for the four selected domains. In the 5-shot setting, the proposed DNNC method consistently attains the best results across all the four domains. The comparison between DNNC-scratch and DNNC shows that our NLI task transfer is effective. In the 10-shot setting, all the approaches generally experience an accuracy improvement due to the additional training data, and the dominant performance of DNNC weakens, although it remains highly competitive. We can see that our DNNC is comparable with or even surpasses some of the 50-shot classifier's scores, and the data augmentation techniques are not always helpful when we use the strong pre-trained model.

Table 4: Testing results on the whole dataset (5 runs).

Entire CLINC150 dataset Next, Table 4 shows results to compare our method with the classifier and USE+ConveRT baselines, on the entire CLINC150 dataset with the 150 intents. USE+ConveRT performs worse than the RoBERTa-based classifier on the OOD detection task. The advantage of DNNC for in-domain intent detection is clear, with its 10-shot in-domain accuracy close to the upper-bound accuracy for the classifier baseline. One observation is that our DNNC method tends to be more confident about its prediction, with the increasing number of the training examples; as a result, the OOS recall becomes lower in the 10-shot setting, while the OOS precision is much higher than the other baselines. Better controlling the confidence output of the model is an interesting direction for future work.

When the USE+ConveRT baseline is evaluated along with the OOS detection task, its overall accuracy is not as good as the other RoBERTa-based models, despite its potential in the purely in-domain classification. This indicates that the fine-tuned (Ro)BERT(a) models are more robust to out-of-distribution examples than shallower models like USE+ConveRT, also suggested in Hendrycks et al. (2020).

5.2 Robustness of DNNC

As described in Section 4.2, we select the threshold to determine OOS by making a trade-off between in-domain classification and OOS detection accuracy. It is therefore desirable to have a model with candidate thresholds that provide high in-domain accuracy as well as OOS precision and recall.

We observe in Figure 3 that in the 5-shot setting, DNNC is the most robust to the threshold selection. The contrast between the classification model and DNNC-scratch suggests that nearest neighbor approaches (in this case DNNC) make for stronger discriminators; the advantage of DNNC over DNNC-scratch further demonstrates the power of the NLI transfer and, perhaps more importantly, the effectiveness of the pairwise discriminative pretraining. This result is consistent with the intuition we gained from Figure 1, and the overall observation is also consistent across different settings.

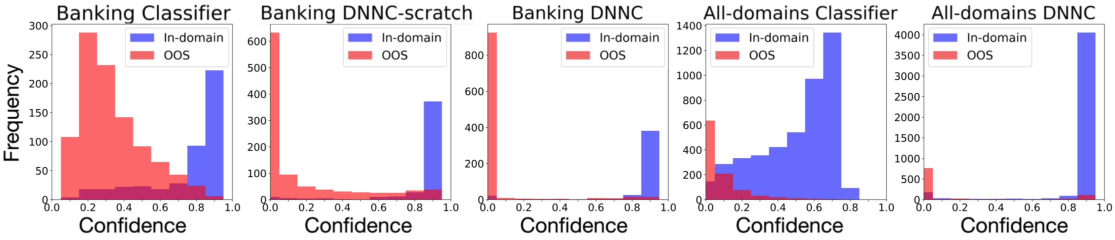

Figure 2: Model confidence level on 5-shot test sets for the banking domain and all domains.

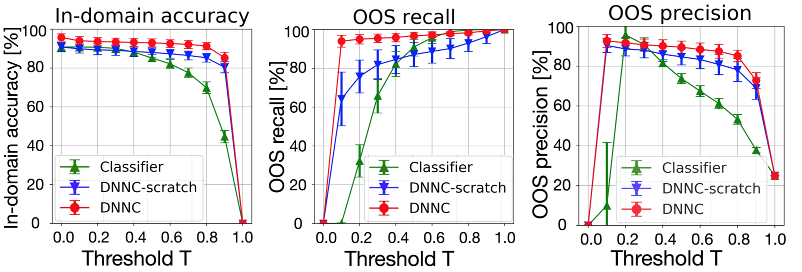

Figure 3: Development set results on the banking domain in the 5-shot setting. In this series of plots, a model with a higher area-under-the-curve is more robust.

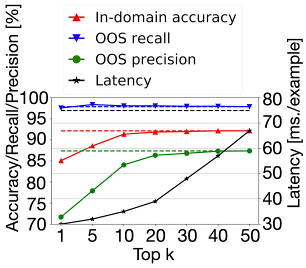

Figure 4: Accuracy vs. latency of DNNC-joint.

	In-domain accuracy		OOS recall		OOS precision		OOS F1		Latency [ms./example]

DNNC	84.9 ± 0.8	91.6 ± 0.3	90.1 ± 1.6	83.0 ± 2.0	64.7 ± 2.5	81.4 ± 2.0	75.3 ± 2.0	82.1 ± 0.3	697	1498

Table 5: Comparison among the nearest neighbor methods on the test sets for the banking domain and all the domains. The latency is measured on a single NVIDIA Tesla V100 GPU, where the batch size is 1 to simulate an online use case. DNNC-joint is based on top-20 Emb-kNN retrieval.

To further understand the differences in behaviors between the classification model and DNNC method, we examine the output from the final softmax/sigmoid function (model confidence score) in Figure 2. At 5-shot, the classifier method still struggles to fully distinguish the in-domain examples from the OOS examples in its confidence scoring, while DNNC already attains a clear distinction between the two. Again, we can clearly see the effectiveness of the NLI transfer.

With the model architectures for BERT-based classifier and DNNC being the same (RoBERTa is used for both methods) except for the final layer (multi-class-softmax vs. binary sigmoid), this result suggests that the pairwise NLI-like training is more sample-efficient, making it an excellent candidate for the few-shot use case.

5.3 DNNC-joint for Faster Inference

Despite its effectiveness in few-shot intent and OOS settings, the proposed DNNC method might not scale in high-traffic use cases, especially when the number of classes, N, is large, due to the inference-time bottleneck (Section 3.4). With this in mind, we proposed the DNNC-joint approach, wherein a faster model is used to filter candidates for the fine-tuned DNNC model.

We compare the accuracy and inference latency metrics for various methods in Table 5. Note that Emb-kNN and RN-kNN exhibit excellent latency performance, but they fall considerably short in both the in-domain intent and OOS detection accuracy, compared to DNNC and the DNNC-joint methods. On the other hand, the DNNC-joint model shows competitiveness in both inference latency and accuracy. These results indicate that the current text embedding approaches like SBERT are not enough to fully capture fine-grained semantics.

Intuitively, there is a trade-off between latency and inference accuracy: with aggressive filtering, the DNNC inference step needs to handle a smaller number of training examples, but might miss informative examples; with less aggressive filtering, the NLI model sees more training examples during inference, but will take longer to process single user input. This is illustrated in Figure 4, where the in-domain intent and OOS accuracy metrics (on the development set of the banking domain in the 5-shot setting) improve with the increase of k, while the latency increases at the same time. Empirically, $k = 20$ appears to strike the balance between latency and accuracy, with the accuracy metrics similar to those of the DNNC method, while being much faster than DNNC (dashed lines are the corresponding DNNC references).

6 Discussions and Related Work

Interpretability Interpretability is an important line of research recently (Jiang et al., 2019; Sydorova et al., 2019; Asai et al., 2020). The nearest neighbor approach (Simard et al., 1993) is appealing in that we can explicitly know which training example triggers each prediction. Table 11 in Appendix C shows some examples.

Call for better embeddings Emb-kNN and RN-kNN are not as competitive as DNNC. This encourages future work on the task-oriented evaluation of text embeddings in kNN.

Training time Our DNNC method needs longer training time than that of the classifier (e.g., 90 vs. 40 seconds to train a single-domain model), because we synthesize the pairwise examples. As a first step, we used all the training examples to investigate the effectiveness, but it is an interesting direction to seek more efficient pairwise training.

Distilled model Another way to speedup our model is to use distilled pre-trained models (Sanh et al., 2019). We replaced the RoBERTa model with a distilled RoBERTa model, and observed large variances with significantly lower OOS accuracy. Hendrycks et al. (2020) also suggested that the distilled models would not be robust to out-of-distribution examples.

Few-shot text classification Few-shot classification (Fei-Fei et al., 2006; Vinyals et al., 2016b) has been applied to text classification tasks (Deng et al., 2019; Geng et al., 2019; Xu et al., 2019), and few-shot intent detection is also studied but without OOS (Luo et al., 2018; Casanueva et al., 2020). There are two common scenarios: 1) learning with plenty of examples and then generalizing to unseen classes with a few examples, and 2) learning with a few examples for all seen classes. Meta-learning (Finn et al., 2017; Geng et al., 2019) is widely studied in the first scenario. In our paper, we have focused on the second scenario, assuming that there are only a limited number of training examples for each class. Our work is related to metric-based approaches such as matching networks (Vinyals et al., 2016a), prototypical networks (Snell et al., 2017) and relation networks (Sung et al., 2018), as they model nearest neighbours in an example-embedding or a class-embedding space. We showed that a relation network with the RoBERTa embeddings does not perform comparably to our method. We also considered several ideas from prototypical networks (Sun et al., 2019), but those did not outperform our Emb-kNN baseline. These results indicate that deep self-attention is the key to the nearest neighbor approach with OOS detection.

7 Conclusion

In this paper, we have presented a simple yet efficient nearest-neighbor classification model to detect user intents and OOS intents. It includes paired encoding and discriminative training to model relations between the input and example utterances. Moreover, a seamless transfer from NLI and a joint approach with fast retrieval are designed to improve the performance in terms of the accuracy and inference speed. Experimental results show superior performance of our method on a large-scale multi-domain intent detection dataset with OOS. Future work includes its cross-lingual transfer and cross-dataset (or cross-task) generalization.

Appendix

A Training Details

Dataset preparation To use the CLINC150 dataset (Larson et al., 2019)[9] in our ways, especially for the single-domain experiments, we provide preprocessing scrips accompanied with our code.

General training This section describes the details about the model training in Section 4.3. For each component related to RoBERTa and SRoBERTa, we solely follow the two libraries, transformers and sentence-transformers, for the sake of easy reproduction of our experiments.[10] The example code to train the NLI-style models is also available.[11] We use the `roberta-base` configuration[12] for all the RoBERTa/SRoBERTa-based models in our experiments. All the model

parameters including the RoBERTa parameters are updated during all the fine-tuning processes, where we use the AdamW (Loshchilov and Hutter, 2017) optimizer with a weight decay coefficient of 0.01 for all the non-bias parameters. We use a gradient clipping technique (Pascanu et al., 2013) with a clipping value of 1.0, and also use a linear warmup learning-rate scheduling with a proportion of 0.1 with respect to the maximum number of training epochs.

Pre-training on NLI tasks For the pre-training on NLI tasks, we fine-tune a `roberta-base` model on three publicly available datasets, i.e., SNLI (Bowman et al., 2015), MNLI (Williams et al., 2018), and WNLI (Levesque et al., 2011) from the GLUE benchmark (Wang et al., 2018). The optimizer and gradient clipping follow the above configurations. The number of training epochs is set to 4; the batch size is set to 32; the learning rate is set to $2e-5$. We use a linear warmup learning-rate scheduling with a proportion of 0.06 by following Liu et al. (2019). The evaluation results on the development sets are shown in Table 6, where the low accuracy of WNLI is mainly caused by the data size imbalance. We note that these NLI scores are not comparable with existing NLI scores, because we converted the task to the binary classification task for our model transfer purpose.

Text pre-processing For all the RoBERTa-based models, we used the RoBERTa `roberta-base`'s tokenizer provided in the transformers library.[13] We did not perform any additional pre-processing in our experiments.

Hyper-parameter settings Table 7 shows the hyper-parameters we tuned on the development sets in our RoBERTa-based experiments. For a single-domain experiment, we take a hyper-parameter set and apply it to the ten different runs to select the threshold in Section 4.2 on the development set. We then select the best hyper-parameter set along with the corresponding threshold, which achieves the best $J_{\text{in\_oos}}$ in Equation (9) on the development set, among all the possible hyper-parameter sets. Finally, we apply the selected model and the threshold to the test set. We follow the same process for the all-domain experiments, except that we run each experiment five times. Table 8 and Table 9 summarize the hyper-parameter settings used for the evaluation on the test sets. We note that each model was not very sensitive to the different hyper-parameter settings, as long as we have a large number of training iterations.

B Data Augmentation

We describe the details about the classifier baselines with the data augmentation techniques in Section 4.3.

EDA Classifier-EDA uses the following four data augmentation techniques in Wei and Zou (2019): synonym replacement, random insertion, random swap, and random deletion. We follow the publicly available code.[14] For every training example, we empirically set one augmentation based on every technique. We apply each technique separately to the original sentence and therefore every training example will have four augmentations. The probability of a word in an utterance being edited is set to 0.1 for all the techniques.

BT For classifier-BT, we use the English-German corpus in Negri et al. (2018), which is widely used in an annual competition for automatic post-editing research on IT-domain text (Chatterjee et al., 2019). The corpus contains about 7.5 million translation pairs, and we follow the *base* configuration to train a transformer model (Vaswani et al., 2017) for each direction. Based on the initial trial in our preliminary experiments to generate diverse examples, we decided to use a temperature sampling technique instead of a greedy or beam-search strategy. More specifically, logit vectors during the machine translation process are multiplied by τ to distort the output distributions, where we set $\tau = 5.0$. For each training example in the intent detection

dataset, we first translate it into German and then translate it back to English. We repeat this process to generate up to five unique examples, and use them to train the classifier model. Table 10 shows such examples, and we will release all the augmented examples for future research.

C Additional Results

Visualization Figure 5 shows the same curves in Figure 3 along with the corresponding 10-shot results. We can see that the 10-shot results also exhibit the same trend. Figure 6 shows more visualization results with respect to Figure 1. Again, the 10-shot visualization shows the same trend.

Figure 7 and Figure 8 show 5-shot and 10-shot confidence levels on the test sets of the banking domain and all domains, respectively. Both Classifier and Emb-kNN cannot perform well to distinguish the in-domain examples from the OOS examples, while DNNC has a clearer distinction between the two.

Faster inference Figure 9 shows the same curves in Figure 4 also for the 10-shot setting. We can see the same trend with the 10-shot results.

Case studies Table 11 shows four DNNC prediction examples from the development set of the banking domain. For the first example, the input utterance is correctly predicted with a high confidence score, and it has a similarly matched utterance to the input utterance; for the second example, the input utterance is predicted incorrectly with a high confidence score, where the matched utterance is related to money but it has a slightly different meaning with the input utterance. For the third example, the model gives a very low confidence score to predict an OOS user utterance as an in-domain intent; the last example is an incorrect case where the input utterance and the matched utterance have a topically similar meaning, resulting in a high confidence score for the wrong label, "bill due." Based on these observations, it is an important direction to improve the model's robustness (even with the large-scale pre-trained models) towards such confusing cases.

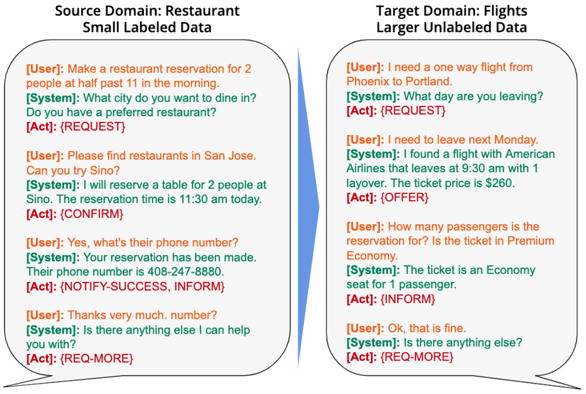
Abstract

The concept of Dialogue Act (DA) is universal across different task-oriented dialogue domains - the act of "request" carries the same speaker intention whether it is for restaurant reservation or flight booking. However, DA taggers trained on one domain do not generalize well to other domains, which leaves us with the expensive need for a large amount of annotated data in the target domain. In this work, we investigate how to better adapt DA taggers to desired target domains with only unlabeled data. We propose MASKAUGMENT, a controllable mechanism that augments text input by leveraging the pre-trained MASK token from BERT model. Inspired by consistency regularization, we use MASKAUGMENT to introduce an unsupervised teacher-student learning scheme to examine the domain adaptation of DA taggers. Our extensive experiments on the Simulated Dialogue (GSim) and Schema-Guided Dialogue (SGD) datasets show that MASKAUGMENT is useful in improving the cross-domain generalization for DA tagging.

1 Introduction

Dialog act (DA) tagging, one of the important NLU components of modern task-oriented dialog systems, aims to capture the speaker's intention behind the utterances at each dialog turn. Several different schema and taxonomies have been introduced by several different researchers (Core and Allen, 1997; Stolcke et al., 2000; Bunt et al., 2010; Mezza et al., 2018) over the years. However, the main focus of the recent work (Kumar et al., 2018; Chen et al., 2018; Raheja and Tetreault, 2019) on DA tagging was on human-human social conversations (Godfrey et al., 1992; Jurafsky et al., 1997), which is less applicable for task-oriented setting.



[User]: Make a restaurant reservation for 2 people at half past 11 in the morning.
[System]: What city do you want to dine in? Do you have a preferred restaurant?
[Act]: {REQUEST}

[User]: Please find restaurants in San Jose. Can you try Sino?
[System]: I will reserve a table for 2 people at Sino. The reservation time is 11:30 am today.
[Act]: {CONFIRM}

[User]: Yes, what's their phone number?
[System]: Your reservation has been made. Their phone number is 408-247-8880.
[Act]: {NOTIFY-SUCCESS, INFORM}

[User]: Thanks very much. number?
[System]: Is there anything else I can help you with?
[Act]: {REQ-MORE}

[User]: I need a one way flight from Phoenix to Portland.
[System]: What day are you leaving?
[Act]: {REQUEST}

[User]: I need to leave next Monday.
[System]: I found a flight with American Airlines that leaves at 9:30 am with 1 layover. The ticket price is $260.
[Act]: {OFFER}

[User]: How many passengers is the reservation for? Is the ticket in Premium Economy.
[System]: The ticket is an Economy seat for 1 passenger.
[Act]: {INFORM}

[User]: Ok, that is fine.
[System]: Is there anything else?
[Act]: {REQ-MORE}

Figure 1: Overview of dialog act tagging task and cross-domain generalization scenario of similar dialog acts. The specific contents of the utterances of the same dialog act (DA) are distinct due to the domain difference, making the cross-domain generalization challenging.

Recently, several task-oriented dialogue datasets (Shah et al., 2018; Henderson et al., 2014; Budzianowski et al., 2018) have been released. However, the discrepancy in their annotation schema hinders the progress on building DA taggers that can generalize across domains and possibly datasets. To address this issue, Paul et al. (2019) propose a universal schema for DAs by aligning annotations for multiple existing corpora. In this regard, another useful corpora employed as a testbed in this work is Schema-guided dialogues (SGD) (Rastogi et al., 2020), which covers 20 domains under the same DA annotation schema.

It is often challenging and costly to obtain a large amount of in-domain dialogues with annotations. However, unlabeled dialogue corpora in target domain can easily be curated from past conversation logs or collected via crowd-sourcing (Byrne et al., 2019; Budzianowski et al., 2018) at a more reasonable cost. The goal of this work is to investigate how to leverage pre-trained masked language models (e.g., BERT) to better adapt DA taggers to unseen domains with available unlabeled dialogues. Pre-trained language models (Devlin et al., 2019; Liu et al., 2019) have been successful for several NLP tasks including dialogue systems (Wolf et al.,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5083–5089,
November 16–20, 2020. ©2020 Association for Computational Linguistics

Figure 2: Given a dialogue turn in target domain, we obtain *teacher* and *student* representations by applying two different maskings on its flattened original representation. We use the output binary probability distributions (per dialog act) of the teacher as soft targets to train the student. Orange and green colored boxes indicate different segment ids.

2019; Zhang et al., 2019; Bao et al., 2020; Henderson et al., 2019; Wu et al., 2020). However, domain adaptation capabilities of these models remain to be further explored for goal-oriented dialogues.

In this paper, we use the pre-trained MASK token of BERT model to define MASKAUGMENT, which stochastically augments text input by randomly replacing its tokens with the MASK token. We adopt consistency regularization approach (Sajjadi et al., 2016) to introduce an unsupervised teacher-student learning scheme by leveraging MASKAUGMENT for generating teacher and student representations retaining different amount of the original content from the unlabeled dialogue example. Our extensive experiments on GSim (Shah et al., 2018) and SGD (Rastogi et al., 2020) datasets suggest: (i) BERT establishes a much stronger baseline compared to previous work (Paul et al., 2019), (ii) The proposed teacher-student learning via MASKAUGMENT is useful in further improving the target domain F1 score over BERT baseline: up to 3% when the full source domain data is used, and up to 10% for the low-resource setting.

2 MASKAUGMENT

In this section, we first discuss the task setup, BERT-based DA tagging model, and relevant background. We then define the proposed fine-tuning objectives leveraging MASKAUGMENT.

2.1 Task Setup

We start by formalizing the DA tagging task, depicted in Figure 1, as a multi-label classification problem. Let $D = [T_1, T_2, \ldots, T_n]$ denote a dialogue of n turns as a series of user and system utterances. Let $A = \{a_j\}_1^m$ be the predefined set of m different DAs in the schema. The objective of dialogue act tagging is to determine a subset $A_k \subseteq A$ of DAs that apply to the current turn T_k given the conversation history $D_{:k} = [T_1, T_2, \ldots, T_k]$ so far. We formulate this objective simply as a classification problem with binary labels $y_j \in \{0, 1\}$ for each act a_j where $y_j = 1$ if $a_j \in A_k$ and $y_j = 0$ otherwise. As defined above, dialogue act tagging is a turn-level classification problem, hence every turn T_k constitutes: (i) a labeled example $(D_{:k}, A_k)$ if we have a set A_k of DA annotations, or (ii) an unlabeled example $(D_{:k}, \cdot)$ otherwise.

2.2 Model

Given a conversation history $D_{:k}$ as input, we first convert it into a sequence of words by concatenating user and system utterances. Before concatenating each utterance, we prepend it with corresponding speaker tag using [SYS] and [USR] special tokens indicating system and user sides, respectively. Finally, the whole flattened sequence is finalized by prepending it with [CLS] special token to obtain the final *dialogue history representation*:

$$x = [\text{CLS}]...[\text{USR}]\ T_i\ [\text{SYS}]\ T_{i+1}... \quad (1)$$

The segment ids are set to 0 and 1 for the tokens of past turns and the current turn, respectively.

For DA tagging task, dialogue history x is used as input to pre-trained language model M, and the model computes a probability vector $p_\theta(\cdot|x) = \sigma(WM(x) + b)$ where $M(x) \in \mathbb{R}^d$ is the output contextualized embedding corresponding to CLS token, $W \in \mathbb{R}^{m \times d}$ and $b \in \mathbb{R}^m$ are trainable weights of a linear projection layer, σ is the sigmoid function, θ denotes the entire set of trainable parameters of model M along with (W, b), and finally $p_\theta(a_j|x)$ indicates the probability of tag a_j being triggered. The following objective is used to train the model parameters.

Supervised tagging loss (STL). This objective is used to update the DA tagger via the supervision coming from labeled source data S. We use binary-cross entropy loss $\mathcal{J}_{\text{STL}}(\theta; x, y)$ defined as:

$$-\left[y \cdot \log p_\theta(\cdot|x) + (1-y) \cdot \log(1 - p_\theta(\cdot|x))\right] \quad (2)$$

2.3 Learning with MASKAUGMENT

Semi-supervised learning (SSL) (Berthelot et al., 2019, 2020; Sohn et al., 2020; Li et al., 2020) is an effective approach for improving deep learning models by leveraging in-domain unlabeled data. Unlike traditional SSL setting, our objective is to primarily address the underlying source-to-target domain shift. In prior work (Xie et al., 2019; Wei and Zou, 2019), unsupervised data augmentation methods including word replacement and back-translation have been shown useful for short written text classification. However, such augmentation methods are shown to be less effective (Shleifer, 2019) when used with pre-trained models. Besides, back-translation is less applicable in our scenario as translation of multi-turn dialogue itself is a rather challenging task compared to short text.

Instead, we propose a simple and controllable data augmentation–MASKAUGMENT–to explore a new unsupervised teacher-student learning scheme for domain adaptation of DA taggers. MASKAUGMENT augments the original text input by randomly replacing its tokens with MASK token at a specified probability. We follow the masking policy in (Devlin et al., 2019). Formally, let $z(\bar{x}|x,\epsilon)$ denote the MASKAUGMENT as a stochastic transformation with ϵ-probability for input x. Below we define three fine-tuning objectives leveraging MASKAUGMENT that are used in addition to $\mathcal{J}_{\text{STL}}$.

Masked tagging loss (MTL). We incorporate MASKAUGMENT into the STL objective by perturbing its input sequence x as follows:

$$\mathcal{J}_{\text{MTL}}(\theta; x, y, \epsilon) = \mathbb{E}_{\bar{x}\sim z(\bar{x}|x,\epsilon)}\left[\mathcal{J}_{\text{STL}}(\theta; \bar{x}, y)\right].$$

Masked LM loss (MLM). This is the original objective that BERT is pre-trained with. The objective of MLM training is to correctly reconstruct a randomly selected subset (with probability ϵ) of input tokens leveraging the unmasked context. We denote this loss by $\mathcal{J}_{\text{MLM}}(\theta; x, \epsilon)$.

Teacher-Student Learning with Disagreement Loss (DAL). We adopt consistency regularization (Sajjadi et al., 2016; Laine and Aila, 2017) widely used in traditional SSL (Berthelot et al., 2019; Sohn et al., 2020; Li et al., 2020) and define *disagreement loss*, which employs MASKAUGMENT in a novel way to give rise to an unsupervised teacher-student training. The core idea is to contrast the amount of controllable perturbations to learn more generalizable representations. We propose a stochastic imputation-based teacher and student selection by leveraging MASKAUGMENT. As in Figure 2, we sample two augmentations $\bar{x}^{(t)} \sim z(\bar{x}|x,\epsilon_t)$ and $\bar{x}^{(s)} \sim z(\bar{x}|x,\epsilon_s)$ for teacher and student, respectively. We take $\epsilon_t < \epsilon_s$ to ensure that the teacher augmentation $\bar{x}^{(t)}$ retains more of the original content x than the student augmentation $\bar{x}^{(s)}$, hence is more reliable. The disagreement loss $\mathcal{J}_{\text{DAL}}(\theta; x, \epsilon_t, \epsilon_s)$ is then computed as the binary cross-entropy loss between the teacher $p_\theta(\cdot|\bar{x}^{(t)})$ and the student $p_\theta(\cdot|\bar{x}^{(s)})$ distributions as in Eq. 2, treating teacher as the soft target (y).

3 Experiments

3.1 Datasets

GSIM (Shah et al., 2018) consists of machine-machine task-oriented dialogues in two tasks of two different domains: buying a movie ticket (GMov) and reserving a restaurant table (GRes). It contains 1500/469/1117 dialogues for the train/dev/test sets. Following (Paul et al., 2019), its dialogue acts are mapped to 13 tags in universal schema.

SGD (Rastogi et al., 2020) consists of 22,825 schema-guided single/multi-domain dialogues where domains can have multiple schemas, each defined by a set of tracking slots. We use single-domain dialogues of smaller sizes including music (SMusic), media (SMedia), ride-sharing (SRide) as source domains to study generalization on flights (SFlights), the largest one, as the target domain.

3.2 Training and Implementation Details

The final loss function is the sum of the active ones among $\mathcal{J}_{\text{STL}}, \mathcal{J}_{\text{MTL}}, \mathcal{J}_{\text{DAL}}, \mathcal{J}_{\text{MLM}}$ except $\mathcal{J}_{\text{MLM}}$ is multiplied with 0.1 when active. DAL is activated after 1 epoch of training with the remaining objectives. We perform a tuning of $\epsilon_t \in [0, 0.1]$ and $\epsilon_s \in [0.1, 0.5]$ for DAL objective. We optimize the loss using AdamW (Loshchilov and Hutter, 2017). The learning rate is tuned on $[10^{-5}, 5 \times 10^{-5}]$ with no warmup steps. We use a batch of 16 examples with maximum sequence length of 128, which covers around 9.9, 10.3, 9.9 turns on average for train, dev, test splits, respectively. We use *transformers* library[1] for our implementation.

3.3 Results and Discussion

We begin our discussion with our main findings on domain adaptation as presented in Table 1. We explore the effect of incorporating our proposed MTL and DAL objectives on top of STL (baseline) for both Transformer (Vaswani et al., 2017) and BERT (Devlin et al., 2019) models. Transformer baseline model on DA tagging with STL

STL + MTL + DAL	92.8	94.0
STL + MTL + DAL + MLM	94.1	94.4

Table 2: Micro-F1 scores on target (GRes) domain for pre-BERT (obtained by domain-adaptive pre-training) in comparison with scratch-BERT (initialized from BERT) across different fine-tuning objectives. We also highlight the effect of MLM when used as a fine-tuning objective on unlabeled target domain examples in the second and fourth rows.

	Precision		**Recall**	
Model	Dev	Test	Dev	Test
scratch-BERT				
STL	87.8	88.3	89.6	91.1
STL + MTL + DAL	91.5	90.7	95.3	95.0
pre-BERT				
STL	91.8	91.4	92.1	92.4
STL + MTL + DAL	93.1	92.4	95.6	95.6

Table 3: Precision and recall scores on target (GRes) domain for pre-BERT and scratch-BERT including dev set results.

Model	**#Dials: 10**	**#Dials: 20**	**#Dials: 50**
scratch-BERT			
STL	53.3	65.5	73.6
STL + MTL + DAL	58.4	69.0	78.2
pre-BERT			
STL	59.8	73.9	82.9
STL + MTL + DAL	70.4	77.8	85.1

Table 4: F1 scores on target domain (GRes) under the low-resource setting. #Dials denote the number of labeled dialogues (randomly sampled) used in the source domain (GMov). We report the average of 3 runs with different samples.

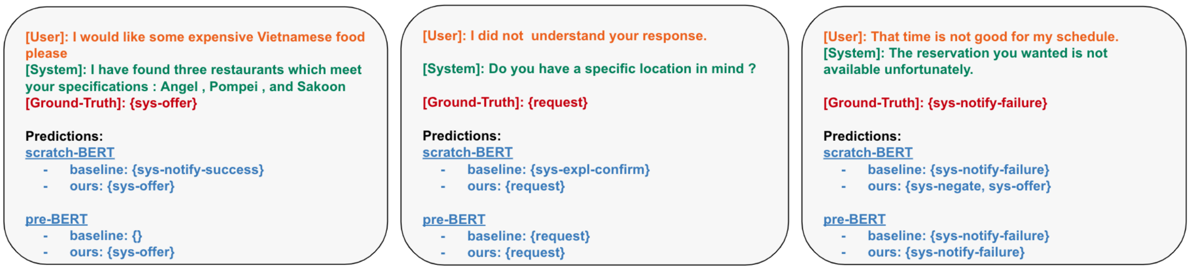
objective leads to considerable improvements on the LSTM (Paul et al., 2019). Fine-tuning BERT with STL objective from scratch provides further improvements on Transformer, establishing a much stronger baseline both on source and target domain performance. For both Transformer and BERT models, our proposed DAL and MTL objectives are independently useful in further improving the cross-domain generalization over strong baselines that are trained only with STL objective while not hurting the source domain performance. Moreover, fine-tuning on the combined unsupervised objective of DAL and MTL leads to the best performance (last row) on target domains across the board, hinting they provide orthogonal benefits.

Domain-adaptive pre-training (pre-BERT). As shown useful by Gururangan et al. (2020), we explore domain-adaptive pre-training of BERT model on the combination of source and target domain dialogues with MLM loss before fine-tuning it on the task. As presented in Table 2, pre-BERT helps improve the F1 score on the target domain (GRes) by up to 2.2% over the strong scratch-BERT model across different training objectives. Incorporating MASKAUGMENT into pre-BERT via our proposed DAL and MTL objectives leads to 2.1% boost over fine-tuning with only STL, achieving 4.8% F1 score improvement over LSTM (Paul et al., 2019) (89.2%) trained on the full labeled data (GRes) itself in a supervised way. This might partly be due to the effect of learning a more domain-aware MASK token, which in return may lead to a more informed and useful teacher representations.

The effect of MLM in fine-tuning. We also conduct experiments on using MLM as unsupervised fine-tuning objective on the target domain dialogues. As shown in Table 2, it helps improve the cross-domain generalization performance. Specifically, our ultimate model (last row) achieves 94.1% and 94.4% F1 scores on the target domain for scratch-BERT and pre-BERT models, respectively.

Consistent gains on precision and recall. In Table 3, we demonstrate that our proposed approach leads to consistent gains on both precision and recall. While the improvement is consistent, we observe that MASKAUGMENT significantly helps close the recall gap between scratch-BERT and pre-BERT (i.e., from 2.5% to 0.3% on the dev set and from 1.3% to 0.6% on the test set).

Low-resource setting for source domain. As shown in Table 4, we observe that the benefit of



[User]: I would like some expensive Vietnamese food please

- ours: {sys-notify-failure}

(a) Improved example for *sys-offer*. (b) Improved example for *request*. (c) Failure example for *sys-notify-failure*.

Figure 3: Qualitative examples comparing baseline and proposed approach across scratch-BERT and pre-BERT settings.

		scratch-BERT		**pre-BERT**	
Acts	**Frequency**	Baseline	Ours	Baseline	Ours
affirm	13%	92.0	94.3	95.5	94.2
inform	30%	95.3	95.0	95.3	95.8
repeat	1%	95.2	90.9	98.3	89.5
request	15%	92.2	97.8	97.0	99.3
sys-expl-confirm	6%	76.5	87.4	86.8	89.6
sys-negate	3%	89.8	78.2	84.9	82.3
sys-notify-failure	4%	93.8	82.4	85.0	84.5
sys-notify-success	3%	80.7	91.8	95.1	88.2
sys-offer	13%	69.2	89.3	71.5	91.1
thank-you	2%	98.5	85.5	98.5	97.1
user-hi	6%	99.6	99.9	99.7	99.2
user-negate	4%	87.4	88.5	89.8	91.9

Table 5: Micro-F1 scores for each dialog act (DA) on the test split of target (GRes) domain. Note that we use the target data without their labels in totally unsupervised fashion, where only the source (GMov) domain provides label supervision. We compare baseline (STL) and our proposed training scheme (STL + MTL +DAL) through MASKAUGMENT for both scratch-BERT and pre-BERT settings. Frequency indicates the occurrence ratio of the corresponding dialog act in the test split of the target domain. We highlighted the rows with more than 10% frequency. Green highlighting indicates the tags on which our method is superior to baseline, and red highlighting indicates the opposite.

MASKAUGMENT through DAL and MTL objectives becomes larger as the number of labeled dialogues in the source domain gets smaller. The effect of domain-adaptive pre-training also becomes stronger, providing 12% improvement over scratch-BERT when only 10 labeled dialogues are available in the source domain while achieving 85.1% F1 score on the target domain with 50 labeled dialigues when combined with MASKAUGMENT.

Adaptation performance across DAs. In Table 5, we present additional analysis on the adaptation performance across the set of all dialog acts in the schema. MASKAUGMENT provides significant improvement across most of the DAs including frequent ones such as *request* and *sys-offer* while not hurting the performance much (if not improving) on other frequent acts such as *affirm* and *inform*. For scratch-BERT setting, baseline (STL) objective obtains superior performance on less frequent DAs including *sys-negate*, *sys-notify-failure*, and *thank-you*, for which the performance drop is mostly bridged in pre-BERT setting. On the other hand, Pre-BERT provides consistent adaptation improvement over scratch-BERT across all dialog acts except for *sys-negate* and *sys-notify-failure*.

Qualitative analysis of the approach. In Figures 3a and 3b, we provide examples for improved predictions on *sys-offer* and *request* acts, respectively. These are some of the most frequent DAs that MASKAUGMENT can provide a significant (5-20%) improvement over the baseline approach for both scratch-BERT and pre-BERT settings. In Figure 3c, we include an example where scratch-BERT with MASKAUGMENT fails on predicting *sys-notify-failure* act correctly as opposed the baseline. However, most of such failure cases vanish for pre-BERT setting, where the gap in F1 score drops from 11.4% in scatch-BERT to only 0.5% in pre-BERT as shown in Table 5.

4 Conclusion

We study cross-domain generalization of pre-trained language models for DA tagging. While the fine-tuned BERT model performs well on in-domain DA tagging, its cross-domain generalization is still not satisfactory. To combat this shortcoming, we investigate domain adaptation through the proposed unsupervised teacher-student training that leverages the MASKAUGMENT method for data augmentation. Our empirical results show that the proposed training scheme leads to significant improvements on domain adaptation for dialog act taggers. In the future, we plan to explore MASKAUGMENT for other tasks in NLP domain.

Low-Resource Domain Adaptation for Compositional Task-Oriented Semantic Parsing

Abstract

Task-oriented semantic parsing is a critical component of virtual assistants, which is responsible for understanding the user's intents (set reminder, play music, etc.). Recent advances in deep learning have enabled several approaches to successfully parse more complex queries (Gupta et al., 2018; Rongali et al., 2020), but these models require a large amount of annotated training data to parse queries on new *domains* (e.g. reminder, music).

In this paper, we focus on adapting task-oriented semantic parsers to low-resource domains, and propose a novel method that outperforms a supervised neural model at a 10-fold data reduction. In particular, we identify two fundamental factors for low-resource domain adaptation: better *representation learning* and better *training techniques*. Our representation learning uses BART (Lewis et al., 2020) to initialize our model which outperforms encoder-only pre-trained representations used in previous work. Furthermore, we train with optimization-based meta-learning (Finn et al., 2017) to improve generalization to low-resource domains. This approach significantly outperforms all baseline methods in the experiments on a newly collected multi-domain task-oriented semantic parsing dataset (TOPv2[1]).

1 Introduction

Virtual Assistants now play an ever increasingly important role in our daily life, and can help users perform a wide spectrum of tasks ranging from setting personal reminders, checking local weather, to controlling smart home devices and online shopping. A critical step in any virtual assistant is to understand the user's intent (e.g. set reminder, get weather info, etc.) given the user utterance. In recent years, a number of successful models have emerged to tackle such task-oriented semantic parsing task, for both simple and more complex queries.

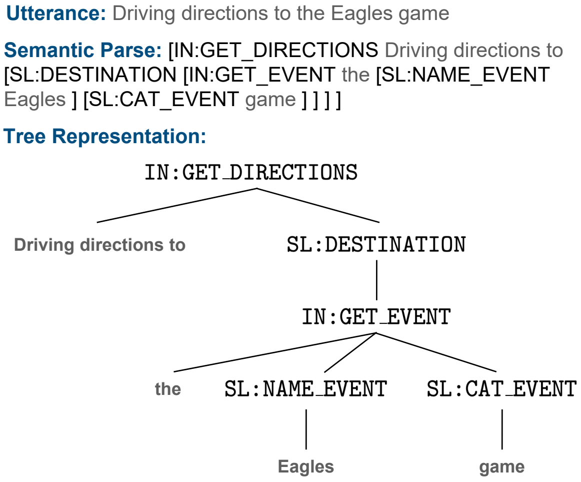

Figure 1: An compositional query from TOP dataset.

Traditionally, task-oriented semantic parsers treat the problem as a joint *intent classification* and *slot filling* task (Liu and Lane, 2016), where the model first predicts the intent of the input utterance from a set of pre-defined intent labels, and then identify all the necessary slots for that intent. For instance, for the query *"How's the weather in San Francisco?"*, the model would predict the GET_WEATHER intent, and tag *San Francisco* as a LOCATION slot. With the elevated expectation of virtual assistants, however, techniques for handling the more complex *compositional* queries have been proposed recently using neural parsers (Gupta et al., 2018) or Seq2Seq models (Rongali et al., 2020). In particular, these approaches can handle complicated queries with multiple intents or nested slots. For example, the following query from the TOP dataset (Gupta et al., 2018) "*Driving directions to the Eagles game*" is composed of a GET_DIRECTIONS intent and a GET_EVENT one nested in a tree structure (Figure 1).

---

[1] The dataset can be downloaded at https://fb.me/TOPv2Dataset

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5090–5100,
November 16–20, 2020.

On the other hand, most of these deep neural models require a large amount of annotated training data to achieve a good performance, which is aggravated by the fact that virtual assistants need to support hundreds of tasks each mandating a separate set of labeled training samples. Therefore, in order to support more diverse use cases without an excessive need in human annotated data, it becomes crucial that the semantic parsing model has the capability to generalize to new *tasks* or *domains* (reminder, music, etc.) with a limited number of labeled samples in the target domain. While transfer learning methods have been proposed for traditional sequence tagging models (Jaech et al., 2016; Goyal et al., 2018) to help facilitate learning slot filling models for domains with less annotated data, the efforts have been lacking when it comes to developing compositional semantic parsers in such low-resource domain adaptation setting.

Therefore, we in this paper show it is possible to build compositional task-oriented semantic parsers for low-resource domains (e.g. 25 training samples per intent or slot label), and propose a solution that is competitive against supervised models trained with 10x more data. We identify two key factors for successfully adapting task-oriented semantic parsers to new domains: better **representation learning** and better **training techniques**.

We first show that pre-trained language representations are critical in the low-resource setting for the model to quickly generalize to new intents and slots. Furthermore, most pre-trained language representations used in previous work such as BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2019) are encoder-only models, and are hence not ideal for a compositional parser with an encoder-decoder (seq2seq) architecture. We therefore propose to use BART (Lewis et al., 2020), a pre-trained seq2seq model that can be used to initialize both the encoder and decoder of our semantic parser, which significantly outperforms other pre-trained representations such as RoBERTa.

More importantly, these large pre-trained models are sometimes known to pose challenges to fine-tuning with very few training samples. In order to better adapt the semantic parser to low-resource domains, we employ *optimization-based meta-learning* (Finn et al., 2017) to improve generalization of the BART model trained on the source domains, making it easier to be fine-tuned on the target domains with very little training data.

Finally, in order to evaluate our approach, we collect a multi-domain compositional task-oriented semantic parsing dataset (`TOPv2`), based on the original `TOP` (Gupta et al., 2018) dataset. In addition to the *navigation* and *event* domains found in `TOP`, our `TOPv2` dataset has 6 new domains: *alarm, messaging, music, reminder, timer*, and *weather*, with more than $137k$ new samples. We conduct extensive experiments on this new dataset, showing that our proposed method significantly outperforms all the baseline models in the low data regime. We further show that our model achieves competitive performance compared to supervised state-of-the-art models while using 10x less data.

2 Problem Setup

We first formally define the task of domain adaptation (or *domain scaling*) for task-oriented semantic parsing. As illustrated in Figure 1, the task-oriented parsing task aims to predict the semantic parse given the *user utterance* (or *query*). The *semantic parse* has a tree structure and is represented using a serialized tree representation defined in the `TOP` dataset (Gupta et al., 2018). Following recent state-of-the-art practices (Rongali et al., 2020), we formulate the problem as a sequence-to-sequence (seq2seq) task, where the utterance is treated as the *source sequence* $\mathcal{S}$, while the semantic parse serves as the *target sequence* $\mathcal{T}$.

In our domain scaling setting, the goal is to develop a semantic parser with minimal training examples on a set of new *target domains*.[2] Formally, denote $\mathbb{T} = \{D^T_1, ..., D^T_N\}$ as the set of N target domains. On the other hand, we assume access to training data for a number of *source domains*, which can be used to help build models on the target domains. Denote $\mathbb{S} = \{D^S_1, ..., D^S_M\}$ as the set of M source domains. For each source domain $d \in \mathbb{S}$, there exists a set of annotated training data $D^d = (\mathcal{S}_d, \mathcal{T}_d)$ where $\mathcal{S}_d$ and $\mathcal{T}_d$ are the utterance and semantic parse, respectively.

For a target domain $t \in \mathbb{T}$, however, only a very limited number of training instances exist. As domains differ drastically in terms of complexity (shown in Table 1), we would expect models to require varying amount of training data for each. To normalize for such effects, we introduce a new task-specific measure of training set size: **SPIS**, which

---

[2] Zero-shot transfer is very challenging since a new domain has unique otherwise unseen intents and slots. Previous work (Lee and Jha, 2019) on zero-shot transfer relied on additional prior knowledge such as slot descriptions.

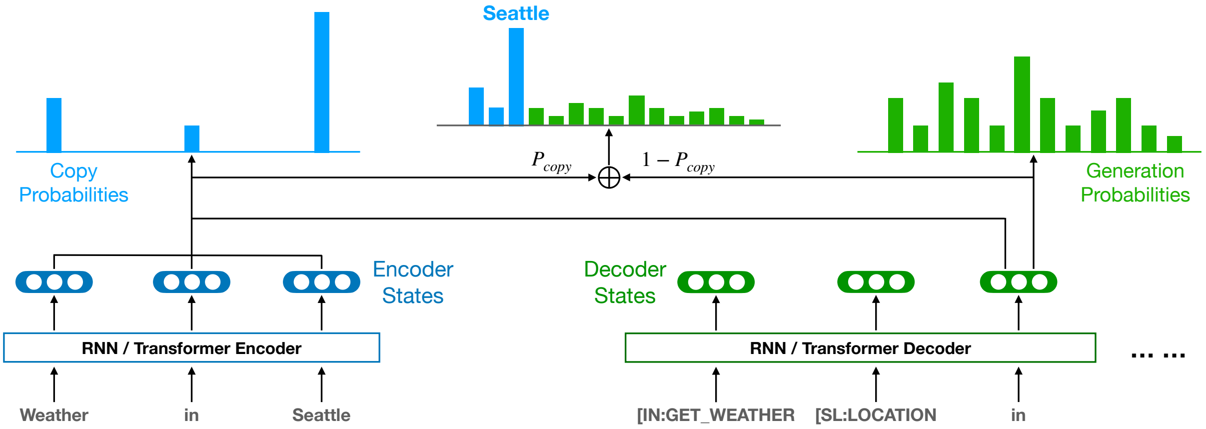

Figure 2: Overview of our sequence-to-sequence architecture with copy pointer (SEQ2SEQ-COPYPTR). Note that the target sequence is slightly different from original `TOP` dataset, as explained in the pre-processing steps in §5.2.

stands for *samples per intent and slot*, indicating the number of training samples available for each intent and slot label. Traditionally, at least a few hundreds of training samples are needed for each label to successfully train a deep neural semantic parser (see §5.3). In the low-resource setting, in contrast, we focus on a scenario with much less training data at 25 SPIS. That is, for each intent and slot in the target domain, 25 training samples are required[3]. (See §5.4 for discussions on more SPIS settings.) To benchmark the performance on the low-resource domains, we compare with various high-resource supervised baselines trained with much more data up to 500 or 1000 SPIS.

3 Base Model

In this section, we present our core model architecture. Our meta-learning technique will be introduced in Section 4. We follow recent state-of-the-art approaches (Rongali et al., 2020; Aghajanyan et al., 2020) and adopt a seq2seq model as our base architecture (SEQ2SEQ-COPYPTR), derived from the Pointer Generator Network (See et al., 2017). The base architecture is shown in Figure 2.

For an input sequence $\mathcal{S} = [w_1, w_2, \ldots, w_n]$, the encoder first encodes it into a series of hidden vectors (encoder states) $[\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_n]$. The encoder states are then passed to an decoder that autoregressively produces target tokens $\boldsymbol{o}_t$ for each timestamp t. Specifically, the decoder first outputs a hidden decoder state $\boldsymbol{d}_t$ based on the decoder states from previous timestamps as well as all encoder states:

$$\boldsymbol{d}_t = Decoder(\boldsymbol{e}_1, \ldots, \boldsymbol{e}_n; \boldsymbol{d}_1, \ldots, \boldsymbol{d}_{t-1})$$

In task-oriented semantic parsing, the target sequence consists of two types of tokens: *utterance tokens* that always come from the source sequence, and *ontology tokens* that represent intent and slot labels. Therefore, two probability distributions are formulated and combined in order to produce the output token, namely the *copy probability* and the *generation probability*. The generation probability $\boldsymbol{g}_t$ is produced by the decoder by mapping the decoder state onto the output vocabulary, which only includes ontology tokens but not utterance tokens.

$$\boldsymbol{g}_t = softmax(OutputEmbed(\boldsymbol{d}_t))$$

The copy probability $\boldsymbol{c}_t$, on the other hand, indicates whether to copy one of the source tokens as the decoder output for timestamp t, and is predicted by using $\boldsymbol{d}_t$ as the query to perform a multi-head attention (MHA, Vaswani et al., 2017) over the encoder states.

$$\begin{aligned} \boldsymbol{c}_t, \boldsymbol{\omega}_t &= \mathrm{MHA}(\boldsymbol{e}_1, \ldots, \boldsymbol{e}_n, Linear(\boldsymbol{d}_t)) \\ P_{copy} &= sigmoid(Linear([\boldsymbol{d}_t; \boldsymbol{\omega}_t])) \end{aligned}$$

where $\boldsymbol{c}_t$ are the attention weights indicating the copy probability and $\boldsymbol{\omega}_t$ is the attended vector used to compute a scalar P_{copy} to weigh between copying and generation when constructing the final output token $\boldsymbol{o}_t$:

$$\boldsymbol{o}_t = P_{copy} \cdot \boldsymbol{c}_t + (1 - P_{copy}) \cdot \boldsymbol{g}_t$$

3.1 Pre-trained Language Representations

In §3, we introduce a general model framework where the encoder and decoder can be any RNN

---

[3] Note that one sample may contain multiple intents and slots. Empirically, only around 10 distinct samples are selected for each intent and slot (Table 2).

or Transformer (Vaswani et al., 2017) architecture. In practice, pre-trained language representations such as BERT (Devlin et al., 2019) have greatly improved performance across many NLP tasks. For task-oriented semantic parsing, in particular, Rongali et al. (2020) achieved state-of-the-art performance with RoBERTa (Liu et al., 2019). Departing from previous work, we argue that such encoder-only pre-trained models are not the most suitable choice for a seq2seq semantic parser, as it couples a pre-trained encoder with a randomly initialized decoder, resulting in challenges during training. Instead, we adopt BART (Lewis et al., 2020), a pre-trained seq2seq model, which can be used to initialize both the encoder and decoder in our SEQ2SEQ-COPYPTR model.

3.2 Training Stages

Finally, we clarify the terminology adopted for various training stages. Several training strategies exist for domain adaptation. For instance, one can employ *joint training* that trains a single model with all the available data on both source and target domains (with optional upsampling on the target domains). Another approach, which we found superior (Table 2), is the *pre-training + fine-tuning* strategy, where a model is first trained on the source domains and then fine-tuned on the low-resource target domains.

On the other hand, as pre-trained language representations such as RoBERTa or BART are adopted, the latter strategy becomes a 3-stage training process: train RoBERTa/BART; fine-tune on the source domains; fine-tune again on the target domains. To avoid confusion, we standardize the terminology used to refer to each of these three stages. The first stage, which is out of scope for this paper, is the **pre-training** stage where self-supervised language representations are learned. Then, it is fine-tuned on the source domains. We call this stage **source training** to avoid ambiguity with the final stage. In the final stage, which is denoted as **fine-tuning**, the source-trained model is fine-tuned again on the target domains. It is possible to omit the second stage and directly fine-tune pre-trained RoBERTa/BART on the target domains. As shown in Table 2, however, source-training significantly improves the final performance.

4 Meta Learning

As mentioned in §3.2, model training for low-resource domain adaptation consists of two stages: source training and fine-tuning (or target training), where the model (initialized with pre-trained representations) is first trained on the source domains and then fine-tuned on each low-resource target domain. As target domain training data is scarce, it might be challenging to effectively fine-tune a large BART model with only 25 samples per intent and slot. One reason is that traditional source training optimizes the model performance solely for the source domains, which may result in a model with strong performance on the source domains but less than ideal for transferring to new target domains via fine-tuning.

Therefore, we propose to replace source training with optimization-based meta-learning (Finn et al., 2017) to improve generalization. Instead of directly optimizing towards source domain accuracy, meta-learning, when trained on the source domains, looks for a good *initialization* $\boldsymbol{\theta}_0$ that can easily be adapted to new tasks (domains) with minimal fine-tuning. In order to learn a model that is easier to be fine-tuned on new tasks with a small amount of training data, meta-learning adopts a different training objective that explicitly optimizes for generalization by *repeatedly simulating low-resource fine-tuning* during training.

Specifically, in each iteration (episode), the MAML (Finn et al., 2017) algorithm samples two batches of training samples from a source domain $d \in \mathbb{S}$: D_s^d and D_q^d, conventionally named the *support* and *query* set respectively. In standard source training, one simply computes the loss on D_s^d and takes a gradient step to update the model. In MAML, however, low-resource fine-tuning is simulated at each training episode. Let $\boldsymbol{\theta}$ denote the model parameters being meta-learned, MAML first takes a gradient step on D_s^d that leads to:

$$\boldsymbol{\theta}^d \leftarrow \boldsymbol{\theta} - \eta \nabla_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta}; D_s^d)$$

where η is the *inner* learning rate. $\boldsymbol{\theta}^d$ can be viewed as a minimally fine-tuned model with only one fine-tuning iteration on the source domain d. We then use D_q^d to evaluate how well $\boldsymbol{\theta}^d$ generalizes to new unseen data and update of our original model $\boldsymbol{\theta}$ with this generalization loss:

$$\begin{aligned} \boldsymbol{\theta} &\leftarrow \boldsymbol{\theta} - \alpha \nabla_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta}^d; D_q^d) \qquad (1) \\ &= \boldsymbol{\theta} - \alpha \nabla_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta} - \eta \nabla_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta}; D_s^d); D_q^d) \end{aligned}$$

Table 1: Statistics of the `TOPv2` dataset. #Int: *number of intents*; #Slt: *number of slots*; Flat%: *percentage of flat (depth* ≤ 2*) queries*; Depth: *average depth of queries*. (The example in Figure 1 has a depth of 4.)

where α is the *outer* learning rate. Such updates are performed repeatedly on all source domains to simulate the low-resource fine-tuning scenario, which eventually learns a better initialization that only requires a small amount of data for fine-tuning to achieve good performance on the target domains. Also note that one can accumulate gradients from multiple episodes (domains) before updating the model $\boldsymbol{\theta}$, but we choose to update $\boldsymbol{\theta}$ after every episode following Antoniou et al. (2019).

Finally, MAML requires the computation of second derivatives when unrolling Equation (1), which consumes too much memory for large models such as BART. Therefore, we instead adopt a first-order meta-learning algorithm, Reptile (Nichol et al., 2018), which has shown comparative or even superior performance than MAML despite its simplicity (Dou et al., 2019). In Reptile, $k > 1$ batches of training instances $D_1^d, \ldots, D_k^d$ are sampled for a source domain $d \in \mathbb{S}$ in each episode, and the model is updated as follows:

$$\boldsymbol{\theta}^d \leftarrow \mathrm{Adam}^k(\boldsymbol{\theta}; D_{1..k}^d, \eta),$$
$$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \alpha(\boldsymbol{\theta}^d - \boldsymbol{\theta}),$$

where $\mathrm{Adam}^k(.; D_{1..k}^d, \eta)$ denotes performing k consecutive updates on $D_1^d, \ldots, D_k^d$ using Adam (Kingma and Ba, 2015) with inner learning rate η. Note that this surprisingly simple algorithm becomes equivalent to standard source training when $k = 1$. When $k > 1$, however, Reptile behaves differently and performs similar updates compared to MAML as shown by Nichol et al. (2018) using Taylor Series analysis.

5 Experiments

In this section, we first introduce `TOPv2`, a multi-domain task-oriented semantic parsing dataset we are releasing to the community. It is an extension to the `TOP` dataset with 6 additional domains and $137k$ new samples. We then outline the setup of our low-resource domain scaling experiments in §5.2, and present the experimental results in §5.3.

5.1 The `TOPv2` Dataset

While multiple datasets exist for task-oriented semantic parsing such as ATIS (Price, 1990) or SNIPS (Coucke et al., 2018), the `TOP` dataset (Gupta et al., 2018) is unique in that it contains compositional queries with complex and hierarchical structures (Figure 1). On the other hand, the queries from the `TOP` dataset are limited to only two domains, namely *navigation* and *event*, making it unsuited for domain scaling experiments. To this end, we extend the `TOP` dataset with 6 additional domains: *alarm*, *messaging*, *music*, *reminder*, *timer*, and *weather*, with a good mixture of simple (flat) and complex (compositional) domains. Table 1 shows some basic statistics of the `TOPv2` dataset. We follow the same process of dataset collection as outlined in the `TOP` paper.

№	Target Domain	reminder			weather

5.2 Experimental Setup

To evaluate our model on low-resource domain scaling for both complex and simple (flat) domains, we use *reminder* and *weather* as the target domains. The remaining 6 domains are used as source domains. As mentioned in §2, to study how much data is needed to achieve a good performance on the target domain, we adopt the SPIS strategy (samples per intent and slot) instead of selecting a fixed number of training samples for each target domain. In particular, we focus on a low-resource setting of 25 SPIS (see §5.4), where samples are randomly selected to ensure each intent and slot appears in at least 25 training instances. On the other hand, supervised models are trained with 500 or 1000 SPIS to assess the performance of our low-resource domain scaling model. For the source domains, all available training data is utilized.

Validation Set To perform model selection and early stopping, a validation set is adopted, which is also set to 25 SPIS for simplicity. In contrast, the supervised models utilize the entire validation set as shown in Table 2.

Data Preprocessing We first perform standard preprocessing such as lower-casing and tokenization. For models initialized with pre-trained language representations, BPE (Sennrich et al., 2016) tokenization is done to match that used by the pre-trained model. We do not tokenize ontology tokens (intents and slot labels) into BPE, but instead treat them as atomic tokens which are appended to the BPE vocabulary.

We then perform two additional preprocessing (canonicalization) steps, consistent across all models. First of all, note that certain utterance tokens do not contribute to the semantics of the query. For instance, in Figure 1, the phrase *Driving directions to* under `IN:GET_DIRECTIONS` and *the* under `IN:GET_EVENT` can be omitted as their semantics are already captured by the intent labels. Therefore, we only retain utterance tokens under *leaf slots* (*Eagles* and *game* in Figure 1) while removing all others. Furthermore, we sort the children of each node in the semantic parse tree in alphabetical order of the label, since the order of the children does not alter its semantic meaning. In the case of Figure 1, `SL:NAME_EVENT` and `SL:CAT_EVENT` will be reordered. We call the final semantic parse after these two preprocessing steps the **canonical form**, which will be used in all experiments.

5.3 Results and Discussions

Our main experimental results are summarized in Table 2. LSTM-CopyPtr utilizes BiLSTMs as both the encoder and decoder, which are commonly adopted in practice due to their smaller model size, faster inference time, and sometimes better performance when training data is sufficient (Rongali et al., 2020). RoBERTa-CopyPtr is the most similar to the model proposed by Rongali et al. (2020)[4], which uses the RoBERTa encoder and a randomly initialized transformer decoder. BART-COPYPTR is our proposed model (§3) which leverages BART to initialize both the encoder and decoder.

On the other hand, FT in the table refers fine-tuning or target training, and a FT only model trains solely on the 25 SPIS training data on a target domain. In contrast, ST+FT models first go through source training in which the models are trained on all source domain data, and are then fine-tuned on the target domain. JT stands for joint training, where the training data of the source and target domains are concatenated to jointly train the model. Since the target domains have very few samples (25 SPIS) compared to the source domains, upsampling can be conducted. For instance, JT 100x indicates that the target domain samples are duplicated 100 times before concatenated with the source domains. Finally, Reptile+FT is our meta-learning approach, where standard source training is replaced with Reptile, as described in §4.

Pre-trained language representations As demonstrated in Table 2, pre-trained representations is crucial in the low-resource setting with a very small amount of training data, where the knowledge encoded in these representations can dramatically improve the model's generalization. In our experiments, BART outperforms LSTM by 17% in the ST+FT setting (row 10 & 12), and 30% in the FT only setting (row 5 & 6).

Furthermore, we demonstrate that BART is a superior choice over RoBERTa to initialize our SEQ2SEQ-COPYPTR model, indicating that pretraining both the encoder and decoder works well for semantic parsing, even when the pretraining was based on denoising English sentences without using any logical forms. Comparing row 11 and 12, we observe a performance gap of 4.3% between BART and RoBERTa on the *reminder* domain, which is more complex with more labels and deep compositional structures. A closer look on the reminder domain also reveals that BART outperforms RoBERTa by a larger margin on compositional queries than flat ones (8.7% relative improvement on compositional queries vs. 6.3% on flat; numbers not shown in table).

Importance of source training As shown in Table 2, source training also plays a critical role in low-resource domain scaling. With the non-pretrained LSTM model, source training can improve the performance from 33.8% to 55.4% (row 5 & 10), showing that source training can teach the model important inductive biases for the semantic parsing task. With BART, one hypothesis might be that source training is no longer important as BART learns a sufficiently good representation to provide model generalization. Nevertheless, this is not the case as revealed by row 6 and 12, where source training improves the BART model's performance by 8.4%.

One possible explanation is that the model can learn useful knowledge about the semantic spaces (tree structures) as well as certain intents and slots during source training. For instance, the improved accuracy on *reminder* may be explained in part by its similarity to various source domains such as *alarm* and *timer*. In addition, the target domains share some common slots with the source domains, such as `SL:DATE_TIME` and `SL:LOCATION`. When exposed to many more instances of these slot values on the source domains, the model can learn to better capture the semantics of the slots, leading to enhanced performance.

Joint training vs. fine-tuning In this paper, we adopt the source training + fine-tuning strategy. An alternative is joint training where the training data is combined from the source and target domains. Optionally, we can also upsample the target domains training data to increase model exposure. As shown in Table 2 (row 7-9, 12), however, joint training performs worse than ST+FT. It is a consistent empirical observation yet a curious one that fine-tuning achieves superior performance than joint training, which may deserve further investigation. Nonetheless, joint training does not suffer from the *forgetting* issue on the source domains, and may be the preferred choice for building a single model for both the source and target domains.

Meta-learning Finally, we show that meta-learning can improve model training for transferring to low-resource domains (row 12 & 13). When standard source training is replaced with Reptile, the accuracy of the BART model is substantially improved on both target domains and the best performance is achieved across all low-resource models (+2.1%). Even compared to supervised mod-

---

[4] Our implementation (§3) is not identical to Rongali et al. (2020); please refer to their paper for the differences.

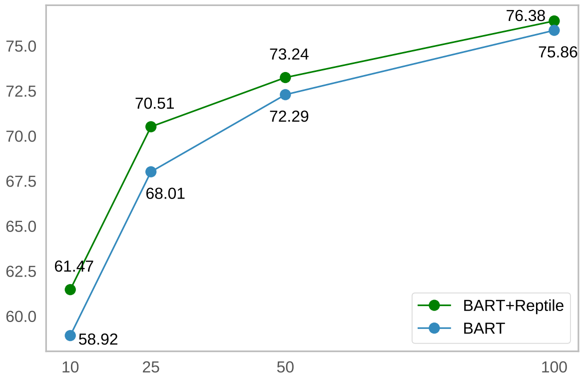

Figure 3: Performance of BART-CopyPtr (ST+FT) and BART-CopyPtr (Reptile+FT) at 10, 25, 50 and 100 SPIS on the *reminder* domain.

els trained with 500 SPIS, a 10-fold data increase, our Reptile+BART model outperforms the LSTM-based model, and is only 3.6% away from the state-of-the-art RoBERTa-based one.

5.4 Accuracy vs. SPIS

Figure 3 shows the performance on the *reminder* domain of our two best models, BART-CopyPtr (ST+FT) and BART-CopyPtr (Reptile+FT), at 10, 25, 50 and 100 SPIS. For each SPIS setting, we take the model with the best validation set accuracy over 5 runs. Similar to the main experiment, the validation set is selected using the same SPIS setting as the training set.

First, we observe that meta-learning proves to be beneficial for the extremely low resource setting and improves the performance of BART by about 2.5% at both 10 and 25 SPIS. The performance gap is gradually reduced as the amount of training data increases. Furthermore, we notice a steeper performance drop for both models when we go below 25 SPIS, which gives us an idea of the amount of annotated data required to achieve an acceptable performance on a new domain. In future work, we plan to push the boundary further to learn effective models with even less training data.

5.5 Implementation Details

For the LSTM models, both the encoder and decoder have 2 layers and a hidden size of 512. Dropout ($p = 0.4$) (Srivastava et al., 2014) is applied. Adam (Kingma and Ba, 2015) is used for optimization, with a learning rate of 10^{-3} for source training and 5×10^{-4} for low-resource fine-tuning. For RoBERTa models, the encoder is a 12-layer transformer with an embedding size of 768, while the decoder is a smaller transformer model with 3 layers and an embedding size of 256. For BART models, both the encoder and decoder follow the size of the pre-trained model with 12 layers and an embedding size of 1024. For all transformer-based models, Dropout ($p = 0.3$) is applied. Adam is again used for optimization, with a learning rate of 10^{-4} for source training and 5×10^{-5} for fine-tuning. In addition, the inverse square-root learning rate schedule is employed with a warmup period of 4000 updates for source training, and 2000 for fine-tuning. For meta-learning, we select $k = 5$ and a batch size of 32 for Reptile, with both inner (η) and outer (α) learning rates being 5×10^{-5}.

All models are trained for 100 epochs on the source domains with a batch size of 128 (except Reptile), using early stopping if the validation accuracy does not improve in the last 10 epochs. Fine-tuning is done for 2000 epochs, with a batch size of either 64 (LSTM and RoBERTa) or 32 (BART and meta-learning). Model validation is performed once every 10 epochs during fine-tuning, and stops early after 20 consecutive validations with no improvements. Our model is implemented with the *fairseq* framework (Ott et al., 2019) and trained on a Nvidia Telsa P100 GPU with 16GB memory.

6 Related Work

Task-Oriented Semantic Parsing has attracted attention from the research community since 1990s with the advent of the ATIS dataset (Price, 1990). Traditionally, the task is formulated as a joint text classification (intent prediction) and sequence tagging (slot filling) problem, and can be tackled with sequence labeling models such as RNNs (Mesnil et al., 2013; Liu and Lane, 2016). These models can only parse *flat* queries with one intent and non-nested slots. More recently, a number of studies propose alternative approaches for handling the more complex *compositional* queries using neural shift-reduce parsers (Gupta et al., 2018; Einolghozati et al., 2018) or seq2seq models (Jia and Liang, 2016; Rongali et al., 2020).

On the other hand, there have been research efforts on scaling task-oriented parsers to new domains with less training data (Jaech et al., 2016; Bapna et al., 2017; Fan et al., 2017; Goyal et al., 2018; Lee and Jha, 2019). These methods, however, only focus on the simpler flat queries. Our proposed method, in contrast, can effectively parse both flat and compositional queries for low-resource target domains.

Meta-Learning (Lake et al., 2015), or learning to learn, aims to learn a model that can quickly adapt to new tasks with a small amount of training data. In particular, Finn et al. (2017) propose MAML, an optimization-based meta-learning method, which learns a good parameter initialization suitable for faster adaptation to new tasks. As MAML requires to compute second derivatives, which are computation and memory intensive, there have been studies to use either first-order approximation such as first-order MAML and Reptile (Nichol et al., 2018), or implicit differentiation (Rajeswaran et al., 2019). Furthermore, meta-learning has also been applied to a number of NLP tasks lately (Gu et al., 2018; Dou et al., 2019; Mi et al., 2019; Qian and Yu, 2019; Sun et al., 2019).

7 Conclusion

In this work, we study the low-resource domain scaling problem for task-oriented semantic parsing. In particular, we focus on the 25 SPIS setting to investigate whether a model can effectively adapt to new *domains* with a very limited amount of training data. Our approach distinguishes itself from previous methods on two fronts. First of all, we argue the encoder-only pre-trained representations used in existing work are not ideal for the seq2seq model employed in task-oriented semantic parsing, and instead propose to use BART, a pre-trained model with an encoder-decoder architecture. More importantly, we adopt optimization-based meta-learning to improve the model's generalization to new target domains with very few training samples.

Our experiments show that our proposed method significantly outperforms all competing methods and achieves the best performance in the low-resource setting. Even when compared with supervised models trained with 500 SPIS, a 10-fold data increase, our best performing model remains competitive, and outperforms a state-of-the-art LSTM-based Pointer Generator Network (Rongali et al., 2020). Last but not least, we collect the `TOPv2` dataset, a large-scale multi-domain task-oriented semantic parsing dataset with 8 domains and more than $180k$ annotated samples to evaluate our models, which we release to the research community.

Abstract

We introduce a new task of rephrasing for a more natural virtual assistant. Currently, virtual assistants work in the paradigm of intent-slot tagging and the slot values are directly passed as-is to the execution engine. However, this setup fails in some scenarios such as messaging when the query given by the user needs to be changed before repeating it or sending it to another user. For example, for queries like 'ask my wife if she can pick up the kids' or 'remind me to take my pills', we need to rephrase the content to 'can you pick up the kids' and 'take your pills'. In this paper, we study the problem of rephrasing with messaging as a use case and release a dataset of 3000 pairs of original query and rephrased query. We show that BART, a pre-trained transformers-based masked language model with auto-regressive decoding, is a strong baseline for the task, and show improvements by adding a copy-pointer and copy loss to it. We analyze different trade-offs of BART-based and LSTM-based seq2seq models, and propose a distilled LSTM-based seq2seq as the best practical model.

1 Introduction

Virtual assistants have achieved very high accuracy in parsing queries for execution (Gupta et al., 2018), such as reciting the weather or setting a reminder. However, in some scenarios, parsing alone is not enough to execute a request as expected. For example, when the user says "Tell Alice I'll meet her in 10 minutes", executing the parsed message would send the tagged content "I'll meet her in 10 minutes" instead of a more appropriate message such as "I'll meet you in 10 minutes". The other scenario where rephrasing is needed to better represent the user's request is when the user asks "Remind me to brush my teeth tonight". A more natural response would be "OK, I'll remind you to brush your teeth tonight".

To make a virtual assistant sound more natural, it needs to rephrase the user's query content before executing it. The task is different from paraphrasing, as we do not want to change the user's wording, i.e., the language formality or choice of words. Instead, we need to make minimal syntactic changes to make the utterance sound natural. As a use case, we work on the messaging domain, where we focus on rephrasing a message that needs to be inferred from the user query. This domain is so named as it covers requests about sending and receiving text and instant messages. Unlike the confirmation case, the message rephrasing is more complicated and can involve syntactic, pronoun or verb changes. Note that our goal is not to paraphrase the user's message but to rephrase it minimally, making it sound more natural when being sent to another user. As such, we need to maintain the semantics and style of the original content.

Our contributions are as follows: (1) We introduce a new task and release a Message Content Rephrasing (MCR) dataset for this task consisting of 3k queries with tagged content and possible rephrases, (2) We explore various modeling approaches to achieve high accuracy on the MCR and modify existing pre-trained models to accommodate for the nature of this task, and (3) We show that distilling the pre-trained models into simple models can significantly close the performance gap.

2 Data

We first collected a task-oriented dataset of messaging utterances by asking our annotators to come up with natural scenarios in which a user wants to send a message to a second user.

We observed that the collected queries contained two distinct types of messaging content: 1) where

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5101–5108,
November 16–20, 2020.

the content needs to be rephrased (REPHRASE) and 2) where the content should be used verbatim (EXACT). As such, the utterances were sent to another set of annotators to mark the message content in the utterances, disregard the ones that do not contain one, and mark whether the utterance belongs to the EXACT or REPHRASE class. Two annotators needed to agree on the labelling for this task, with a possible third for disagreement resolution. In the event of no resolution after three annotators, the query was reviewed individually. Examples of each class is shown in Table 1 where the original content is tagged by brackets around it.

Next, we sent the utterances belonging to the REPHRASE class to a different set of annotators and asked them to rephrase the message content in a way that it would be natural to send to the second user without any additional context.

During annotation, our goal was to minimally rephrase a sentence, e.g., keeping the words and attributes (e.g., formality) of the original content as much as possible. In order to ensure high quality, we asked three annotators to independently rephrase the utterances. In around 30% of the cases, there was not a majority (i.e., two or more annotators agree) and we asked a fourth annotator to resolve. Most of the disagreements were due to changing words that did not need to be changed for minimal rephrasing but there were cases where the minimal rephrase was not obvious. We will discuss this further when introducing our metrics.

Overall, we have around 3k examples (almost half for each class) which we split by 70/20/10 for train/test/validation, respectively. We can see from the training data that rephrasing mostly involves making a question and/or changing the subject pronoun. There are other linguistically complex scenarios such as deciding when to use politeness strategies (e.g. "Could you pick up milk" as opposed to "Can you pick up milk?") among these queries as well. We decided that these complex edge cases were best addressed in future work. As such, we cluster the rephrasing into three main categories. In Table 1, the first example only needs a pronoun change, the second needs the form to be changed to a question, and the third needs both. We have also put the statistics for the changes in table 3. [1]

As mentioned earlier, there is a huge overlap between the source and target sequences. As such, rephrasing can be viewed as a post-editing task more than a generation task. In Table 2, we have showed some basic statistics about the training data for the REPHRASE class in MCR.

3 Evaluation

Our goal is to maximize the rephrasing accuracy while also maintaining a very high accuracy on the EXACT class. Our first metric is the Exact Match (EM) accuracy in which the predicted rephrase should be the same as the original content for the EXACT class and equal to the top rephrased candidate for the REPHRASE class. The downside of this metric is that for utterances such as 'ask her to pick up her phone', we would penalize rephrases such as 'can you pick up your phone' if the gold label was 'pick up your phone'. In order to smooth this metric, we also use EM_{any} in which the rephrased content is correct if it matches any of the provided annotations.

Since the required changes to rephrase the content are usually small, the BLEU score may not be useful. On the other hand, not all the wrong rephrases are equal, e.g., when the model hallucinates. Metrics such as BLEU can penalize these phenomena more than the EM metrics. We also use SARI (Xu et al., 2016), which is commonly used for text-editing tasks. It measures the average F1 score of three editing actions for ngrams: Keep, Add, and Delete.

4 Modeling Approaches

We assume that the gold tagging for the content inside the query is provided. Our base model is an LSTM seq2seq model with two-layers for both encoder and decoder using Glove (Pennington et al., 2014) initialized word embeddings (20k vocab size) concatenated with ELMo (Peters et al., 2018) embeddings to represent the tokens. We also use the pointer-generator mechanism (See et al., 2017), which can choose between copying from the source or generating new tokens using a pointer-attention mechanism. As we can see in Table 4, the copy mechanism is crucial in our task, as most of the tokens are copied from the source.

The copy pointer works as follows: We calculate two token output probabilities; one over the full vocab P^t_{vocab} using the standard softmax and another P^t_{copy} over the source tokens. To obtain P^t_{copy} we use a learned attention between the decoder

---

Query	Query	Rephrase
REPHRASE	Let Kira know [I can pick her up]	I can pick you up
REPHRASE	Message Donna and ask [when dinner is]	when is dinner
REPHRASE	message Brad and ask [if he has my keys]	do you have my keys
EXACT	Tell Jo [I will be on time]	I will be on time
EXACT	ask my boss [will I have to work on Friday]	Will I have to work on Friday

Table 1: Examples of queries and the rephrased utterance

Source	Target	Keep	Add	Delete
7.9	9.3	5.9	3.4	2.0

Table 2: Average Length and overlap between source and target

EXACT (no changes)	57%
REPHRASE (pronoun)	8%
REPHRASE (question)	13%
REPHRASE (pronoun+question)	22%

Table 3: Frequency of the needed changes

hidden h_d^t and the encoder outputs H_e^T. To generate the output, we weigh between copying and generation using a parameter α_{mix} which is also computed as a function of the hidden states, i.e., $P_{output}^t = (1 - \alpha_{mix})P_{vocab}^t + \alpha_{mix}P_{copy}^t$. More precisely:

$$q^t, K, V = h_d^t W_q^T, H_e^T W_k^T, H_e^T W_v^T$$

$$P_{copy}^t = softmax(q^T K)$$

$$\alpha_{mix}^t = sigmoid(W_{mix}.concat(q^T K, V)),$$

where q, K, V are the query, key and value, respectively, needed to calculate the attention and all the W_* matrices are learned parameters.

We have shown the LSTM results alongside ablation on the ELMo and Copying mechanism in Table 4. We can see that copying is crucial, especially for the EXACT class. We show the results for copying the content part of the source in the first row.

We also experiment with using BART (Lewis et al., 2019) for this task. BART is a powerful pre-trained seq2seq model trained on a de-noising objective over massive amount of web data. The training details are listed in the Appendix. During our initial experiments with BART, we realized it can replace proper nouns when rephrasing. Even though BART is a de-noising autoencoder and it has a high proclivity to copy the source through its encoder-decoder attention heads, it is still done over the whole vocabulary space (50k bpe tokens) and not the dozen of source tokens. To address this PEGASUS (Zhang et al., 2019) is pre-trained by generating a selected masked sentence from the input, where some of the selected sentences are not masked. We instead opt to add an explicit copying to BART in the fine-tuning stage.

Since the pre-trained model has no explicit copy mechanism, adding it naively during the fine-tuning phase as above is not effective. In this case, the decoder prefers to use the well-trained generator instead of a randomly initialized attention head for copying. We use two strategies to mitigate this: (1) We initialize the copying attention head with the average of the last layer's pre-trained decoder attention head, and (2) We also add an explicit loss that forces the decoder to use the copying mechanism when it can. For all the target tokens that can be found in the source, we add a hinge loss: $\lambda max(T - P, 0)$ to the cross-entropy loss which forces the copying probability P for those token to be above a threshold T. Hyper-parameters λ and T are optimized over the validation set, 0.25 and 0.9, respectively.

We show results using the BART large model in Table 4. Vanilla BART yields strong results compared with the LSTM seq2seq model for the rephrasing class but slightly lags for EM_{exact}, which requires pure copying. On the other hand, by adding the explicit copying to BART, it significantly improves the accuracy for both classes. Moreover, the gap between EM and EM_{any}, the biggest for BART, shows the proportion of errors due to subtle differences within the resolved annotation, as opposed to errors caused by serious problems such as hallucination.

Model	EM	EM_{any}	BLEU	EM_{exact}	$\text{EM}_{\text{rephrase}}$	SARI
Exact Copy	55.0	55.0	80.6	100	0	26.3
LSTM seq2seq	84.1	85.8	91.0	96.6	68.9	83.1
LSTM seq2seq w/o ELMo	81.3	82.4	89.4	93.8	66.1	81.3
LSTM seq2seq w/o Copy	54.7	55.8	78.9	62.3	39.2	69.7
BART	88.2	90.5	**96.0**	95.5	79.2	**86.4**
BART w copy	**89.3**	**92.1**	**96.1**	**96.9**	**80.0**	**86.5**
LSTM + seq-level KD	84.1	86.1	90.5	96.6	68.9	82.9
LSTM + seq-level KD + FT	85.4	87.2	94.0	95.5	73.0	83.7
LaserTagger	87.4	88.7	94.6	**97.2**	75.8	84.0

Table 4: Rephrasing Model Performance

Model	Semantic	Grammatical	Copy Related	Correct
BART	4%	13%	**24%**	59%
BART w Copy	14%	10%	8%	**68%**
Distilled LSTM	8%	**45%**	8%	39%
LaserTagger	**25%**	38%	4%	33%

Table 5: Prevalence of each category of the models' mispredictions

4.1 Distilling BART

Deploying models such as BART can be prohibitive for real-time applications. It has 514M parameters and around 10X average CPU inference latency compared with the LSTM model that has only 9.6M parameters. Unlike the pointer-generator LSTM model, BART with copying still exhibits an over-generation problem while the LSTM model makes many grammatical errors. As such, we look into Knowledge Distillation (KD) (Hinton et al., 2015) to transfer the language modeling capability of BART while keeping its copying behavior. Transferring the language model of massive pre-trained models into smaller models has been of high interest recently (Sanh et al., 2019; Turc et al., 2020; Sun et al., 2019). Knowledge transfer to simple models has also been discussed in lesser extent (Tang et al., 2019; Mukherjee and Awadallah, 2019). We use the sequence-level distillation introduced in (Kim and Rush, 2016) and train the LSTM model using the BART output. We found that fine-tuning on the gold labels after the KD step is also beneficial to the performance.

4.2 Edit vs Generate

In a pure generation framework, e.g., BART without the copying loss, all the tokens are generated from scratch. On the other side of the spectrum, models such as LaserTagger (Malmi et al., 2019) keep the original utterance and try to edit by adding or removing as needed. Adding the copying mechanism to our models can be considered a middle ground between editing and generation. We use the framework introduced in (Malmi et al., 2019) to edit the queries. It tags each word as Keep or Delete plus the optional phrase that needs to be added before it. We procure the list of phrases that yield high coverage over the training data in MCR. By using the top 100 phrases, we get coverage over 95% of the training data. Note that the verb conjugations needed in our problem can cause a lack of generalization when using such limited vocabulary.

We train a tagging model using the RoBERTa encoder (Liu et al., 2019) with one layer of MLP and CRF on top of it. We have listed the editing model performance on the last line of the Table 4. We can see that the editing yields better EM than the LSTM model but worse than BART. It is unsurprisingly the best model when no rephrasing is needed. On the other hand, the type of rephrasing errors it makes may be worse than the generative models as evidenced by the lower SARI score. For example, we find grammatical errors such as "did you I leave my sunglasses there". This is possibly caused by the added words being treated as categorical classes and not as words in a LM.

4.3 Error Analysis

We cluster the errors into three categories with an additional 'Correct' class which means that the prediction is correct but does not match any of the gold annotation exactly. A prominent example of the latter is the addition of politeness prefixes such as 'Could you' to the beginning of a request which we discussed earlier.

The Grammatical error class represents cases where the semantics can be understood but there are some grammatical errors such as a mismatch between the noun and verb forms (e.g. verb tense not matching noun person or number). In the Semantic error class, the meaning is seriously affected. Semantic errors cover two distinct sub-categories which both change the meaning of the message: hallucinating new content and omission of parts of the content. The Copy-related error category happens mostly for proper nouns that are not carried over as exact copies into the output. Since this is observed mostly in the vanilla BART, we decided to separate this category from the rest of the errors.

Note that if there are multiple classes of errors in the output, we pick the most prominent type of error for that utterance. In Table 5, we have shown the prevalence of each Category. We can see that in BART models, the majority of the ostensible errors are actually correct but the BART model without the explicit copying has the biggest copy-related errors among all models. Moreover, while Grammatical errors is the biggest category in both the distilled LSTM and the LaserTagger, the latter makes many more semantic errors which echoes our qualitative observation.

5 Related Work

5.1 Pre-trained Models for Generation

Pre-training transformers on massive amounts of unlabeled data has resulted in recent advances in language understanding and generation tasks (Devlin et al., 2019; Radford, 2018). Pre-trained encoder-decoder models have unified the benefits for both discriminative and generative tasks through pre-training as de-noising auto-encoders (Song et al., 2019; Lewis et al., 2019; Raffel et al., 2019). (Chen et al., 2019) fine tune such a big pre-trained model and add a copy pointer for a few shot structured tabular data summarization task.

5.2 Paraphrasing

Paraphrase generation using seq2seq models (Sutskever et al., 2014) has been recently discussed in the literature. Prakash et al. (2016) used residual LSTM seq2seq networks to perform paraphrasing. Unlike paraphrasing, in MCR, preserving the semantics of a message is necessary but not enough. Instead, we make minimal changes to make the sentence sound natural.

5.3 Sentence Editing and Simplification

Automatic post-editing is applied to paraphrases and machine translation (Grangier and Auli, 2018). Similar to this is Grammatical Error Correction which seeks to correct errors such as grammar and punctuation (Ng et al., 2014; Zhao et al., 2019). Sentence revision (Ito et al., 2019) extends this to cases for which major rewriting may be needed. Sentence simplification (Nisioi et al., 2017) aims at using techniques such as shortening the sentences to make a text more readable. On the other hand, style transfer is the task of making an utterance conform to a specific style such as formality (Logeswaran et al., 2018; Sennrich et al., 2016). From this perspective, the rephrasing task can be viewed as changing the style from the third-person to the second-person language and/or forming a question.

6 Conclusion

In this paper, we introduce a new task of message rephrasing in task-oriented dialog. We release a dataset, MCR, for this task and propose a new model (BART with copy). We show that adding an explicit loss to a pre-trained generative model during fine-tuning can improve the copying performance without hurting its generation power. We also show that by distilling the pre-trained model into a much smaller LSTM seq2seq model with copy pointer, we can significantly improve the LSTM seq2seq model's language model capability while still keeping its accurate copying.

Table 6: Training Parameters

A Appendix

Here, we describe the details regarding the training. In Table 6, we have shown the training details for all of our models. We use ADAM (Kingma and Ba, 2014) with Learning Rate (LR), Weight Decay (WD), and Batch Size (BSz) values that are listed for each model. We have also shown the number of epochs and the average training time for the full CS data using 4 V100 Nvidia GPUs.

In all of our BART experiments, we have used BART large from PyText[2] (Aly et al., 2018). When adding the copying loss to BART, we fine-tuned the hyper-parameters λ and T over [0.1, 1] and [0.5,1], respectively, with increments of 0.05. We also use the RoBERTa large from PyText for the LaserTagger experiment.

In our LSTM models, the encoder and decoder are 2-layer LSTMs with hidden dimension of 128 and 256, respectively. We also use dropout of 0.3 for all connections. The ELMo and GloVe embeddings have dimesions of 512 and 200, respectively, and we use the top 8k words in GloVe as our vocabulary.

Abstract

Sentence simplification aims to make sentences easier to read and understand. Recent approaches have shown promising results with encoder-decoder models trained on large amounts of parallel data which often only exists in English. We propose a zero-shot modeling framework which transfers simplification knowledge from English to another language (for which no parallel simplification corpus exists) while generalizing across languages and tasks. A shared transformer encoder constructs language-agnostic representations, with a combination of task-specific encoder layers added on top (e.g., for translation and simplification). Empirical results using both human and automatic metrics show that our approach produces better simplifications than unsupervised and pivot-based methods.

1 Introduction

Sentence simplification aims to reduce the linguistic complexity of a text whilst retaining most of its meaning. It has been the subject of several modeling efforts in recent years due to its relevance to various applications (Siddharthan, 2014; Shardlow, 2014). Examples include the development of reading aids for individuals with autism (Evans et al., 2014), aphasia (Carroll et al., 1999), dyslexia (Rello et al., 2013), and population groups with low-literacy skills (Watanabe et al., 2009), such as children and non-native speakers.

Modern approaches (Zhang and Lapata, 2017; Mallinson and Lapata, 2019; Nishihara et al., 2019; Dong et al., 2019) view the simplification task as monolingual text-to-text rewriting and employ the very successful encoder-decoder neural architecture (Bahdanau et al., 2015; Sutskever et al., 2014). In contrast to traditional methods, which target individual aspects of the simplification task, such as sentence splitting (Carroll et al. 1999; Chandrasekar et al. 1996, inter alia) or the substitution of complex words with simpler ones (Devlin, 1999; Kaji et al., 2002), neural models have no special purpose mechanisms for ensuring how to best simplify text. They rely on representation learning to *implicitly* capture simplification rewrites from data, i.e., examples of complex-simple sentence pairs.

While large-scale parallel datasets exist for English (Xu et al., 2015; Zhang and Lapata, 2017) and Spanish (Agrawal and Carpuat, 2019), there is a limited amount of simplification data for other languages. For example, Klaper et al. (2013) automatically aligned 7,000 complex-simple German sentences,[1] and Brunato et al. (2015) released 1,000 complex-simple Italian sentences. But data-driven approaches to simplification, in particular popular neural models, require significantly more training data to achieve good performance, making these datasets better suited for testing or development purposes. Unsupervised approaches (Surya et al., 2019; Artetxe et al., 2018) which forgo the use of parallel corpora are an appealing solution to overcoming the paucity of data. However, in this paper we argue that better simplification models can be obtained by taking advantage of existing complex-simple data in a high-resource language, and bilingual data in a low-resource language (i.e., a language for which no parallel simplification corpus exists).

Drawing inspiration from the success of machine translation (Firat et al., 2016b; Blackwood et al., 2018; Johnson et al., 2017), we propose a modeling framework which transfers simplification knowledge from English to another language while generalizing across language and task barriers during training. The backbone of our model is an encoder-decoder transformer (Vaswani et al., 2017) trained using multi-task learning to either translate, autoencode, simplify, or language model in both high-

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5109–5126,
November 16–20, 2020.

and low-resource languages. Regardless of the task or language, we employ the same base encoder on top of which *task-specific* transformer layers are added, while *language-specific* transformer decoders are used to generate the output sequence. Since the same base encoder is used for all tasks and languages, the model learns task- and language-agnostic representations. A beneficial side-effect is that the proposed architecture can be trained using one language and tasked to simplify another.

As simplifications for multiple languages can be produced within the *same* model, our approach is more scalable compared to pivot-based methods (Mallinson et al., 2018; Conneau et al., 2018). The latter would first translate the complex sentence into a high-resource language, apply a monolingual simplification model, and then translate back the output to the original language. We avoid having to train multiple models and make *multiple* hops, where each hop can add noise and latency, and instead develop a *one-hop* crosslingual zero-shot approach. We evaluate our model using English as our high-resource language and German as our low-resource language on two test sets from different domains, and with different end-users in mind. These include TextComplexityDE (Naderi et al., 2019), a recently created corpus of German Wikipedia sentences deemed complex by second language German learners. We also release a second dataset which contains manual simplifications of articles taken from GEOlino[2], a popular children's magazine. Empirical results using both human and automatic metrics show that our approach produces better simplifications than both unsupervised and pivot-based methods.

Our contributions in this paper are threefold: (1) a cross-lingual architecture which allows the transfer of simplification knowledge from high- to low-resource languages, alleviating the paucity of training data for monolingual simplification; (2) a comprehensive evaluation framework using automatic metrics and human judges; and (3) the release of a dataset in German which we hope will facilitate further research in automatic simplification.[3]

2 Related Work

Simplification The majority of previous work has focused on English, using large-scale datasets like Newsela and Wikipedia (Xu et al., 2015). One of the first neural network approaches to simplification was presented in Zhang and Lapata (2017) who use an encoder-decoder LSTM, trained with reinforcement learning, to optimize for grammaticality, simplicity, and adequacy. Dong et al. (2019) use a Programmer-Interpreter (Reed and de Freitas, 2016), which receives the source sentence as an input, and applies a sequence of edit operations (add, delete, keep). Kriz et al. (2019) propose to rerank a diverse set of simplifications according to fluency, adequacy, and simplicity. Martin et al. (2020a) introduce a simplification model which allows the user to control the generated output and in follow-on work (Martin et al., 2020b) they create multilingual paraphrasing datasets for training their model. Palmero Aprosio et al. (2019) explore different ways to to incorporate non-parallel simplification data to expand small scale training data, including autoencoding and backtranslation.

Translation data, in the form of paraphrases, has also been incorporated into simplification models leading to significant improvements. Guo et al. (2018) use multi-task learning to augment the limited amount of simplification training data. In addition to training on complex-simple sentence pairs, their model employs paraphrases, created automatically using machine translation. Zhao et al. (2018) augment a Transformer-based simplification model with lexical rules obtained from Simple PPDB (Pavlick and Callison-Burch, 2016), a database of paraphrase rules, automatically annotated with simplicity scores.

Unlike previous approaches, we do not train models to create training data, either via backtranslation or extracting paraphrases. Instead, our model is able to train directly on existing datasets, saving computation power and time. In the future, it would be interesting to explore whether additional datasets or tasks improve simplification performance.

Crosslingual Generation Cross-lingual transfer learning-based approaches have originated in machine translation. Dong et al. (2015) translate from one source language to multiple target languages (one-to-many) adding a separate decoder for each. Follow-on work (Luong et al., 2016; Firat et al., 2016a) performs translation with multiple encoders and decoders (many-to-many). Johnson et al. (2017) and Ha et al. (2016) train multilingual models where all languages share encoder and de-

---

[3] Our code and dataset can be found at `http://www.github.com/Jmallins/ZEST`.

coder parameters, and language tags (prepended to the source sentence) are used to specify the target.

Multilingual models are also capable of translating between unpaired languages, thereby performing zero-shot translation (Firat et al., 2016b; Johnson et al., 2017; Ha et al., 2016). Blackwood et al. (2018) propose sharing all parameters but the attention mechanism, while Lu et al. (2018) develop a shared "interlingua layer" at the interface of language-specific encoders and decoders. Advances in unsupervised machine translation (Artetxe et al., 2018; Lample et al., 2018) have further spurred interest in modeling sequence-to-sequence problems without a parallel corpus. Surya et al. (2019) learn from unpaired simple and complex English sentences using a shared encoder, two decoders, denoising, backtranslation and discrimination-based losses. Zhao et al. (2020) propose a similar setup, they create a denoising objective by using simple PPDB, replacing simple phrases with complex phrases. Reinforcement learning is further used to reward the fluency, adequacy and simplicity.

While zero-shot approaches are effective for translating between unpaired languages, they do not consider the case where there exists *no parallel* data for a language. For simplification, we assume that there is no parallel corpus in the low-resource language (e.g., complex-simple German). Furthermore, preliminary results showed that zero-shot translation approaches (Johnson et al., 2017) which prepend a tag in the source sentence — this tag would indicate the simplification task in our case — perform poorly, basically resulting in the source sentence being copied over with no changes made. We circumvent this by replacing tags with task-specific transformer encoder layers which are added on top of the base encoder. This proposed architecture allows us to transfer supervision signals across languages and is potentially useful for other generation tasks, including question generation (Kumar et al., 2019) and sentence compression (Shen et al., 2018; Duan et al., 2019).

3 Zero-shot Simplification

We first define a basic encoder-decoder Transformer before adapting it for zero-shot crosslingual simplification with multi-task learning.

Task	Source Language	Target Language	Target Domain
Translate	HR	HR	complex
Translate	LR	LR	simple
Translate	HR	HR	simple
Translate	LR	LR	complex
Translate	HR	LR	complex
Translate	LR	HR	complex
LM	None	HR	complex
LM	None	HR	simple
LM	None	LR	complex
LM	None	LR	simple
Simplify	HR	HR	simple

Table 1: Training tasks and their instantiations.

3.1 Encoder-Decoder

Given a source sentence $X = (x_1, x_2, ..., x_{|X|})$, our model learns to predict target $Y = (y_1, y_2, ..., y_{|Y|})$, where Y could be a translation (e.g., from English to German) or a simplification (e.g., from complex to simple English). Inferring target Y given source X can be modeled as a sequence-to-sequence learning problem (Bahdanau et al., 2015). Our approach adopts the Transformer's multi-layer and multi-head attention encoder-decoder architecture (Vaswani et al., 2017). The Transformer encoder has n layers (denoted L_i for layer i), which transform the input sequentially, $X^{l+1} = L_i(X^l)$, to yield representations $X^N = L_{1:N}(X)$. For more details regarding the Transformer layer, we refer the reader to Vaswani et al. (2017). The decoder is composed of a stack of identical layers. In addition to self-attention the decoder attends to the source sentence X^N. Encoder and decoder stacks are trained to minimize the cross-entropy loss of Y given X:

$$\mathcal{L}_{\text{CE}} = -\sum_{i=1}^{|Y|} \log p(y_i | y_{<i}, X^N; \theta) \qquad (1)$$

3.2 Multi-task Learning

We define a multi-task crosslingual setup where the model is trained on four basic tasks; namely translation, autoencoding, language modeling, and simplification. We train on different instantiations of these tasks depending on the *source language* which can be high-resource (HR; e.g., English) or low-resource (LR; e.g., German), the *target language* (which is again HR or LR), and the *output domain* which can be simple or complex. We assume we only have monolingual simplification data in the high-resource language and that we have bilingual translation data only in the complex domain. Table 1 has a breakdown of the tasks we consider, with a more detailed description below.

Simplification is the backbone of the model and consists of a complex source sentence which must be transformed into a simple sentence, while still retaining the original meaning. We assume we only have parallel training data in the high-resource language (see last row in Table 1).

Translation consists of a source sentence, which must be translated into the target language while retaining the meaning of the source. By training on translation data, our model learns language-agnostic representations which are helpful for simplifying in the low-resource language.

Autoencoding refers to translating between the same language, as seen in Table 1. As it is trivial to autoencode with attention, we apply source token dropout, where randomly selected source tokens are replaced with a special DROP token (Lample et al., 2018). We apply this dropout to all tasks (translation, autoencoding, and simplification). Additionally, this task allows us to incorporate monolingual non-parallel simple data from the low-resource language.

Language Modeling has no source sentence; instead the decoder must learn to predict the next token based on its history. This task also allows us to incorporate monolingual non-parallel simple data from the low-resource language.

Domains in our case our two, the simple domain which consists of text that is easy to read and the complex domain where text has not been explicitly written for ease of reading. Introducing domains to the model allows us to further inject knowledge about monolingual non-parallel simple sentences from the low-resource language. We use the target audience of the data to determine if it is simple or complex (e.g., if the text comes from Simple Wikipedia or a children's book it is representative of simple language). In practice, there often exists only limited amounts of non-parallel simple sentences in the low-resource setting, highlighting the difficulty of the task.

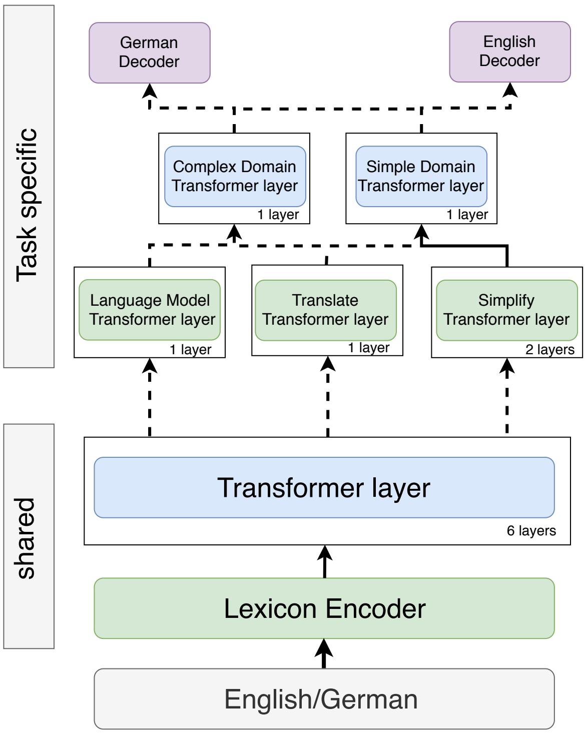

Figure 1: Architecture of our crosslingual encoder-decoder model. The *lexicon Encoder* transforms words into word embeddings. Solid lines indicate mandatory paths, dotted lines indicate possible paths.

3.3 Crosslingual Training

With the tasks defined, we explain how the model is able to switch among them. We propose a modular encoder, where different encoder layers are used for different tasks; an outline of this can be seen in Figure 1. For every task we use the same k base transformer encoder layers, where k is a hyper-parameter. Each task $\mathcal{T}$ (simplification, translation, language modeling), has additional t dedicated transformer layers $L^{\mathcal{T}}_{1:t}$, which are applied to the top of the base k layers, $L^{\mathcal{T}}_{1:t}(L_{1:k}(X))$. Each domain $\mathcal{D}$ (simple/complex), also has d additional dedicated transformer layers $d^{\mathcal{D}}_{1:d}$ applied on top of the task specific layers. The final representation of the source sentence X is:

$$X^N = L^{\mathcal{D}}_{1:d}(L^{\mathcal{T}}_{1:t}(L_{1:k}(X))) \tag{2}$$

Our model is trained end-to-end to minimize cross entropy; for each minibatch we specify the task, domain and output language ($\mathcal{O}$):

$$\mathcal{L}_{\text{CE}} = -\sum_{i=1}^{|Y|} \log P(y|y_{<i}, X^N; \theta, \{\mathcal{D}, \mathcal{T}, \mathcal{O}\}) \tag{3}$$

$\mathcal{D}$ and $\mathcal{T}$ determine the choice of dedicated Transformer encoder layers. We use a dedicated Transformer decoder for each output language $\mathcal{O}$ to encourage the model to learn language-agnostic representations. All text is preprocessed using SentencePiece (Kudo and Richardson, 2018), resulting in a shared vocabulary between LR and HR. This allows for word embeddings to be shared between the encoder and the decoders.

We further force representations to be language-agnostic, by employing a DISCriminator (Ganin and Lempitsky, 2015), a feed-forward network trained to distinguish HR and LR from the hidden representations. The encoder is then trained to perplex the discriminator. Specifically, we add two discriminators to our model; one determines the language of the source sentence ($\mathcal{I}$) using $L_{1:k}(X)$, and the other predicts the target language using the output of the encoder X^N. In this way we ensure the input to the simplification transformer layers is language-agnostic as well as the output. The discriminator is trained to minimize the binary cross-entropy loss (BCE) between its predictions and the ground truth:

$$\sum_{i=1}^{|X|} \text{BCE}(\mathcal{I}, \text{DISC}(L_{1:k}(X)_i; \theta_{d\mathcal{I}})+ \text{BCE}(\mathcal{O}, \text{DISC}(X_i^N); \theta_{d\mathcal{O}}) \tag{4}$$

where $\theta_{d\mathcal{I}}$ and $\theta_{d\mathcal{O}}$ are the parameters of the two discriminators. The encoder is trained using an adversarial loss, to perturb the discriminator:

$$\mathcal{L}_{\text{ADV}} = -\sum_{i=1}^{|X|} \text{BCE}(\mathcal{I}, \text{DISC}(L_{1:k}(X)_i; \theta)+ \text{BCE}(\mathcal{O}, \text{DISC}(X_i^N); \theta) \tag{5}$$

The adversarial loss is combined, and optimized simultaneously, with the cross-entropy loss to produce the training objective of the entire model.

$$\mathcal{L} = \mathcal{L}_{\text{CE}} + \lambda \mathcal{L}_{\text{ADV}} \tag{6}$$

where λ moderates the degree to which the encoder should perturb the discriminators. A high value for λ can cause the encoder to not encode any information regarding the source input.

To perform simplification in the low-resource language at test time, the base encoder is used with the simplification stack which is subsequently decoded with the LR decoder. To perform crosslingual simplification, the decoder can simply be changed to the HR decoder.

4 Experimental Setup

Training Set Our training data is summarized in Table 2. For all experiments we assume that English is the high-resource language and German is the low-resource language. Simplification data in English is taken from WikiLarge (Zhang and Lapata, 2017), a fairly large corpus which consists of a mixture of three automatically-collated Wikipedia simplification datasets (Zhu et al., 2010; Woodsend and Lapata, 2011; Kauchak, 2013). English-German bilingual data is taken from the WMT19 news translation task. Complex monolingual non-parallel data uses one side of the WMT19 translation data. Simple English non-parallel data uses sentences extracted from simple Wikipedia, a simplified version of Wikipedia. Simple German non-parallel data uses sentences scraped from GEOLino (Hancke et al., 2012), a German general-interest magazine for children aged between 8–14.

	Source	Target	Size
WikiLarge	English$_\text{C}$	English$_\text{S}$	300K
WMT19	English$_\text{C}$	German$_\text{C}$	6.0M
GeoLino	—	German$_\text{S}$	200K
Wikipedia	—	English$_\text{S}$	1.4M

Table 2: Training data used in our experiments; monolingual corpora shown under Target; indices are shorthands for Complex and Simple language.

Test Set We evaluated our model on two German simplification datasets, each targeting different users. TextComplexityDE (Naderi et al., 2019) consists of sentences from Wikipedia, which were considered complex by second language German learners. These sentences were then simplified by a native German speaker. In addition, we created a test set from GEOlino. We extracted 20 articles[4] from three categories: nature, physics, and people. A trained German linguist then simplified the articles, sentence by sentence, to be understandable for children aged between 5–7 years. Our simplifying instructions can be found in the Appendix.

Table 2 shows various descriptive statistics on our test sets. GEOlino is larger and consists of both single and multiple source sentences. The FRE readability metric (see the description in the following section) shows that both the source and target sentence are very simple. We also see moderate amounts of sentence splitting (the number of sentences per instance increases in the simplified target). TextComplexityDE is more complex, with the source sentences having the lowest FRE score. The target simplifications, while noticeably simpler than the source, are still more complex than

---

[4] Articles were limited to 20 sentences. Half the articles were reserved for a validation set.

	TextComplexityDE		GEOlino	
	Source	Target	Source	Target
Length	28.66	29.23	15.68	15.05
Sents	1.09	2.17	1.13	1.55
FRE	28.53	49.3	62.87	68.73
Size	122		663	
TER	67.95		24.12	
Insertions	3.20		0.43	
Deletions	3.17		1.08	
Substitution	9.10		1.54	
Shifts	1.70		0.18	

Table 3: Descriptive statistics of test set, including: *Size*, number of instances; *Length*, average number of words; *Sents*, average number of sentences per instance; average *Flesch Reading Ease* (*FRE*; higher is simpler); *TER*, translation error rate measuring distance between source and target; it is composed of four parts: insertions, deletions, substitutions and shifts.

GEOlino. We also observe a significant amount of sentence splitting in this dataset. TextComplexityDE also has a significantly higher Translation Error Rate (TER), However, GEOLino approximately matches the TER of the WikiLarge test set (25.85). While both test sets use a large proportion of substitutions, TextComplexityDE has a much large proportion of insertions, which could be explained by the greater amount of sentence splitting.

Model Parameters During training, the base encoder stack consists of six transformer layers, the decoder stack six layers. The simplification stack consists of two weight tied transformer layers, we note that the simplicity level can be increased by applying the stack multiple times at test time. All other stacks consist of a single layer. Each layer has a hidden dimension of size 512 and an inner dimension size of 2,048. Word embeddings, size 512, were initialized randomly and shared between the encoder and both decoders. We used eight attentional heads. Dropout was set to 0.1; source word dropout was also set to 0.1. The discriminator consists of a four layer feedforward network with dropout set to 0.1. The networks were optimized using Adam (Kingma and Ba, 2014). Multi-tasking was performed by alternating batches of different tasks. Tasks varied in dataset sizes and had different difficulties. As we wished to do equally well with all tasks we select a minibatch from a task with a probability inversely proportional to the training loss of the task. One model was selected using the average FRE-BLEU score across both development sets.

All text was preprocessed using the UDPipe tokenization script (Straka, 2018) and truecasing was applied. SentencePiece was subsequently applied to the text to split words into subwords, with a SentencePiece vocabulary size of 50,000 and a sampling size of $l = \infty$ and a smoothing parameter of $\alpha = 0.25$ (Kudo, 2018).

Evaluation As there is no single agreed-upon metric for simplification (Alva-Manchego et al., 2020; Sulem et al., 2018), we evaluate model output using a combination of four automatically-generated scores.[5] These metrics have been previously shown to correlate with human judgments of simplification quality (Xu et al., 2016) and essentially quantify: a) whether the output is similar to the gold standard reference (*Target*-based, *T*); b) whether the output is similar to the source (*Source*-based, *S*); and c) whether the output is simple on its own, with no regard to preserving the meaning of the original sentence (*Readability*-based, *R*). We indicate the type of each metric using superscripts.

BLEU$^{\mathbf{T}}$ (Papineni et al., 2002) assesses the degree to which generated simplifications agree with the gold standard references.[6]

I-BLEU$^{\mathbf{T,S}}$ (Sun and Zhou, 2012) combines self-BLEU and BLEU to reward systems with high overlap with the reference, and penalize those with high overlap to the source. Self-BLEU computes the BLEU score between the output and the source. It allows us to examine whether the models are making trivial changes to the input. Following Xu et al. (2016), we set the parameter which balances the contribution of the two metrics to $\alpha = 0.9$.

SARI$^{\mathbf{T,S}}$ (Xu et al., 2016) is calculated using the average of three rewrite operation scores: addition, copying, and deletion. It rewards addition operations when the system's output is not in the input but occurs in the references. Analogously, it rewards words deleted/retained if they are in both the system output and the references.[7]

FRE-BLEU$^{\mathbf{T,S,R}}$ is a modification of FKGL-BLEU (Xu et al., 2016), which combines the difference in FKGL of the source and the output and the I-BLEU score. FKGL is a shorthand for the Flesch-Kincaid Grade Level readability score which was originally developed for English but has *not* been ported to German. So instead we use the Flesch

---

[5] Our evaluation procedure can be found at `http://www.github.com/Jmallins/ZEST`

[6] We used `multi-bleu-detok.perl` to calculate corpus-level BLEU.

[7] We use corpus level SARI, using precision for deletion rewards and F1 for addition and copying.

Reading Ease readability test which has been modified for German (FRE; Amstad 1978) and adapt FK-BLEU to use the difference in FRE.[8]

We also evaluated system output by eliciting human judgments via Amazon's Mechanical Turk. Native German speakers (self reported) were asked to rate simplifications on three dimensions: *Grammaticality* (is the output grammatical and fluent?), *Meaning Adequacy* (to what extent is the meaning expressed in the original sentence preserved in the output, with no additional information added?), and *Simplicity* (is the output a simpler version of the input?). Ratings were obtained using a five point Likert scale. We randomly sampled 100 source sentences from each test set (GEOlino and TextComplexityDE), each sample received five ratings, resulting in 500 judgments per test set.

5 Results

Automatic Evaluation Table 4 summarizes our automatic evaluation results. We compare our **ZE**ro-shot cro**S**slingual **S**entence simplifica**T**ion model, which we call ZEST, against multiple baselines, both unsupervised and supervised ones.

Previous work (Artetxe et al., 2018; Lample et al., 2018) demonstrates how an *unsupervised* neural MT model can be trained by optimizing two objectives: (1) *denoising*, where a source sentence is noised and then the corresponding decoder is tasked with reconstructing the original sentence and (2) *on-the-fly back-translation*, which translates the sentence in inference mode; this translation is then encoded and the task is to reconstruct the original sentence. This model can be easily adapted for simplification by considering simple German and complex German to be different languages (U-NMT). Surya et al. (2019) extend this approach further (U-SIMP) by adding two losses, which they show result in better simplifications: (1) an *adversarial loss* using a discriminator which tries to determine if the source sentence is complex or simple, and (2) a *diversification loss*, where a classifier is trained to determine if the source sentence was encoded using the complex or simple encoder. We trained both models using the code provided by Surya et al. (2019) and the same simple and complex *non-parallel* German data used to train our own model (see Table 2; WMT19 complex German and GEOlino simple German).

−ADV	**36.81**	40.47	60.61	**40.98**
−LM	35.46	41.26	57.29	40.33
−AE	35.56	41.60	57.66	36.49
−LM−AE	35.39	**41.71**	55.37	35.42

Table 5: Ablation study examining the impact of removing the adversarial (ADV) loss, and then additionally removing the language modeling loss (LM), and autoencoding loss (AE), separately then together.

We additionally include a supervised baseline based on *pivoting*, which requires three independently trained models, consisting of over twice as many parameters: a complex source German sentence is first translated to English (de → en); it is then simplified (complex en → simple en), before translating it back to German (en → de). All three models consist of a transformer with eight encoder/decoder layers and were trained using the same data as employed in our approach (see Table 2; WMT19 and WikiLarge). On the WMT19 test set, the Pivot-based system obtained a BLEU score of 34.15/31.72 for the en → de/de → en directions. For comparison, ZEST achieved 32.11/30.90 for the same directions. With regard to English simplification (complex en → simple en), the pivot system achieved a SARI score of 36.30 on the WikiLarge test, and ZEST 37.78. On the same test set, Zhang and Lapata (2017), a standard baseline simplification system trained on WikiLarge obtains 37.26, and the state-of-the-art system achieves 41.70 (Martin et al., 2020a). It is possible to incorporate some of the improvements of these approaches (e.g., controlling the amount of compression, paraphrasing, lexical complexity) into our model, however, we leave this to future work.

---

[8] Calculated as $\text{FRE} = 180 - \text{ASL} - (58.5 \cdot \text{ASW})$ where ASL is the average sentence length and ASW the average number of syllables per word.

(b) GEOlino

Table 7: Mean ratings given to simplifications by human participants; highest ratings for each system are **boldfaced**. Models significantly different from ZEST are marked with $^{*}(p < 0.05)$ and $^{**}(p < 0.01)$. Significance tests were performed using a student t-test.

The results in Table 4 show that ZEST obtains the highest results for all metrics on TextComplexityDE. U-SIMP achieves the second best FRE-BLEU score, while Pivot achieves the second best SARI. Overall, U-NMT produces the worst results. Results on GEOlino are more mixed, with no model achieving the highest score across all metrics. ZEST does well across all metrics, scoring the second highest for every metric, whereas the scores for U-SIMP and U-NMT spike on different metrics. U-NMT achieves the best FRE-BLEU score, however, on other metrics it is the second lowest. In contrast, U-SIMP has a low FRE-BLEU score but for all other metrics it scores the highest. Pivot receives the lowest scores across all metrics. Example output is shown in Table 10 and the Appendix.

We further examined the impact different loss functions have on the performance of ZEST, and these results are presented in Table 5. We see that training only on simplification and translation data (−LM−AE) significantly damages the performance of the model, producing the lowest FRE-BLEU scores and the lowest SARI score on GEOlino. We note that by removing both the language modelling loss and autoencoding loss we are removing the non-parallel simple German data (GEOlino), which could explain the performance drop on the GEOLino test set. While in the full model ZEST has access to GEOlino data, the GEOLino test set is simpler than the GEOLino non-parallel training set, as it was further simplified. Additionally, the ability to incorporate extra data is a strength of our approach, as there is no obvious way to include it within the Pivot-based model.

We observed that removing the autoencoding loss (−AE) led to sentences which strayed too far from the source sentence, thereby losing meaning; whereas removing the language modeling loss (−LM) led to sentences being too close to the source sentence, resulting in too little simplification. The inclusion of the adversarial loss (−ADV) showed a small overall increase in FRE-BLEU and a small decrease in SARI.

Human Evaluation Table 7 summarizes the results of the human evaluation. We elicited judgments for three systems, namely ZEST, U-SIMP, and the Pivot-based approach. We also included the gold standard Reference as an upper bound (see the Appendix for examples of sentence pairs shown to crowdworkers). We report mean ratings for Meaning adequacy, Grammaticality and Simplicity, their combined average (AVG), and their (average) Minimum value. We include Minimum because we argue that a simplification is only as good as its weakest dimension. We note that it is trivial to produce a sentence that is perfectly adequate and fluent, by simply repeating the source

Model	lex	SC	RC	pas	suj	gen	spl
Reference	38.7	11.9	10.5	6.8	16.2	12.2	35.5
U-SIMP	41.2	**18.7**	4.3	4.6	7.7	8.0	**3.2**
Pivot	44.9	17.3	7.8	**6.7**	11.6	**14.6**	**3.2**
ZEST	**51.9**	8.3	**11.8**	4.9	**13.0**	5.8	2.3

Table 8: Proportion of simplifications on 100 sentences including lexical (lex), subordinate clause (SC), relative clause (RC), passive voice (pas) subjunctive (suj), genitive (gen), and sentence splitting (spl).

sentence. It is also easy to produce a simple grammatical sentence if we do not care about adequacy.

On TextComplexityDE, ZEST is significantly better than the unsupervised approach across all dimensions. It is on par with Pivot in terms of Grammaticality, Simplicity, and Minimum (ratings are not significantly different). However, ZEST is significantly better in terms of Meaning adequacy, and on average. On GEOlino, ZEST is significantly better against all comparison models on all dimensions. Perhaps unsurprisingly, across datasets, participants perceive gold standard simplifications as superior to the output of all comparison models.

Error analysis We further analysed the types of simplifications produced by each system. We sampled 100 source sentences (50 from each dataset) and elicited judgments from annotators. The annotators were asked to indicate the types of simplification which occurred, including: lexical substitutions, passive to active voice, splitting a sentence into multiple sentences, and rewriting it to avoid subordinate clauses, relative clauses, the subjunctive mood, and the genitive case. The results in Table 8 show that ZEST performs a wide variety of simplification and produces the largest number of lexical simplifications. While all models produce more lexical substitutions than the references, the references split sentences frequently, whereas in all cases, the models split the sentence minimally. The Pivot model simplifies genitives the most while U-SIMP simplifies subordinate clauses most. ZEST produces the largest number of lexical simplifications, and simplifications related to relative clauses and subjunctives.

Crosslingual Simplification We next explore how different tasks can be combined with no additional training data. We illustrate how our model can be used to tackle the tasks of both simplifying *and* translating. We now assume that the source complex sentence is in English and the simplified output sentence is in German. As there currently exist no crosslingual German simplification test sets, for evaluation purposes we hand-translated 100 complex sentences from each of the German test sets into English. Results[9] can be seen in Table 9 and example output in the Appendix. For comparison, we provide the results of Pivot, which requires two independently-trained models: a complex source English sentence is first simplified (complex en → simple en), and then translated into German (en → de). While the results show that ZEST and Pivot are comparable, the fact that we can train our model on single tasks and then recombine task-specific layers to allow zero-shot transfer to unseen task combinations opens up exciting new opportunities for future work.

Models	FRE-BLEU	I-BLEU	BLEU	SARI

6 Conclusions

In this paper we developed a general approach for transferring generation data from high- to low-resource languages. Experimental results on transferring simplification knowledge from English to German showed that our model was able to produce significantly better German simplifications than unsupervised and pivot-based approaches. In addition to zero-shot simplification, we showed that our model can generate German simplifications given English input, without any additional training. In the future, we plan to explore this approach with other language pairs and other generation tasks.

Acknowledgments The authors gratefully acknowledge the support of the European Research Council (award number 681760; Lapata) and the Swiss National Science Foundation (MUTAMUR, no. 176727; Sennrich). We thank all those who helped with German: Sabine Webber, Ivana Balažević, Denis Emelin, Frank Keller, and Steven Kleinegesse.

---

[9] Both SARI and FRE-BLEU are monolingual evaluation metrics, as such we use the original German source sentence.

A Simplification Instructions

This annotation experiment is concerned with simplification. You will be presented with a document. Your task is to read each sentence and simplify it such that children aged between 5 and 7 can understand it. The simplified version should be grammatical and retain all the important information of the original sentence.

In producing simplifications, you are free to delete words, add new words, substitute them, or reorder them. In addition, you might find it useful to change a complex sentence into multiple simple sentences.

To help you with the simplification task, we have produced a set of guidelines which you can follow. However, not all guidelines will always be applicable, so if you believe you can produce a simpler version,n then you may ignore the guidelines. We split the guidelines into two sections: word-level and sentence-level guidelines.

A.1 Word-level Guidelines

1. Special characters are not allowed, with the exception of: full stops, question marks, exclamation marks, quotation marks, and Mediopunkts (used to indicate compound splitting).
2. Numbers should be written as digits and not words.
3. The word *ein* (‘one’) should only be written with a 1 when it represents a number, not when it takes the role of an indefinite article.
4. Roman numerals must be avoided.
5. Large numbers, percentages and year dates should be used sparsely.
6. Use easy, short and well-known words. In case a difficult word is needed, it should be explained using simple words. For a list of simple words, please consult this dictionary: `https://hurraki.de/wiki/Hauptseite`.
7. Technical terms, foreign words and abbreviations should be avoided. Common acronyms like CD or *WC* may be used if their full forms (compact disc, water closet) are less common.

A.2 Sentence-level Guidelines

1. Coordinate and subordinate clauses are forbidden and should be transformed into independent main clauses. Main clauses should preferably contain active voice, and present, or past perfect tense. The subject-verb-object (SVO) word order should be chosen, unless another word order is more understandable.
2. Nominalizations and passive constructions are forbidden.
3. Attributive genitives should also be avoided. If possible, the genitive attribute should be transferred into a prepositional phrase using *von* (‘of’).
4. Negation should be avoided. If needed, it is better to formulate a sentence with *nicht* (‘not’) instead of *kein* (‘no’).
5. Transparent metaphors like leichte Sprache may be used if they can be easily understood. More complex metaphors and idioms should be replaced by literal expressions.
6. Split complex sentences into multiple simple sentences at semicolons and dashes. Also split sentences after colons if the segment after the colon is a complete sentence and not just an enumeration.
7. If a subordinate conjunction is found, split the sentence at the conjunction; edit and rephrase both resulting segments to form independent sentences. Add suitable connectives that express the intended rhetorical relation and restore word order.
8. Rephrase concessive clauses with subjunctions like *obwohl* (‘although’) the connective *trotzdem* (‘however’).
9. Analogously, rephrase consecutive clauses starting with *sodass* (‘so that’) using *deshalb* (‘therefore’).
10. Rephrase final clauses using the modal verb *wollen* (‘want’) and the connective *deshalb* (‘therefore’). Since the subject is not mentioned overtly in German final clauses containing *um zu* (‘in order to’), it has to be retrieved from the main clause.
11. Split coordinate clauses at coordinating conjunctions (e.g., *und* (‘and’), *oder* (‘or’), *aber* (‘but’), *dennoch* (‘however’)). The second clause can start with *und* (‘and’) and *oder* (‘or’) to emphasize that they are linked to the previous sentence.

12. Replace appositions by sentences in which the noun phrase referred to by the apposition forms the subject (X) and the apposition itself becomes the predicative noun (Y), yielding an X is Y structure.

A.3 Final Remarks

The annotation will proceed on a document-by-document basis. In simplifying individual sentences you should ensure that:

- You have preserved all important information in the original sentence.
- The sentences are understandable to children aged 5 to 7.
- You did not render the resulting document incoherent or unreadable.
- You have preserved the grammaticality of the simplified sentences.

B System Output

In Table 10 we present examples of simplifications from both GEOlino and TextComplexityDE. We show the input Complex sentence, the Reference simplification, and the output of our model, ZEST, and two comparison systems U-SIMP and Pivot (see Section 5 in the main paper for more details). To provide some further insight on what the models are doing we have annotated words and phrases in the examples which constitute violations of simple language according to our guidelines above and those provided in `https://hurraki.de/pruefung/pruefung.htm`.

Table 11 contains additional examples, without annotation, while Table 12 presents crosslingual simplicity examples. Specifically, we show model output in German (DE ZEST) when the input is complex English (EN Source), and for comparison German output (DE ZEST) when the input is complex German (DE Source).

Complex	Von hier aus erhaltet ihr einen **[eindrucksvollen]**[1] Rundum-Blick über die ganze Schlucht **[hinweg]**[2] bis hin zu ihren etwa **[5000]**[3] Meter hohen Kraterwänden.
Reference	Von hier aus erhaltet ihr einen Rundum-Blick über die ganze Schlucht. Ihr seht hier bis hin zu ihren etwa **[5000]**[3] Meter hohen Kraterwänden.
U-SIMP	Von hier eraus ihr haltet einen umfassenden Rundum-Blick über die ganze bis **[hinweg]**[2] hinweg zu hin zu ihren **[5000]**[3] Meter hohen Kraterwände.
Pivot	Von hier genießen Sie einen **[beeindruckenden]**[1] Rundumblick über die gesamte Schlucht bis **[zu]**[2] den 500 m hohen Kraterwänden.
ZEST	Von hier aus erhaltet ihr einen Rundum-Blick auf die ganze Schlucht.

Abstract

Aided by technology, people are increasingly able to communicate across geographical, cultural, and language barriers. This ability also results in new challenges, as interlocutors need to adapt their communication approaches to increasingly diverse circumstances. In this work, we take the first steps towards automatically assisting people in adjusting their language to a specific communication circumstance.

As a case study, we focus on facilitating the accurate transmission of pragmatic intentions and introduce a methodology for suggesting paraphrases that achieve the intended level of politeness under a given communication circumstance. We demonstrate the feasibility of this approach by evaluating our method in two realistic communication scenarios and show that it can reduce the potential for misalignment between the speaker's intentions and the listener's perceptions in both cases.

1 Introduction

Technological developments have greatly enhanced our communication experience, providing the opportunity to overcome geographic, cultural and language barriers to interact with people from different backgrounds in diverse settings (Herring, 1996). However, this opportunity brings additional challenges for the interlocutors, as they need to adjust their language to increasingly diverse communication circumstances.

As humans, we often make conscious attempts to account for the communication setting. For instance, we may simplify our expressions if we know our listener has relatively limited language proficiency, and we tend to be more polite towards people with higher status. However, managing these stylistic adjustments can be cognitively taxing, especially when we are missing relevant information—e.g., the language proficiency or the status of a conversational partner we meet online.

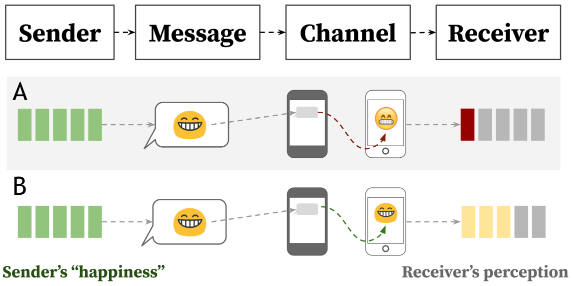

Figure 1: Berlo's Sender-Message-Channel-Receiver model suggests that the intended and perceived style of a message can be misaligned if: **A**. the `channel` does not faithfully transmit the message, or **B**. the `receiver` has a different reading of the message compared to the `sender`. Examples are inspired by Miller et al. (2016).

If we do not adjust our language, we risk not properly conveying our pragmatic intentions (Thomas, 1983). In particular, Berlo's Sender-Message-Channel-Receiver model (Berlo, 1960) points to two potential circumstance-specific causes for misalignments between intentions and perceptions (Figure 1). In this work we explore a method for assisting speakers to avoid such misalignments by suggesting for each message a paraphrase that is more likely to convey the original pragmatic intention when communicated in a given circumstance, as determined by the properties of the `sender`, `channel`, and `receiver`.

As a case study, in this work, we focus on one particular pragmatic aspect: politeness. It is important to assist people to accurately transmit their intended politeness, as this interpersonal style (Biber, 1988) plays a key role in social interactions (Burke and Kraut, 2008; Murphy, 2014; Hu et al., 2019; Maaravi et al., 2019). Furthermore, politeness is known to be a circumstance-sensitive phenomenon (Kasper, 1990; Herring, 1994; Forgas, 1998; Mousavi and Samar, 2013), making it a good case for our study. Concretely, we propose the task of generating a paraphrase for a given

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5127–5140,
November 16–20, 2020. ©2020 Association for Computational Linguistics

message that is more likely to deliver the intended level of politeness after transmission (henceforth *intention-preserving*), considering the properties of the `sender`, `channel`, and `receiver` (Section 3).

Taking the properties of the `channel` into account is important because communication `channels` may not always faithfully deliver messages (Figure 1A). For example, in translated communication, politeness signals can often be lost or corrupted (Allison and Hardin, 2020). To demonstrate the potential of our framework in mitigating `channel`-induced misunderstandings, we apply it to suggest paraphrases that are *safer to transmit*—i.e., less likely to have their politeness altered—over a commercial machine translation service.

We also need to account for the fact that the `sender` and `receiver` can have different interpretations of the same message (Figure 1B). For example, people may perceive politeness cues differently depending on their cultural background (Thomas, 1983; Riley, 1984). In our second application scenario, the interlocutors' perceptions of politeness are misaligned, and we aim to suggest paraphrases that reduce the potential for misinterpretation.

To successfully produce such circumstance-sensitive paraphrases, we need to depart from existing style transfer methodology (see Li et al., 2020 for a survey, and Madaan et al., 2020 for politeness transfer in particular). First, since we must account for arbitrary levels of misalignment, we need *fine-grained* control over the target stylistic level, as opposed to binary switches (e.g., from impolite to polite). Second, we need to determine the target stylistic level at run time, in an *ad hoc* fashion, rather than assuming predefined targets.

To overcome these new technical challenges, we start from the intuition that the same level of politeness can be conveyed through different combinations of *pragmatic strategies* (Lakoff, 1973; Brown and Levinson, 1987), with some being more appropriate to the given circumstance than others. We consider a classic two-step approach (Section 4), separating *planning*—choosing a viable combination of strategies that can achieve a desired stylistic level in a particular circumstance—, from the step of *realization*—incorporating this plan into generation outputs. For a given fine-grained target stylistic level (i.e., the level intended by the sender), we find the optimal strategy plan via Integer Linear Programming (ILP). We then realize this plan using a modification of the 'Delete-Retrieve-Generate' (DRG) paradigm (Li et al., 2018) that allows for strategy-level control in generation.

Our experimental results indicate that in both our application scenarios, our method can suggest paraphrases that narrow the potential gap between the intended and perceived politeness, and thus better preserve the sender's intentions. These results show that automated systems have the potential to help people better convey their intentions in new communication circumstances, and encourage further work exploring the feasibility and implications of such communication assistance applications.

To summarize, in this work, we motivate and formulate the task of circumstance-sensitive intention-preserving paraphrasing (Section 3). Focusing on the case of pragmatic intentions, we introduce a model for paraphrasing with fine-grained politeness control (Section 4). We evaluate our method in two realistic communication scenarios to demonstrate the feasibility of the approach (Section 5).

2 Further Related Work

Style transfer. There has been a wide range of efforts in using NLP techniques to generate alternative expressions, leading to tasks such as text simplification (see Shardlow, 2014 for a survey), or more generally, paraphrase generation (Meteer and Shaked, 1988; Quirk et al., 2004; Fu et al., 2019, inter alia). When such paraphrasing effort is focused on the stylistic aspect, it is also referred to as text style transfer, which has attracted a lot of attention in recent years (Xu et al., 2012; Ficler and Goldberg, 2017; Fu et al., 2018; Prabhumoye et al., 2018, inter alia). While these tasks are focused on satisfying specific predefined linguistic properties at the utterance-level, they are not designed for fine-grained adjustments to changing non-textual communication circumstances.

Controllable generation. Style transfer or paraphrasing can both be seen as a special case of the broader task of *controllable* text generation (Hu et al., 2017; Keskar et al., 2019; Dathathri et al., 2020, inter alia). While not focused on paraphrasing, relevant work in this area aims at controling the level of politeness for translation (Sennrich et al., 2016) or dialog response (Niu and Bansal, 2018).

AI-assisted communications or writing. Beyond paraphrasing, AI tools have been used to provide communication or writing assistance in diverse settings: from the mundane task of grammar and spell checking (Napoles et al., 2019; Stevens, 2019), to creative writing (Clark et al., 2018), to negotiations (Zhou et al., 2019), and has led to discussions of ethical implications (Hancock et al., 2020).

Models of communication. While Berlo's model provides the right level of abstraction for inspiring our application scenarios, many other models exist (Velentzas and Broni, 2014; Barnlund, 2017), most of which are under the influence of the Shannon–Weaver model (Shannon and Weaver, 1963).

3 Task Formulation

Given a message that a `sender` attempts to communicate to a `receiver` over a particular communication `channel`, the task of circumstance-sensitive intention-preserving paraphrasing is to generate a paraphrase that is more likely to convey the intention of the `sender` to the `receiver` after transmission, under the given communication circumstance.

Formulation. To make this task more tractable, our formulation considers a single gradable stylistic aspect of the message that can be realized through a collection of *pragmatic strategies* (denoted as $\mathcal{S}$). While in this work we focus on politeness, other gradable stylistic aspects might include formality, humor and certainty.

We can then formalize the relevant features of the communication circumstance as follows:

1. For the communication `channel`, we consider whether it can safely transmit each strategy $s \in \mathcal{S}$. In particular, $f_c\ (s) = 1$ indicates that strategy s is *safe* to use, whereas $f_c\ (s) = 0$ implies that s is *at-risk* of being lost.
2. For the `sender` and `receiver`, we quantify the level of the stylistic aspect each of them perceive in a combination of pragmatic strategies via two mappings $f_{send} : \mathcal{P}(\mathcal{S}) \rightarrow \mathbb{R}$ and $f_{rec} : \mathcal{P}(\mathcal{S}) \rightarrow \mathbb{R}$, respectively, with $\mathcal{P}(\mathcal{S})$ denoting the powerset of $\mathcal{S}$.

With our focus on politeness, our task can then be more precisely stated as follows: given an input message m, we aim to generate a politeness paraphrase for m, under the circumstance specified by (f_{send}, f_c, f_{rec}), such that the level of politeness perceived by the `receiver` is as close to that intended by the `sender` as possible.

We show that our theoretically-grounded formulation can model naturally-occurring challenges in communication, by considering two possible application scenarios, each corresponding to a source of misalignment highlighted in Figure 1.

Application A: translated communication. We first consider the case of conversations mediated by translation services, where `channel`-induced misunderstandings can occur (Figure 1A): MT models may systematically drop certain politeness cues due to technical limitations or mismatches between the source and target languages.

For instance, despite the difference in intended politeness level (indicated in parentheses) of the following two versions of the same request,[1]

Could you please proofread this article? (POLITE)
Can you proofread this article? (SOMEWHAT POLITE)

Microsoft Bing Translator would translate both versions to the same utterance in Chinese.[2] By dropping the politeness marker 'please', and not making any distinction between 'could you' and 'can you', the message presented to the Chinese receiver is likely to be more imposing than originally desired by the English sender.

To avoid such `channel`-induced misunderstandings, the sender may consider using only strategies that are known to be safe with the specific MT system they use.[3] However, since the inner mechanics of such systems are often opaque (and in constant flux), the sender would benefit from automatic guidance in constructing such paraphrases.

Application B: misaligned perceptions. We then consider the case when `senders` and `receivers` with differing perceptions interact. Human perceptions of pragmatic devices are subjective, and it is not uncommon to observe different interpretations of the same utterance, or pragmatic cues within, leading to misunderstandings (Thomas, 1983; Kasper, 1990) (Figure 1B). For instance, a study comparing Japanese speakers' and American native English speakers' perceptions of English requests find that while the latter group takes the request '*May I borrow a pen?*' as strongly polite, their Japanese counterparts regard the expression as almost neutral (Matsuura, 1998). In this case, if a native speaker still wishes to convey their good will, they need to find a paraphrase that would be perceived as strongly polite by Japanese speakers.

---

[1] Annotations from 5 native speakers on a 7-point Likert scale ranging from VERY IMPOLITE to VERY POLITE.

[2] Translating on May, 2020 to 你能校对这篇文章吗?

[3] E.g., they might consider expressing gratitude (e.g., 'thanks!') rather than relying on subjunctive ('could you').

4 Method

When compared to style transfer tasks, our circumstance-sensitive intention-preserving paraphrasing task gives rise to important new technical challenges. First, in order to minimize the gap in perceptions, we need to have fine-grained control over the stylistic aspect, as opposed to switching between two pre-defined binarized targets (e.g., polite vs. impolite). Second, the desired degree of change is only determined at run-time, depending on the speaker's intention and on the communication circumstance. We address these challenges by developing a method that allows for *ad hoc* and *fine-grained* paraphrase planning and realization.

Our solution starts from a strategy-centered view: instead of aiming for monolithic *style labels*, we think of *pragmatic strategies* as (stylistic) LEGO bricks. These can be stacked together in various combinations to achieve similar stylistic levels. Depending on the circumstance, some bricks might, or might not, be available. Therefore, given a message with an intended stylistic level, our goal is to find the optimal collection of available bricks that can convey the same level—ad hoc fine-grained planning. Given this optimal collection, we need to assemble it with the rest of the message into a valid paraphrase—fine-grained realization.

Politeness strategies. In the case of politeness, we derive the set of pragmatic strategies from prior work (Danescu-Niculescu-Mizil et al., 2013; Voigt et al., 2017; Yeomans et al., 2019). We focus on strategies that are realized through local linguistic *markers*. For instance, the Subjunctive strategy can be realized through the use of markers like *could you* or *would you*. In line with prior work, we further assume that markers realizing the same strategy has comparable *strength* in exhibiting politeness and are subject to the same constraints. The full list of 18 strategies we consider (along with their example usages) can be found in Table 1. Strategy extraction code is available in ConvoKit.[4]

Strategy	Example usage
Actually	it **actually** needs to be ...
Adverb.Just	i **just** noticed that ...
Affirmation	**excellent point**, i have added it ...
Apology	**sorry** to be off-topic, but ...
By.The.Way	okay - **by the way**, do you want me ...?
Conj.Start	**so** where is the article ?
Filler	**uh**, hey, can you...?
For.Me	is it alright **for me** to archive it now?
For.You	i can fetch one **for you** in a moment! ...
Gratitude	**thanks** for the info , ...
Greeting	**hey** simon , help is needed if possible ...
Hedges	**maybe** some kind of citation is needed ...
Indicative	**can you** create one for me?
Please	can you **please** check it?
Please.Start	**please** stop . if you continue ...
Reassurance	**no problem**, happy editing. ...
Subjunctive	..., **could you** check?
Swearing	what **the heck** are you talking about?

Table 1: Politeness strategies we consider, along with example usage and example markers (in bold). More details for the strategies can be found in Table A1 in the Appendix.

Ad hoc fine-grained planning. Our goal is to find a target strategy combination that is estimated to provide a comparable pragmatic force to the sender's intention, using only strategies appropriate in the current circumstance. To this end, we devise an Integer Linear Programming (ILP) formulation that can efficiently search for the desired strategy combination to use (Section 4.1).

Fine-grained realization. To train a model that learns to merge the strategy plan into the original message in the absence of parallel data, we take inspirations from the DRG paradigm (Li et al., 2018), originally proposed for style transfer tasks. We adapt this paradigm to allow for direct integration with strategy-level planning, providing finer-grained control over realization (Section 4.2).

4.1 Fine-Grained Strategy Planning

Formally, given a message m using a set of strategies $\mathcal{S}_{in}$, under a circumstance specified by (f_{send}, f_c, f_{rec}), the planning goal is to find the set of strategies $\mathcal{S}_{out} \subseteq \mathcal{S}$ such that $f_c\ (s) = 1, \forall s \in \mathcal{S}_{out}$ —i.e., they can be safely transmitted through the communication `channel`—and $f_{send}\ (\mathcal{S}_{in}) \approx f_{rec}\ (\mathcal{S}_{out})$—i.e., the resultant `receiver` perception is similar to the intention the `sender` had when crafting the original message.

Throughout, we assume that both perception mappings f_{send} and f_{rec} are linear functions:

$$f_{send}(\mathcal{S}_{in}) = \textstyle\sum_{s \in \mathcal{S}} a_s \mathbb{1}_{\mathcal{S}_{in}}(s) + a_0$$

$$f_{rec}(\mathcal{S}_{out}) = \textstyle\sum_{s \in \mathcal{S}} b_s \mathbb{1}_{\mathcal{S}_{out}}(s) + b_0$$

where the linear coefficients a_s and b_s are reflective of the strength of a strategy, as perceived by the `sender` and `receiver`, respectively.[5]

---

[4] `https://convokit.cornell.edu`.

[5] We acknowledge that considering only linear models may result in sub-optimal estimations.

Naive approach. One greedy type of approach to this problem is to consider each at-risk strategy $s \in \mathcal{S}_{in}$ at a time, and replace s with a safe strategy s' that is closest in strength. Mathematically, this can be written as $s' = \arg\min_{\hat{s} \in \mathcal{S}, f_c(\hat{s})=1} |a_s - b_{\hat{s}}|$. In our analogy, this amounts to reconstructing a LEGO model by replacing each 'lost' brick with the most similar brick that is available.

Our approach: ILP formulation. The greedy approach, while easy to implement, can not consider solutions that involve an alternative *combination* of strategies. In order to more thoroughly search for an appropriate strategy plan in the space of possible solutions in a flexible and efficient manner, we translate this problem into an ILP formulation.[6]

Our objective is to find a set of safe strategies $\mathcal{S}_{out}$ that will be perceived by the `receiver` as close as possible to the `sender`'s intention, i.e., one that that minimizes $|f_{send}(\mathcal{S}_{in}) - f_{rec}(\mathcal{S}_{out})|$.

To this end, we introduce a binary variable x_s for each strategy s in $\mathcal{S}$, where we take $x_s = 1$ to mean that strategy s should be selected to be present in the suggested alternative strategy combination $\mathcal{S}_{out}$. We can identify the optimal value of x_s (and thus the optimal strategy set $\mathcal{S}_{out}$) by solving the following ILP problem:[7]

$$\begin{array}{ll} \text{MIN} & y \\ \text{subj to} & (\sum a_s \mathbb{1}_{\mathcal{S}_{in}}(s) + a_0) - (\sum b_s x_s + b_0) \leq y \\ & (\sum b_s x_s + b_0) - (\sum a_s \mathbb{1}_{\mathcal{S}_{in}}(s) + a_0) \leq y \\ & x_s \leq f_c(s), x_s \in \{0,1\}, \forall s \in \mathcal{S} \end{array}$$

which is a rewriting our objective to minimize $|f_{send}(\mathcal{S}_{in}) - f_{rec}(\mathcal{S}_{out})|$ that satisfies the linearity requirement of ILP via an auxiliary variable y, and where our target variables x_s replace the indicator function $\mathbb{1}_{\mathcal{S}_{out}}(s)$ in the linear expression of f_{rec}.

The `channel` constraints are encoded by the additional constraints $x_s \leq f_c(s)$, allowing only safe strategies (i.e., those for which $f_c(s) = 1$) to be included. Additional strategy-level constraints can be similarly specified through this mechanism to obtain strategy plans that are easier to realize in natural language (Section C in the Appendix).

4.2 Fine-Grained Realization

To transform the ILP solutions into natural language paraphrases, we build on the general DRG framework, which has shown strong performance in style transfer without parallel data.[8] We modify this framework to allow for the fine-grained control needed to realize strategy plans.

As the name suggests, the vanilla DRG framework consists of three steps. With *delete*, lexical markers (n-grams) that are strongly indicative of style are removed, resulting in a 'style-less' intermediate text. In the *retrieve* step, target markers are obtained by considering those used in training examples that are similar to the input but exhibit the desired property (e.g., target sentiment valence). Finally, in the *generate* step, the generation model merges the desired target markers with the style-less intermediate text to create the final output.

Importantly, the DRG framework is primarily designed to select to-be-inserted markers based on pre-defined binary style classes. As such, it cannot directly allow the ad hoc fine-grained control needed by our application. We now explain our modifications in detail (follow the sketch of our pipeline in Figure 2):

Plan (instead of Retrieve). We first perform a Plan step, which substitutes the Retrieve step in DRG, but it is performed first in our pipeline as our version of the Delete step is dependent on the planning results. For an input message, we identify the politeness strategies it contains and set up the corresponding ILP problem (Section 4.1) to obtain their *functional alternatives*. By factoring in the communication circumstance into the ILP formulation, we obtain an ad hoc strategy plan to achieve the intended level of politeness. This is in contrast with the Retrieve step in DRG, in which target markers from similar-looking texts are used for direct *lexical substitution*.

Delete. Instead of identifying style-bearing lexical markers to delete with either frequency-based heuristics (Li et al., 2018), or sentence context (Sudhakar et al., 2019), we rely on linguistically informed politeness strategies. To prepare the input message for the new strategy plan, we compare the strategy combination from the ILP solution with those originally used. We then *selectively* remove strategies that do not appear in the ILP solution by deleting the corresponding markers found in the input message. As such, in contrast with DRG, our post-deletion context is not necessarily style-less, and it is also possible that no deletion is performed.

---

[6] A brute force alternative would inevitably be less scalable.

[7] All summations are over the entire strategy set $\mathcal{S}$. Throughout, we use the `PuLP` package (Mitchell et al., 2011) with `GLPK` solver to obtain solutions.

[8] Since the politeness strategies we consider are local, they fit the assumptions of DRG framework well.

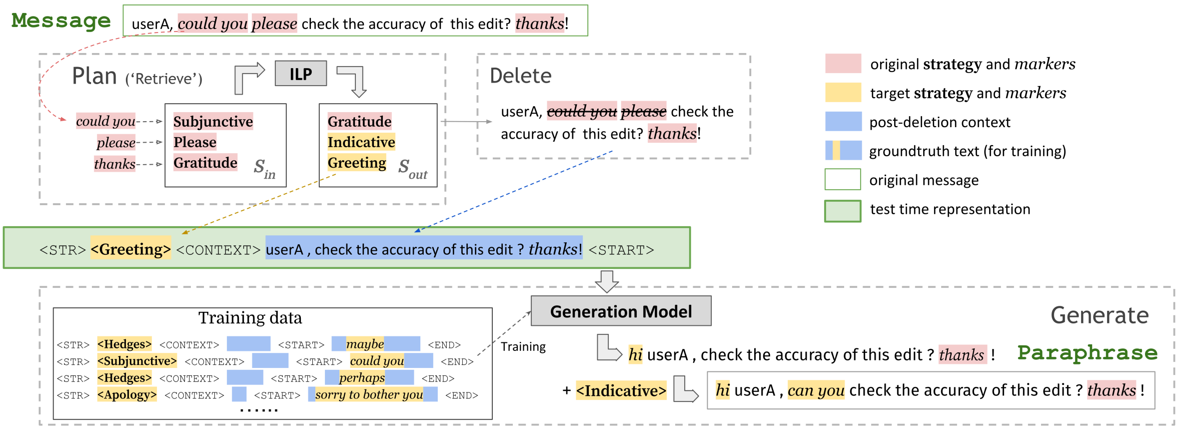

Figure 2: Sketch of our pipeline for generating politeness paraphrases. Given an input message, we first identify the politeness strategies ($\mathcal{S}_{in}$) and the corresponding markers it contains. In the **plan** step, we use ILP to compute a target strategy combination ($\mathcal{S}_{out}$) that is appropriate under the circumstance. We then **delete** markers corresponding to strategies that need to be removed to obtain the post-deletion context. Finally, we sequentially insert the new strategies from the ILP solution into this context to **generate** the final output.

Generate. Finally, we need to generate fluent utterances that integrate the strategies identified by the Plan step into the post-deletion context. To this end, we adapt `G-GST` (Sudhakar et al., 2019), whose generation model is fine-tuned to learn to integrate lexical markers into post-deletion context. To allow smooth integration of the ILP solution, we instead train the generation model to incorporate politeness strategies directly.

Concretely, training data exemplifies how each target strategy can be integrated into various post-deletion contexts. This data is constructed by finding GROUNDTRUTH utterances containing markers corresponding to a certain STRATEGY, and removing them to obtain the post-deletion CONTEXT. These training instances are represented as (STRATEGY, CONTEXT, GROUNDTRUTH) tuples separated by special tokens (examples in Figure 2). The model is trained to minimize the reconstruction loss.[9]

At test time, we sequentially use the model to integrate each STRATEGY from the plan into the post-deletion CONTEXT. We perform beam search of size 3 for each strategy we attempt to insert and select the output that best matches the intended level of politeness as the paraphrase suggestion.[10]

5 Evaluation

To test the feasibility of our approach, we set up two parallel experiments with different circumstance specifications, so that each illustrates one potential source of misalignment as described in Section 3.[11]

5.1 Experiments

Data. We use the annotations from the Wikipedia section of the Stanford Politeness Corpus (henceforth annotations) to train perception models that will serve as approximations of f_{send} and f_{rec}. In this corpus, each utterance was rated by 5 annotators on a 25-point scale from very impolite to very polite, which we rescale to the $[-3, 3]$ range.

To train the generation model, we randomly sample another (unannotated) collection of talk-page messages from WikiConv (Hua et al., 2018). For each strategy, we use 1,500 disjoint instances for training (27,000 in total, 2000 used for validation) and additionally resource 200 instances per strategy as test data. Both the Stanford Politeness Corpus and WikiConv are retrieved from ConvoKit (Chang et al., 2020b).

Experiment A: translated communication. We first consider MT-mediated English to Chinese communication using Microsoft Translator, where `channel`-induced misunderstandings may occur.

For this specific `channel`, we estimate its f_c by performing back-translation[12] (Tyupa, 2011) on a

---

[9] We adapted the implementation from Sudhakar et al. (2019) to incorporate our modification described above, and we use their default training setup.

[10] We set an upper bound of at most 3 new strategies to be introduced to keep sequential insertion computationally manageable. This is a reasonable assumption for short utterances.

[11] Code and data is available at `https://github.com/CornellNLP/politeness-paraphrase`.

[12] Back-translation refers to the process of translating the

sampled set of utterances from the collection of Stack Exchange requests from the Stanford Politeness Corpus. We consider a strategy s to be at-risk under this MT-mediated `channel` if the majority of messages using s have back-translations that no longer uses it. We identify four at-risk strategies, leading to the following channel specification: f_c $(s) = 0$, if $s \in \{\text{Subjunctive, Please, Filler, Swearing}\}$; $f_c\ (s) = 1$ otherwise.

For the `sender` and the `receiver`, we make the simplifying assumption that they both perceive politeness similar to a prototypical 'average person' (an assumption we address in the next experiment), and take the average scores from the annotations to train a linear regression model f_{avg} to represent the perception model, i.e., $f_{send} = f_{rec} = f_{avg}$.

We retrieve test data corresponding to the four at-risk strategy types as test messages (4×200 in total). We estimate the default perception gap (i.e., when **no intervention** takes place) by comparing the intended level of politeness in the original message and the level of politeness of its back-translation, which roughly approximates what the `receiver` sees after translation, following Tyupa (2011). This way, we can avoid having to compare politeness levels across different languages.

Experiment B: misaligned perceptions. We then consider communication between individuals with misaligned politeness perceptions. Under this circumstance, we assume a perfect `channel`, which allows any strategy to be safely transmitted, i.e., $f_c\ (s) = 1, \forall s \in S$. We then consider the top 5 most prolific annotators as potential `senders` and `receivers`. To obtain f_{send} (and f_{rec}), we use the respective annotator's annotations to train an individual linear regression model.[13]

We take all permutations of `(sender, receiver)` among the chosen annotators, resulting in 20 different directed pairs. For each pair, we select as test data the top 100 utterances with the greatest (expected) perception gap in the test set. We take the default perception gap within the pair (with **no intervention**) as the difference between the `sender`'s intended level of politeness (as judged by f_{send}) and the `receiver`'s perceived level of politeness (as judged by f_{rec}).

Baselines. Beyond the base case with no intervention, we consider baselines with different degrees of planning. We first consider binary-level planning by directly applying vanilla **DRG** in our setting: for each message, we retrieve from the generation training data the most similar utterance that has the same politeness polarity as the input message,[14] and take the strategy combination used within as the new strategy plan. We then consider a finer-grained strategy planning based on the naive **greedy** search, for which we substitute each at-risk strategy by an alternative that is the closest in strength. To make fair comparisons among different planning approaches, we apply the same set of constraints (either circumstance-induced or generation-related) we use with ILP.[15]

Evaluation. We compare the paraphrasing outputs using both automatic and human evaluations. First, we consider our *main objective*: how effective each model is at reducing the potential gap between intended and perceived politeness. We compare the predicted perceived politeness levels of paraphrases generated by each model with the intended politeness levels of the original inputs in terms of mean absolute error (**MAE** $_{gen}$), with smaller values corresponding to smaller gaps. We additionally evaluate the (pre-generation) quality of the planned strategy set (**MAE** $_{plan}$) to account for cases in which the plan is not perfectly realized.

To check the extent to which the generated paraphrases could be readily used, we assess how natural they sound to humans. We sample 100 instances from each set of the generated outputs and ask one non-author native English speaker to judge their naturalness on a scale of 1 to 5 (5 is very natural). The task is split among two annotators, and we obtain one annotation for each utterance. Each annotator was presented with an even distribution of retrieval-based, greedy-based and ILP-based generation outputs, and was not given any information on how the outputs are obtained.[16]

To validate that the original content is not drastically altered, we report BLEU scores (Papineni et al., 2002) obtained by comparing the generation outputs with the original message (BLEU-S), Additionally, we provide a rough measure of how 'ambitious' the paraphrasing plan is by counting the number of new strategies that are ADDED.

---

translated text back into the source language.

[13] Details about the choice of annotators and their perception models are described in Section B in the Appendix. While in practice individual perception models may not be available, they could potentially be approximated based on annotations from people with similar (cultural) backgrounds.

[14] We use f_{avg} to determine the binary politeness polarity.

[15] We note that even if we do not enforce these additional constraints, the baselines still under-perform the ILP solution.

[16] Table A2 in the Appendix shows the exact instructions.

	Translated communication (A)				**Misaligned perceptions (B)**			
	MAE $_{plan}$	**MAE** $_{gen}$	BLEU-S	#-ADDED	**MAE** $_{plan}$	**MAE** $_{gen}$	BLEU-S	#-ADDED
No intervention	0.43	0.43	64.2	0	1.01	1.01	100	0
Retrieval (DRG)	0.66	0.61	74.7	1.09	0.81	0.76	72.0	1.07
Greedy	0.35	0.35	73.5	1.20	0.48	0.47	70.3	1.82
ILP-based	**0.14**	**0.21**	67.0	2.38	**0.03**	**0.12**	68.8	2.30

Table 2: Our method is the most efficient at reducing the potential for misalignment (bolded, t-test $p < 0.001$).

	Input / Output	**Gap**
Experiment A	could you clarify what type of image is requested of centennial olympic park? thanks!	0.23
	can you clarify what type of image is requested of centennial olympic park for me ? thanks !	0.11
	where the hell did i say that? i was referring to the term 'master'.	1.30
	so where did i actually say that ? i was referring to the term 'master'.	0.70

	hi, no problem. thanks for accepting. how and when do we start?	0.03
	i'd like to try out kissle, so would you please add me to [it]? thanks.	1.06
	hi ! i ' d like to try out kissle , so will you just add me to [it]?	0.01
Error case	hi, would you please reply to me at the article talk page? thanks.	0.97
	good idea . sorry , would you please reply to me at the article talk page for you ?	0.01

Table 3: Example generation outputs (we highlight the original and newly introduced markers through which the strategies are realized). For reference, we also show the (estimated) gap between the `sender`'s intention and the `receiver`'s perception after transmission. More example outputs and error cases are shown in Tables A3 and A4 in the Appendix.

Results. Table 2 shows that our **ILP-based** method is capable of significantly reducing the potential gap in politeness perceptions between the `sender` and the `receiver`, in both experiments (t-test $p < 0.001$). The comparison with the baselines underlines the virtues of supporting fine-grained planning: the effectiveness of the eventual paraphrase is largely determined by the quality of the strategy plan. This can be seen by comparing across the MAE $_{plan}$ column which shows misalignments that would result if the plans were perfectly realized. Furthermore, when planning is done too coarsely (e.g., at a binary granularity for vanilla DRG), the resultant misalignment can be even worse than not intervening at all (for translated communication).

At the same time, the paraphrases remain mostly natural, with the average annotator ratings generally fall onto 'mostly natural' category for all generation models. The exact average ratings are 4.5, 4.2, and 4.2 for the retrieval-based, greedy-based, and ILP-based generation respectively. These generation outputs also largely preserve the content of the original message, as indicated by the relatively high BLEU-S scores.[17] Considering that the ILP-based method (justifiably) implements a more ambitious plan than the baselines (compare #-ADDED), it is expected to depart more from the original input; in spite of this, the difference in naturalness is small.

5.2 Error Analysis

By inspecting the output (examples in Tables 3, A3 and A4), we identify a few issues that are preventing the model to produce ideal paraphrases, opening avenues for future improvements:

Available strategies. Between the two experimental conditions reported in Table 2, we notice that the performance (**MAE** $_{gen}$) is worse for the case of translated communication. A closer analysis reveals that this is mostly due to a particularly hard-to-replace at-risk strategy, Swearing, which is one of the few available strategies that have strong negative politeness valence. The strategy set we operationalize is by no means exhaustive. Future work

---

[17] As a comparison point, we note that the outputs of all methods have higher BLEU-S scores than the back-translations. We have also verified that the generated paraphrases preserve more than 90% of the non-marker tokens, further suggesting the degree of content preservation.

can consider a more comprehensive set of strategies, or even individualized collections, to allow more diverse expressions.

Capability of the generation model. From a cursory inspection, we find that the generation model has learned to incorporate the planned strategies, either by realizing simple maneuvers such as *appending* markers at sentence boundaries, to the more complex actions such as *inserting* relevant markers in reasonable positions within the messages (both exemplified in Table 3). However, the generation model does not always fully execute the strategy plan, and can make inappropriate insertions, especially in the case of the more ambitious ILP solutions. We anticipate more advanced generation models may help further improve the quality and naturalness of the paraphrases. Alternatively, dynamically integrating the limitations of the generation model as explicit planning constraints might lead to solutions that are easier to realize.

6 Discussion

In this work, we motivate and formulate the task of circumstance-sensitive intention-preserving paraphrasing and develop a methodology that shows promise in helping people more accurately communicate politeness under different communication settings. The results and limitations of our method open up several natural directions for future work.

Modeling politeness perceptions. We use a simple linear regression model to approximate how people internally interpret politeness and restrict our attention to only the set of local politeness strategies. Future work may consider more comprehensive modeling of how people form politeness perceptions or obtain more reliable causal estimates for strategy strength (Wang and Culotta, 2019).

Task formulation. We make several simplifying assumptions in our task formulation. First, we focus exclusively on a gradable stylistic aspect that is mostly decoupled from the content (Kang and Hovy, 2019), reducing the complexity required from both the perception and the generation models. Future work may consider more complex stylistic aspects and strategies that are more tied to the content, such as switching from active to passive voice. Second, we consider binary channel constraints, but in reality, the channel behavior is often less clear-cut. Future work can aim to propose more general formulations that encapsulate more properties of the circumstance.

Forms of assistance. While we have focused on offering paraphrasing options as the form of assistance, it is not the only type of assistance possible. As our generation model may not (yet) match the quality of human rewrites, there can be a potential trade-off. While an entirely automatic assistance option may put the least cognitive load on the user, it may not produce the most natural and effective rewrite, which may be possible if humans are more involved. Hence, while we work towards providing fully automated suggestions, we might also want to utilize the language ability humans possess and consider assistance approaches in the form of interpretable (partial) suggestions.

Evaluation. In our experiments, we have relied exclusively on model predictions to estimate the level of misalignment in politeness perceptions. Given the fine-grained and individualized nature of the task, using humans to ascertain the politeness of the outputs would require an extensive and relatively complex annotation setup (e.g., collecting fine-grained labels from annotators with known backgrounds for training and evaluating individualized perception models). Furthermore, to move towards more practical applications, we would also need to conduct communication-based evaluation (Newman et al., 2020) in addition to annotating individual utterances. Future work can consider adapting experiment designs from prior work (Gao et al., 2015; Hohenstein and Jung, 2018) to establish the impact of offering such intention-preserving paraphrases in real conversations, potentially by considering downstream outcomes.

Bridging the gaps in perceptions. While we focus on politeness strategies, they are not the only circumstance-sensitive linguistic signals that may be lost or altered during transmission, nor the only type that are subject to individual or cultural-specific perceptions. Other examples commonly observed in communication include, but are not limited to, formality (Rao and Tetreault, 2018) and emotional tones (Chhaya et al., 2018; Raji and de Melo, 2020). As we are provided with more opportunities to interact with people across cultural and language barriers, the risk of misunderstandings in communication also grows (Chang et al., 2020a). Thus, it is all the more important to develop tools to mitigate such risk and help foster mutual understandings.

Acknowledgments. We thank Jonathan P. Chang, Caleb Chiam, Hajin Lim, Justine Zhang, and the reviewers for their helpful comments, Kim Faughnan and Ru Zhao for the naturalness annotations. We also thank Sasha Draghici for showing us his extensive LEGO collection, which was an inspiration for the analogy used in this paper. This research was supported in part by NSF CAREER award IIS-1750615 and NSF Grant IIS-1910147.

Appendices

A Politeness Strategies

We show the complete list of politeness strategies we use in Table A1, together with the coefficients for the average model f_{avg} used in Experiment A is shown in Table A1.

Recognizing that individual markers may not always fully encompass the politeness-bearing portion of the text, we consider two modes of deletion depending on strategy (Table A1): *token* mode deletes only the identifier marker, whereas in *segment* mode the whole sentence segment (as defined by within-sentence punctuations) will be removed:

Token mode	Can you ~~please~~ explain?
Segment mode	~~Thanks for your help,~~ I will try again.

B Prolific Annotators

For experiment B, we sample the top five most prolific annotations from the Wikipedia section of the Stanford Politeness Corpus, with the most prolific one having annotated 2,063 instances, and the least prolific among the five having 715 annotations.

When training individual perception models, we note that some less frequently used strategies tend to be under annotated at the individual level, and may thus create artificially high difference in coefficients. We thus use the coefficient from the average model for any strategy that is annotated for less than 15 times by the individual annotator.

C Additional Details on ILP

We consider a few linguistic constraints to help exclude some counter-intuitive strategy combinations. It should be noted that, with increased quality of a generation model, or by dynamically integrating the limitation of the generation model into the planning step, the process of inserting such additional constraints may be automated:

Negativity constraint. While our simple linear model estimates the level of politeness by the aggregated effects of all strategies used regardless of their polarity, humans are known to have a negativity bias (Baumeister et al., 2001): while the presence of polite markers in an otherwise impolite utterance may soften the tone, the use of a negative marker in an otherwise polite utterance may be overshadowing. As a result, when an input is judged to be positive in politeness, we consider the additional constraint to exclude use of negative strategies, i.e., $x_s = 0, \forall s \in \{s : b_s < 0\}$.

Subjunctive and Indicative constraint. Admittedly, among the set of markers we consider, some are more decoupled from contents than others—while removing *just* is almost guaranteed to keep the original meaning of the sentence intact, for an utterance that starts with either Subjunctive or Indicative, e.g., *could you clarify?*, simply removing *could you* would have already made its meaning ambiguous.[18] To account for this, we add the constraint that the use of Subjunctive and Indicative should be substituted within themselves, i.e., $x_{\text{Subjunctive}} + x_{\text{Indicative}} = \mathbb{1}_{\mathcal{S}_{in}}(\text{Subjunctive}) + \mathbb{1}_{\mathcal{S}_{in}}(\text{Indicative})$.[19]

D Details on Human Evaluations

To evaluate on the naturalness of the generated text, we ask two non-author native speaker for naturalness ratings on a scale of 1 (very unnatural) to 5 (very natural). The exact instruction is shown in Table A2.

---

[18] For instance, *can I clarify?* and *can you clarify?* would both be linguistically plausible requests containing *clarify*, yet they differ significantly in meaning.

[19] We acknowledge that under certain circumstances, this constraint may be impossible to fulfill.

Strategy	Coeff.	Example markers	Delete mode	Example usage
Actually	-0.358	really, actually	token	it **actually** needs to be ...
Adverb.Just	-0.004	just	token	i **just** noticed that ...
Affirmation	0.171	ok, good [work]	segment	**excellent point**, i have added it ...
Apology	0.429	sorry, [i] apologize	segment	**sorry** to be off-topic but ...
By.The.Way	0.331	by the way, btw	token	okay - **btw**, do you want me ...?
Conj.Start	-0.245	so, and, but	token	**so** where is the article ?
Filler	-0.245	hmm, um	token	**uh**, hey, can you...?
For.Me	0.128	for me	token	is it alright **for me** to archive it now?
For.You	0.197	for you	token	i can fetch one **for you** in a moment! ...
Gratitude	0.989	thanks, [i] appreciate	segment	**thanks** for the info , ...
Greeting	0.491	hi, hello	token	**hey** simon , help is needed if possible ...
Hedges	0.131	possibly, maybe	token	**maybe** some kind of citation is needed ...
Indicative	0.221	can you, will you	token	**can you** create one for me?
Please	0.230	please	token	can you **please** check it?
Please.Start	-0.209	please	token	**please** stop . if you continue ...
Reassurance	0.668	no worries	segment	**no problem**, happy editing. ...
Subjunctive	0.454	could you, would you	token	..., **could you** check?
Swearing	-1.30	the hell, fucking	token	what **the heck** are you talking about?

Table A1: Local politeness strategies being considered. For each strategy, we show its corresponding coefficients in the linear regression model, example markers, together with example usages.

Ignoring punctuations, typos, and missing context, on a scale of 1-5, how natural does the text sound?

5. **Very natural**: It's possible to imagine a native speaker sending the message online.
4. **Mostly natural**: While there are some minor errors, simple edits can make it become 'very natural'.
3. **Somewhere in between**: While the text is comprehensible, it takes more involved edits to make it sound natural.
2. **Mostly unnatural**: There are significant grammatical issues that make the text almost not comprehensible.
1. **Very unnatural**: Entirely broken English.

Table A2: Instruction for naturalness annotations.

E Additional Generation Examples

We show additional generation outputs in Table A3, and a categorization of failure cases in Table A4.

Strategy plan	Input (upper) / Output (lower)	Score
Please, Subjunctive, Gratitude	could you then please make some contributions in some of your many areas of expertise? thanks.	
Greeting, Subjunctive, Adverb.Just, For.Me	hi , could you then just make some contributions for me in some of your many areas of expertise ?	5
Please	can someone please explain why there's a coi tag on this article? it's not evident from the talk page.	
For.Me, Hedges	can someone explain why there ' s a coi tag on this article for me ? it ' s not apparent from the talk page .	5
Conj.Start, Filler	uh...ok...whatever...did you get that user name yet? or do you prefer hiding behind your ip?	
Actually, By.The.Way, Conj.Start, Please.Start	ok . . . whatever . . . did you actually get that user name yet ? or do you prefer hiding behind your ip ?	5
Please, Subjunctive	could you please stop your whining, and think about solutions instead? tx.	
By.The.Way, Hedges, Indicative	btw , can you maybe stop your whining , and think about solutions instead ? tx .	5

Table A3: Additional examples from the generation outputs, together with strategy information (*original strategy combination* for inputs in italics, realized strategies underlined for outputs) and naturalness scores. We also highlight the original and newly introduced markers through which the strategies are realized. Refer to Table A4 for common types of failure cases.

Error type	Input (upper) / Output (lower)	Score
`Grammatical mistake`	the bot seems to be down again. could you give it a nudge?	
	the bot seems to be down again . **maybe** can you give it a nudge for me ?	3
	i see you blocked could you provide your rationale? thanks - ()	
	i see you blocked **provide** your rationale ? (**please**)	2
`Strategy misfit`	hello, this image has no license info, could you please add it? thank you.	
	hello , this image has no license info , **sorry** . could you add it **for you** ? thank you .	3
	can you please review this or block or have it reviewed at ani? thank you	
	no worries . sorry , can you review this or block or have it reviewed for me at ani ?	3

Table A4: Examples demonstrating two representative error types with naturalness scores. `Grammatical mistake` represents cases when the markers are in inappropriate positions or introduce errors to the sentence structure. `Strategy misfit` represents cases when the use of suggested strategies (regardless of choice of markers to realize them) do not seem appropriate. Problematic portions of the outputs are in bold.

CAT-Gen: Improving Robustness in NLP Models via Controlled Adversarial Text Generation

Abstract

NLP models are shown to suffer from robustness issues, i.e., a model's prediction can be easily changed under small perturbations to the input. In this work, we present a Controlled Adversarial Text Generation (CAT-Gen) model that, given an input text, generates adversarial texts through controllable attributes that are known to be irrelevant to task labels. For example, in order to attack a model for sentiment classification over product reviews, we can use the product categories as the controllable attribute which should not change the sentiment of the reviews. Experiments on real-world NLP datasets demonstrate that our method can generate more diverse and fluent adversarial texts, compared to many existing adversarial text generation approaches. We further use our generated adversarial examples to improve models through adversarial training, and we demonstrate that our generated attacks are more robust against model retraining and different model architectures.

1 Introduction

It has been shown that NLP models are often sensitive to random initialization (Zhou et al., 2020), out-of-distribution data (Hendrycks et al., 2020; Wang et al., 2019), and adversarially generated attacks (Jia and Liang, 2017; Jin et al., 2020; Alzantot et al., 2018). One line of research to improve models' robustness to adversarial attacks is by generating adversarial examples in either the input text space (discrete, e.g., Alzantot et al. (2018); Jin et al. (2020)) or some intermediate representation space (continuous, e.g., Zhao et al. (2018); Zhu et al. (2020)). However, existing adversarial text generation approaches that try to perturb in the input text space might lead to generations *lacking diversity or fluency*. On the other hand, approaches focusing on perturbing in the intermediate representation space can often lead to generations that are not related to the input. We show some adversarial examples generated by existing works in Table 1.

In this work, we aim to explore *adversarial* text generation through *controllable* attributes. We propose to utilize text generation models to produce more diverse and fluent outputs. Meanwhile, we constrain the language generation within certain controllable attributes, leading to high quality outputs that are semantically close to input sentences. Formally, we denote the input text as x, the label for the main task (e.g., text classification) as y, a model's prediction over x as $f(x)$, and controllable attributes (e.g., category, gender, domain) as a. Our goal is to create adversarial attacks x' that can successfully fool the classifier into making an incorrect prediction $f(x) \neq f(x')$, while keeping the ground truth task label *unchanged*, i.e., $(x, y) \rightarrow (x', y)$.

To achieve these goals, we propose CAT-Gen, a **C**ontrolled **A**dversarial **T**ext **Gen**eration model. It consists of an encoder and a decoder for text generation, and a module network that encodes the information of controllable attributes and generates adversarial attacks via changing the controllable attributes. The encoder and decoder are trained over a large text corpus and thus can generate more fluent and diverse output. We control the generated output through an attribute a. We assume the attribute a is pre-specified and is known to be irrelevant to the main task-label, and can be learned through an *auxiliary* dataset. In this way, the attribute training and task training (for attack) can be disentangled, and note that we do not require a parallel corpus for the auxiliary dataset when learning the attribute. We present experiments on real-world NLP datasets to demonstrate the applicability and generalizability of our proposed methods. We show that our generated attacks are more fluent (defined

Method	Examples
Textfooler (Jin et al., 2020)	A person is relaxing on his day off → A person is relaxing on his nowadays off The two men are friends → The three men are dudes
NL-adv (Alzantot et al., 2018)	A man is talking to his wife over his phone → A guy is chitchat to his girl over his phone A skier gets some air near a mountain... → A skier gets some airplane near a mountain...
Natural-GAN (Zhao et al., 2018)	a girl is playing at a looking man . → a white preforming is lying on a beach . two friends waiting for a family together . → the two workers are married .

Table 1: Examples over existing adversarial text generation methods on SNLI (Bowman et al., 2015) dataset. Adversarial text generated by word substitution based methods (Textfooler & NL-adv) may lack fluency or diversity; GAN based methods (Natural-GAN) tend to generate sentences not related to the original sentences.

by language model perplexity), more diverse (defined by BLEU-4 score) and more robust against model re-training and various model architectures.

2 Related Work

NLP models' robustness has drawn a lot of attention in recent years, among those, a specific line of work tries to address this issue by generating adversarial examples, including (Guu et al., 2018; Iyyer et al., 2018; Alvarez-Melis and Jaakkola, 2017; Jia and Liang, 2017; Ebrahimi et al., 2018; Naik et al., 2018). For example, both Alzantot et al. (2018) and Jin et al. (2020) generate adversarial texts by substituting words with their synonyms (defined by similarity in the word embedding space) that can lead to a model prediction change. Zhao et al. (2018) propose to generate natural and legible adversarial examples using a Generative Adversarial Network, by searching in the semantic space of continuous data representation. Jia et al. (2019) propose to find the combination of word substitutions by minimizing the upper bound on the worst-case loss. More recently, rather than directly generating text outputs, Zhu et al. (2020) add adversarial perturbations to word embeddings and minimize the adversarial risk around input examples.

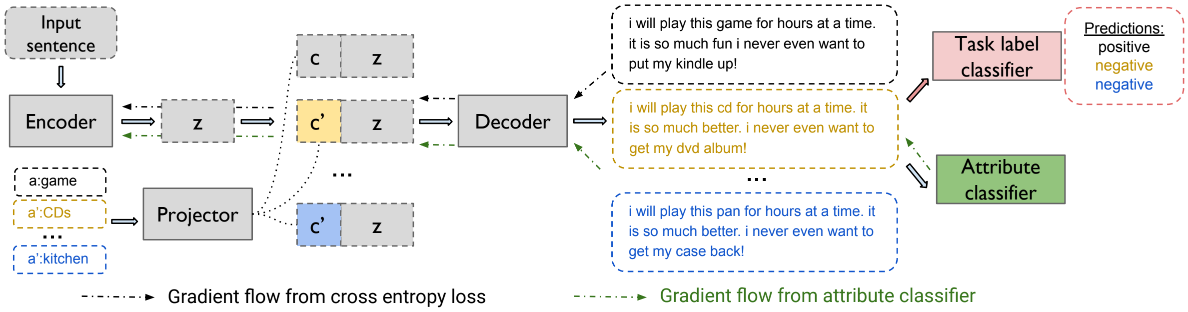
Our work is also closely related to controllable text generation, e.g., Hu et al. (2017) use variational auto-encoders and holistic attribute discriminators, Dathathri et al. (2020) utilize a pre-trained language model with one or more simple attribute classifiers to guide text generation, and Shen et al. (2017) propose to achieve style transfer using non-parallel text. In addition, our work is connected with (adversarial) domain adaptation, since the controlled attributes can be different domains. NLP models have been shown to lack robustness when been tested over out-of-distribution data, e.g., Hendrycks et al. (2020); Wang et al. (2019).

3 Controlled Adversarial Text Generation Model

In Figure 1, we present an overview of the CAT-Gen model, where we aim to generate attacks against a main *task* (e.g., sentiment classification) by controlling the *attribute* (e.g., product category) over an input sentence (e.g., product reviews). Similar to controlled text generation works (Hu et al., 2017; Shen et al., 2017; Dathathri et al., 2020), the model consists of an encoder and a decoder, with an attribute classifier. We add components to accommodate both change of attributes and attack generation over an input task model. We assume an auxiliary dataset for training the attribute. Our model training involves three stages:

Pre-training. We pre-train the encoder and the decoder (both are RNNs in our case but could be other models) to allow the generation model to learn to copy an input sentence s_a (assuming the input sentence has an attribute a) using teacher-forcing. A cross entropy loss is placed between the input text ids and the output logits of each token: $\ell_{c,z} = -\sum_{t=1}^{T} \log p(s_a^t | s_a^{<t}; c, z)$, where z is the encoder output and c is the hidden representation (set to 256 dimensions in our experiments) over attribute a generated by feeding a one-hot encoding of a into a projector. Meanwhile, we pre-train the attribute classifier using the auxiliary dataset.

Change of attribute. In the second stage, we focus on updating the decoder to enable the model to generate an output that has a desired attribute $a' \neq a$. To generate this new sentence $s_{a'}$, we obtain c' by feeding the one-hot encoding of a' into the same projector (used to map a to c). Then we use the pre-trained attribute classifier to guide the training of our decoder. Note that we do not



i will play this game for hours at a time. it is so much fun i never even want to put my kindle up!

i will play this cd for hours at a time. it is so much better. i never even want to get my dvd album!

i will play this pan for hours at a time. it is so much better. i never even want to get my case back!

Figure 1: Overview of our Controlled Adversarial Text Generation (CAT-Gen) model. We backpropagate: 1. cross entropy loss (black dash line) to ensure the generated sentence has a similar semantic meaning as the input sentence; 2. attribute loss (green dash line) to manipulate the attribute (irrelevant to task label) in the generated sentence. The task label (sentiment) prediction on generated text varies when changing the attribute a (category).

update the parameters of the attribute classifier in this stage. Since producing hard word ids involves a non-differentiable argmax operation, we adopt soft embeddings (Jang et al., 2017) to ensure gradients can be back-propagated through the network. Specifically, we apply the attribute classifier on the generated sentence $s_{a'}$ (soft embeddings) and compute an attribute loss with respect to c':

$$\ell_{c',z} = -\mathbb{E}_{p(c')p(z)}[\log q_A(c'|D_\tau(c',z))],$$

where D is the decoder, q_A is the conditional distribution defined by attribute classifier A and τ is a temperature; by annealing τ, the distribution over the vocabulary gets more peaked and closer to the discrete case.

Optimizing for attacks. In the final stage, we enumerate the attribute space to encourage the model's generated output ($s_{a'}$) to be able to successfully attack the task model. In order to generate stronger attacks, for each input s_a, we search through the whole attribute space of $a' \neq a$ and look for the attribute a^* that maximizes the cross-entropy loss between the task-label predictions over $s_{a'}$ and the ground-truth task-label y (we use the ground-truth task label from the input sentence since we assume it is unchanged):

$$a^* = \arg\max_{\{a' \neq a\}}[-\sum_y y \log p(y|s_{a'})].$$

Generalizability of our framework. By utilizing a text generation model and a larger search space over the controlled attributes, our model is able to generate more diverse and fluent adversarial texts compared to existing approaches. Our framework can be naturally extended to many different problems, e.g., domain transfer (different domains as a), style transfer, as well as fairness applications (e.g., using different demographic attributes as a).

4 Experiments

In this section, we present experiments over real-world datasets, and demonstrate that our model creates adversarial texts that are more diverse and fluent, and are most robust against model re-training as well as different model architectures.

Dataset. We use the Amazon Review dataset (He and McAuley, 2016) with 10 categories (electronics, kitchen, games, books, etc.). Our main task is a *sentiment classification* task over reviews, with different *product categories* as attribute a. We filter out reviews with number of tokens over 25. The attribute (category) classifier is trained on a set of $60,000$ reviews per category. The attribute training data is also balanced by sentiment to better disengtangle the attribute and the task-label. We use another training set ($80,000$ positive and $80,000$ negative) to learn the sentiment classifier. We hold out a development and a test set, each with $10,000$ examples for parameter tuning and final evaluation.

Implementation details. We adopt the convolutional text classification model (wordCNN, Kim (2014)) for both attributes (category) and task labels (sentiment). We use a one-layer MLP as the projector. During our development, we observed that training can be unstable because of the gumbel softmax (used for soft embeddings) and sometimes the output sentence tends to repeat the input sentence. We carefully tuned the temperature for gumbel softmax as suggested by (Hu et al., 2017). We also found that using a low-capacity network (e.g. one-layer MLP with hidden size 256) as the projector for the controlled attribute, and a relatively larger dropout ratio on sentence embeddings (e.g. 0.5) help stabilize the training procedure.

Attribute ($a \to a'$)	Original sentence with attribute a	Generated sentence with perturbed attribute a'
Kitchen → Phone	amazing knife, used for my edc for a long time, only switched because i got tired of the same old knife (Pos.)	amazing case. used for my iphone5 for a long time, only problem because i got tired of the same old kindle (Neg.)
Book → Kitchen	not as helpful as i wanted. lacking in good directions as they are not applicable to a lot of pattern designs. (Neg.)	not as helpful as i wanted. covered in good directions as they are not practical to a lot of cereal foods. (Pos.)
Movie → Clothing	good fluffy, southern mystery. not as predictable as some. promising ending. i will probably read the rest of the series. (Pos.)	good fabric, no thin. not as predictable as pictured. last well. i will probably read the rest of the series. (Neg.)

Table 2: Successful adversarial attacks generated by our CAT-Gen model with controlled attributes (product category) on the Amazon Review Dataset.

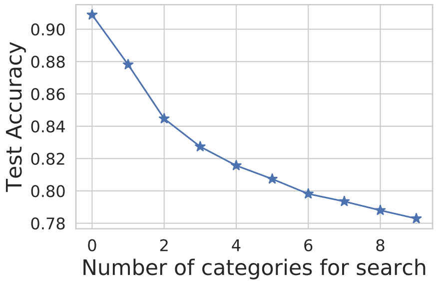


Figure 2: Test accuracy drops when increasing the number of categories available for searching attacks. Note this is over all generated outputs without filtering on whether they are successful attacks. With filtering we can further decrease the test accuracy close to zero.

Qualitative results. Qualitative examples of our CAT-gen model are shown in Table 2. We see that the model is able to generate fluent and diverse adversarial texts, and many words from the original input have been replaced to fit into the new category attribute a', which would be relatively hard to achieve by swaps based on synonyms or nearest-neighbor search in the word embedding space as in Jin et al. (2020); Alzantot et al. (2018). For example, our model can successfully change the goods description from *good fluffy, southern mystery* into *good fabric, no thin*, matching the attribute change (movie → clothing).

Attack search space. Figure 2 shows the test set accuracy by increasing the number of categories available for searching attacks. We see that our controlled generation model can create successful attacks to the main task model (the accuracy decreases). Increasing the number of categories further decreases the accuracy. This shows that the number of different values the attribute can take is important and enlarging the attack search space helps to generate stronger adversarial examples.

Diversity and fluency. In Table 3, we measure the diversity and fluency of the generated adversarial examples. More specifically, to measure diversity, we compute the BLEU-4 score of generated text with respect to the input text. To measure fluency, we use pretrained language models and compute the perplexity score of the generated text. Compared to other adversarial methods, our CAT-Gen model can generate texts with better diversity (lower BLEU-4 score) as well as better fluency (lower perplexity score).

Transferability. In Table 4, we show the transferability of our examples compared to popular adversarial text generation methods (Jin et al., 2020; Alzantot et al., 2018). We conduct two series of experiments. In *WordCNN retraining* experiment, we first use CAT-Gen to attack a WordCNN sentiment classifier and collect some successful adversarial examples. Note that on those examples, the WordCNN sentiment classifier always makes mistakes, thus has a zero performance. We then retrain this WordCNN sentiment classifier and re-test it on those successful adversarial examples. The performance goes up to 49.3%, meaning 49.3% of those successful adversarial examples now fail to attack this retrained WordCNN sentiment classifier. In other words, 49.3% of adversarial examples are not robust to model retraining. In *WordLSTM* experiment, instead of retraining the WordCNN classifier, we train a WordLSTM classifier and evaluate to what extent those adversarial examples are robust against model architecture change. As shown in Table 4, adversarial examples generated by CAT-Gen demonstrate the highest transferability (lowest attack success rate against model re-training and model architecture change).

Adversarial training. Table 5 presents results of adversarial training (Goodfellow et al., 2015),

		TextFooler (Jin et al., 2020)	NL-adv (Alzantot et al., 2018)	CAT-Gen
Diversity (BLEU-4 (Papineni et al., 2002), want ↓)		68.9	64.3	38.8
Fluency (in perplexity, want ↓)	Language Model 1	1853.7	964.3	729.5
	Language Model 2	1805.4	1188.5	868.7
	Language Model 3	336.7	479.9	358.9

Table 3: Comparison of our model with other methods. Evaluation is done over the attacks generated from the test set. Language model 1 & 2 are both from (Baevski and Auli, 2018), pretrained on Google Billion Words and WikiText-103 respectively; language model 3 (Ng et al., 2019) is pretrained on WMT news dataset.

	TextFooler (Jin et al., 2020)	NL-adv (Alzantot et al., 2018)	CAT-Gen
WordCNN re-training	84.7	82.9	49.3
WordLSTM	85.6	80.5	51.5

Table 4: Accuracy for various attacks over a re-trained model and a different architecture (want ↓). Note that the accuracy on the original model is zero since the evaluation contains a hold-out $1K$ set with only successful attacks.

	Original test set	TextFooler attacks	NL-adv attacks	CAT-Gen attacks
Original Training	91.9	84.7	82.9	49.3
+TextFooler (Jin et al., 2020)	92.7	89.5	88.6	52.7
+NL-adv (Alzantot et al., 2018)	92.2	86.4	94.6	51.2
+CAT-Gen	92.4	84.4	83.4	92.5

Table 5: We augment the original training set with adversarial attacks (rows) and evaluate the accuracy (want ↑) on hold-out $1K$ adversarial attacks (columns) generated by our method and two other baselines.

which is a typical way to leverage adversarial examples to improve models. Specifically, we divide generated adversarial examples into two subsets, one is used for augmenting the training data, and the other is a hold-out set used for testing. With the augmented training data, we retrain the wordCNN sentiment classifier model (the same one as in Table 4), and test it on the hold-out set. In Table 5, we augment training data with adversarial examples generated by each method (as shown by the rows), and evaluate the model performance on the hold-out set (again from each method respectively, as shown by the columns). As we can see, augmenting with CAT-Gen examples improves performance on CAT-Gen attacks much better than baselines, which both use narrower substitutions, and also maintains high accuracy on baseline attacks.

5 Conclusion and Discussion

In this paper, we propose a controlled adversarial text generation model that can generate more diverse and fluent adversarial texts. We argue that our model creates more natural and meaningful attacks to real-world tasks by demonstrating our attacks are more robust against model re-training and across model architectures.

Our current generation is controlled by a few pre-specified attributes that are label-invariant by definition. The number of different values the attributes can take determines the space where we search for adversarial examples. One benefit of our framework is that it is flexible enough to incorporate multiple task-irrelevant attributes and our optimization allows the model to figure out which attributes are more susceptible to attacks. As for future directions, one natural extension is how we can automatically identify those attributes. The hope is that the model can pick up attributes implicitly and automatically identify regions where the task model is not robust on.

Seq2Edits: Sequence Transduction Using Span-level Edit Operations

Felix Stahlberg and Shankar Kumar
Google Research
`{fstahlberg,shankarkumar}@google.com`

Abstract

We propose Seq2Edits, an open-vocabulary approach to sequence editing for natural language processing (NLP) tasks with a high degree of overlap between input and output texts. In this approach, each sequence-to-sequence transduction is represented as a sequence of edit operations, where each operation either replaces an entire source span with target tokens or keeps it unchanged. We evaluate our method on five NLP tasks (text normalization, sentence fusion, sentence splitting & rephrasing, text simplification, and grammatical error correction) and report competitive results across the board. For grammatical error correction, our method speeds up inference by up to 5.2x compared to full sequence models because inference time depends on the number of edits rather than the number of target tokens. For text normalization, sentence fusion, and grammatical error correction, our approach improves explainability by associating each edit operation with a human-readable tag.

1 Introduction

Neural models that generate a target sequence conditioned on a source sequence were initially proposed for machine translation (MT) (Sutskever et al., 2014; Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2015; Vaswani et al., 2017), but are now used widely as a central component of a variety of NLP systems (e.g. Tan et al. (2017); Chollampatt and Ng (2018)). Raffel et al. (2019) argue that even problems that are traditionally not viewed from a sequence transduction perspective can benefit from massive pre-training when framed as a text-to-text problem. However, for many NLP tasks such as correcting grammatical errors in a sentence, the input and output sequence may overlap significantly. Employing a full sequence model in these cases is often wasteful as most tokens are simply copied over from the input to the output. Another disadvantage of a full sequence model is that it does not provide an explanation for why it proposes a particular target sequence.

In this work, inspired by a recent increased interest in text-editing (Dong et al., 2019; Malmi et al., 2019; Mallinson et al., 2020; Awasthi et al., 2019), we propose *Seq2Edits*, a sequence *editing* model which is tailored towards problems that require only small changes to the input. Rather than generating the target sentence as a series of tokens, our model predicts a sequence of edit operations that, when applied to the source sentence, yields the target sentence. Each edit operates on a span in the source sentence and either copies, deletes, or replaces it with one or more target tokens. Edits are generated auto-regressively from left to right using a modified Transformer (Vaswani et al., 2017) architecture to facilitate learning of long-range dependencies. We apply our edit operation based model to five NLP tasks: text normalization, sentence fusion, sentence splitting & rephrasing, text simplification, and grammatical error correction (GEC). Our model is competitive across all of these tasks, and improves the state-of-the-art on text normalization (Sproat and Jaitly, 2016), sentence splitting & rephrasing (Botha et al., 2018), and the JFLEG test set (Napoles et al., 2017) for GEC.

Our model is often much faster than a full sequence model for these tasks because its runtime depends on the number of edits rather than the target sentence length. For instance, we report speedups of >5x on GEC for native English in initial experiments. If applicable, we also predict a task-specific edit-type class (“tag”) along with each edit which explains why that edit was proposed. For example in GEC, the correction of a misspelled word would be labelled with a `SPELL` (spelling error) whereas changing a word from say first person to third person would be associated with a tag such as `SVA` (subject-verb agreement error).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5147–5159,
November 16–20, 2020.

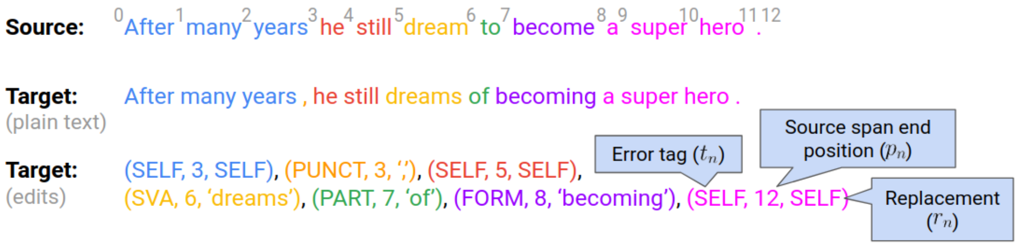

Figure 1: Representing grammatical error correction as a sequence of span-based edit operations. The implicit start position for a source span is the end position of the previous edit operation. `SELF` indicates spans that are copied over from the source sentence ($\mathbf{x}$). The probability of the first two edits is given by: $P(\text{After many years ,}|\mathbf{x}) = P(t_1 = \text{SELF}|\mathbf{x}) \cdot P(p_1 = 3|\text{SELF}, \mathbf{x}) \cdot P(r_1 = \text{SELF}|\text{SELF}, 3, \mathbf{x}) \cdot P(t_2 = \text{PUNCT}|\text{SELF}, 3, \text{SELF}, \mathbf{x}) \cdot P(p_2 = 3|\text{SELF}, 3, \text{SELF}, \text{PUNCT}, \mathbf{x}) \cdot P(r_2 = ,|\text{SELF}, 3, \text{SELF}, \text{PUNCT}, 3, \mathbf{x})$.

2 Edit-based Sequence Transduction

2.1 Representation

A vanilla sequence-to-sequence (seq2seq) model generates a plain target sequence $\mathbf{y} = y_1^J = y_1, y_2, \dots, y_J \in V^J$ of length J given a source sequence $\mathbf{x} = x_1^I = x_1, x_2, \dots, x_I \in V^I$ of length I over a vocabulary V of tokens (e.g. subword units (Sennrich et al., 2016)). For example, in our running grammar correction example in Fig. 1, the source sequence is the ungrammatical sentence $\mathbf{x}$ =“*After many years he still dream to become a super hero .*” and the target sequence is the corrected sentence $\mathbf{y}$ =“*After many years , he still dreams of becoming a super hero .*”. The probability $P(\mathbf{y}|\mathbf{x})$ is factorized using the chain rule:

$$P(\mathbf{y}|\mathbf{x}) = \prod_{j=1}^{J} P(y_j|y_1^{j-1}, \mathbf{x}). \tag{1}$$

Instead of predicting the target sequence $\mathbf{y}$ directly, the *Seq2Edits* model predicts a sequence of N edit operations. Each edit operation $(t_n, p_n, r_n) \in T \times \mathbb{N}_0 \times V$ is a 3-tuple that represents the action of replacing the span from positions p_{n-1} to p_n in the source sentence with the replacement token r_n associated with an explainable tag t_n (T is the tag vocabulary).[1] $t_n = r_n =$ `SELF` indicates that the source span is kept as-is. Insertions are modelled with $p_n = p_{n-1}$ that corresponds to an empty source span (see the insertion of “,” in Fig. 1), deletions are represented with a special token $r_n =$ `DEL`. The edit operation sequence for our running example is shown in Fig. 1. The target sequence $\mathbf{y}$ can be obtained from the edit operation sequence using Algorithm 1.

Algorithm 1 ApplyEdits()

```
$p_0 \leftarrow 0$ {First span starts at 0.}
$\mathbf{y} \leftarrow \epsilon$ {Initialize $\mathbf{y}$ with the empty string.}
for $n \leftarrow 1$ to $N$ do
    if $t_n =$ SELF then
        $\mathbf{y} \leftarrow \text{concat}(\mathbf{y}, x_{p_{n-1}}^{p_n})$
    else if $r_n \neq$ DEL then
        $\mathbf{y} \leftarrow \text{concat}(\mathbf{y}, r_n)$
    end if
end for
return $\mathbf{y}$
```

Our motivation behind using span-level edits rather than token-level edits is that the representations are much more compact and easier to learn since local dependencies (within the span) are easier to capture. For some of the tasks it is also more natural to approach the problem on the span-level: a grammatical error is often fixed with more than one (sub)word, and span-level edits retain the language modelling aspect within a span.

Our representation is flexible as it can represent any sequence pair. As an example, a trivial (but not practical) way to construct an edit sequence for any pair $(\mathbf{x}, \mathbf{y})$ is to start with a deletion for the entire source sentence $\mathbf{x}$ ($p_1 = I$, $r_1 =$ `DEL`) and then insert the tokens in $\mathbf{y}$ ($p_{j+1} = I$, $r_{j+1} = y_j$ for $j \in [1, J]$).

Edit sequences are valid iff. spans are in a monotonic left-to-right order and the final span ends at the end of the source sequence, i.e.:

$$p_N = I \wedge \forall n \in [1, N) : p_n \leq p_{n+1} \tag{2}$$

None of our models produced invalid sequences at inference time even though we did not implement any feasibility constraints.

---

[1] In our ablation experiments without tags, each edit operation is represented by a 2-tuple (p_n, r_n) instead.

2.2 Inference

The output of the edit operation model is a sequence of 3-tuples rather than a sequence of tokens. The probability of the output is computed as:

$$P(\mathbf{y}|\mathbf{x}) = P(t_1^N, p_1^N, r_1^N|\mathbf{x}) = \prod_{n=1}^{N} P(t_n, p_n, r_n|t_1^{n-1}, p_1^{n-1}, r_1^{n-1}, \mathbf{x}). \tag{3}$$

For inference, we factorize the conditional probabilities further as:

$$\begin{aligned} &P(t_n, p_n, r_n|t_1^{n-1}, p_1^{n-1}, r_1^{n-1}, \mathbf{x}) \\ =&P(t_n|t_1^{n-1}, p_1^{n-1}, r_1^{n-1}, \mathbf{x}) \\ &\cdot P(p_n|t_1^{n}, p_1^{n-1}, r_1^{n-1}, \mathbf{x}) \\ &\cdot P(r_n|t_1^{n}, p_1^{n}, r_1^{n-1}, \mathbf{x}). \end{aligned} \tag{4}$$

The decoding problem can thus be written as a flat product of conditional probabilities that correspond to tag, span and replacement predictions, that are interleaved:

$$\begin{aligned} \underset{N,t_1^N,p_1^N,r_1^N}{\arg\max}\ & P(t_1|\mathbf{x}) \cdot P(p_1|t_1, \mathbf{x}) \cdot P(r_1|t_1, p_1, \mathbf{x}) \\ &\cdot P(t_2|t_1, p_1, r_1, \mathbf{x}) \cdots P(r_N|t_1^N, p_1^N, r_1^{N-1}, \mathbf{x}). \end{aligned} \tag{5}$$

At inference time we perform beam decoding over this flat factorization to search for the most likely edit operation sequence. In practice, we scale the scores for the different target features:

$$\begin{aligned} \underset{N,t_1^N,p_1^N,r_1^N}{\arg\max} \sum_{n=1}^{N} & \lambda_t \log P(t_n|t_1^{n-1}, p_1^{n-1}, r_1^{n-1}, \mathbf{x}) \\ &+ \lambda_p \log P(p_n|t_1^{n}, p_1^{n-1}, r_1^{n-1}, \mathbf{x}) \\ &+ \lambda_r \log P(r_n|t_1^{n}, p_1^{n}, r_1^{n-1}, \mathbf{x}). \end{aligned} \tag{6}$$

where the three scaling factors λ_t, λ_p, λ_r are optimized on the respective development set.

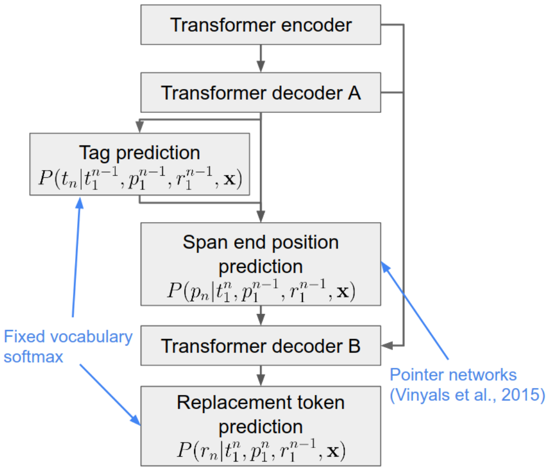

Figure 2: *Seq2Edits* consists of a Transformer (Vaswani et al., 2017) encoder and a Transformer decoder that is divided horizontally into two parts (A and B). The tag and span predictions are located in the middle of the decoder layer stack between both parts. A single step of prediction is shown.

Encoder layers	6	6
Decoder A layers	3	4
Decoder B layers	3	4
No. of parameters (w/o embeddings)	53M	246M

Table 1: The "Base" and "Big" configurations.

2.3 Neural Architecture

Our neural model (illustrated in Fig. 2) is a generalization of the original Transformer architecture of Vaswani et al. (2017). Similarly to the standard Transformer we feed back the predictions of the previous time step into the Transformer decoder (A). The feedback loop at time step n is implemented as the concatenation of an embedding of t_{n-1}, the p_{n-1}-th encoder state, and an embedding of r_{n-1}. The Transformer decoder A is followed by a cascade of tag prediction and span end position prediction. We follow the idea of pointer networks (Vinyals et al., 2015) to predict the source span end position using the attention weights over encoder states as probabilities. The input to the pointer network are the encoder states (keys and values) and the output of the previous decoder layer (queries). The span end position prediction module is a Transformer-style (Vaswani et al., 2017) single-head attention ("scaled dot-product") layer over the encoder states:

$$P(p_n|t_1^n, p_1^{n-1}, r_1^{n-1}, \mathbf{x}) = \text{softmax}(\frac{QK^T}{\sqrt{d}}), \tag{7}$$

where Q is a d-dimensional linear transform of the previous decoder layer output at time step n, $K \in \mathbb{R}^{I \times d}$ is a linear transform of the encoder states, and d is the number of hidden units.

A 6-dimensional embedding of the predicted tag t_n and the encoder state corresponding to the source span end position p_n are fed into yet another Transformer decoder (B) that predicts the replacement token r_n. Alternatively, one can view A and

Table 2: Statistics for the task-specific training data. The I, J, and N variables are introduced in Sec. 2.1. Our subword-based systems use the implementation available in Tensor2Tensor (Vaswani et al., 2018) with a vocabulary size of 32K. The pre-training data is described in the text. See Appendix A for the full tag vocabularies.

B as a single Transformer decoder layer stack, in which we added the tag prediction and the span end position prediction as additional layers in the middle of that stack. We connect the decoders A and B with residual connections (He et al., 2016) to facilitate learning. The network is trained by optimizing the sum of three cross-entropies that correspond to tag prediction, span prediction, and replacement token prediction, respectively.[2] In our experiments without tags we leave out the tag prediction layer and the loss computed from it. We experiment with two different model sizes: "Base" and "Big". The hyper-parameters for both configurations are summarized in Table 1. Hyper-parameters not listed here are borrowed from the *transformer_clean_base* and *transformer_clean_big* configurations in the Tensor2Tensor toolkit (Vaswani et al., 2018).

3 Experiments

We evaluate our edit model on five NLP tasks:[3]

- Text normalization for speech applications (Sproat and Jaitly, 2016) – converting number expressions such as "*123*" to their verbalizations (e.g. "*one two three*" or "*one hundred twenty three*", etc.) depending on the context.

- Sentence fusion (Geva et al., 2019) – merging two independent sentences to a single coherent one, e.g. "*I need his spirit to be free. I can leave my body.*" → "*I need his spirit to be free so that I can leave my body.*"

- Sentence splitting & rephrasing (Botha et al., 2018) – splitting a long sentence into two fluent sentences, e.g. "*Bo Saris was born in Venlo, Netherlands, and now resides in London, England.*" → "*Bo Saris was born in Venlo , Netherlands. He currently resides in London, England.*"

- Text simplification (Zhang and Lapata, 2017) – reducing the linguistic complexity of text, e.g. "*The family name is derived from the genus Vitis.*" → "*The family name comes from the genus Vitis.*"

- Grammatical error correction (Ng et al., 2014; Napoles et al., 2017; Bryant et al., 2019) – correcting grammatical errors in written text, e.g. "*In a such situaction*" → "*In such a situation*".

Our models are trained on packed examples (maximum length: 256) with Adafactor (Shazeer and Stern, 2018) using the Tensor2Tensor (Vaswani et al., 2018) library. We report results both with and without pre-training. Our pre-trained models for all tasks are trained for 1M iterations on 170M sentences extracted from English Wikipedia revisions and 176M sentences from English Wikipedia round-trip translated via German (Lichtarge et al., 2019). For grammatical error correction we use ERRANT (Bryant et al., 2017; Felice et al., 2016) to derive span-level edits from the parallel text. On other tasks we use a minimum edit distance heuristic to find a token-level edit sequence and convert it to span-level edits by merging neighboring edits.

The task-specific data is described in Table 2. The number of iterations in task-specific training is set empirically based on the performance on the development set (between 20K-75K for fine-tuning,

---

[2] We use an unweighted sum as we did not observe gains from weighting the three losses during training.

[3] Citations in this bullet list refer to the test sets we used and do not necessarily point to the pioneering works.

Table 4: Single model results. For metrics marked with "↑" (SARI, P(recision), R(ecall), $F_{0.5}$) high scores are favorable, whereas the sentence error rate (SER) is marked with "↓" to indicate the preference for low values. Tuning refers to optimizing the decoding parameters listed in Table 3 on the development sets.

between 100K-300K for training from scratch). Fine-tuning is performed with a reduced learning rate of 3×10^{-5}. For each task we tune a different set of decoding parameters (Table 3) such as the λ-parameters from Sec. 2.2, on the respective development sets. For text simplification and grammatical error correction, we perform multiple beam search passes (between two and four) by feeding back the output of beam search as input to the next beam search pass. This is very similar to the iterative decoding strategies used by Lichtarge et al. (2019); Awasthi et al. (2019); Ge et al. (2018); Grundkiewicz et al. (2019) with the difference that we pass through n-best lists between beam search passes rather than only the single best hypothesis. During iterative refinement we follow Lichtarge et al. (2019) and multiply the score of the identity mapping by a tunable identity penalty to better control the trade-off between precision and recall. We use a beam size of 12 in our rescoring experiments in Table 10 and a beam size of 4 otherwise.

Table 4 gives an overview of our results on all tasks. The tag set consists of semiotic class labels (Sproat and Jaitly, 2016) for text normalization, discourse type (Geva et al., 2019) for sentence fusion, and ERRANT (Bryant et al., 2017; Felice et al., 2016) error tags for grammatical error correction.[4] For the other tasks we use a trivial tag set: `SELF`, `NON_SELF`, and `EOS` (end of sequence). We report sentence error rates (SERs↓) for text normalization, SARI↑ scores (Xu et al., 2016) for sentence fusion, splitting, and simplification, and ERRANT (Bryant et al., 2017) span-based P(recision)↑, R(ecall)↑, and $F_{0.5}$-scores on the BEA development set for grammar correction.[5]

Text normalization is not amenable to our form of pre-training as it does not use subword units and it aims to generate vocalizations rather than text like in our pre-training data. All other tasks, however, benefit greatly from pre-training (compare rows **a** & **b** with rows **c** & **d** in Table 4). Pre-training yields large gains for grammar correction as the pre-training data was specifically collected for this task (Lichtarge et al., 2019). Tuning the decoding parameters (listed in Table 3) gives improvements for tasks like simplification, but is less crucial on sentence fusion or splitting (compare rows **c** & **d** with rows **e** & **f** in Table 4). Using tags is especially effective if non-trivial tags are available (compare rows **a** with **b**, **c** with **d**, and **e** with **f** for text normalization and grammar correction).

We next situate our best results (big models with pre-training in rows **e** and **f** of Table 4) in the context of related work.

3.1 Text Normalization

Natural sounding speech synthesis requires the correct pronunciation of numbers based on context e.g. whether the string *123* should be spoken as *one hundred twenty three* or *one two three*. Text normalization converts the textual representation of numbers or other semiotic classes such as abbre-

viations to their spoken form while both conveying meaning and morphology (Zhang et al., 2019). The problem is highly context-dependent as abbreviations and numbers often have different feasible vocalizations. Context-dependence is even more pronounced in languages like Russian in which the number words need to be inflected to preserve agreement with context words.

We trained our models on the English and Russian data provided by Sproat and Jaitly (2016). Similarly to others (Zhang et al., 2019; Sproat and Jaitly, 2016) we use characters on the input but full words on the output side. Table 5 shows that our models perform favourably when compared to other systems from the literature on both English and Russian. Note that most existing neural text normalization models (Zhang et al., 2019; Sproat and Jaitly, 2016) require pre-tokenized input[6] whereas our edit model operates on the untokenized input character sequence. This makes our method attractive for low resource languages where high-quality tokenizers may not be available.

3.2 Sentence Fusion

Sentence fusion is the task of merging two independent sentences into a single coherent text and has applications in several NLP areas such as dialogue systems and question answering (Geva et al., 2019). Our model is on par with the FELIX tagger (Mallinson et al., 2020) on the DiscoFuse dataset (Geva et al., 2019) but worse than the BERT2BERT model of Rothe et al. (2019) (Table 6). We hypothesize that BERT2BERT's strategy of making use of target-side pre-training under a language model objective via BERT (Devlin et al., 2019) is particularly useful for sentence fusion.

3.3 Sentence Splitting & Rephrasing

Sentence splitting is the inverse task of sentence fusion: Split a long sentence into two fluent shorter sentences. Our models are trained on the WikiSplit dataset (Botha et al., 2018) extracted from the edit history of Wikipedia articles. In addition to SARI scores we report the number of exact matches in Table 7. Our edit-based model achieves a higher number of exact matches and a higher SARI score compared to prior work on sentence splitting.

3.4 Text Simplification

Our text simplification training set (the WikiLarge corpus (Zhang and Lapata, 2017)) consists of 296K examples, the smallest amongst all our training corpora. Table 8 shows that our model is competitive, demonstrating that it can benefit from even limited quantities of training data. However, it does not improve the state of the art on this test set.

3.5 Grammatical Error Correction

For grammatical error correction we follow a multi-stage fine-tuning setup.[8] After training on the common pre-training data described above, we fine-tune for 30K steps on the public Lang-8 (Mizumoto et al., 2012) corpus, followed by 500 steps on the FCE (Yannakoudakis et al., 2011) and W&I (Bryant et al., 2019) corpora. To improve comparability with related work across the different corpora we use ERRANT (Bryant et al.,

---

[6] Each token in this context is a full semiotic class instance, for example a full date or money expression.

[7] We report SARI scores as (re)computed by Mallinson et al. (2020) for all systems in Table 8 to ensure comparability.

[8] Multi-stage fine-tuning has been proven effective for other sequence tasks such as machine translation (Khan et al., 2018; Saunders et al., 2019).

Table 10: Ensemble results for grammatical error correction. Our full sequence baseline achieves 68.2 $F_{0.5}$ on BEA-test, 63.8 $F_{0.5}$ on CoNLL-14, and 62.4 GLEU on JFLEG-test.

2017; Felice et al., 2016) to compute span-based P(recision)↑, R(ecall)↑, and $F_{0.5}$-scores on the BEA development and test sets (Bryant et al., 2019), the M2 scorer (Dahlmeier and Ng, 2012) on the CoNLL-2014 (Ng et al., 2014) test set, and GLEU↑ on the JFLEG test set (Napoles et al., 2017). However, the training data used in the literature varies vastly from system to system which limits comparability as (synthetic) data significantly impacts the system performance (Grundkiewicz et al., 2019).

Table 9 compares our approach with the best single model results reported in the literature. Our model tends to have a lower precision but higher recall than other systems. We are able to achieve the highest GLEU score on the JFLEG test set.

To further improve performance, we applied two techniques commonly used for grammatical error correction (Grundkiewicz et al., 2019, inter alia): ensembling and rescoring. Table 10 compares our 5-ensemble with other ensembles in the literature. Rescoring the n-best list from the edit model with a big full sequence Transformer model yields significant gains, outperforming all other systems in Table 10 on BEA-test and JFLEG.[9]

One of our initial goals was to avoid the wasteful computation of full sequence models when applied to tasks like grammatical error correction with a high degree of copying. Table 11 summarizes CPU decoding times on an Intel® Xeon® W-2135 Processor (12-core, 3.7 GHz).[10] We break down the measurements by English proficiency level. The full sequence baseline slows down for higher proficiency levels as sentences tend to be longer (second column of Table 11). In contrast, our edit operation based approach is faster because it does not depend on the target sequence length but instead on the number of edits which is usually small for advanced and native English speakers. We report speed-ups of 4.7-4.8x in these cases without using tags. When using tags, we implemented the following simple heuristics to improve the runtime ("shortcuts"): 1) If the tag $t_n = \texttt{SELF}$ is predicted, directly set $r_n = \texttt{SELF}$ and skip the replacement token prediction. 2) If the tag $t_n = \texttt{EOS}$ is predicted, set $p_n = I$ and $r_n = \texttt{EOS}$ and skip the span end position and the replacement token predictions. These shortcuts do not affect the results in practice but provide speed-ups of 5.2x for advanced and native English compared to a full sequence model.

The speed-ups of our approach are mainly due to the shorter target sequence length compared to a full sequence model. However, our inference scheme in Sec. 2.2 still needs three times more

---

[9] This resembles the inverse setup of Chollampatt and Ng (2018) who used edit features to rescore a full sequence model.

[10] We note that our experimental decoder implementation is not optimized for speed, and that absolute runtimes may differ with more efficient implementations.

English proficiency	**Avg. source length (I)**	**Avg. number of edits (N)**	**Sentences per second↑**			
			Full sequence	**Edit operation based**		
				ERRANT tags	**No tags**	**ERRANT tags (with shortcuts)**
Beginner (CEFR-A)	20.4	7.8	0.34	0.55 (1.6x)	0.69 (2.0x)	0.69 (2.0x)
Intermediate (CEFR-B)	25.9	6.0	0.34	0.83 (2.4x)	1.04 (3.0x)	1.07 (3.1x)
Advanced (CEFR-C)	23.0	4.2	0.31	1.21 (3.9x)	1.46 (4.7x)	1.59 (**5.2x**)
Native	26.6	4.0	0.26	1.03 (4.0x)	1.24 (4.8x)	1.34 (**5.2x**)

Table 11: CPU decoding speeds without iterative refinement on BEA-dev averaged over three runs. Speed-ups compared to the full sequence baseline are in parentheses.

Oracle constraints		**Text normalization (SER↓)**		**Grammar correction (BEA-dev)**		
Tag (t_n)	**Span end position (p_n)**	**English**	**Russian**	**P↑**	**R↑**	**F$_{0.5}$ ↑**
		1.36	3.95	55.2	36.2	50.0

	✓	0.48	3.58	64.9	65.5	65.0
✓	✓	0.24	3.58	71.9	71.9	71.9

Table 12: Partially constraining the decoder with oracle tags and/or span positions (no iterative refinement).

time steps than the number of edits, i.e. around $4.0 \times 3 = 12$ for native English (last row in Table 11). The observed speed-ups of 4.0x-5.2x are even larger than we would expect based on an average source length of $I = 26.6$. One reason for the larger speed-ups is that the decoding runtime complexity under the Transformer is quadratic in length, not linear. Another reason is that although the three elements are predicted sequentially, not each prediction step is equally expensive: the softmax for the tag and span predictions is computed over only a couple of elements, not over the full 32K subword vocabulary. Furthermore, efficient decoder implementations could reuse most of the computation done for the tag prediction for the span position.

3.6 Oracle Experiments

Our model can be viewed from a multi-task perspective since it tries to predict three different features (tag, span position, and replacement token). To better understand the contributions of these different components we partially constrained them using the gold references for both text normalization and grammatical error correction tasks. We avoid constraining the *number* of edits (N) in these oracle experiments by giving the constrained decoder the option to repeat labels in the reference. Table 12 shows that having access to the gold tags and/or span positions greatly improves performance. We hypothesize that these gains can be largely attributed to the resolution of confusion between self and non-self. An interesting outlier is text normalization on Russian which benefits less from oracle constraints. This suggests that the challenges for Russian text normalization are largely in predicting the replacement tokens, possibly due to the morphological complexity of Russian.

System	**Tagging accuracy**		
	P↑	**R↑**	**F$_{0.5}$ ↑**
Lasertagger	54.9	33.7	48.8
This work (unconstrained)	67.9	25.8	51.2
This work (span-constrained)	94.7	52.4	81.5

Table 13: Tagging accuracy on BEA-dev (no iterative refinement).

Since the motivation for using tags was to improve explainability we also evaluated the accuracy of the tag prediction on grammatical error correction. For comparison, we trained a baseline Lasertagger (Malmi et al., 2019) on a subset of the BEA training set (30.4K examples) to predict the ERRANT tags. Insertions are represented as composite tags together with the subsequent tag such that the total Lasertagger vocabulary size is 213. The model was initialized from a pre-trained BERT (Devlin et al., 2019) checkpoint. Decoding was performed using an autoregressive strategy with a Transformer decoder. We used the default hyper-parameters without any task-specific optimization. Table 13 shows that the tag prediction of our unconstrained model is more accurate than the Lasertagger baseline. Errors in this unconstrained setup are either due to predicting the wrong tag or predicting the wrong span. To tease apart these error sources we also report the accuracy under oracle span constraints. Our span constrained model achieves a recall of 52.4%, i.e. more than half of the non-self tags are classified correctly (28 tags).

4 Related Work

A popular way to tackle NLP problems with overlap between input and output is to equip seq2seq models with a copying mechanism (Jia and Liang, 2016; Zhao et al., 2019; Chen and Bansal, 2018; Nallapati et al., 2016; Gulcehre et al., 2016; See et al., 2017; Gu et al., 2016), usually borrowing ideas from pointer networks (Vinyals et al., 2015) to point to single tokens in the source sequence. In contrast, we use pointer networks to identify entire spans that are to be copied which results in a much more compact representation and faster decoding. The idea of using span-level edits has also been explored for morphological learning in the form of symbolic span-level rules, but not in combination with neural models (Elsner et al., 2019).

Our work is related to neural multi-task learning for NLP (Collobert and Weston, 2008; Dong et al., 2015; Luong et al., 2015; Søgaard and Goldberg, 2016). Unlike multi-task learning which typically solves separate problems (e.g. POS tagging and named entity recognition (Collobert and Weston, 2008) or translation into different languages (Luong et al., 2015; Dong et al., 2015)) with the same model, our three output features (tag, source span, and replacement) represent the same output sequence (Algorithm 1). Thus, it resembles the stack-propagation approach of Zhang and Weiss (2016) who use POS tags to improve parsing performance.

A more recent line of research frames sequence editing as a labelling problem using labels such as `ADD`, `KEEP`, and `DELETE` (Ribeiro et al., 2018; Dong et al., 2019; Mallinson et al., 2020; Malmi et al., 2019; Awasthi et al., 2019), often relying heavily on BERT (Devlin et al., 2019) pre-training. Similar operations such as insertions and deletions have also been used for machine translation (Gu et al., 2019b; Stern et al., 2019; Gu et al., 2019a; Östling and Tiedemann, 2017; Stahlberg et al., 2018). We showed in Sec. 3 that our model often performs similarly or better than those approaches, with the added advantage of providing explanations for its predictions.

5 Discussion

We have presented a neural model that represents sequence transduction using span-based edit operations. We reported competitive results on five different NLP problems, improving the state of the art on text normalization, sentence splitting, and the JFLEG test set for grammatical error correction. We showed that our approach is 2.0-5.2 times faster than a full sequence model for grammatical error correction. Our model can predict labels that explain each edit to improve the interpretability for the end-user. However, we do not make any claim that *Seq2Edits* can provide insights into the internal mechanics of the neural model. The underlying neural model in *Seq2Edits* is as much of a black-box as a regular full sequence model.

While our model is advantageous in terms of speed and explainability, it does have some weaknesses. Notably, the model uses a tailored architecture (Figure 2) that would require some engineering effort to implement efficiently. Second, the output of the model tends to be less fluent than a regular full sequence model, as can be seen from the examples in Table 19. This is not an issue for localized edit tasks such as text normalization but may be a drawback for tasks involving substantial rewrites (e.g. GEC for non-native speakers).

Even though our approach is open-vocabulary, future work will explore task specific restrictions. For example, in a model for dialog applications, we may want to restrict the set of response tokens to a predefined list. Alternatively, it may be useful to explore generation in a non left-to-right order to improve the efficiency of inference.

Another line of future work is to extend our model to sequence rewriting tasks, such as Machine Translation post-editing, that do not have existing error-tag dictionaries. This research would require induction of error tag inventories using either linguistic insights or unsupervised methods.

Abstract

We study the degree to which neural sequence-to-sequence models exhibit fine-grained controllability when performing natural language generation from a meaning representation. Using two task-oriented dialogue generation benchmarks, we systematically compare the effect of four input linearization strategies on controllability and faithfulness. Additionally, we evaluate how a phrase-based data augmentation method can improve performance. We find that properly aligning input sequences during training leads to highly controllable generation, both when training from scratch or when fine-tuning a larger pre-trained model. Data augmentation further improves control on difficult, randomly generated utterance plans.

1 Introduction

In this work, we study the degree to which neural sequence-to-sequence (S2S) models exhibit fine-grained controllability when performing natural language generation (NLG) from a meaning representation (MR). In particular, we focus on an S2S approach that respects the realization ordering constraints of a given utterance plan; such a model can generate utterances whose phrases follow the order of the provided plan.

In non-neural NLG, fine-grained control for planning sentence structure has received extensive study under the names *sentence* or *micro-planning* (Reiter and Dale, 2000; Walker et al., 2001; Stone et al., 2003). Contemporary practice, however, eschews modeling at this granularity, instead preferring to train an S2S model to directly map an input MR to a natural language utterance, with the utterance plan determined implicitly by the model which is learned from the training data (Dušek et al., 2020).

We argue that robust and fine grained control in an S2S model is desirable because it enables neural implementations of various psycho-linguistic theories of discourse (e.g., Centering Theory (Grosz et al., 1995), or Accessibility Theory (Ariel, 2001)). This could, in turn, encourage the validation and/or refinement of additional psychologically plausible models of language production.

In this paper, we study controllability in the context of task-oriented dialogue generation (Mairesse et al., 2010; Wen et al., 2015), where the input to the NLG model is an MR consisting of a dialogue act (i.e. a communicative goal) such as to REQUEST EXPLANATION, and an unordered set of attribute-value pairs defining the semantics of the intended utterance (see Figure 1 for an example).

The NLG model is expected to produce an utterance that adequately and faithfully communicates the MR. In the S2S paradigm, the MR must be "linearized" (i.e. represented as a linear sequence of tokens corresponding to the dialogue act and attribute-value pairs) before being presented to the S2S encoder. We explore several linearization strategies and measure their effectiveness for controlling phrase order, as well as their effect on model faithfulness (i.e., the semantic correctness of generated utterances).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5160–5185,
November 16–20, 2020.

Of particular note, *alignment training* (i.e. at training time, linearizing the attribute-value pairs according to the order in which they are realized by their corresponding reference utterance) produces highly controllable S2S models. While we are not the first to observe this (c.f., Nayak et al. (2017)), we study this behavior extensively. We refer to an ordered sequence of attribute-value pairs $x_1, x_2, \ldots, x_n$ as an *utterance plan*, and evaluate models on their ability to follow such plans given by either another model, a human, or, most difficultly, from random permutation.

Additionally, we experiment with a data augmentation method, where we create fragmentary MR/utterance pairs obtained from the constituent phrases of the original training data. We find that this data augmentation results in reduced semantic error rates and increases the ability of a model to follow an arbitrary utterance plan.

We summarize our contributions as follows. (1) We show that **alignment training produces highly controllable language generation models**, especially when following a model created utterance plan. (2) We demonstrate that **phrase-based data augmentation improves the robustness of the control** even on arbitrary and difficult to follow utterance plans. (3) We conclude with a human evaluation that shows that **phrase-based data augmentation training can increase the robustness of control without hurting fluency.**[1]

2 Methods

In an MR-to-text task, we are given as input an MR $\mu \in \mathcal{M}$ from which to generate an appropriate natural language utterance $\mathbf{y} \in \mathcal{Y}$, where μ consists of a dialogue act that characterizes the communicative goal of the utterance and an unordered and variably sized set of attribute-value pairs. Attributes are either binary or categorical variables (e.g., *family-friendly*: ["yes", "no"] or *food*: ["Chinese", "English", "French", ...]).[2]

Let each attribute-value pair x and dialogue act a be tokens from a vocabulary $\mathcal{V}$, and define the size of an MR, denoted $|\mu|$, to be the number of attribute-value pairs $x \in \mu$. A linearization strategy $\pi : \mathcal{M} \rightarrow \mathcal{V}^*$ is a mapping of the dialogue act and attribute-value pairs in μ to an ordered sequence, i.e. $\pi(\mu) = [a, x_1, x_2, \ldots, x_{|\mu|}]$. Regardless of the choice of π, the first token in $\pi(\mu)$ is always the dialogue act a.

We experiment with both gated recurrent unit (GRU) (Cho et al., 2014) and Transformer (Vaswani et al., 2017) based S2S model variants to implement a conditional probability model $p(\cdot|\pi(\mu);\theta) : \mathcal{Y} \rightarrow (0,1)$ over utterances. The model parameters, θ, are learned by approximately maximizing the log-likelihood $\mathcal{L}(\theta) = \sum_{(\mu,\mathbf{y})\in\mathcal{D}} \log p(\mathbf{y}|\pi(\mu);\theta)$ on the training set $\mathcal{D}$. Additionally, we experiment with a pretrained S2S Transformer, BART (Lewis et al., 2020), with parameters θ_0 fine-tuned on $\mathcal{L}(\theta_0)$.

2.1 Linearization Strategies

Because of the recurrence in the GRU and position embeddings in the Transformer, it is usually the case that different linearization strategies, i.e. $\pi(\mu) \neq \pi'(\mu)$, will result in different model internal representations and therefore different conditional probability distributions. These differences can be non-trivial, yielding changes in model behavior with respect to faithfulness and control.

We study four linearization strategies, *(i) random*, *(ii) increasing-frequency*, *(iii) fixed-position*, and *(iv) alignment training*, which we describe below. For visual examples of each strategy, see Figure 2. Note that linearization determines the order of the attribute-value pairs presented to the S2S encoder, and **only** in the case of alignment training does it correspond to the order in which the attribute-value pairs are realized in the utterance. When presenting a linearized MR to the model encoder, we always prepend and append distinguished *start* and *stop* tokens respectively.

Random (RND) In the *random* linearization (RND), we randomly order the attribute-value pairs for a given MR. This strategy serves as a baseline for determining if linearization matters at all for faithfulness. RND is similar to token level noise used in denoising auto-encoders (Wang et al., 2019) and might even improve faithfulness. During training, we resample the ordering for each example at every epoch. We do not resample the validation set in order to obtain stable results for model selection.

Increasing Frequency (IF) In the *increasing frequency* linearization (IF), we order the attribute-value pairs by increasing frequency of occurrence in the training data (i.e., $\text{count}(x_i) \leq$

---

[1] Code, outputs, augmented data, and other materials can be found here: `https://github.com/kedz/cmr2text`.

[2] There are also list-valued attributes but we treat them as individual attribute-value pairs (i.e. in Figure 1, both *genres* = "role-playing" and *genres* = "hack-and-slash" are in μ).

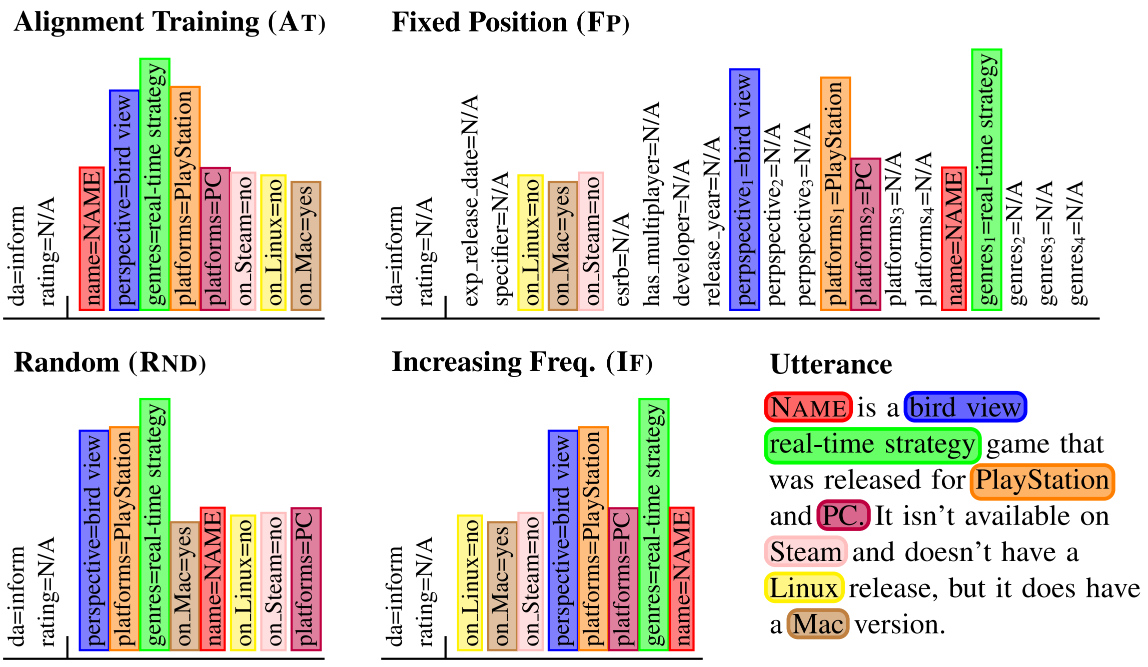

Figure 2: Example MR linearization strategies for the utterance above from the ViGGO training set.

count(x_{i+1})). We hypothesize that placing frequently occurring items in a consistent location may make it easier for p to realize those items correctly, possibly at the expense of rarer items.

Fixed Position (FP) We take consistency one step further and create a fixed ordering of all attributes, *n.b.* not attribute-values, ordering them in increasing frequency of occurrence on the training set (i.e. every instance has the same order of attributes in the encoder input). In this *fixed position* linearization (FP), attributes that are not present in an MR are explicitly represented with an "N/A" value. For list-valued slots, we determine the maximum length list in the training data and create that many repeated slots in the input sequence. This linearization is feasible for datasets with a modest number of unique attributes but may not easily scale to 10s, 100s, or larger attribute vocabularies.

Alignment Training (AT) In the *alignment training* linearization (AT), during training, the order of attribute-value pairs $x_1, x_2, \ldots, x_{|\mu|}$ matches the order in which they are realized in the corresponding training utterance. This is feasible because in the majority of cases, there is a one-to-one mapping of attribute-values and utterance subspans.

We obtain this ordering using a manually constructed set of matching rules to identify which utterance subspans correspond to each attribute-value pair (see §3.1).

$\pi(\mu) =$ [inform, name=Aromi, eat_type=coffee shop, area=city centre]
$\hat{\mathbf{y}} =$ *Aromi is a coffee shop in the city centre.*

$\pi(\mu) =$ [inform, eat_type=coffee shop, name=Aromi, area=city centre]
$\hat{\mathbf{y}} =$ *There is a coffee shop called Aromi in the city centre.*

$\pi(\mu) =$ [inform, eat_type=coffee shop, area=city centre, name=Aromi]
$\hat{\mathbf{y}} =$ *For coffee in the centre of the city, try Aromi.*

Figure 3: Example outputs ($\hat{\mathbf{y}}$) from a controllable model, i.e. a S2S model trained with AT linearization, under different input utterance plans ($\pi(\mu)$).

Crucially, AT stands in contrast to the first three strategies (RND, IF, and FP) which do not have any correspondence between the the order of attribute-value pairs in $\pi(\mu)$ and the order in which they are realized in the corresponding utterance $\mathbf{y}$.

At test time, when there is no reference utterance AT cannot specify a linearization. However, models trained with AT can generate an utterance from an arbitrary utterance plan $x_1, x_2, \ldots, x_{|\mu|}$ provided by an external source, such as an utterance planner model or human reference. See Figure 3 for an example of how an AT-trained model might follow three different plans for the same MR.

2.2 Phrase-based Data Augmentation

We augment the training data with MR/utterance pairs taken from constituent phrases in the original training data. We parse all training utterances and enumerate all constituent phrases governed by NP,

	E2E		Viggo	
	Orig.	Phr.	Orig.	Phr.
# ex.	33,523	443,192	5,103	67,445
Avg. $\|\mu\|$	5.3	1.8	6.8	3.8
Avg. $\|\mathbf{y}\|$	23.6	7.0	24.4	6.7

Table 1: Statistics of original training and phrase data.

VP, ADJP, ADVP, PP, S, or Sbar non-terminals.[3] We then apply the attribute-value matching rules used for AT (see §3.1) to obtain a corresponding MR, keeping the dialogue act of the original utterance. We discard phrases with no realized attributes. See Table 1 for augmented data statistics.

Because we reclassify the MR of phrases using the matching rules, the augmented data includes examples of how to invert binary attributes, e.g. from the phrase "*is not on Mac,*" which denotes *has_mac_release* = "no," we obtain the phrase "*on Mac*" which denotes *has_mac_release* = "yes." When presenting the linearized MR of phrase examples to the model encoder we prepend and append phrase specific *start* and *stop* tokens respectively (e.g., *start-NP* and *stop-NP*) to discourage the model from ever producing an incomplete sentence when generating for a complete MR.

3 Datasets

We run our experiments on two English language, task-oriented dialogue datasets, the E2E Challenge corpus (Novikova et al., 2017) and the ViGGO corpus (Juraska et al., 2019). These datasets provide MR/utterance pairs from the restaurant and video game domains, respectively. Examples from the E2E corpus (33,523 train/1,426 dev/630 test) can have up to eight unique attributes. There is only one dialogue act for the corpus, INFORM. Attribute-values are either binary or categorical valued.

The ViGGO corpus (5,103 train/246 dev/359 test) contains 14 attribute types and nine dialogue acts. In addition to binary and categorical valued attributes, the corpus also features list-valued attributes (see the *genres* attribute in Figure 1) which can have a variable number of values, and an open-class *specifier* attribute (see §A.1 for details).

3.1 MR/Utterance Alignments

The original datasets do not have alignments between individual attribute-value pairs and the subspans of the utterances they occur in, which we need for the AT linearization strategy. We manually developed a list of heuristic pattern matching rules (e.g. *not kid-friendly* → *family_friendly* = "no"). For ViGGO, we started from scratch, but for E2E we greatly expanded the rule-set created by Dušek et al. (2019). To ensure the correctness of the rules, we iteratively added new matching rules, ran them on the training and validation sets, and verified that they produced the same MR as was provided in the dataset. This process took one author roughly two weeks to produce approximately 25,000 and 1,500 rules for the E2E and ViGGO datasets respectively. Note that the large number of rules is obtained programmatically, i.e. creating template rules and inserting matching keywords or phrases (e.g., enumerating variants such as *not kid-friendly*, *non kid-friendly*, *not family-friendly*, etc.).

In cases where the matching rules produced different MRs than provided in the original dataset, we manually checked them. In many cases on the E2E dataset and several times on ViGGO, we found the rule to be correct and the MR to be incorrect for the given utterance. In those cases, we used the corrected MRs for training and validation. We do not modify the test sets in any way. Using the matching rules, we can determine alignments between the provided MR and the realized utterances.

For most cases, the attribute-values uniquely correspond to a non-overlapping subspan of the utterance. The *rating* attribute in the ViGGO dataset, however, could have multiple reasonable mappings to the utterance, so we treat it in practice like an addendum to the dialogue act, occurring directly after the dialogue act as part of a "header" section in any MR linearization strategy (see Figure 2 where *rating* = "N/A" occurs after the dialogue act regardless of choice of linearization strategy).

4 Models

4.1 Generation Models

We examine the effects of linearization strategy and data augmentation on a bidirectional GRU with attention (biGRU) and Transformer-based S2S models. Hyperparameters were found using grid-search, selecting the model with best validation BLEU (Papineni et al., 2002) score. We performed a separate grid-search for each architecture-linearization strategy pairing in case there was no one best hyperparameter setting.

---

[3] We used the Stanford CoreNLP parser v3.9.2.

Additionally, we fine-tune BART (Lewis et al., 2020), a large pretrained Transformer-based S2S model. We stop fine-tuning after validation set cross-entropy stops decreasing.

Complete architecture specification, hyperparameter search space, and validation results for all three models can be found in Appendix A.

Decoding When decoding at test time, we use beam search with a beam size of eight. Beam candidates are ranked by length normalized log likelihood. Similar to Dušek et al. (2019) and Juraska et al. (2019) we rerank the beam output to maximize the F-measure of correctly generated attribute-values using the matching-rules described in §3.1.

For models using the RND linearization, at test time, we sample five random MR orderings and generate beam candidates for each. Reranking is then performed on the union of beam candidates.

4.2 Utterance Planner Model

We experiment with three approaches to creating a test-time utterance plan for the AT trained models. The first is a bigram language model (BGUP) over attribute-value sequences. Attribute-value bigram counts are estimated from the training data (using Lidstone smoothing (Chen and Goodman, 1996) with $\alpha = 10^{-6}$) according to the ordering determined by the matching rules (i.e. the AT ordering).

The second model is a biGRU based S2S model, which we refer to as the neural utterance planner (NUP). We train the NUP to map IF ordered attribute-values to the AT ordering. We grid-search model hyperparameters, selecting the model with highest average Kendall's τ (Kendall, 1938) on the validation set AT orderings. See Appendix B for hyperparameter/model specification details. Unlike the BGUP model, the NUP model also conditions on the dialogue act, so it can learn ordering preferences that differ across dialogue acts.

For both BGUP and NUP, we use beam search (with beam size 32) to generate candidate utterance plans. The beam search is constrained to only generate attribute-value pairs that are given in the supplied MR, and to avoid generating repeated attributes. The search is not allowed to terminate until all attribute-values in the MR are generated. Beam candidates are ranked by log likelihood.

The final ordering we propose is the ORACLE ordering, i.e. the utterance plan implied by the human-authored test-set reference utterances. This plan represents the model performance if it had *a priori* knowledge of the reference utterance plan. When a test example has multiple references, we select the most frequent ordering in the references, breaking ties according to BGUP log-likelihood.

5 Experiments

5.1 Test-Set Evaluation

In our first experiment, we compare performance of the proposed models and linearization strategies on the E2E and ViGGO test sets. For the IF and AT+NUP models we also include variants trained on the union of original training data and phrase-augmented data (see §2.2), which we denote +P.

Evaluation Measures For automatic quality measures, we report BLEU and ROUGE-L (Lin, 2004) scores.[4] Additionally, we use the matching rules to automatically annotate the attribute-value spans of the model generated utterances, and then manually verify/correct them. With the attribute-value annotations in hand we compute the number of missing, wrong, or added attribute-values for each model. From these counts, we compute the semantic error rate (SER) (Dušek et al., 2020) where

$$\text{SER} = \frac{\#missing + \#wrong + \#added}{\#attributes}.$$

On ViGGO, we do not include the *rating* attribute in this evaluation since we consider it part of the dialogue act. Additionally, for AT variants, we report the order accuracy (OA) as the percentage of generated utterances that correctly follow the provided utterance plan. Utterances with wrong or added attribute values are counted as not following the utterance plan. Additional metrics and SER error break downs can be found in Appendix C.

All models are trained five times with different random seeds; we report the mean of all five runs. We report statistical significance using Welch's t-test (Welch, 1947), comparing the score distribution of the five runs from the best linearization strategy against all other strategies at the 0.05 level.

Baselines On the ViGGO dataset we compare to the Transformer baseline of Juraska et al. (2019), which used a beam search of size 10 and heuristic slot reranker (similar to our matching rules).

On the E2E dataset, we report the results of TGen+ (Dušek et al., 2019), an LSTM-based S2S

---

[4] We use the official E2E evaluation script to compute these numbers.

model, which also uses beam search with a matching rule based reranker to select the most semantically correct utterance and is trained on a cleaned version of the corpus (similar to our approach).

5.2 Random Permutation Stress Test

Differences between an AT model following a utterance planner model and the human oracle are often small so we do not learn much about the limits of controllability of such models, or how they behave in extreme conditions (i.e. on an arbitrary, random utterance plan, not drawn from the training data distribution). In order to perform such an experiment we generate random utterance plans (i.e. permutations of attribute-values) and have the AT models generate utterances for them, which we evaluate with respect to SER and OA (we lack ground truth references with which to evaluate BLEU or ROUGE-L). We generate random permutations of size $3, 4, \ldots, 8$ on the E2E dataset, since there are 8 unique attributes on the E2E dataset. For ViGGO we generate permutations of size $3, 4, \ldots, 10$ (96% of the ViGGO training examples fall within this range). For each size we generated 100 random permutations and all generated plans were given the INFORM dialogue act. In addition to running the AT models on these random permutations, we also compare them to the same model after using the NUP to reorder them into an easier[5] ordering. Example outputs can be found in Appendix D.

5.3 Human Evaluation

In our final experiment, we had human evaluators rank the 100 outputs of the size 5 random permutations for three BART models on both datasets: (i) AT+P model with NUP, (ii) AT+P model, and (iii) AT model. The first model, which uses an utterance planner, is likely to be more natural since it doesn't have to follow the random order, so it serves as a ceiling. The second and third models will try to follow the random permutation ordering, and are more likely to produce unnatural transitions between awkard sequences of attribute-values. Differences between these models will allow us to understand how the phrase-augmented data affects the fluency of the models. The annotators were asked to rank outputs by their naturalness/fluency. Each set was annotated twice by different annotators so we can compute agreement. More details can be found in Appendix E.

6 Results

AT models accurately follow utterance plans. See Table 2 and Table 3 for results on E2E and ViGGO test sets respectively. The best non-ORACLE results are bolded for each model and results that are not different with statistical significance to the best results are underlined. We see that the AT+NUP strategy consistently receives the lowest semantic error rate and highest order accuracy, regardless of architecture or dataset, suggesting that alleviating the model's decoder of content planning is highly beneficial to avoiding errors. The Transformer AT model is able to consistently achieve virtually zero semantic error on E2E using either the bigram or neural planner model.

We also see that fine-tuned BART is able to learn to follow an utterance plan as well. When following the neural utterance planner, BART is highly competitive with the trained from scratch Transformer on E2E and surpassing it on ViGGO in terms of semantic error rate.

Generally, the AT models had a smaller variance in test-set evaluation measures over the five random initializations as compared to the other strategies. This is reflected in some unusual equivalency classes by statistical significance. For example, on the E2E dataset biGRU models, the AT+NUP+P strategy acheives 0% semantic error and is significantly different than all other linearization strategies **except** the FP strategy even though the absolute difference in score is 6.54%. This is unusual because the AT+NUP+P strategy **is** significantly different from AT+NUP but the absolute difference is only 0.26%. This happens because the variance in test-set results is higher for FP making it harder to show signficance with only five samples.

Transformer-based models are more faithful than biGRU on RND, FP, and IF linearizations. On the ViGGO dataset, BART and Transformer IF achieve 1.86% and 7.50% semantic error rate respectively, while the biGRU IF model has 19.20% semantic error rate. These trends hold for FP and RND, and on the E2E dataset as well. Because there is no sequential correspondence in the input, it is possible that the recurrence in the biGRU makes it difficult to ignore spurious input ordering effects. Additionally, we see that RND does offer some

---

[5] Easier in the sense that the NUP re-ordering is closer to the training set distribution of AT utterance plans.

[6] Since their model does not realize *specifier* attributes, we do not include them in SER calculation. When including them, their model achieves 2.6% SER.

benefits of denoising; RND models have lower semantic error rate than IF models in 3 of 6 cases and FP models in 5 out of 6 cases.

Model based plans are easier to follow than human reference plans. On E2E, there is very little difference in semantic error rate when following either the bigram-based utterance planner, BGUP, or neural utterance planner, NUP. This is also true of the ViGGO BART models as well. In the small data (i.e. ViGGO) setting, biGRU and Transformer models achieve better semantic error rate when following the neural utterance planner. In most cases, neural utterance planner models have slightly higher BLEU and ROUGE-L than the bigram utterance planner, suggesting the neural planner produces utterance plans closer to the reference orderings. The neural and bigram planner models have slightly lower semantic error rate than when following the ORACLE utterance plans. This suggests that the models are producing orders more commonly seen in the training data, similar to how neural language generators frequently learn the least interesting, lowest entropy responses (Serban et al., 2016). On the other hand, when given the ORACLE orderings, models achieve much higher word overlap with the reference, e.g. achieving an E2E ROUGE-L ≥ 77.

Phrase-training reduces SER. We see that phrase data improves semantic error rate in 8 out of 12 cases, with the largest gains coming from the biGRU IF model. Where the base semantic error rate was higher, phrase training has a more noticeable effect. After phrase training, all E2E models are operating at near zero semantic error rate and almost perfectly following the neural utterance planner. Model performance on ViGGO is more varied, with phrase training slighting hurting

Model	E2E SER↓	E2E OA↑	ViGGo SER↓	ViGGo OA↑
biGRU	1.14	94.44	13.58	46.72
+P	0.54	97.34	14.46	49.26
+NUP	0.22	98.72	9.62	62.04
+NUP+P	**0.02**	**99.86**	**8.98**	**64.50**
Transformer	0.78	95.20	28.34	18.70
+P	0.40	98.10	25.72	18.10
+NUP	0.08	99.64	24.18	31.34
+NUP+P	**0.02**	**99.86**	**21.64**	**31.86**
BART	0.42	97.78	2.30	82.00
+P	0.22	98.78	1.82	87.98
+NUP	0.64	96.52	1.34	91.40
+NUP+P	**0.20**	**99.02**	**0.76**	**95.32**

Table 4: Random permutation stress test of AT models.

	Model	1	2	3	Avg.
E2E	AT+NUP+P	61.5	16.5	22.0	**1.61**
	AT+P	30.0	44.0	26.0	1.96
	AT	25.0	49.5	25.5	2.01
ViGGO	AT+NUP+P	57.5	27.5	15.0	**1.58**
	AT+P	10.0	29.5	60.5	2.51
	AT	43.0	46.0	11.0	1.68

Table 5: Human Evaluation results. Table shows the percent of times each model was ranked 1 (best), 2, 3 (worst) in terms of naturalness and average rank.

the biGRU AT+NUP model, but otherwise helping performance.

Random Permutation Stress Test Results of the random permutation experiment are shown in Table 4. Overall, all models have an easier time following the neural utterance planner's reordering of the random permutations. Phrase training also generally improved semantic error rate. All models perform quite well on the E2E permutations. With phrase-training, all E2E models achieve less than 0.6% semantic error rate following random utterance plans. Starker differences emerge on the ViGGO dataset. The biGRU+NUP+P model achieves a 8.98% semantic error rate and only correctly follows the given order 64.5% of the time, which is a large decrease in performance compared to the ViGGO test set.

Human Evaluation Results of the human evaluation are shown in Table 5. We show the number of times each system was ranked 1 (most natural), 2, or 3 (least natural) and the average rank overall. Overall, we see that BART with the neural utterance planner and phrase-augmentation training is preferred on both datasets, suggesting that the utterance planner is producing natural orderings of the attribute-values, and the model can generate reasonable output for it. On the E2E dataset, we also see small differences in between the AT+P and AT models suggesting that when following an arbitrary ordering, the phrase-augmented model is about as natural as the non-phrase trained model. This is encouraging as the phrase trained model has lower semantic error rates. On the ViGGO dataset we do find that the phrase trained model is less natural, suggesting that in the small data setting, phrase-training may hurt fluency when trying to follow a difficult utterance plan.

For agreement we compute average Kendall's τ between each pair of annotators for each dataset. On E2E, we have $\tau = .853$ and ViGGO we have $\tau = .932$ suggesting very strong agreement.

7 Discussion

One consistently worrying sign throughout the first two experiments is that the automatic metrics are not good indicators of semantic correctness. For example the ROUGE-L score of the E2E AT ORACLE models is about 8 points higher than the AT+NUP models, but the AT+NUP models make fewer semantic errors. Other similar examples can be found where the automatic metric would suggest picking the more error prone model over another. As generating fluent text becomes less of a difficult a problem, these shallow ngram overlap methods will cease to suffice as distinguishing criteria.

The second experiments also reveal limitations in the controllable model's ability to follow arbitrary orderings. The biGRU and Transformer models in the small-data ViGGO setting are not able to generalize effectively on non-training distribution utterance plans. BART performance is much better here, but is still hovering around 2% semantic error rate and only roughly 88% of outputs conform to the intended utterance plan. Thankfully, if an exact ordering is not required, using the neural utterance planner to propose an order leads to more semantically correct outputs.

8 Limitations

While we are able to acheive very low test-set SER for both corpora, we should caution that this required extensive manual development of matching rules to produce MR/utterance alignments, which in turn resulted in significant cleaning of the training datasets. We chose to do this over pursuing a model based strategy of aligning utterance subspans to attribute-values because we wanted to better understand how systematically S2S models can represent arbitray order permutations independent of alignment model error.

Also we should note that data cleaning can yield more substantial decreases in semantic errors (Dušek et al., 2019; Wang, 2019) and is an important consideration in any practical neural NLG.

9 Related Work

MR linearizations for S2S models have been studied in a variety of prior works. Nayak et al. (2017) explore several ways of incorporating sentence planning into an MR linearization for S2S models, comparing a flat alignment order (equivalent to the alignment order used in this paper) against various sentence level groupings. Reed et al. (2018) add additional sentence and discourse structuring variables to indicate contrasts or sentential groupings. Balakrishnan et al. (2019) experiment both with tree structured MRs and encoders and compare them to linearized trees with standard S2S models. They also find that properly aligned linearization can lead to a controllable generator. These papers do not, however, explore how other linearization strategies compare in terms of faithfulness, and they do not evaluate the degree to which a S2S model can follow realization orders not drawn from the training distribution.

Castro Ferreira et al. (2017) compare a S2S NLG model using various linearizations of abstract meaning representation (AMR) graphs, including a model-based alignment very similar to the AT linearization presented in this work. However, they evaluate only on automatic quality measures and do not explicitly measure the semantic correctness of the generated text or the degree to which the model realizes the text in the order implied by the linearized input.

Works like Moryossef et al. (2019a,b) and Castro Ferreira et al. (2019) show that treating various planning tasks as separate components in a pipeline, where the components themselves are implemented with neural models, improves the overall quality and semantic correctness of generated utterances relative to a completely end-to-end neural NLG model. However, they do not test the systematicty of the neural generation components, i.e. the ability to perform correctly when given an arbitrary or random input from the preceding component, as we do here with the random permutation stress test.

Other papers mention linearization order anecdottally but do quantify its impact. For example, Juraska et al. (2018) experiment with random linearization orderings during development, but do not use them in the final model or report results using them, and Gehrmann et al. (2018) report that using a consistent linearization strategy worked best for their models but do not specify the exact order. Juraska et al. (2018) also used sentence level data augmentation, i.e. splitting a multi-sentence example in multiple single sentence examples, similar in spirit to our proposed phrase based method, but they do not evaluate its effect independently.

10 Conclusion

We present an empirical study on the effects of linearization order and phrase based data augmentation on controllable MR-to-text generation. Our findings support the importance of aligned linearization and phrase training for improving model control. Additionally, we identify limitations to this ability, specifically in the small data, random permutation setting, and will focus on this going forward.

Acknowledgments

We would like to thank the anonymous reviewers, as well as Katy Gero and Faisal Ladhak for their comments and discussion when drafting this paper. We would also like to thank Juraj Juraska for making the outputs of their ViGGO models available.

A Models and Hyper-paramter Search Details

A.1 General Details

Utterance text was sentence and word tokenized, and all tokens were lower-cased. A special *sentence-boundary* token was inserted between sentences. All words occurring fewer than 3 times on the training set were replaced with a special *unknown* token. We used a batch size of 128 for all biGRU and Transformer models. All models were trained on a single Nvidia Tesla v100 for at most 700 epochs.

Delexicalization The ViGGO corpus is relatively small and the attributes *name*, *developer*, *release_year*, *expected_release_date*, and *specifier* can have values that are only seen several times during training. Neural models often struggle to learn good representations for infrequent inputs, which can, in turn, lead to poor test-set generalization. To alleviate this, we delexicalize these values in the utterance. That is, we replace them with an attribute specific placeholder token.

Additionally, for *specifier* whose values come from the open class of adjectives, we represent the specified adjective with a placeholder which marks two features, whether it is consonant (C) or vowel initial (V) (e.g. "dull" vs. "old") and whether it is in regular (R) or superlative (S) form (e.g. "dull" vs. "dullest") since these features can effect the surrounding context in which the adjective is realized. See the following lexicalized/delexicalized examples:

- *specifier* = "oldest" – vowel initial, superlative
    - *What is the oldest game you've played?*
    - *What is the SPECIFIER_V_S game you've played?*
- *specifier* = "old" – vowel initial, regular
    - *What is an old game you've played?*
    - *What is an SPECIFIER_V_R game you've played?*
- *specifier* = "new" – consonant initial, regular
    - *What is a new game you've played?*
    - *What is a SPECIFIER_C_R game you've played?*

All generated delexicalized utterances are post-processed with the corresponding attribute-values before computing evaluation metrics (i.e., they are re-lexicalized with the appropriate value strings from the input MR).

A.2 biGRU Model Definition

Let $\mathcal{V}$ be the encoder input vocabulary, and $\mathbf{E} \in \mathbb{R}^{|\mathcal{V}| \times D_w}$ an associated word embedding matrix where $\mathbf{E}_x \in \mathbb{R}^{D_w}$ denotes the D_w-dimensional embedding for each $x \in \mathcal{V}$. Given a linearized MR $\pi(\mu) = \mathbf{x} = \left[a, x_1, x_2, \ldots, x_{|\mu|}\right] \in \mathcal{V}^m$ where the length of the sequence is $m = |\mu| + 1$, let $\mathbf{v}_i = \mathbf{E}_{\mathbf{x}_i}$ for $i \in \{1, \ldots m\}$.

The hidden states of the first GRU encoder layer are computed as

$$\begin{aligned}
\hat{\boldsymbol{h}}_0^{(1)} &= \check{\boldsymbol{h}}_{m+1}^{(1)} = \mathbf{0} \\
\hat{\boldsymbol{h}}_i^{(1)} &= \mathrm{GRU}\left(\mathbf{v}_i, \hat{\boldsymbol{h}}_{i-1}^{(1)}; \hat{\eta}^{(1)}\right) \quad \text{for } i \in 1, \ldots, m \\
\check{\boldsymbol{h}}_i^{(1)} &= \mathrm{GRU}\left(\mathbf{v}_i, \check{\boldsymbol{h}}_{i+1}^{(1)}; \check{\eta}^{(1)}\right) \quad \text{for } i \in m, \ldots, 1 \\
\boldsymbol{h}_i^{(1)} &= \left[\hat{\boldsymbol{h}}_i, \check{\boldsymbol{h}}_i\right]
\end{aligned}$$

where $[\cdot]$ is the concatenation operator, $\hat{\boldsymbol{h}}_i^{(1)}, \check{\boldsymbol{h}}_i^{(1)} \in \mathbb{R}^{D_h}$, $\boldsymbol{h}_i^{(1)} \in \mathbb{R}^{2D_h}$, and $\hat{\eta}^{(1)}$ and $\check{\eta}^{(1)}$ are the forward and backward encoder GRU parameters.

When using a two layer GRU, we similarly compute

$$\begin{aligned}
\hat{\boldsymbol{h}}_0^{(2)} &= \check{\boldsymbol{h}}_{m+1}^{(2)} = \mathbf{0} \\
\hat{\boldsymbol{h}}_i^{(2)} &= \mathrm{GRU}\left(\boldsymbol{h}_i^{(1)}, \hat{\boldsymbol{h}}_{i-1}^{(2)}; \hat{\eta}^{(2)}\right) \quad \text{for } i \in 1, \ldots, m \\
\check{\boldsymbol{h}}_i^{(2)} &= \mathrm{GRU}\left(\boldsymbol{h}_i^{(1)}, \check{\boldsymbol{h}}_{i+1}^{(2)}; \check{\eta}^{(2)}\right) \quad \text{for } i \in m, \ldots, 1 \\
\boldsymbol{h}_i^{(2)} &= \left[\hat{\boldsymbol{h}}_i, \check{\boldsymbol{h}}_i\right]
\end{aligned}$$

where $\hat{\boldsymbol{h}}_i^{(2)}, \check{\boldsymbol{h}}_i^{(2)} \in \mathbb{R}^{D_h}$, $\boldsymbol{h}_i^{(2)} \in \mathbb{R}^{2D_h}$, and $\hat{\eta}^{(2)}$ and $\check{\eta}^{(2)}$ are the forward and backward encoder GRU parameters for the second layer.

Going forward, let $\boldsymbol{h}_i$ correspond to the final encoder output, i.e. $\boldsymbol{h}_i = \boldsymbol{h}_i^{(1)}$ in the one-layer biGRU case, and $\boldsymbol{h}_i = \boldsymbol{h}_i^{(2)}$ in the two layer case.

Let $\mathcal{W}$ be the vocabulary of utterance tokens, and $\mathbf{D} \in \mathbb{R}^{|\mathcal{W}| \times D_w}$ an associated embedding matrix, where $\mathbf{D}_y \in \mathbb{R}^{D_w}$ denotes a D_w-dimensional embedding for each $y \in \mathcal{W}$.

Given the decoder input sequence $\mathbf{y} = y_1, y_2, \ldots, y_{|\mathbf{y}|}$, let $\mathbf{w}_i = \mathbf{D}_{y_i}$ for $i \in \{1, \ldots n\}$. where $n = |\mathbf{y}| - 1$

We compute the hidden states of the i-th layer

Table 6: Winning hyperparameter settings for biGRU models. LS and WD indicate label smoothing and weight decay respectively. Train time is in hours.

of the decoder as,

$$\boldsymbol{g}_0^{(i)} = \tanh\left(\mathbf{W}^{(i)}\boldsymbol{h}_m^{(i)} + \mathbf{b}^{(i)}\right)$$

for $j \in 1, \ldots, n$

$$\boldsymbol{g}_j^{(i)} = \mathrm{GRU}\left(\boldsymbol{g}_j^{(i-1)}, \boldsymbol{g}_{j-1}^{(i)}; \zeta^{(i)}\right)$$

where $\boldsymbol{g}_j^{(0)} = \mathbf{w}_j$, $\boldsymbol{g}_j^{(i)} \in \mathbb{R}^{D_h}$, $\mathbf{W}^{(i)} \in \mathbb{R}^{D_h \times 2D_h}$, $\mathbf{b}^{(i)} \in \mathbb{R}^{D_h}$ and $\zeta^{(i)}$ are the decoder GRU parameters.

Going forward, let $\boldsymbol{g}_i$ correspond to the final decoder output, i.e. $\boldsymbol{g}_i = \boldsymbol{g}_i^{(1)}$ in the one-layer biGRU case, and $\boldsymbol{g}_i = \boldsymbol{g}_i^{(2)}$ in the two layer case.

Then the decoder states attend to the encoder states,

$$\bar{\boldsymbol{h}}_i = \sum_{j=1}^{m} \alpha_{i,j}\boldsymbol{h}_j \qquad \text{for } i \in 1, \ldots, n$$

where $\alpha_{i,j} \in (0,1)$ is the attention weight of decoder state i on encoder state j and $\sum_{j=1}^{m} \alpha_{i,j} = 1$. We compute attention in one of two ways (the attention method is a hyperparemeter option):

1. Feed-forward "Bahdanau" style attention (Bahdanau et al., 2015), also known as "concat" (Luong et al., 2015):

   $$\alpha_{i,j} = \mathbf{k}\tanh\left(\mathbf{K}\left[\begin{array}{c}\boldsymbol{g}_i \\ \boldsymbol{h}_j\end{array}\right]\right)$$

   with $\mathbf{K} \in \mathbb{R}^{D_h \times 3D_h}$ and $\mathbf{k} \in \mathbb{R}^{D_h}$.

2. "general" (Luong et al., 2015) :

   $$\alpha_{i,j} = \boldsymbol{g}_i \mathbf{K} \boldsymbol{h}_j$$

   with $\mathbf{K} \in \mathbb{R}^{D_h \times 2D_h}$.

Finally, for $i \in 1, \ldots, n$ we compute

$$\mathbf{z}_i = \tanh\left(\mathbf{W}^{(z)}\left[\begin{array}{c}\boldsymbol{g}_i \\ \bar{\boldsymbol{h}}_i\end{array}\right] + \mathbf{b}^{(z)}\right)$$

and

$$p\left(y_{i+1} | y_{\leq i}, \pi(\mu)\right) = \operatorname{softmax}\left(\mathbf{W}^{(o)}\mathbf{z}_i + \mathbf{b}^{(o)}\right)_{y_{i+1}}$$

where $\mathbf{W}^{(z)} \in \mathbb{R}^{D_h \times 3D_h}$, $\mathbf{b}^{(z)} \in \mathbb{R}^{D_h}$, $\mathbf{b}^{(o)} \in \mathbb{R}^{|\mathcal{W}|}$, and $\mathbf{W}^{(o)} \in \mathbb{R}^{|\mathcal{W}| \times D_h}$ is the output embedding matrix. As a hyperparamter setting, we consider tieing the decoder input and output embedding matrices, i.e. $\mathbf{D} = \mathbf{W}^{(o)}$. Dropout of 0.1 is applied to all embedding, GRU outputs, and linear layer outputs. We set $D_w = D_h = 512$.

A.3 biGRU Hyperparameter Search

We grid-search over the following hyperparameter values:

- **Layers:** 1, 2
- **Label Smoothing:** 0, 0.1
- **Weight Decay:** 0, 10^{-5}

- **Optimizer/Learning Rate:** Adam/10^{-3}, Adam/10^{-4}, Adam/10^{-5}, SGD/0.5, SGD/0.25, SGD/0.1
- **Tie Decoder Embeddings:** tied, untied
- **Attention:** Bahdanau, General

During hyperparameter search, we train for at most 500 epochs, evaluating BLEU every 25 epochs to select the best model. We decay the learning if validation log-likelihood stops increasing for five epochs. We decay the learning rate by $lr^{i+1} = .99 \times lr^{i}$.

Winning hyperparameter settings are presented Table 6.

A.4 Transformer Model Definition

Each Transformer layer is divided into blocks which each have three parts, (i) layer norm, (ii) feed-forward/attention, and (iii) skip-connection. We first define the components used in the transformer blocks before describing the overall S2S transformer. Starting with layer norm (Ba et al., 2016), let $\mathbf{H} \in \mathbb{R}^{m \times n}$, then we have $\mathrm{LN} : \mathbb{R}^{m \times n} \rightarrow \mathbb{R}^{m \times n}$,

$$\mathrm{LN}(\mathbf{H}; \mathbf{a}, \mathbf{b}) = \mathbf{A} \odot (\mathbf{H} - \boldsymbol{\mu}) \odot \Lambda + \mathbf{b}$$

where $\mathbf{a}, \mathbf{b} \in \mathbb{R}^{n}$ are learned parameters, $\odot$ is the elementwise product, $\mathbf{A} = [\mathbf{a}, \ldots, \mathbf{a}] \in \mathbb{R}^{m \times n}$ is a tiling of the parameter vector, $\mathbf{a}$, m times, and $\boldsymbol{\mu}, \boldsymbol{\Lambda} \in \mathbb{R}^{m \times n}$ are defined elementwise as

$$\boldsymbol{\mu}_{i,j} = \frac{1}{n} \sum_{k=1}^{n} \mathbf{H}_{i,k}$$

and

$$\boldsymbol{\Lambda}_{i,j} = \left(\sqrt{\frac{1}{n-1} \sum_{k=1}^{n} \left(\mathbf{H}_{i,k} - \boldsymbol{\mu}_{i,j} \right)^{2} + \epsilon} \right)^{-1}$$

respectively. The ϵ term is a small constant for numerical stability, set to 10^{-5}.

The inplace feed-forward layer, FF, is a simple single-layer perceptron with ReLU activation ($\mathrm{ReLU}(\mathbf{H}) = \max(\mathbf{0}, \mathbf{H})$) (Nair and Hinton, 2010), applied to each row of an $m \times n$ input matrix, i.e. a sequence of m objects with n features,

$$\mathrm{FF}\left(\mathbf{H}; \mathbf{W}^{(i)}, \mathbf{W}^{(j)}, \mathbf{b}^{(i)}, \mathbf{b}^{(j)}\right) = \mathrm{ReLU}\left(\mathbf{H}\mathbf{W}^{(i)} + \mathbf{b}^{(i)}\right) \mathbf{W}^{(j)} + \mathbf{b}^{(j)}$$

where $\mathbf{W}^{(i)} \in \mathbb{R}^{D_w \times D_h}$, $\mathbf{b}^{(i)} \in \mathbb{R}^{D_h}$, $\mathbf{W}^{(j)} \in \mathbb{R}^{D_h \times D_w}$, $\mathbf{b}^{(j)} \in \mathbb{R}^{D_w}$ are learned parameters and matrix-vector additions (i.e. $\mathbf{X} + \mathbf{b}$) are broadcast across the matrix rows.

The final component to be defined is the multi-head attention, MultiAttn which is defined as

$$\mathrm{MultiAttn}(\mathbf{Q}, \mathbf{K}; \mathbf{W}^{(a_1)}, \mathbf{W}^{(a_2)}) = \begin{bmatrix} \mathrm{Attn}\left(\mathbf{Q}\mathbf{W}^{(a_1)}_{1,1}, \mathbf{K}\mathbf{W}^{(a_1)}_{2,1}, \mathbf{K}\mathbf{W}^{(a_1)}_{3,1}\right), \\ \vdots \\ \mathrm{Attn}\left(\mathbf{Q}\mathbf{W}^{(a_1)}_{1,H}, \mathbf{K}\mathbf{W}^{(a_1)}_{2,H}, \mathbf{K}\mathbf{W}^{(a_1)}_{3,H}\right) \end{bmatrix} \mathbf{W}^{(a_2)}$$

where $[\cdot]$ indicates column-wise concatenation, $\mathbf{W}^{(a_1)}_{1,*} \in \mathbb{R}^{D_w \times D_w / H}$ and $\mathbf{W}^{(a_2)} \in \mathbb{R}^{D_w \times D_w}$ are learned parameters, H is the number of attention heads, and Attn is defined,

$$\mathrm{Attn}\left(\mathbf{Q}, \mathbf{K}, \mathbf{V}\right) = \mathrm{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^{T}}{\sqrt{D_w}}\right) \mathbf{V}.$$

Additionally, there is a masked variant of attention, $\mathrm{MultiAttn}_{M}$ where the attention is computed

$$\mathrm{Attn}\left(\mathbf{Q}, \mathbf{K}, \mathbf{V}\right) = \mathrm{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^{T} \odot \mathbf{M}}{\sqrt{D_w}}\right) \mathbf{V}$$

where $\mathbf{M} \in \mathbb{R}^{n \times m}$ is a lower triangular matrix, i.e. values on or below the diagonal are 1 and all other values are $-\infty$.

Given these definitions, we now define the S2S transformer. Let $\mathcal{V}$ be the encoder input vocabulary, and $\mathbf{E} \in \mathbb{R}^{|\mathcal{V}| \times D_w}$ an associated word embedding matrix where $\mathbf{E}_x \in \mathbb{R}^{D_w}$ denotes the D_w-dimensional embedding for each $x \in \mathcal{V}$. Given a linearized MR $\pi(\mu) = \mathbf{x} = \left[a, x_1, x_2, \ldots, x_{|\mu|}\right] \in \mathcal{V}^{m}$ where the length of the sequence is $m = |\mu| + 1$, let $\mathbf{v}_i = \mathbf{E}_{\mathbf{x}_i}$ for $i \in \{1, \ldots m\}$.

Additionally let $\mathbf{P} \in \mathbb{R}^{m_{max} \times D_w}$ be a sinusoidal position embedding matrix defined elementwise with

$$\mathbf{P}_{i,2j} = \sin\left(\frac{i}{10,000^{\frac{2j}{D_w}}}\right)$$

$$\mathbf{P}_{i,2j+1} = \cos\left(\frac{i}{10,000^{\frac{2j}{D_w}}}\right).$$

The encoder input sequence $\mathbf{H}^{(0)} \in \mathbb{R}^{m \times D_w}$ is then defined by

$$\mathbf{H}^{(0)} = \begin{bmatrix} \mathbf{v}_1 + \mathbf{P}_1, \\ \mathbf{v}_2 + \mathbf{P}_2, \\ \vdots \\ \mathbf{v}_m + \mathbf{P}_m \end{bmatrix}$$

A sequence of l transformer encoder layers are then applied to the encoder input, i.e. $\mathbf{H}^{(i+1)} = \mathrm{TF}^{(i)}_{enc}\left(\mathbf{H}^{(i)}\right)$. Each encoder transformer layer computes the following,

(Self-Attention Block)

$$\check{\mathbf{H}}^{(i)} = \mathrm{LN}\left(\mathbf{H}^{(i)}; \mathbf{a}^{(i,1)}, \mathbf{b}^{(i,1)}\right)$$

$$\bar{\mathbf{H}}^{(i)} = \mathrm{MultiAttn}\left(\check{\mathbf{H}}^{(i)}, \check{\mathbf{H}}^{(i)}; \mathbf{W}^{(i,a_1)}, \mathbf{W}^{(i,a_2)}\right)$$

$$\hat{\mathbf{H}}^{(i)} = \mathbf{H}^{(i)} + \bar{\mathbf{H}}^{(i)}$$

(Feed-Forward Block)

$$\dot{\mathbf{H}}^{(i)} = \mathrm{LN}\left(\hat{\mathbf{H}}^{(i)}; \mathbf{a}^{(i,2)}, \mathbf{b}^{(i,2)}\right)$$

$$\ddot{\mathbf{H}}^{(i)} = \mathrm{FF}\left(\dot{\mathbf{H}}^{(i)}; \mathbf{W}^{(i,1)}, \mathbf{W}^{(i,2)}, \mathbf{b}^{(i,1)}, \mathbf{b}^{(i,2)}\right)$$

$$\mathbf{H}^{(i+1)} = \hat{\mathbf{H}}^{(i)} + \ddot{\mathbf{H}}^{(i)}$$

We denote the final encoder output for l layers as $\mathbf{H} = \mathbf{H}^{(l)}$.

Let $\mathcal{W}$ be the vocabulary of utterance tokens, and $\mathbf{D} \in \mathbb{R}^{|\mathcal{W}| \times D_w}$ an associated embedding matrix, where $\mathbf{D}_y \in \mathbb{R}^{D_w}$ denotes a D_w-dimensional embedding for each $y \in \mathcal{W}$.

Given the decoder input sequence $\mathbf{y} = y_1, y_2, \ldots, y_{|\mathbf{y}|}$, let $\mathbf{w}_i = \mathbf{D}_{y_i}$ for $i \in \{1, \ldots n\}$. where $n = |\mathbf{y}| - 1$

$$\mathbf{G}^{(0)} = \begin{bmatrix} \mathbf{w}_1 + \mathbf{P}_1, \\ \mathbf{w}_2 + \mathbf{P}_2, \\ \vdots \\ \mathbf{w}_n + \mathbf{P}_n \end{bmatrix}.$$

A sequence of l transformer decoder layers are then applied to the decoder input, i.e. $\mathbf{G}^{(i+1)} = \mathrm{TF}^{(i)}_{dec}\left(\mathbf{G}^{(i)}\right)$. Each decoder transformer layer computes the following,

(Masked Self-Attention Block)

$$\check{\mathbf{G}}^{(i)} = \mathrm{LN}\left(\mathbf{G}^{(i)}; \mathbf{a}^{(i,1)}, \mathbf{b}^{(i,1)}\right)$$

$$\bar{\mathbf{G}}^{(i)} = \mathrm{MultiAttn}_M\left(\check{\mathbf{G}}^{(i)}, \check{\mathbf{G}}^{(i)}; \mathbf{W}^{(i,a_1)}, \mathbf{W}^{(i,a_2)}\right)$$

$$\hat{\mathbf{G}}^{(i)} = \mathbf{G}^{(i)} + \bar{\mathbf{G}}^{(i)}$$

(Encoder-Attention Block)

$$\grave{\mathbf{G}}^{(i)} = \mathrm{LN}\left(\hat{\mathbf{G}}^{(i)}; \mathbf{a}^{(i,2)}, \mathbf{b}^{(i,2)}\right)$$

$$\tilde{\mathbf{G}}^{(i)} = \mathrm{MultiAttn}\left(\grave{\mathbf{G}}^{(i)}, \mathbf{H}; \mathbf{W}^{(i,a_3)}, \mathbf{W}^{(i,a_4)}\right)$$

$$\acute{\mathbf{G}}^{(i)} = \hat{\mathbf{G}}^{(i)} + \tilde{\mathbf{G}}^{(i)}$$

(Feed-Forward Block)

$$\dot{\mathbf{G}}^{(i)} = \mathrm{LN}\left(\acute{\mathbf{G}}^{(i)}; \mathbf{a}^{(i,3)}, \mathbf{b}^{(i,3)}\right)$$

$$\ddot{\mathbf{G}}^{(i)} = \mathrm{FF}\left(\dot{\mathbf{G}}^{(i)}; \mathbf{W}^{(i,1)}, \mathbf{W}^{(i,2)}, \mathbf{b}^{(i,1)}, \mathbf{b}^{(i,2)}\right)$$

$$\mathbf{G}^{(i+1)} = \acute{\mathbf{G}}^{(i)} + \ddot{\mathbf{G}}^{(i)}$$

Let the $\mathbf{G} = \mathbf{G}^{(l)}$ denote the final decoder output, and let $\mathbf{g}_i$ be the i-th row of $\mathbf{G}$ corresponding to the decoder representation of the i-th decoder state. The probability of the next word is

$$p\left(y_{i+1} | y_{\leq i}, \pi(\mu)\right)$$

$$= \mathrm{softmax}\left(\mathbf{W}^{(o)}\mathbf{g}_i + \mathbf{b}^{(o)}\right)_{y_{i+1}}$$

where $\mathbf{W}^{(o)} \in \mathbb{R}^{|\mathcal{W}| \times D_w}$ and $\mathbf{b}^{(o)} \in \mathbb{R}^{D_w}$ are learned parameters.

The input embedding dimension is $D_w = 512$ and inner hidden layer size is $D_h = 2048$. The encoder and decoder have separate parameters. We used $H = 8$ heads in all multi-head attention layers. We used Adam with the learning rate schedule provided in Rush (2018) (factor=1, warmup=8000). Dropout was set to 0.1 was applied to input embeddings and each skip connection (i.e. the third line in each block definition). As a hyperparameter, we optionally tie the decoder input and output embeddings, i.e. $\mathbf{D} = \mathbf{W}^{(o)}$.

A.5 Transformer Hyperparameter Search

We grid searched over the following Transformer hyper-parameters:

- **Tied Decoder Embeddings:** tied, untied
- **Layers:** 1, 2
- **Label Smoothing:** 0.0, 0.1

During hyperparameter search, we train for at most 500 epochs, evaluating BLEU every 25 epochs to select the best model.

Winning hyperparameter settings are presented Table 7.

A.6 BART Model Hyperparameters

We use the same settings as the fine-tuning for the CNN-DailyMail summarization task, although we modify the maximum number of updates to be roughly to be equivalent to 10 epochs on the training set when using a 500 token batch size, since the number of updates effects the learning rate scheduler. We selected the model iterate with lowest validation set cross-entropy.

While BART is unlikely to have seen any linearized MR in its pretraining data, its use of subword encoding allows it to encode arbitrary strings. Rather than extending it's encoder input vocabulary to add the MR tokens, we simply format the input MR as a string (in the correpsonding linearization order), e.g. “inform rating=good name=NAME platforms=PC platforms=Xbox”.

Table 10: Validation and test set Kendall's τ for BgUP and NUP models.

A.7 Validation Results

Validation set results are shown in Table 8 and Table 9 for the E2E and ViGGO datasets respectively. Unlike the test results, reported in the main paper and appendix, validation SER and OA are computed automatically and not manually validated. All results are the average of five random initializations. Also we use the corrected MR produced by our attribute-value matching rules as input, rather than the original validation set MR.

B Neural Utterance Planner Model and Hyper-Parameter Search

We use the same general recurrent neural network model as defined in §A.2 with Bahdanau style attention (Bahdanau et al., 2015) to implement the neural utterance planner model. We trained for at most 50 epochs with batch size 128. We used the Adam optimizer with 0.0 weight decay. Decoder input/output embeddings were not tied. Models used embeddings and hidden layers of 512 dimensions. Models were trained to map If inputs to At outputs. We grid-searched over the following hyper-parameters:

- **Layers:** 1, 2
- **Learning Rate:** $10^{-3}, 10^{-4}, 10^{-5}$
- **RNN cell:** GRU, LSTM
- **Bidirectional Encoder:** uni, bi

- **Label Smoothing:** 0.0, 0.1

with the following winning settings determined by Kendall's τ on the validation set:

- E2E — 1 layers, biLSTM, lr $= 10^{-5}$, 0.1 label smoothing
- ViGGO — 1 layer, uniLSTM, lr $= 10^{-4}$, 0.1 label smoothing

Validation and test set Kendall's τ are shown in Table 10.

C Expanded Test Set Results

We show full automatic evaluation metrics from the E2E official evaluation script. E2E and ViGGO results are shown in Table 11 and Table 12 respectively. We also show full manual semantic evaluation results in Table 13 and Table 14 for E2E and ViGGO respectively. We break out the counts of missing, wrong, and added attributes used for SER calculation. Wrong attributes occur when an attribute is realized with the wrong value. Added attribute indicate the model realized an attribute-value that was not given in the input MR. Repeated attributes, even when specified in the input MR are included in added counts. We also include the percentage of utterances with correct semantics regardless of order (Perf.).

D Random Permutation Examples

We show examples of random permutation utterance plans, and those plans reordered using the BGUP and NUP models. We then show model realizations of those plans.

Random Utterance Plan
1 *food* = "Japanese"
2 *family_friendly* = "yes"
3 *area* = "riverside"
4 *name* = "Blue Spice"
5 *customer_rating* = "high"

BGUP Utterance Plan
1 *name* = "Blue Spice"
2 *family_friendly* = "yes"
3 *food* = "Japanese"
4 *area* = "riverside"
5 *customer_rating* = "high"

NUP Utterance Plan
1 *name* = "Blue Spice"
2 *food* = "Japanese"
3 *area* = "riverside"
4 *family_friendly* = "yes"
5 *customer_rating* = "high"

biGRU AT (Random) There is a Japanese child friendly place in the riverside area called Blue Spice with a high customer rating.

biGRU AT (BGUP) Blue Spice is a kid friendly Japanese place in the riverside area with a high customer rating.

biGRU AT (NUP) Blue Spice serves Japanese food in the riverside area. It is kid friendly and has a high customer rating.

biGRU AT+P (Random) There is a Japanese child friendly place in the riverside area called Blue Spice which has a high customer rating.

biGRU AT+P (BGUP) Blue Spice is kid friendly and serves Japanese food. It is located in the riverside. Its customer rating is high.

biGRU AT+P (NUP) Blue Spice serves Japanese food in the riverside area. It is child friendly and has a high customer rating.

Transformer AT (Random) There is a Japanese kid friendly place in the riverside area called Blue Spice. It has a high customer rating.

Transformer AT (BGUP) Blue Spice is a kid friendly Japanese place in the riverside area with a high customer rating.

Transformer AT (NUP) Blue Spice serves Japanese food in the riverside area. It is kid friendly and has a high customer rating.

Transformer AT+P (Random) There is a Japanese child friendly establishment in the riverside area called Blue Spice. It has a high customer rating.

Transformer AT+P (BGUP) Blue Spice is a kid friendly Japanese place by the riverside with a high customer rating.

Transformer AT+P (NUP) Blue Spice serves Japanese food in the riverside area. It is child friendly and has a high customer rating.

BART AT (Random) There is a Japanese kid friendly place in the riverside area called Blue Spice that has a high customer rating.

BART AT (BGUP) Blue Spice is a kid friendly Japanese food place in the riverside area with a high customer rating.

BART AT (NUP) Blue Spice serves Japanese food in the riverside area. It is kid friendly and has a high customer rating.

BART AT+P (Random) There is a Japanese family friendly place in the riverside area called Blue Spice with a high customer rating.

BART AT+P (BGUP) Blue Spice is a kid friendly Japanese food place in riverside with a high customer rating.

BART AT+P (NUP) Blue Spice serves Japanese food in the riverside area. It is child friendly and has a high customer rating.

Random Utterance Plan

1 *genres* = “arcade”
2 *player_perspective* = “first person”
3 *has_mac_release* = “no”
4 *platforms* = “Nintendo”
5 *name* = “The Legend of Zelda: Ocarina of Time”

BGUP Utterance Plan

1 *player_perspective* = “first person”
2 *genres* = “arcade”
3 *platforms* = “Nintendo”
4 *name* = “The Legend of Zelda: Ocarina of Time”
5 *has_mac_release* = “no”

NUP Utterance Plan

1 *name* = “The Legend of Zelda: Ocarina of Time”
2 *player_perspective* = “first person”
3 *genres* = “arcade”
4 *platforms* = “Nintendo”
5 *has_mac_release* = “no”

biGRU AT (Random) If you like arcade first person games, but it is a Mac release for the Nintendo. It is The Legend of Zelda: Ocarina of Time.

biGRU AT (BGUP) If you’re looking for a first person arcade game you can play on Nintendo, try The Legend of Zelda: Ocarina of Time. It has a Mac release.

biGRU AT (NUP) The Legend of Zelda: Ocarina of Time is a first person arcade game for Nintendo, and it is not available on Mac.

biGRU AT+P (Random) If you’re looking for an arcade first person game, though it doesn’t have a Mac release or a Nintendo game is The Legend of Zelda: Ocarina of Time.

biGRU AT+P (BGUP) If you’re looking for a first person arcade game for Nintendo, try The Legend of Zelda: Ocarina of Time. It is not available on Mac.

biGRU AT+P (NUP) The Legend of Zelda: Ocarina of Time is a first person arcade game for Nintendo. It is not supported on Mac.

Transformer AT (Random) If you like arcade first person perspective games, then you should try the Nintendo video game called The Legend of Zelda: Ocarina of Time.

Transformer AT (BGUP) If you like first person arcade games, then you should try the Nintendo video game called The Legend of Zelda: Ocarina of Time.

Transformer AT (NUP) The Legend of Zelda: Ocarina of Time is a first person arcade game for Nintendo. It is a game that is not available for Mac.

Transformer AT+P (Random) If you like arcade first person games, then you should try the Nintendo video game called The Legend of Zelda: Ocarina of Time. It was released for Nintendo.

Transformer AT+P (BGUP) If you’re looking for a first person arcade game for the Nintendo, try The Legend of Zelda: Ocarina of Time. It’s not available for Mac.

Transformer AT+P (NUP) The Legend of Zelda: Ocarina of Time is a first person arcade game for the Nintendo. It is not available on Mac or Linux.

BART AT (Random) If you’re looking for an arcade game with a first person perspective that doesn’t have a Mac release, then you should try the Nintendo game The Legend of Zelda: Ocarina of Time.

BART AT (BGUP) If you like first person arcade games, then you should try the Nintendo video game called The Legend of Zelda: Ocarina of Time. Unfortunately, it doesn’t have a Mac release.

BART AT (NUP) The Legend of Zelda: Ocarina of Time is a first person arcade game for Nintendo, but it is not supported on Mac.

BART AT+P (Random) If you’re looking for an arcade game with a first person perspective that doesn’t have a Mac release, you should check out the Nintendo video game called The Legend of Zelda: Ocarina of Time.

BART AT+P (BGUP) If you’re looking for a first person arcade game for Nintendo consoles, check out The Legend of Zelda: Ocarina of Time. It’s not available on Mac though.

BART AT+P (NUP) The Legend of Zelda: Ocarina of Time is a first person arcade game for Nintendo consoles only. It is not available on Mac.

Random Utterance Plan
1 *genres* = “puzzle”
2 *genres* = “driving/racing”
3 *name* = “Metro 2033”
4 *genres* = “platformer”
5 *genres* = “music”

BGUP Utterance Plan
1 *genres* = “music”
2 *genres* = “platformer”
3 *genres* = “puzzle”
4 *name* = “Metro 2033”
5 *genres* = “driving/racing”

NUP Utterance Plan
1 *name* = “Metro 2033”
2 *genres* = “driving/racing”
3 *genres* = “platformer”
4 *genres* = “puzzle”
5 *genres* = “music”

biGRU AT (Random) If you like puzzle racing games, try Metro 2033. It is a platformer music game.

biGRU AT (BGUP) The music platformer puzzle game, Metro 2033, is a driving/racing game.

biGRU AT (NUP) Metro 2033 is a driving/racing platformer with puzzle elements. It’s a music game.

biGRU AT+P (Random) If you like puzzle games, Metro 2033 is a driving/racing platformer. It is a music game.

biGRU AT+P (BGUP) If you like music platformer games with puzzles, Metro 2033 is a driving/racing game.

biGRU AT+P (NUP) Metro 2033 is a driving/racing platformer with puzzle solving. It is a music game.

Transformer AT (Random) If you like puzzle games, Metro 2033 is a driving/racing platformer. It is a platformer game.

Transformer AT (BGUP) If you like music games, then you should try the puzzle platformer, try Metro 2033.

Transformer AT (NUP) Metro 2033 is a driving/racing platformer with puzzle solving.

Transformer AT+P (Random) If you are looking for a puzzle platformer, try Metro 2033. It is a driving/racing platformer game that is a music game.

Transformer AT+P (BGUP) If you like music games, then you should try Metro 2033. It’s a puzzle driving/racing game.

Transformer AT+P (NUP) Metro 2033 is a driving/racing platformer puzzle game.

BART AT (Random) If you’re looking for a puzzle driving/racing game, try Metro 2033. It’s a platformer with music elements.

BART AT (BGUP) If you’re looking for a music platformer with puzzle solving, Metro 2033 is a driving/racing game.

BART AT (NUP) Metro 2033 is a driving/racing platformer with puzzle and music elements.

BART AT+P (Random) If you’re looking for a puzzle game with driving/racing, Metro 2033 is a platformer with music elements.

BART AT+P (BGUP) If you’re looking for a music platformer with puzzle solving, Metro 2033 is a driving/racing game.

BART AT+P (NUP) Metro 2033 is a driving/racing, platformer, puzzle, music game.

E Human Evaluation Details

Two separate annotators ranked the 100 E2E outputs and another two annotators ranked the 100 ViGGO outputs. The annotators were either undergraduate or PhD students experienced in NLP research but not involved in the paper. Three were native English speakers and the fourth was a highly fluent English speaker. When computing Kendall's τ on E2E, three instances were not computable because one annotator gave all three outputs the same rank. These three instances were assigned $\tau = 0$ equivalent to no correlation.

Annotators were given the following instructions and then made their ranking annotations in Google Sheet:

Instructions: *You will be shown 3 utterances that are informing you about either a restaurant or a video game. Please rank the utterances according to their naturalness (i.e. fluency and/or degree to which you believe they were written by a native English speaker). 1 = most natural, 3 = least natural.*

Here is an example:

	Rank
(0) There is an English food place near the Sorrento with a price range of less than £20 called Blue Spice.	2
(1) Blue Spice serves English food for less than £20 and is located near the Sorrento.	1
(2) Serving English food near the Sorrento with a price range of less than £20 is Blue Spice.	3

Here I have decided that (1) feels the most natural, nicely breaking up information into a conjunction, while (2) seems least natural because of its run on gerund phrase in a copula. (0) is a little bit of a run on but not egregious.

Do not worry if one utterance does not have all the same or inconsistent facts as the others. Judge them only on their naturalness.

In many cases you will probably feel that two or more examples are equivalent in naturalness. In this case give them the same rank. E.g.,

	Rank
(0) There is a place that serves Japanese food in the riverside area near Café Sicilia called the Twenty Two.	1
(1) The Twenty Two serves Japanese food and is located near Café Sicilia in the riverside area.	1
(2) Serving Japanese food in the riverside area near Café Sicilia is the Twenty Two.	2

When making ties, make sure the next lowest rank follows numerically, i.e. if there is a tie for 1, the next lowest rank should be 2. In other words don't do this:

	Rank
(0) There is a place that serves Japanese food in the riverside area near Café Sicilia called the Twenty Two.	1
(1) The Twenty Two serves Japanese food and is located near Café Sicilia in the riverside area.	1
(2) Serving Japanese food in the riverside area near Café Sicilia is the Twenty Two.	3

You will annotate 100 sets of 3 utterances.

Blank Language Models

Tianxiao Shen* **Victor Quach*** **Regina Barzilay** **Tommi Jaakkola**

Abstract

We propose Blank Language Model (BLM), a model that generates sequences by dynamically creating and filling in blanks. The blanks control which part of the sequence to expand, making BLM ideal for a variety of text editing and rewriting tasks. The model can start from a single blank or partially completed text with blanks at specified locations. It iteratively determines which word to place in a blank and whether to insert new blanks, and stops generating when no blanks are left to fill. BLM can be efficiently trained using a lower bound of the marginal data likelihood. On the task of filling missing text snippets, BLM significantly outperforms all other baselines in terms of both accuracy and fluency. Experiments on style transfer and damaged ancient text restoration demonstrate the potential of this framework for a wide range of applications.[1]

1 Introduction

Neural language models have shown impressive performance across many applications such as machine translation and summarization where the text is generated from scratch (Bahdanau et al., 2014; Rush et al., 2015). However, a broader set of text generation tasks — including text editing, information fusion, and ancient text restoration — requires the model to start with partially specified text and generate the missing fragments. In the general setup, the input document may have any number of missing spans, and each span may have an unknown number of missing tokens. To perform this text infilling task (Zhu et al., 2019), a model should: (1) provide fine-grained control over the generation location, (2) accommodate a variable number of missing tokens, and (3) respect both the preceding and following context.

They also have ____ which ____ .
They also have *ice cream* which *is really good* .

Figure 1: BLM fills in blanks of arbitrary length.

Existing approaches focus on adapting left-to-right language models for text infilling. Intricate inference algorithms leveraging dynamic programming or gradient search are proposed to find the filling content that has a high likelihood within the surrounding context (Sun et al., 2017; Liu et al., 2019a; Zaidi et al., 2020). These methods make simplified Markov assumptions, require high decoding time complexity, and cannot adapt to variable infilling length. Alternatively, Donahue et al. (2020) predict the concatenation of the infilling content, but do not guarantee that the output will match the number of missing spans in the input.

In this work, we introduce the Blank Language Model (BLM), which uses a special "__" symbol to control where tokens can be placed. The generation of BLM follows the grammar of replacing a blank with a word and possibly adjoining blanks. By jointly modeling context and missing content, BLM supports the control of generation location and produces consistent infilling of variable length.

Our model can start from a single blank or partial text with blanks in specified locations. It maps the entire input into a sequence of vector representations, and further processes the representations in blank positions to determine the generation action. Generation actions are performed iteratively until there are no blanks. Since multiple trajectories of BLM actions can produce the same final text, we train the model by maximizing a lower bound of the log-likelihood marginalized over trajectories. At test time, we can use simple greedy decoding or beam search to fill in the blanks in the input text.

BLM shows superior performance in text infilling (Zhu et al., 2019), ancient text restoration (As-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5186–5198,
November 16–20, 2020.

	Canvas c	Action a			
Step t		Location b	Word w	(Left l,	Right r)
0.	__#1__	#1	is	Y	Y
1.	__#1__ is __#2__	#1	customer	N	Y
2.	customer __#1__ is __#2__	#2	awesome	N	N
3.	customer __#1__ is awesome	#1	service	N	N
4.	customer service is awesome	-End-			

Figure 2: An example trajectory that generates the sentence "customer service is awesome". Each action is a tuple (b, w, l, r), indicating the blank location b selected for expansion, the word w to fill in, whether to create a left blank l, and whether to create a right blank r.

sael et al., 2019) and style transfer (Shen et al., 2017), demonstrating its flexibility to generate text in diverse conditions. Our model achieves 92.5% accuracy and BLEU score of 23.1 on the Amazon dataset for sentiment transfer. On the task of restoring ancient text that lost half of the characters, we reduce the error rate by 3.3 points compared to previous methods.

2 Related Work

Recent work has explored various sequence models for non-autoregressive machine translation (Gu et al., 2017). The Insertion Transformer supports dynamic canvas with word insertion (Stern et al., 2019), but does not allow users to specify where to insert. The model is unaware of which parts of the canvas are contiguous text spans that should remain intact, and which (potentially scattered) parts need to be filled in. Directly forcing the Insertion Transformer to perform text infilling can therefore lead to suboptimal solutions. The Levenshtein Transformer combines insertion and deletion through complex policy learning (Gu et al., 2019b). Its insertion mechanism is a two-stage process in which placeholders are first predicted and then filled-in in a masked language model (MLM) manner. In text infilling where the blanks/placeholders are given, it reduces to an MLM.

MLMs are commonly used in representation learning (Devlin et al., 2018; Joshi et al., 2020). To use them in rewriting tasks, one needs to specify the insertion length in advance and heuristically determine the generation order among the masks (Fedus et al., 2018; Wang and Cho, 2019; Ghazvininejad et al., 2019). Similarly, XL-Net requires absolute positional embedding and thus does not support unknown-length text infilling (Yang et al., 2019; Shih et al., 2019). BLM provides a natural formulation for generative modeling that can dynamically accommodate insertions of various length.

Another line of work focuses on finding an optimal language generation order, such as syntax-based generation (Dyer et al., 2016) and learning adaptive generation order (Gu et al., 2019a). These approaches are tailored to generation from scratch in a specific order. Our model instead is attuned for text rewriting, where the missing parts can be located anywhere in the input text, and the algorithm must flexibly complete them.

3 Blank Language Models

A blank language model (BLM) generates sequences by creating and filling in blanks. Generation starts with a single blank and ends when there is no blank. In each step, the model selects a blank "__", predicts a word w, and fills the blank with "w", "__ w", "w __", or "__ w __". This way, a blank can be expanded to any number of words.

We define a *canvas* as a sequence of words interspersed with special "__" tokens. The subsequent action is conditioned on this intermediate stage of generation. Suppose the current canvas is $c = (c_1, \cdots, c_n)$ with blanks located at indices $b_1, \cdots, b_k$ (i.e. c_{b_i} = "__", for $i = 1, \ldots, k$). BLM maps this canvas to a distribution over actions specifying how the canvas is to be revised:

$$p(b, w, l, r | c; \theta) = \mathrm{BLM}(c) \qquad (1)$$

where $b \in \{b_1, \cdots, b_k\}$ is a blank location; w is a word in the vocabulary V; $l, r \in \{0, 1\}$ denote whether or not to create a blank to the left and right of w; and θ are the model parameters. The *action*, defined as the tuple (b, w, l, r) uniquely specifies the next state of canvas (see Fig. 2 for illustration).

Alternatively, we can view the actions in BLM as production rules in a grammar. Each blank represents a nonterminal symbol or the start symbol,

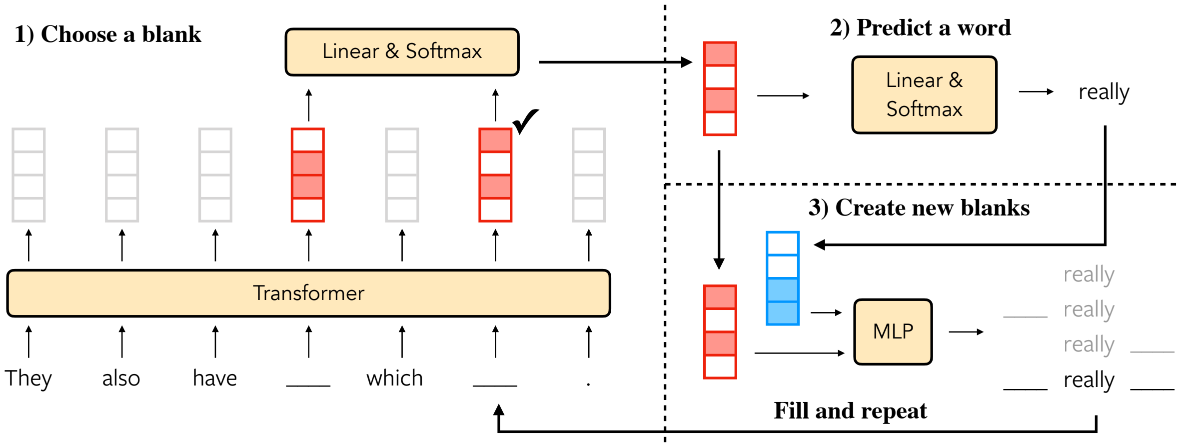

Figure 3: Architecture of the BLM. In the first stage, an index is chosen among all current blank positions. For that location, a word is selected in the second stage. In the final stage, the blank representation is concatenated with the chosen word's embedding and fed into an MLP to determine the creation of the following blanks.

and the terminal symbols come from the vocabulary V. The production rules are restricted to be of the form "__" → "__?w__?" for $w \in V$, where "?" indicates that the preceding symbol is optional. In contrast to context-free grammars, the probability distribution over production rules in BLM is conditioned on the entire canvas generated so far.

Model Architecture We encode the canvas c into a sequence of representations $(z_1, \cdots, z_n)$, and take representations $Z = (z_{b_1}, \cdots, z_{b_k})$ where the blanks are located. Let d denote the dimension of z's. We factorize the joint distribution $p(b, w, l, r|c; \theta)$ into three parts (shown in Fig. 3):

1. Choose a blank:

$$p(b_i|c;\theta) = \text{Softmax}(u^T Z) \tag{2}$$

where $u \in \mathbb{R}^d$ is a parameter vector to project z's into one-dimensional logits.

2. Predict a word for the selected blank:

$$p(w|c, b_i;\theta) = \text{Softmax}(W z_{b_i}) \tag{3}$$

where $W \in \mathbb{R}^{|V|\times d}$ is a parameter matrix to project z_{b_i} into the vocabulary.

3. Decide whether or not to create blanks to the left and right of the predicted word:

$$p(l, r|c, b_i, w;\theta) = \text{MLP}(z_{b_i}, v_w) \tag{4}$$

where v_w is the word vector of w, and MLP is a multilayer perceptron with 4 output classes: Left.Yes/No × Right.Yes/No.

Likelihood Now let us consider the probability $p(x;\theta)$ of generating a sentence/paragraph $x = (x_1, \cdots, x_n)$ under the BLM. We call the generating process from an initial blank to complete text a *trajectory*. The same final text x can be realized by multiple trajectories. However, if we specify the order in which the words in x are generated, the trajectory will be uniquely determined. Consider the example trajectory of a 4-word sentence in Fig. 2. Given the order $(3, 1, 4, 2)$, at step 0 when we generate x_3, both left and right blanks are created for future generations of x_1 and x_2, x_4. In step 1 of generating x_1, only a right blank is created for the future x_2. Subsequent steps can be deduced by analogy. The correspondence between trajectories and generation orders allows us to write the marginal likelihood as:

$$\begin{aligned} p(x;\theta) &= \sum_{\sigma\in S_n} p(x, \sigma;\theta) \\ &= \sum_{\sigma\in S_n} \prod_{t=0}^{n-1} p(a_t^{x,\sigma}|c_t^{x,\sigma};\theta) \end{aligned} \tag{5}$$

where S_n is the set of all n-permutations; $a_t^{x,\sigma}, c_t^{x,\sigma}$ denote the action and canvas at step t under sentence x and order σ, respectively (cf. Fig. 2).

Training Different losses have been proposed to train generalized sequence models. For instance, BERT and XL-Net mask and predict 15% of tokens conditioned on the rest. This strategy is more suitable for representation learning rather than generation. Insertion Transformer masks different numbers of tokens and weights them with uniform loss or binary tree loss (Stern et al., 2019; Chan et al.,

Algorithm 1 BLM training[2]

```
Initialize model parameters $\theta$
repeat
    Sample a training example $x = (x_1, \cdots, x_n)$
    Sample $t$ from 0 to $n - 1$
    Sample an $n$-permutation $\sigma$
    Construct canvas $c$ that keeps tokens $x_{\sigma_j}$ ($j = 1, \cdots, t$) and collapses remaining tokens as blanks
    Get $n - t$ target actions $a_{j-t}$ for filling $x_{\sigma_j}$ ($j = t + 1, \cdots, n$) into canvas $c$
    Compute $\text{loss}(\{a_1, \cdots, a_{n-t}\}, \text{model.forward}(c))$ from Eq. (8)
    Update $\theta$ by gradient descent
until Convergence
```

2019). It aims to perform fast inference through parallel decoding. Here, we present a training objective from the language modeling perspective by estimating the log likelihood of generating x.

Directly computing the marginal likelihood over $n!$ orders is intractable. We apply Jensen's inequality to lower bound the log likelihood:

$$\log p(x;\theta) = \log \sum_{\sigma \in S_n} \prod_{t=0}^{n-1} p(a_t^{x,\sigma} | c_t^{x,\sigma}; \theta)$$

$$\geq \log(n!) + \frac{1}{n!} \sum_{\sigma \in S_n} \sum_{t=0}^{n-1} \log p(a_t^{x,\sigma} | c_t^{x,\sigma}; \theta) \quad (6)$$

where equality holds when the posterior $p(\sigma|x;\theta)$ is uniform. By maximizing this lower bound, we do not favor any particular order, but encourage the model to realize x equally well in all orders. It can help the model to complete any partial input text regardless of the position of blanks.

A naive training algorithm is to directly estimate the lower bound in Eq. (6): first uniformly sample a permutation σ from S_n and a step t from 0 to $n-1$, then construct the canvas $c_t^{x,\sigma}$, and compute the estimated loss $[-\log(n!) - n \cdot \log p(a_t^{x,\sigma}|c_t^{x,\sigma};\theta)]$. However, this procedure has a large variance and can only compute the loss of a single action in one pass (in contrast to left-to-right language models that compute n word losses per pass).

To train the model more efficiently, we note that the canvas $c_t^{x,\sigma}$ depends only on the first t elements of σ. Hence we can combine into one pass the loss calculations of trajectories that are the same in the first t steps but different at the $t+1$ step. Switching the summation order of σ and t, we have:

They also have ____ which ____ .
They also have ice cream which is really good .

τε εγγονον εισαι???????σοφιαι
τε εγγονον εισαιου του σοφιαι

The employees were **super nice** and **efficient** !
The employees were rude and unprofessional !

Figure 4: Examples of input and output for text infilling, ancient text restoration, and style transfer tasks.

$$\begin{aligned}
&\sum_{t=0}^{n-1} \frac{1}{n!} \sum_{\sigma \in S_n} \log p(a_t^{x,\sigma} | c_t^{x,\sigma}; \theta) \\
&= n \cdot \mathbb{E}_t \mathbb{E}_{\sigma_{1:t}} \mathbb{E}_{\sigma_{t+1}} \mathbb{E}_{\sigma_{t+2:n}} \left[\log p(a_t^{x,\sigma} | c_t^{x,\sigma}; \theta)\right] \\
&= n \cdot \mathbb{E}_t \mathbb{E}_{\sigma_{1:t}} \mathbb{E}_{\sigma_{t+1}} \left[\log p(a_t^{x,\sigma} | c_t^{x,\sigma}; \theta)\right] \\
&= \mathbb{E}_t \mathbb{E}_{\sigma_{1:t}} \left[\frac{n}{n-t} \sum_{\sigma_{t+1}} \log p(a_t^{x,\sigma} | c_t^{x,\sigma}; \theta) \right] \quad (7)
\end{aligned}$$

which leads to our efficient training algorithm: sample t from 0 to $n-1$ and partial permutation $\sigma_{1:t}$, construct the canvas $c_t^{x,\sigma}$, and compute loss:

$$-\log(n!) - \frac{n}{n-t} \sum_{\sigma_{t+1}} \log p(a_t^{x,\sigma} | c_t^{x,\sigma}; \theta) \quad (8)$$

The whole process is illustrated in Algorithm 1. In this way, we can compute in expectation $n/2$ action losses per pass.

4 Experiments

We test BLM's capacity to rewrite specified portions of text on three tasks: text infilling (Zhu et al., 2019), ancient text restoration (Assael et al., 2019) and style transfer (Shen et al., 2017). Fig. 4 displays example inputs and outputs for these tasks. We also measure the perplexity of BLM on language modeling benchmarks and compare with traditional left-to-right language models.

Experimental Details In all experiments, the sequence representations in BLM are obtained using the encoder module of `transformer_base` (Vaswani et al., 2017) (6 layers, 8 heads, $d_{model} = 512$, $d_{ff} = 2048$, $d_k = d_v = 64$). The MLP used for blank prediction has one hidden layer of size 1024. Weight decay, learning rate, and dropout are tuned based on the loss on the validation set for each dataset respectively. When decoding, we use beam size in $\{1, 5, 10\}$ and choose the best value as

Table 2: Infilling failure rate (%) of seq2seq models. Other methods always produce valid outputs.

observed on the validation set. We note that beam search in BLM does not search for the sentence with the maximum marginal likelihood $p(x;\theta)$, but instead for a sentence *and* a trajectory that have the maximum joint likelihood $p(x,\sigma;\theta)$.

4.1 Text Infilling

Dataset We experiment on the Yahoo Answers dataset, which has 100K/10K/10K documents for train/valid/test respectively (Yang et al., 2017). A document has a maximum length of 200 words, with an average of 78 words. Following Zhu et al. (2019), we automatically compile test data by deleting portions of documents. For each document x, we randomly mask a given ratio r of its tokens. Contiguous masked tokens are collapsed into a single "__", resulting in a canvas c to be completed.

Metrics We measure generation's accuracy by computing its BLEU score against the original document x, and fluency as its perplexity evaluated by a pre-trained (left-to-right) language model. We also report the failure rate, which is the percentage of invalid generations, such as missing existing words or not filling in all the blanks.

Baselines We compare BLM with five baselines:

- *Insertion Transformer (InsT)*: By default, InsT does not support controlling the insertion position. We force it to produce valid generations by normalizing the predictions over valid locations, disabling the ⟨eos⟩ prediction unless all blanks have been filled, and prioritizing slots that have not been filled yet. Without these steps, InsT would have a failure rate $\geq 88\%$.
- *MLM (oracle length)*: MLM for text infilling requires predicting the length of each blank. Here we replace blanks with the target number of ⟨mask⟩ tokens, and fill them autoregressively by the most-confident-first heuristic.
- *BERT+LM*: We use BERT's representation of each blank as seed for a left-to-right language model that learns to generate the tokens in the corresponding blank. At inference time, the multiple blanks are filled in one after another, conditioned on previous generations.
- *Seq2seq-full* (Donahue et al., 2020): We train a seq2seq model to output the full document x from input c. Note that it may have invalid outputs that do not match the input format, such as missing existing tokens in c or generating tokens in incorrect locations.
- *Seq2seq-fill* (Donahue et al., 2020): We train a seq2seq model to output only tokens to be placed in the blanks, with a special '|' token to indicate separation. For the example in Fig. 4, its target output will be "ice cream |is really good". Unlike *seq2seq-full*, *seq2seq-fill* does not have the problem of losing existing tokens in c. However, it may still fail to generate the correct number of '|' that matches the input.

Results As shown in Table 1, BLM achieves the highest BLEU score at all mask ratios: 0.7 to 1.7 higher than InsT, 2.6 to 4.1 higher than MLM with oracle length, and 3.7 to 9.4 higher than BERT+LM. InsT is not trained with insertion position control. Restricting it to generate at the specified positions thus bias the model towards making suboptimal

Figure 5: Example generations of different models for text infilling on Yahoo Answers. Completions are in italic. Invalid completions are in red. For Seq2seq-fill, we present model outputs along with the merged document.

completions. MLM is trained to independently predict masked tokens instead of jointly modeling them. Even with the target number of ⟨mask⟩ tokens given, its performance is still inferior to BLM. BERT+LM lags behind other models. In BERT training, one mask corresponds to one token, whereas a blank here can cover multiple tokens, and the distance between words is not fixed. Hence, it is difficult for the LM to complete the sentence from BERT representations.

Seq2seq-full has BLEU scores closest to BLM. However, its failure rate ranges from 15% to 40.6% as the mask ratio increases. Seq2seq-fill performs worse than Seq2seq-full, possibly because the decoder has to model segmented text while counting the number of blanks.

In terms of fluency, outputs of BLM, InsT and Seq2seq-full all have perplexity lower than original data perplexity. This is because with beam search, models tend to generate the most typical output with the highest likelihood (Holtzman et al., 2019).

Examination of model generations confirms the superiority of BLM. In Fig. 5, we showcase example outputs by each model at different mask ratios. In low mask ratio settings, models only need to fill in the blanks with a single word to produce grammatical completions. Most models succeed in this task. With a higher mask ratio of 50%, the main ideas of the document are concealed, and the infilling task is much more challenging. Models need to creatively generate sentences that fit the imposed canvas. Although the original meaning of the sentence is not recovered, BLM is the only model able to produce a coherent document with consistency between the question and the answer.

Overall, BLM displays the best performance both quantitatively and qualitatively. Its inherent text infilling ability frees it from length, order, or termination heuristics used by other methods.

4.2 Ancient Text Restoration

Ancient text restoration is a form of text infilling where there are fragments in ancient documents that are illegible due to time-related damages and need to be recovered. Assael et al. (2019) introduces the PHI-ML dataset made of fragments of ancient Greek inscriptions. Restoration is performed at the character-level. The number of characters to recover is assumed to be known and indicated by a corresponding number of '?' symbols, as shown in the second row of Fig. 4. In reality, when epigraphists restore a deteriorated document, the length of the lost fragment is unknown and needs to be guessed as a first step. While models proposed by Assael et al. (2019) relies on expert conjectures, we note that BLM can bypass this limitation and flexibly generate completions without this additional knowledge. However, in order to compute the character error rate (CER) for each '?' and have a fair comparison with previous work, we evaluate our model in the length-aware setting.

	Single-	Multi-slot		
Mask ratio	1%	25%	40%	50%
Human	57.3%	-	-	-
Pythia	32.5%	-	-	-
Pythia-Word	**29.1%**	**36.9%**	42.3%	44.9%
L-BLM	33.7%	37.1%	**37.9%**	**41.6%**

Table 3: CER for ancient text restoration.

Length-aware BLM (L-BLM) We present a variant of BLM adapted to the specific features of this task. The vocabulary V is an alphabet of characters from the ancient Greek language. We extend V with special "$\underline{\quad [t] \quad}$" tokens that denote the length of the fragment to recover. Specifically, as a preprocessing step, consecutive '?' characters are collapsed into a single "$\underline{\quad [t] \quad}$" token, where t is the number of '?' symbols. For each such blank token, L-BLM is trained to predict a character to fill in and the length $l \in \{0, \cdots, t-1\}$ of the new blank to its left. The length of the new blank on the right is accordingly $t - 1 - l$.

Dataset The PHI-ML dataset contains about 3 million words / 18 million characters. We evaluate models in two settings: *single-slot* and *multi-slot*. For the single-slot setting, we use the testing script of Assael et al. (2019) which samples a context of length $L = 1000$ from an inscription, then samples a slot of length $C \in [1, 10]$ from that context. The characters from the slot are replaced with '?' and constitute the target. For the multi-slot setting, we progressively increase the number of slots, yielding mask ratios of 25%, 40% and 50% respectively.

Baselines Assael et al. (2019) proposed two models: *Pythia*, a character-level seq2seq-based approach; and *Pythia-Word*, a variant of Pythia that uses both character and word representations as input. During training, the model learns to recover the missing characters of examples where a random slot has been masked. When testing on the multi-slot setting, Pythia(-Word) is applied iteratively with beam size 20 for each slot.

Results Table 3 summarizes the CER of all models in both settings. L-BLM achieves similar CER as Pythia in the single-slot setting, significantly outperforming human experts. Augmented with word representations, Pythia-Word further decreases the error rate compared to character-only methods.

In reality, restoring damaged inscriptions requires reconstructing multiple lost fragments. As a larger proportion of text is missing, Pythia-Word's performance is degraded. L-BLM is robust to the setting change and outperforms Pythia-Word at the mask ratio of 40% and 50% by 4.4 and 3.3 points, respectively. We posit that L-BLM's advantage lies in its ability to maximize the joint likelihood of the completions over all slots. In contrast, Pythia-Word's is only aware of one slot at a time, and beam search is performed locally within each slot.

4.3 Sentiment Transfer

The goal of sentiment transfer is to modify the sentiment of a sentence while maintaining its topic (Shen et al., 2017). An example is described on the third row of Fig. 4. Inspired by the way humans perform rewriting, we follow a recent line of work in style transfer that adopts a two-step approach (Li et al., 2018; Xu et al., 2018; Wu et al., 2019b):

1. Remove words and expressions of high polarity from the source sentence;
2. Complete the partial sentence with words and expressions of the target sentiment.

Specifically, we adapt the *Mask-And-Infill (M&I)* framework of Wu et al. (2019b). We perform Step 1 by training a Bi-LSTM sentiment classifier and masking words whose attention weight is above average. We evaluate the contribution of our model as an infilling module in Step 2 in place of their fine-tuned BERT model. To this end, we train two instances of BLM on the dataset, one for each sentiment. At test time, the corresponding BLM is used to produce completions of the target sentiment.

Wu et al. (2019b) further train the infilling model with the classifier to improve transfer accuracy. They use soft words relaxation to backprop gradients from the classifier to the generator. For BLM, however, we cannot pick locations or insert blanks as "soft" choices, making it challenging to employ a classifier at training time. Nevertheless, we can easily apply the classifier to guide inference. We sample 10 outputs and keep the one with the highest classifier ranking. It is not slower than beam search with size 10 and can be fully parallelized.

Datasets We test on the Yelp and Amazon review datasets (Shen et al., 2017; Li et al., 2018). The Yelp dataset has 450K/4K/1K non-parallel sentences for train/valid/test respectively, and the Amazon dataset has 555K/2K/1K sentences. Each sentence is labeled as either positive or negative.

	Yelp		Amazon	
	ACC	BLEU	ACC	BLEU

it is n't perfect , but it is very good .

Figure 6: Example generations by BLM for sentiment transfer on Yelp. The first line is the source sentence with masked words in bold. The second line is BLM's completion. The third line is a human reference.

Metrics We use evaluation methods introduced by prior work (Shen et al., 2017; Li et al., 2018). To assess the accuracy of generated sentences with respect to the target sentiment, we use a pretrained CNN classifier that achieves 97.7% accuracy on the Yelp dataset and 82.2% accuracy on the Amazon dataset. We also measure the BLEU score between transferred sentences and human references.

Results In Table 4, we can see that directly applying BLM as the infilling module is significantly better than MLM. The accuracy on Yelp and Amazon datasets is increased by 38.1% and 20.8%, respectively. In addition to the aforementioned problem of MLM being trained to predict masked tokens independently, it must generate the same number of tokens as in the source sentence, whereas our BLM formulation is not subject to this constraint. Our simple use of a classifier at inference time further improves accuracy. It achieves the highest accuracy of 92.5% on Amazon with a small decrease in BLEU, indicating that BLM can easily find high-quality outputs.

In Fig. 6, we show examples generated by BLM on Yelp. It can dynamically adapt to the imposed canvas and fill in blanks with expressions of varied lengths, e.g., "**nowhere to be** found" → "the best i found" and "**definitely not**" → "always". We note that failure cases arise when negative words like "either" are left unmasked; BLM is then unable to produce satisfactory outputs from the canvas.

4.4 Language Modeling

Language modeling is a special case of text infilling where sequences are generated from scratch. Traditional left-to-right models dominate this task, but are not suitable for text infilling. Conversely, unconventional sequence models are rarely evaluated on language modeling. Here, we study the perplexity of BLM and Insertion Transformer, and compare them with left-to-right language models to provide additional insights.

We use the Monte-Carlo method to estimate the likelihood in Eq. (5) with m samples. While the estimate is unbiased, given that per-word perplexity is a convex function of per-sentence likelihood, sampling estimates like ours are likely yielding a value higher than the actual perplexity (see Appendix B for a proof). As m increases, it converges to the actual perplexity.

Datasets We test on three benchmark datasets: Penn Treebank (PTB) which has about 1M tokens (Mikolov et al., 2010), WikiText-2 (WT2) which has 2M tokens, and WikiText-103 (WT103) which has 103M tokens (Merity et al., 2016).

Results Table 5 shows the trend of estimated PPL with the number of samples m. We choose $m = 1000$ in our evaluation, which is close to convergence. Table 6 summarizes the perplexity of our model in comparison with previous work. The top results are achieved by the Transformer-XL (Dai et al., 2019) and the adaptive embedding method (Baevski and Auli, 2018). They use larger model sizes and supplementary techniques that can also be combined with our model. BLM rivals the Insertion Transformer and outperforms left-to-right language models with LSTM and Temporal Convolutional Network (TCN) architecture. Language modeling seems to still be challenging for free-order models. By reporting the perplexity of unconventional models like BLM, we hope to stimulate future work in this area to close the performance gap with traditional left-to-right models.

5 Conclusion

In this paper, we proposed the Blank Language Model for flexible text generation. Given partially specified text with one or more blanks, BLM will fill in the blanks with a variable number of tokens consistent with the context. We demonstrate the effectiveness of our model on various text rewriting tasks, including text infilling, ancient text restoration and style transfer.

The action of BLM consists of selecting a blank and replacing it with a word and possibly adjoining blanks. We train BLM by optimizing a lower bound on the marginal data likelihood that sums over all possible generation trajectories. In this way, we encourage the model to realize a sentence equally well in all orders, which is suitable for filling arbitrary blanks. Appendix C shows examples generated by BLM along with their trajectories. Depending on the application, we could also train the model to generate in specific orders by placing higher weights on the corresponding trajectories.

BLM has plenty of future applications, including template filling, information fusion, assisting human writing, etc. Moreover, we can extend our formulation to a conditional generative model. Such models can be used in machine translation to support editing and refining translation, as well as in dialogue systems to compose a complete sentence with given elements. While we proposed BLM for language generation, it would also be interesting to compare the representations learned by BLM with those produced by other pre-training methods.

Acknowledgments

We thank all reviewers and the MIT NLP group for their thoughtful feedback.

Appendix

A Implementation Details for Text Infilling Baselines

A.1 Insertion Transformer

We implement the Insertion Transformer in our own framework, using the same Transformer encoder module as for BLM and replacing the prediction layers by Insertion Transformer's mechanism. The canvas is also generated according to the training procedure of Insertion Transformer.

A.2 Masked Language Model

We use the `RobertaForMaskedLM` architecture in the Transformers library for MLM (Wolf et al., 2019; Liu et al., 2019b).

At test time, the model is given an easier version of the text infilling task where blanks are expanded into sequences of $\langle\text{mask}\rangle$ tokens of the target length (or equivalently, the model uses an oracle to predict the length of the infilling).

We experiment with three decoding strategies: (1) one-shot: the model predicts all masks simultaneously (2) left-to-right: the model fills in the masks from left to right (3) confident-first: the model fills one mask at a time that has the highest score. We report results for the confident-first strategy which has the best performance.

A.3 BERT+LM

We use the `bert-base-uncased` model as served by the Transformers library (Wolf et al., 2019; Devlin et al., 2018). The left-to-right language model is a Transformer decoder to predict tokens in a blank. Its input word embedding is concatenated with BERT's output in the blank position at each time step.

A.4 Seq2seq-full and Seq2seq-fill

For both seq2seq baselines, we use Fairseq's `transformer_iwslt_de_en` architecture (Ott et al., 2019). To generate training data, we apply the blanking procedure to the input dataset and generate k copies of each sentence with different masks. We experiment with $k \in \{1, 10, 100\}$ and report the best performance, obtained by $k = 10$.

B Monte-Carlo Estimate of Perplexity

For a sentence x of length n, we estimate $p(x; \theta)$ in Eq. (5) with m samples:

$$X_m = \frac{n!}{m} \sum_{i=1}^{m} p(x, \sigma_i; \theta)$$

where σ_i's are randomly sampled orders.

Note that X_m is an unbiased estimate of $p(x; \theta)$:

$$\mathbb{E}[X_m] = p(x; \theta)$$

The estimated PPL is accordinly:

$$Y_m = X_m^{-1/n}$$

Since $z^{-1/n}$ is a convex function of z,

$$\mathbb{E}[Y_m] = \mathbb{E}[X_m^{-1/n}] \geq \mathbb{E}[X_m]^{-1/n} = p(x; \theta)^{-1/n}$$

i.e., the expectation of the estimated PPL $\geq$ the actual PPL. As m increases, the variance of X_m decreases, and the inequality becomes tighter.

Hence, we will observe that as m increases, the estimated PPL becomes smaller and converges to the real PPL.

COD3S: Diverse Generation with Discrete Semantic Signatures

Nathaniel Weir[1] **João Sedoc**[2] **Benjamin Van Durme**[1]

Abstract

We present COD3S, a novel method for generating semantically diverse sentences using neural sequence-to-sequence (seq2seq) models. Conditioned on an input, seq2seq models typically produce semantically and syntactically homogeneous sets of sentences and thus perform poorly on one-to-many sequence generation tasks. Our two-stage approach improves output diversity by conditioning generation on locality-sensitive hash (LSH)-based *semantic sentence codes* whose Hamming distances highly correlate with human judgments of semantic textual similarity. Though it is generally applicable, we apply COD3S to causal generation, the task of predicting a proposition's plausible causes or effects. We demonstrate through automatic and human evaluation that responses produced using our method exhibit improved diversity without degrading task performance.

1 Introduction

Open-ended sequence generation problems such as dialog, story generation, image captioning, or causal generation pose a practical challenge to neural sequence-to-sequence (seq2seq) models, as they necessitate a diverse set of predicted outputs. The typical sampling method for seq2seq decoding is beam search, which produces a set of candidate sequences that generally have high syntactic, lexical, and semantic overlap.

Recent methods for improved diversity generation make slight modifications to the neural architecture or beam search algorithm (Xu et al., 2018; Li et al., 2016b), or impose lexical constraints during decoding (Post and Vilar, 2018; Hu et al., 2019a). Shu et al. (2019) propose the use of *sentence codes*, a technique in which generation is conditioned on a discrete code that aims to induce diversity in syntax or semantics. While their approach is effective for syntactic codes, it is less so for semantics.

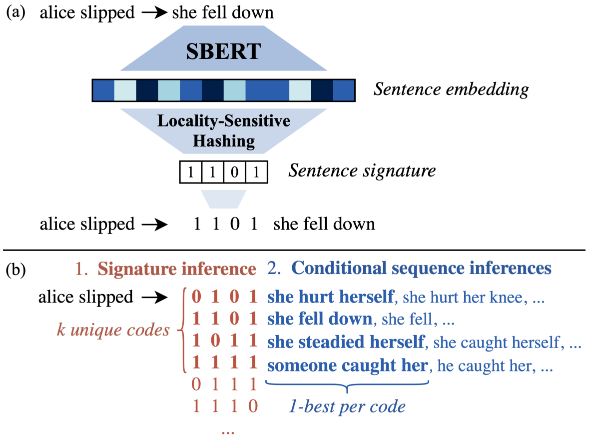

Figure 1: Overview of the COD3S method. In training **(a)**, the target side is prefixed with a discrete signature computed using locality-sensitive hashing (LSH) of the target's SBERT embedding. At inference **(b)**, a beam search is conditioned on each of *k* decoded signatures.

In this work, we introduce an improved method for diverse generation conditioned on inferred sentence codes that explicitly capture meaningful semantic differences. We use the contextual sentence embeddings from Sentence-BERT (SBERT; Reimers and Gurevych, 2019), the cosine distances between which correlate highly with human scalar judgments of semantic textual similarity (STS). We construct discrete codes from these embeddings using *locality-sensitive hashing* (Indyk and Motwani, 1998; Charikar, 2002), producing short binary signatures whose Hamming distances well-preserves the cosine distances between inputs.

Our method induces a bitwise hierarchy of semantic bins whose similarities in signature imply similarities in semantics. Conditioning generation on a signature as a target-side prefix indicates the bin into which the generated sequence falls. We implement a two-stage decoding process that (1) infers the most relevant signatures and (2) decodes sequences via separate prefix-conditioned beams. We term our method COD3S: **CO**nstrained **D**ecoding with **S**emantic **S**entence **S**ignatures.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5199–5211,
November 16–20, 2020. ©2020 Association for Computational Linguistics

We demonstrate the effectiveness of COD3S in the context of causal sequence generation (Li et al., 2020) through BLEU- and cosine-based diversity measures as well as human evaluation.

2 Related Work

We draw inspiration from recent work in multilingual machine translation (MT) (Ha et al., 2016) and domain adaptation (Chu and Dabre, 2019) in which a language code (e.g. **en**, **de**) is prepended to the target to guide generation. Our method for encoding sentence diversity is closely related to MT work by Shu et al. (2019), who condition generation on prefixed *sentence* codes. They improve the syntactic diversity of sampled translations using codes produced from improved semantic hashing (Kaiser and Bengio, 2018) with a TreeLSTM-based autoencoder. Their experiments with semantic coding via clustering of BERT (Devlin et al., 2019) and FastText (Bojanowski et al., 2017) embeddings lead to negligible or negative effects. Outside of MT, Keskar et al. (2019) in a similar vein condition on manually categorized "control codes" that specify style and content, and Mallinson and Lapata (2019) condition on annotated syntactic or lexical change markers that can be learnt from data. We refer readers to Ippolito et al. (2019) for an overview of diverse decoding methods. Few to our knowledge explicitly and effectively encode open-domain semantic diversity.

Text-based causal knowledge acquisition is a well-studied challenge in NLP (Radinsky et al., 2012). Recent efforts have investigated *open ended* causal generation using neural models (Bosselut et al., 2019; Li et al., 2020). The latter train a conditional generation model to propose cause or effect statements for a given proposition. The model is trained on the co-released corpus CausalBank, which comprises causal statements harvested from English Common Crawl (Buck et al., 2014).

Applications of LSH (Indyk and Motwani, 1998; Charikar, 2002) in NLP began with Ravichandran et al. (2005) who demonstrated its use in fast lexical similarity comparison; later, Van Durme and Lall (2010) showed such hashing could be performed online. More similar to our use case, Petrović et al. (2010) binned tweets via LSH to enable fast *first story detection*. Most related to ours is work by Guu et al. (2018), who describe a generative sentence model that edits a 'prototype' sentence using lexically similar ones retrieved via LSH.

3 COD3S Approach

Our signature construction method, depicted in Figure 1(a), produces a sequence of bits that collectively imply a highly specific bin of sentences with similar semantic meaning. This is accomplished by encoding sentences into high-dimensional vectors that encode degrees of semantic difference and then discretizing the vectors in a way that approximately preserves the difference.

Semantic Embedding Model We embed a sentence using the contextual encoder Sentence-BERT (SBERT; Reimers and Gurevych, 2019), a siamese network trained to produce embeddings whose cosine similarity approximates the semantic textual similarity (STS) of the underlying sentences. We select this *single sentence* encoder over other popular encoders, e.g. BERT, which best encode concatenations of pairs of sentences and therefore do not produce individual embeddings that encode semantic difference retrievable under vector similarity metrics (Reimers and Gurevych, 2019; Shu et al., 2019). The cosine similarity of embeddings from SRoBERTa-L, the instance of SBERT that we use as our COD3S encoder, has a Spearman ρ correlation of .863 with human STS judgements from STSbenchmark (Cer et al., 2017).[1] We provide a list of cosine/STS correlations using other models in Appendix E.[2]

Discretization via LSH Locality-sensitive hashing (LSH; Indyk and Motwani, 1998) maps high-dimensional vectors into low-dimensional sketches for quick and accurate similarity comparison under measures such as cosine or Euclidean distance. We use the popular variant by Charikar (2002), which computes a discrete b-bit signature $\texttt{LSH}(\vec{v}) = [\texttt{LSH}_1(\vec{v}), \dots \texttt{LSH}_b(\vec{v})]$. Appendix A provides an overview of this approach. The Hamming distance between two LSH signatures approximates the cosine distance of the underlying vectors:

$$\cos(\vec{u}, \vec{v}) = \frac{\vec{u} \cdot \vec{v}}{|\vec{u}||\vec{v}|} \approx \cos\left(\frac{\pi}{b} \sum_{i=1}^{b} \mathbb{1}\{\texttt{LSH}_i(\vec{u}) \neq \texttt{LSH}_i(\vec{v})\}\right)$$

This approximation degrades with coarser-grained signatures, as shown by the drop in STS correlation in Table 1 (right columns) for LSH with fewer bits.

---

[1] We use the released SRoBERTa instance that was fine-tuned on natural language inference (NLI) and then STS.

[2] We refer readers to Reimers and Gurevych (2019) (Sec.4) for a comprehensive overview using other STS datasets.

	Cosine	*b*-Bit LSH Hamming Distance				
	1024D	256b	128b	32b	16b	8b
STS ρ	.863	.845	.828	.742	.652	.549

Table 1: Correlation of SRoBERTa-L embedding cosine distance and LSH Hamming distance with STS judgements from STSBenchmark.

A Hierarchy of Signatures Using LSH on SBERT embeddings whose cosine similarity correlates highly with STS induces a *hierarchy of semantic bins*; the $i+1$th bit partitions each of a set of i-bit bins in two. Bins whose signatures differ by few bits have higher semantic overlap, and as the bitwise distance between two signatures increases, so does the difference in meaning of the underlying sentences. Sentences that hash to the same bin—particularly for longer signatures—have very high SBERT cosine similarity and are thus likely semantically homogeneous.

Diverse Decoding Using Signatures Given source and target sentences x, y, we compute the b-bit signature $s^y = \texttt{LSH}(\texttt{SBERT}(y))$. We then train a model to decode the concatenated sequence $[s^y\ y]$, with the s^y treated as a b-length sequence of individual 0/1 tokens. At inference time, we decompose the typical conditional decision problem $\hat{y} = \text{argmax}_y\{\log p(y \mid x)\}$ into two steps:

$$\hat{s} = \underset{s}{argmax}\{\log p(s \mid x)\};\ \ \hat{y} = \underset{y}{argmax}\{\log p(y \mid x, \hat{s})\}$$

As previous work associates the strength of a causal relationship with pointwise mutual information (PMI) (Gordon et al., 2012), we modify our objective to maximize the MI between x and each of s and y; we adapt the **MMI-bidi** objective from Li et al. (2016a):

$$\hat{s} = \underset{s}{argmax}\{\log p(s \mid x) + \lambda_s \log p(x \mid s)\} \qquad (1)$$

$$\hat{y} = \underset{y}{argmax}\{\log p(y \mid x, \hat{s}) + \lambda_y \log p(x \mid y)\} \qquad (2)$$

As shown in Figure 1(b), we first decode the k-best distinct sentence codes $\hat{s}_1, \ldots \hat{s}_k$ as in Eq. 1. We then perform k conditional inferences in Eq. 2; we take the 1-best sentence from each to produce $\hat{y}_1, \ldots \hat{y}_k$. For both signature and sentence decoding, we follow Li et al. and sample an n-best list from the forward score $\log p(s \mid x)$ (resp. $\log p(y \mid x, \hat{s})$) before re-ranking with the added λ-weighted backward score.[3] We approximate the forward scores using length-normalized beam search with beam size 100 for signatures and 40 for sentences. While $\log p(s \mid x)$ and $\log p(y \mid x, s)$ can be scored using a single forward model, we find it beneficial to train two, so that the first only learns to score signatures.

Hamming Distance Threshold As sentences whose signatures differ by few bits show to have highly similar semantics, we impose a threshold heuristic for decoded signatures $\hat{s}_1, \ldots, \hat{s}_k$: $\min_{i \neq j} D(\hat{s}_i, \hat{s}_j) > t$, where $D(\cdot)$ is Hamming distance.[4] We enforce this using a greedy algorithm that considers higher-scoring signatures first, keeping those that satisfy the threshold given the currently kept set and removing those that violate it.

Taken as a whole, our decoding approach aims to generate the single highest-scoring applicable response that falls in each of the N-best inferred *sufficiently different* semantic bins. The threshold parameter thus provides a way to effectively tune the model to a desired level of semantic diversity.

4 Experiments

We apply COD3S to the task of open-ended causal generation for free-form textual inputs as considered by Li et al. (2020). Given an input statement, the model must suggest a *diverse* set of possible causes or effects. We train models on sentence pairs from Li et al.'s released dataset, CausalBank, which is scraped from Common Crawl using templatic causal patterns. Following their work, we use 10 million sentence pairs that match the patterns "X, so Y" to train cause-to-effect models and "X because Y" for effect-to-cause models.

We experiment with 16-bit LSH signatures of SBERT embeddings.[5] After prepending target-side bit signatures, pairs are encoded with byte-pair encoding (BPE; Sennrich et al., 2016) using a vocabulary size of 10K. We train Transformer models (Vaswani et al., 2017) using the FAIRSEQ library (Ott et al., 2019). Appendix B provides details for reproducibility.[6]

Evaluation We show that COD3S induces sensible inference of diverse but relevant semantic bins and causal statements. Examples of generation are shown in Table 3 and additionally Appendix C. We quantitatively compare COD3S against the out-

---

[3] We find effective values $\lambda_s = 1000, \lambda_y = 0.3$ for 16-bit COD3S using qualitative examination of predictions.

[4] We find the threshold $t = 2$ best for 16-bit COD3S.

[5] Statistics describing the distribution of the 10M training targets into signature bins are given in Appendix E.

Table 2: **(Upper)** Diversity metrics (**BLEU-1 / BLEU-2 / SBERT**) over 3-best decoded outputs. **(Lower)** Count of semantically distinct effect outputs out of 10, with duplicates ruled out using SBERT cosine.

puts of regular seq2seq beam search, as well as of lexically constrained decoding with disjunctive positive constraints (DPC) and random sample decoding (S2S-RS) provided by Li et al.[7] We included in the comparison instances of COD3S with and without MMI reranking, as well as with random sampling in place of beam search.

Automatic Diversity Metrics We use the formula of Shu et al. (2019), which takes the pairwise average of dissimilarity score Δ over output set Y.

$$\text{Diversity}(Y) = \frac{1}{|Y|(|Y|-1)} \sum_{y,y' \in Y;\ y \neq y'} \Delta(y, y')$$

To measure *lexical* diversity, we set $\Delta(y, y')$ to be the sentences' inverse (100 minus) BLEU-1 and -2 scores.[8] To measure *semantic* diversity, we set Δ to be the cosine distance between their SBERT embeddings. Higher scores imply greater diversity. Following Li et al., we evaluate on 100 examples from an out-of-distribution dev split of the Choice of Plausible Alternatives dataset (COPA; Gordon et al., 2012), with results shown in Table 2.[9] In both cases, COD3S outperforms all other methods except random sampling, the addition of which also improves the diversity of COD3S itself.[10] We also use the SBERT diversity score to *count* semantically diverse outputs by marking as duplicates those for which the embedding of the completed phrase ("X . . . Y") falls below some distance threshold from that of an earlier candidate. Table 2 (lower) shows that both the best COD3S model as well as random sampling produce far more semantically distinct statements than the beam search baseline.

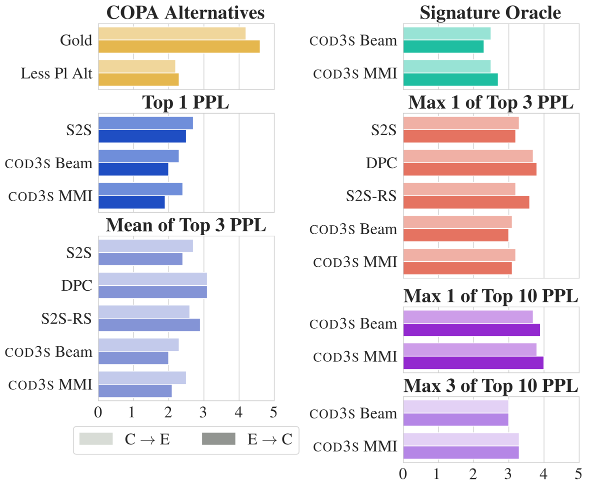

Figure 2: Results of human evaluation of plausibility. Ratings are shown in comparison to the gold answer and less plausible alternative from COPA. Mean/max ratings per input are presented for 1, 3-best outputs ranked by forward score (PPL). To demonstrate that COD3S produces plausible response from many semantic bins, we also show max ratings from top-10 outputs.

Human Evaluation Our automatic metrics quantify diversity without tracking task effectiveness, which we evaluate by collecing judgments on Amazon Mechanical Turk. We ask workers to judge the plausibility of responses as causal completions (on a 0-5 Likert scale). For all methods except COD3S, we use the exact outputs evaluated in Li et al. (2020) and provided to us by the authors. The response sets for these models contain the top 3 decoded sentences under perplexity (PPL). We compare these to the top 3 as well as the top 10 sentences decoded by COD3S with and without MMI re-ranking (signature and sentence, no random sampling) ordered by PPL of the signature tokens. This discrepancy in per-model outputs reflects that we seek to evaluate COD3S, which is specifically crafted to produce a large set of distinct viable candidates, as directly

---

[7] We also compare against our own S2S-RS using the same FAIRSEQ model as the COD3S methods.

[8] Implemented using the SacreBLEU toolkit (Post, 2018).

[9] Results over 10 outputs and over a within-distribution train split from CausalBank are shown in Appendix Table 4.

[10] We verified the significance of numerical results using Wilcoxon two-sided signed-rank tests implemented via SciPy with p=.05.

Cause Input: my favorite song came on the radio		
Bin Medoid	*I will try this version for sure*	*I was quite excited to finally experience it*
Ranked Predictions	**I decided to listen to it** I decided to hear it I figured I'd try it	**I was excited to hear it again** I was pleasantly surprised to hear it I'm glad to see it here
Effect Input: the executive decided not to hire the applicant		
Bin Medoid	*I knew that they expected it*	*they are what earn you cash*
Ranked Predictions	**they knew she was not qualified** they knew it would be a mistake she knew she had to	**they could not afford the payments** it would cost them money she was paid

Table 3: Examples of generation conditioned on semantic bins. Predictions are ranked according to maximum mutual information (MMI) and shown aside the given bin's representative medoid.

as possible against the Li et al. (2020) responses from models that are not necessarily crafted with the identical aim. Naturally occurring propositions have far more than 10 plausible and distinct causes and effects, and so we would hope that the 10th output of our one-to-many model would have similar quality to the 1st of the other models.

Results are shown in Figure 2.[11] We observe that top 1 and 3 COD3S responses according to PPL (blue) are comparable albeit slightly lower on average than those of the other models.[12] This may partially be attributed to the difficulty of the signature inference step, in which the differences in the top 100 predicted binary sequence PPLs are typically small. A COD3S 'oracle' that conditions generation on the gold answer's signature (which often has low predicted likelihood) performs more competitively (green).

We find that at least 1 of the top 3 signatures predicted by COD3S yields a competitively plausible sentence; when we take the highest plausibility score from the top 3 of each model under their respective PPL orderings (red), COD3S and baseline S2S to be interchangeable. If we expand to the larger set of 10 outputs for COD3S models, we find that the mean of the 3 highest plausibility scores (faded purple) for the MMI model is comparable to the 1 best of the base seq2seq (red) and better than the mean of the top 3 PPL (faded blue) for any model. This indicates that the 10 output set, which shows under automatic metrics to contain higher numbers of semantically diverse statements, also contains at worst a set of 3 outputs that are better than the 3 from models not designed for one-to-many diverse prediction.

Qualitative Analysis Table 3 shows examples of models predicting and re-ranking sentences within inferred signature bins. Candidate predictions listed in order of MMI score reflect the ability of MMI-based reranking to select the candidates within a bin that are most relevant to the input. Outputs are shown beneath a representative bin *medoid*, i.e. the sentence with minimized embedding cosine distance from all other training sentences that fall in the bin. The two-step inference process depicted here allows for a level of interpretability on the signature level, as sampling training sentences from the inferred semantic bin gives a snapshot of an inferred semantic space that can be more informative than individual sentences alone.

Future work might explore alternative methods for signature inference. The bit sequence likelihoods predicted by COD3S are often clumped together and/or biased towards signatures that intuitively do not apply to an input but are overrepresented in the training set. We also observe that although MMI decoding discourages bland context insensitive statements, there is still a model tendency towards a small set of generic predicates, e.g. 'having,' 'knowing,' or 'being able to.'

5 Conclusion

We have outlined COD3S, a method for producing semantically diverse statements in open-ended generation tasks. We design sentence LSH signatures that encode bitwise the semantic similarity of underlying statements; conditioning generation on different signatures yields outputs that are semantically heterogeneous. COD3S leads to more diverse outputs in a multi-target generation task in a controllable and interpretable manner, suggesting the potential of semantically guided diverse decoding for a variety of text generation tasks in the future.

---

[11] A tabular form of the results is given in Appendix Table 5.

[12] DPC and S2S-RS output PPLs were not provided by Li et al., so they are omitted from top-1 comparison.

A Random Hyperplane LSH Details

The popular LSH variant introduced by Charikar (2002) leverages *random hyperplane projections* to compute discrete b-length bit signatures. Each individual bit is determined from the sign of the dot product between a given embedding and one of a set of b pre-computed random normal vectors. One geometric intuition is that the hyperplane implied by each random normal vector partitions the full embedding space in half, and the sign of the dot product designates the partition into which the input embedding falls. This is illustrated in Figure 3 using a simplified case with a 2-D vector v and three random vectors r_1, r_2, r_3 indicating partitions of the Cartesian plane.[13]

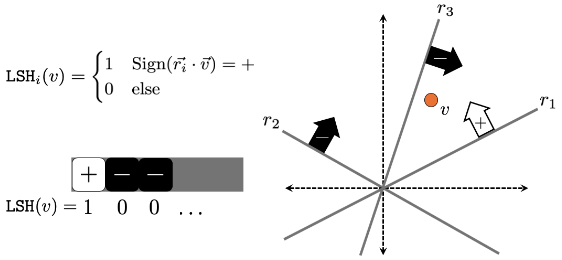

Figure 3: Computation of a 2D vector v's LSH bit signature as the signs of the dot products with d random normal vectors $r_1, \ldots, r_b$.

Formally, given a set of high-dimensional vectors in $\mathbb{R}^D$, we randomly sample $b \ll D$ random vectors $\vec{r}_1, \ldots \vec{r}_d$ from the $D-$dimensional Gaussian distribution. Then, given a high-dimensional embedding $\vec{v}$, we construct the b-bit signature $\mathtt{LSH}(v) = [\mathtt{LSH}_1(v), \ldots \mathtt{LSH}_d(v)]$ using the hash functions

$$\mathtt{LSH}_i(v) = \begin{cases} 1 & \text{if } \vec{r}_i \cdot \vec{v} \geq 0 \\ 0 & \text{if } \vec{r}_i \cdot \vec{v} < 0 \end{cases}$$

The number of matching bits in the signatures of two vectors u, v provides an estimate of their *hash collision probability*, i.e. the likelihood that they fall in the same partition of any random hyperplane. This probability is provably[14] monotonically increasing with the vectors' inner product. Goemans and Williamson (1995) similarly prove that the Hamming distance between signatures is proportional to the angle between the vectors, which correlates highly with cosine distance barring high discrepancies in vector norms.

B Training Details

```
fairseq-train
 --adam-betas "(0.9, 0.98)"
 --arch transformer_iwslt_de_en
 --criterion
   label_smoothed_cross_entropy
 --label-smoothing 0.1
 --dropout 0.1 --weight-decay 0
 --bpe sentencepiece
 --optimizer adam  --clip-norm 0.1
 --lr 5e-4 --lr-scheduler inverse_sqrt
 --warmup-updates 4000
 --max-epoch 10
 --share-all-embeddings
```

We train models with FAIRSEQ using the `transformer_iwslt_de_en` architecture. We use 6 encoder and decoder layers with 512-dimensional hidden states and shared embedding layers (a total of 36.6M trainable parameters). Signature tokens are assigned special tokens during BPE encoding. We train models for 10 epochs with an early stopping patience of 2 validations. We use the Adam optimizer (Kingma and Ba, 2015) with 0.1-smoothed cross entropy loss, a 5e−4 learning rate with inverser square root scheduling, 0.1 dropout and 0.1 norm clipping. All other training parameters were the FAIRSEQ defaults at the time of submission. We observe performance drops when 1) norm clipping threshold is not sufficiently low, 2) BPE vocabulary size is 32K instead of 10K, and 3) weight decay is set to .001. Training takes roughly 12 hours on two Titan 24GB RTX GPUs for each of four models (two forward, two backward for MMI reranking).

Backwards scoring models for MMI-bidi are trained with the opposite dataset as their corresponding forward models; we find training most effective when the data's syntactic direction ("X ... Y") matches the direction of inference (X → Y). In other words, all C→ E models are trained on "X, so Y" data regardless of their use as forward or backward scoring models. We used the "X because Y" training split from Li et al. (2020). We constructed the 10M "X so Y" examples ourselves: we took a 20M random sample of all such examples in the dataset, filtered to remove sentences a) containing numerical and special characters or b) containing either a source or target with greater than 12 tokens, and then downsampled the remaining set to a 10M/4K/4K train/dev/test split.

Table 5: Tabular form of human evaluation results displayed in Figure 2.

C Decoding According to Semantic Bins

We experimented with bit lengths of 8, 16, and 32, and found the middle value to best balance specificity with accuracy. We also explored a variant that merged signatures into a single token rather than treating them as token-per-bit, but found the model to perform qualitatively worse. We experimented with Hamming distance heuristic thresholds of 0 through 6 and found the best value (2) for 16-bit COD3S using qualitative analysis of side-by-side predictions. The MMI-bidi λ_s, λ_y values were found using simple grid search, comparison of automatic metrics, and side-by-side analysis. The nature of the output set is sensitive to only large changes (orders of magnitude) in λ_s values, as the likelihoods of signature sequences are rather close in value; however, smaller, 0.1-increment changes to the sentence weight λ_y showed to have a greater effect on the relevance and specificity of output causes/effects. This comports with results from previous applications of MMI-bidi decoding for sentences (Li et al., 2016a).

Table 7 shows side-by-side outputs of models with and without MMI re-ranking conditioned on the same n-best inferred signatures. Table 4 shows results of automatic diversity evaluation on the in-distribution training sample from CausalBank following Li et al. (2020). Table 5 provides a tabular version of the human plausibility scores depicted in Figure 2.

D Counting Semantically Distinct Outputs using SBERT

We construct a method for automatically counting the number of semantically diverse sentences in a candidate cause/effect set. We encode each prediction with the context of the input by taking the SBERT embedding of the completed sentence ”X {because, so} Y.” We then rule out all sentences whose embedding cosine distance from that of a higher-ranked candidate is lower than some threshold. We use a simple grid search over various threshold values and find that a value of .1 yields a sensitivity to paraphrastic cause/effect predictions similar to that of a human reader. As other tasks might merit different such thresholds, we provide multiple such counts in Table 2. Table 6 shows example cases of duplicate detection among generated candidate sets.

	Cause: the tenant misplaced his keys to his apartment			**Effect: the man threw out the bread**	
1	he couldn't leave the house		1	he didn't want to eat it	
2	*he couldn't get out of the house*	*Dupl. of 1 (.01)*	2	he didn't like it	
3	he had to get a new one		3	*he didn't like the taste*	*Dupl. of 2 (.05)*
4	he had to go back to the hotel		4	it was too much for him to handle	
5	*he had to find a new one*	*Dupl. of 3 (.02)*	5	*he didn't want to cook it*	*Dupl. of 1 (.07)*
6	*he couldn't get into the house*	*Dupl. of 1 (.06)*	6	he didn't know how to cook it	
7	he had to go back to the house		7	*it wasn't good for him*	*Dupl. of 1 (.07)*
8	*he couldn't leave the building*	*Dupl. of 1 (.02)*	8	*he didn't like how it tasted*	*Dupl. of 2 (.05)*
9	he had to go to the police station		9	*he couldn't eat it*	*Dupl. of 1 (.06)*
10	*he had to go back to his apartment*	*Dupl. of 7 (.07)*	10	it was overcooked	

Table 6: Detection of duplicate causes and effects using a threshold SBERT embedding cosine distance of 0.1. We embed the full "X . . . Y" statements so as to provide context to the paraphrase detection. Model outputs are those of a regular seq2seq.

E Cosine/LSH Hamming Correlations with STS and Bin Statistics

Table 8 shows the Spearman ρ coefficient with STSbenchmark judgments for cosine and approximate LSH Hamming distances of embeddings for BERT, SBERT (and larger variant SRoBERTa), and pBERT (Hu et al., 2019b), a BERT model fine-tuned to predict paraphrastic similarity, albiet not via angular similarity of embeddings. Table 9 provides details regarding the distributions of sentences into LSH bins of differing levels of granularity using SRoBERTa-L embeddings.

F Human Evaluation of Plausibility

We showed 200 COPA input statements (100 each for cause-to-effect and effect-to-cause) to Amazon Mechanical Turk workers and asked them to judge the plausibility of model predictions, specifically as completions of a causal statement of the form "X because Y" or "Y, so X." The order of the examples were randomized. Four annotators rated each input/prediction pair. We required annotators to have at least a 97% approval rating, be located in the US, and have completed at least 500 HITs. Annotators were given an hour to complete each HIT. The median completion time for the task was 5 minutes, and workers were paid $0.50 per HIT. We included at least two attention checks.

W/O MMI Reranking	**W/ MMI Reranking**	***Conditioned Bin Medoid***
Cause: I was confused by the professor’s lecture **Gold Effect: I asked the professor questions**		
I asked him about it	**I asked a few questions**	***I need some feedback from you*** **(Gold bin)**
I decided to try it	I decided to look it up	*I will try this version*
I thought I’d ask here	I decided to ask the teacher	*I might change them at some point*
I decided to open it up	I opened it up and started reading	*you can check it out*

Please Note

- You have to be an **English Native Speaker**
- You have to complete judgments for all sentences. **All fields are required**.

Instructions

In this task you will read and judge a series of program-generated causal statements of the form "X because Y." The program receives the X statement and attempts to produce Y responses that logically complete the full statement.

For each X statement, you will read a series of possible Y responses, and make the following judgment:

Plausibility: The extent to which Y could have been a cause of X, **creating a natural statement "X because Y" and/or "Y so X."**

0 is completely implausible, while 5 is completely plausible.

Examples

X* because *Y	**How plausible?**
The woman went to the bank because *pigs fly*.	0
The woman went to the bank because *she is*.	0
The woman went to the bank because *the bank was closed*.	1
The woman went to the bank because *she had enough cash on hand*.	1

Automatic Extraction of Rules Governing Morphological Agreement

Abstract

Creating a descriptive grammar of a language is an indispensable step for language documentation and preservation. However, at the same time it is a tedious, time-consuming task. In this paper, we take steps towards automating this process by devising an automated framework for extracting a first-pass grammatical specification from raw text in a concise, human- *and* machine-readable format. We focus on extracting rules describing *agreement*, a morphosyntactic phenomenon at the core of the grammars of many of the world's languages. We apply our framework to all languages included in the Universal Dependencies project, with promising results. Using cross-lingual transfer, even with no expert annotations in the language of interest, our framework extracts a grammatical specification which is nearly equivalent to those created with large amounts of gold-standard annotated data. We confirm this finding with human expert evaluations of the rules that our framework produces, which have an average accuracy of 78%. We release an interface demonstrating the extracted rules at https://neulab.github.io/lase/. The code is publicly available here.[1]

1 Introduction

While the languages of the world are amazingly diverse, one thing they share in common is their adherence to grammars — sets of morpho-syntactic rules specifying how to create sentences in the language. Hence, an important step in the understanding and documentation of languages is the creation of a *grammar sketch*, a concise and human-readable description of the unique characteristics of that particular language (e.g. Huddleston (2002) for English, or Brown and Ogilvie (2010) for the world's languages).

One aspect of morphosyntax that is widely described in such grammatical specifications is *agreement*, the process wherein a word or morpheme selects morphemes in correspondence with another word or phrase in the sentence (Corbett, 2009). Languages have varying degrees of agreement ranging from none (e.g. Japanese, Malay) to a large amount (e.g. Hindi, Russian, Chichewa). Patterns of agreement also vary across syntactic subcategories. For instance, regular verbs in English agree with their subject in number and person but modal verbs such as "will" show no agreement.

Having a concise description of these rules is of obvious use not only to linguists but also language teachers and learners. Furthermore, having such descriptions in machine-readable format will further enable applications in natural language processing (NLP) such as identifying and mitigating gender stereotypes in morphologically rich languages (Zmigrod et al., 2019).

The notion of describing a language "in its own terms" based solely on raw data has an established tradition in descriptive linguistics (e.g. Harris (1951)). In this work we present a framework (outlined in Figure 1) that *automatically* creates a first-pass specification of morphological agreement rules for various morphological features (Gender, Number, Person, etc.) from a raw text corpus for the language in question. First, we perform syntactic analysis, predicting part-of-speech (POS) tags, morphological features, and dependency trees. Using this analyzed data, we then learn an agreement prediction model that contains the desired rules. Specifically, we devise a binary classification problem of identifying whether agreement will be observed between a head and its dependent token on a given morphological property. We use decision trees as our classification model because

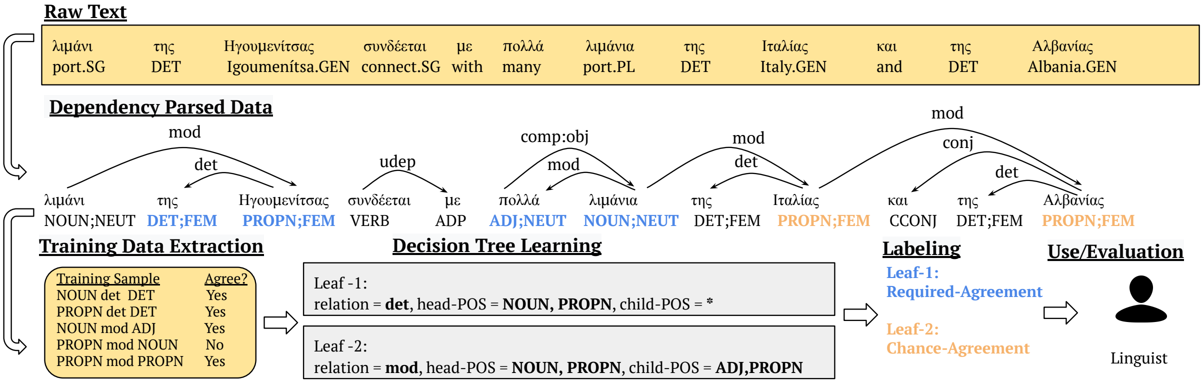

Figure 1: An overview of our method's workflow for gender agreement in Greek. The example sentence translates to "The port of Igoumenitsa is connected to many ports in Italy and Albania." First, we dependency parse and morphologically analyze raw text to create training data for our binary agreement classification task. Next, we learn a decision tree to extract the rule set governing gender agreement, and label the extracted leaves as either representing required or chance agreement. Finally these rules are presented to a linguist for perusal.

they are easy to interpret and we can easily *extract* the classification rules from the tree leaves to get an initial set of potential agreement rules. Finally, we perform *rule labeling* of the extracted rules, identifying which tree leaves correspond to probable agreement. This is required because not all agreeing head/dependent token pairs are necessarily due to some underlying rule. For instance, in Figure 1's example of Greek gender agreement, both the head and its dependent token Ιταλίας→Αλβανίας have feminine gender, but this agreement is purely by-chance, as correctly identified by our framework.

The quality of the learnt rules depends crucially on the quality and quantity of dependency parsed data, which is often not readily available for low-resource languages. Therefore, we experiment with not only gold-standard treebanks, but also trees generated automatically using models trained using cross-lingual transfer learning. This assesses the applicability of the proposed method in a situation where a linguist may want to explore the characteristics of agreement in a language that does not have a large annotated dependency treebank.

We evaluate the correctness of the extracted rules conducting human evaluation with linguists for Greek, Russian, and Catalan. In addition to the manual verification, we also devise a new metric for automatic evaluation of the rules over unseen test data. Our contributions can be summarized to:

1. We propose a framework to automatically extract agreement rules from raw text, and release these rules for 55 languages as part of an interface[2] which visualizes the rules in detail along with examples and counter-examples.
2. We design a human evaluation interface to allow linguists to easily verify the extracted rules. Our framework produces a decent first-pass grammatical specification with the extracted rules having an average accuracy of 78%. We also devise an automated metric to evaluate our framework when human evaluation is infeasible.
3. We evaluate the quality of extracted rules under real zero-shot conditions (on Breton, Buryat, Faroese, Tagalog, and Welsh) as well as low-resource conditions (with simulation experiments on Spanish, Greek, Belarusian and Lithuanian) varying the amount of training data. Using cross-lingual transfer, rules extracted with as few as 50 sentences with gold-standard syntactic analysis are nearly equivalent to the rules extracted when we have hundreds/thousands of gold-standard data available.

2 Problem Formulation

For a head h and a dependent d that are in a dependency relation r, we will say that they *agree* on a morphological property f if they share the same value for that particular property i.e. $f_h = f_d$. Some agreements that we observe in parsed data can be attributed to an underlying grammatical rule. For example, in Figure 2 the Spanish A.1 shows an example of where subject (*enigmas*) and verb (*son*) need to agree on number. We will refer to such rules as *required-agreement*. Such a required agreement rule dictates that an example like A.2 is ungrammatical and would not appear in well-formed Spanish sentences, since the subject and

Figure 2: Subject-verb number agreement is required in Spanish, as in example A.1, which renders example A.2 ungrammatical. Object-verb agreement is not required, so both B.1 and B.2 are grammatical. The object and the verb in B.1 only agree by chance.

the verb do not have the same number marking. However, not all word pairs that agree do so because of some underlying rule, and we will refer to such cases as *chance-agreement*. For example, in Figure 2 the object (*perro*) and verb (*tiene*) in B.1 only agree in number by chance, and example B.2 (where the object of a singular verb is plural) is perfectly acceptable.

Our goal is to extract, from textual examples, the set of *rules* $\mathcal{R}_l^f$ that concisely describe the agreement process for language l. Concretely, this will indicate for which head-dependent pairs the language displays *required-agreement* and for which we will observe at most *chance-agreement*. Canonically, agreement rules are defined over syntactic features of a language as seen in Figure 2 where we have the following rule for Spanish: “subjects agree with their verbs on number”.[3] To formalize this notion, we define a *rule* to be a set of features which are defined over the dependency relation, head and dependent token types. In this paper, we make the simplifying assumption that head and dependent tokens are represented by only part-of-speech features, as we would like our extracted rules to be *concise* and easily interpretable downstream, although this assumption could be relaxed in future work.

The rule discovery process consists of two major steps: a *rule extraction* step followed by a *rule labeling* and *merging* step (also see Figure 1).

2.1 Rule Extraction

To create our training data for rule extraction, we first annotate raw text with part-of-speech (POS) tags, morphological analyses, and dependency trees. We then base our training data on these annotations by converting each dependency relation into a triple $\langle h, d, r\rangle$, indicating the head token, dependent/child token, and dependency relation between h and d respectively. From the whole treebank, we now have input features $X_f = \{\langle h_1, d_1, r_1\rangle, \dots, \langle h_n, d_n, r_n\rangle\}$ and binary output labels $Y{=}y_1, \dots, y_n$, where if the head and the dependent token agree on feature f (such that $f_h{=}f_d$) we set $y = 1$, otherwise $y = 0$. We filter out the tuples where either of the linked tokens does not display the morphological feature f.

We train a model for $p(Y|X)$ using decision trees (Quinlan, 1986) using the CART algorithm (Breiman et al., 1984). A major advantage of decision trees is that they are easy to interpret and we can visualize the exact features used by the decision tree to split nodes. The decision tree induces a distribution of agreement over training samples in each leaf, e.g. 99% agree, 1% not agree in Leaf-3 for gender agreement in Spanish (Figure 3(a)).

2.2 Rule Labeling

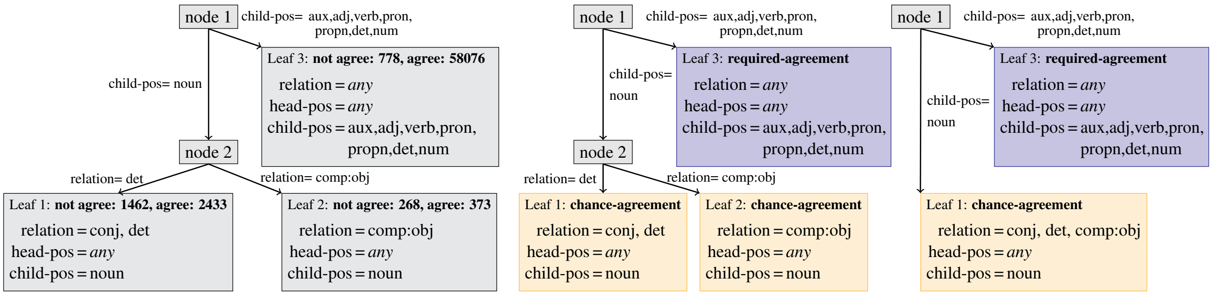
Now that we have constructed a decision tree where each tree leaf corresponds to a salient partition of the possible syntactic structures in the language, we then label these tree leaves as *required-agreement* or *chance-agreement*. For this we apply a threshold on the ratio of agreeing training samples within a leaf – if the ratio exceeds a certain number the leaf will be judged as *required-agreement*. We experiment with two types of thresholds:

Hard Threshold: We set a hard threshold on the ratio that is identical for all leaves. In all experiments, we set this threshold to 90% based on manually inspecting some resulting trees to find a threshold that limited the number of non-agreeing syntactic structures being labeled as *required-agreement*.

Statistical Threshold: Leaves with very few examples may exceed the hard threshold purely by chance. In order to better determine whether the agreements are indeed due to a true pattern of required agreement, we devise a thresholding strategy based on significance testing. For all agreement-majority leaves, we apply a chi-squared goodness of fit test to compare the observed output distri-

---

[3] Sometimes semantic features are used for agreement for eg. *United Nations* <u>is</u>, despite *United Nations* being plural, it is treated as singular for purposes of agreement.



(a) Rule Extraction (b) Rule Labeling (c) Rule Merging

Figure 3: Extracting gender agreement rules in Spanish. (a) A decision tree is learned over dependency link triples, inducing a distribution of agreement over examples in each leaf. However, simple majority voting leads to false positives: Leaf-1 includes more agreeing data points, but in reality this agreement is purely by chance. (b) With a statistically-inspired threshold to label the leaves, Leaf-1 gets correctly labeled as *chance-agreement*. (c) We merge leaves with the same label to get a concise representation. Every dependency link triple receives the label of the unique leaf it falls under.

bution with an expected probability distribution specified by a null hypothesis. Our null hypothesis H_0 will be that any agreement we observe is due to chance. If we reject the null hypothesis, we will conclude from the alternate hypothesis H_1 that there exists a grammatical rule requiring agreement for this leaf's cases:

H_0 : The leaf has *chance-agreement*.

H_1 : The leaf has *required-agreement*.

If there is no rule requiring agreement, we assume that the morphological properties of the head and the dependent token are independent and identically distributed discrete random variables following a categorical distribution. We compute the probability of chance agreement based on the number of values that the specific morphological property f can take. Since morphological feature values are not equally probable, we use a probability proportional to the *observed* value counts. For a binary number property where 90% of all observed occurrences are singular and 10% are plural, the probability of chance agreement is equal to $0.82{=}0.9{\times}0.9{+}0.1{\times}0.1$, which gives the observed output distribution $p{=}[0.18, 0.82]$. Using p we compute the expected frequency count $E_i = np_i$ where n is the total number of samples in the given leaf, $i{=}[0,1]$ is the output class of the leaf, and p_i is the hypothesized proportion of observations for class i. The chi-squared test calculates the test statistic χ^2 as follows:

$$\chi^2 = \sum_{i\in[0,1]} \frac{(O_i - E_i)^2}{E_i}$$

where O_i is the observed frequency count in the given leaf. The test outputs a p-value, which is the probability of observing a sample statistic as extreme as the test statistic. If the p-value is smaller than a chosen significance level (we use 0.01) we reject the null hypothesis and label the leaf as *required-agreement*.

The chi-squared test especially helps in being cautious with leaves with very few examples. However, for leaves with larger number of examples statistical significance alone is insufficient, because there are a large number of cases where there are small but significant differences from the ratio of agreement expected by chance.[4] Therefore, in addition to comparing the p-value we also compute the *effect size* which provides a quantitative measure on the magnitude of an effect (Sullivan and Feinn, 2012). Cramér's phi ϕ_c (Cramér, 1946) is a commonly used method to measure the *effect size*:

$$\phi_c = \frac{\chi^2}{N(k-1)}$$

where χ^2 is the test statistic computed from the chi-squared test, N is the total number of samples within a leaf, and k is the degree of freedom (which in this case is 2 since we have two output classes). Cohen (1988) provides rules of thumb for interpreting these effect size. For instance, $\phi_c > 0.5$ is considered to be a large effect size and a large effect size suggests that the difference between the two hypotheses is important. Therefore, a leaf is labeled as *required-agreement* when the p-value is less than the significance value and the effect size is greater than 0.5. Now Leaf-1 in Figure 3(b) is correctly identified as *chance-agreement*.

---

[4] One limitation of this is that rules that show agreement *sometimes* get incorrectly labeled as either *chance-agreement* or *required-agreement*. We consider this in evaluation, but predicting sometimes agreement is relegated to future work.

Rule Merging: Because we are aiming to have a concise, human-readable representation of agreement rules of a language, after labeling the tree leaves we merge sibling leaves with the same label as shown in Figure 3(c). Further, we collapse tree nodes having all leaves with the same label thereby reducing the apparent depth of the tree.

3 Experimental Settings and Evaluation

Our experiments aim to answer the following research questions: (1) can our framework extract linguistically plausible agreement rules across diverse languages? and (2) can it do so even if gold-standard syntactic analyses are not available? To answer the first question we evaluate rules extracted from gold-standard syntactic analysis (Sec. §4). For the second question we experiment in low-resource and zero-shot scenarios using cross-lingual transfer to obtain parsers on the languages of interest, and evaluate the effect of noisy parsing results on the quality of rules (Sec. §5).

3.1 Settings

Data We use the Surface-Syntactic Universal Dependencies (SUD) treebanks (Gerdes et al., 2018, 2019) as the gold-standard source of complete syntactic analysis. The SUD treebanks are derived from Universal Dependencies (UD) (Nivre et al., 2016, 2018), but unlike the UD treebanks which favor content words as heads, the SUD ones express dependency labels and links using purely syntactic criteria, which is more conducive to our goal of learning syntactic rules. We use the tool of Gerdes et al. (2019) to convert UD v.2.5 (Nivre et al., 2020) into SUD. We only use the training portion of the treebanks for learning our rules.

Rule Learning We use `sklearn`'s (Pedregosa et al., 2011) implementation of decision trees and train a separate model for each morphological feature f for a given language. We experiment with six morphological features (Gender, Person, Number, Mood, Case, Tense) which are most frequently present across several languages. We perform a grid search over the decision tree parameters (detailed in Appendix A.1) and select the model performing best on the validation set. We report results with the *Statistical Threshold* because on manual inspection we find the trees to be more reliable than the ones learnt from the *Hard Threshold* (see Appendix A.5 for an example).

3.2 Evaluation

We explore two approaches to evaluate the extracted rules, one based on expert annotations, and an automated proxy evaluation.

Expert Evaluation Ideally, we would collect annotations for all head-relation-dependent triples in a treebank, but this would involve annotating hundreds of triples, requiring a large time commitment from linguists in each language we wish to evaluate. Instead, for each language/treebank we extract and evaluate the top 20 most frequent "head POS, dependency relation, dependent POS" triples for the six morphological features amounting to 120 sets of triples to be annotated.[5] We then present these triples with 10 randomly selected illustrative examples and ask a linguist to annotate whether there is a rule in this language governing agreement between the head-dependent pair for this relation. The allowed labels are: *Almost always agree* if the construction must almost always exhibit agreement on the given feature; *Sometimes agree* if the linked arguments sometimes must agree, but sometimes do not have to; *Need not agree* if any agreement on the feature is random. An example of the annotation interface is shown in the Appendix A.2.

For each of the human annotated triples in feature f, we extract the label assigned to it by the learnt decision tree $\mathcal{T}$. We find the leaf to which the given triple t belongs and assign that leaf's label to the triple, referred by $l_{\text{tree},f,t}$. The human evaluation score (HS) for each triple marking feature f is given by:

$$\text{HS}_{f,t} = \mathbb{1}\begin{cases} 1 & l_{\text{human},f,t} = l_{\text{tree},f,t} \\ 0 & \text{otherwise} \end{cases}$$

where $l_{\text{human},f,t}$ is the label assigned to the triple t by the human annotator. These scores are then averaged across all annotated triples T_f to get the human evaluation metric (HRM) for feature f

$$\text{HRM}_f = \frac{\sum_{t \in T_f} \text{HS}_{f,t}}{|T_f|}.$$

Automated Evaluation As an alternative to the infeasible manual evaluation of all rules in every language, we propose an *automated rule metric* (ARM) that evaluates how well the rules extracted from decision tree $\mathcal{T}$ fit to unseen gold-annotated test data. For each triple t marking feature f, we

---

[5] The top 20 most frequent triples covered approximately 95% of the triples where this feature was active on average.

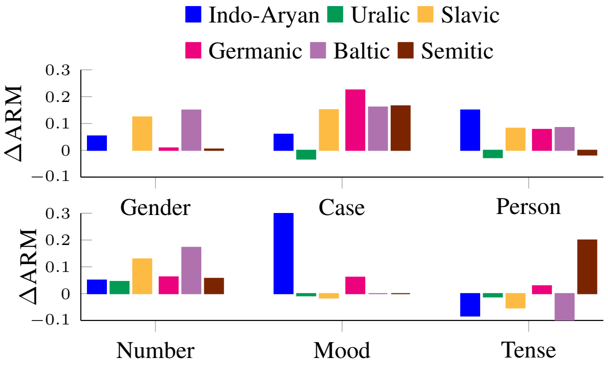


Figure 4: Difference in the ARM scores of decision trees over gold-standard syntactic analysis with baseline trees where all leaves predict *chance-agreement*.

first retrieve all examples from the test data corresponding to that triple. Next, we calculate the empirical agreement by counting the fraction of test samples that exhibit agreement, referred by $q_{f,t}$. For a *required-agreement* leaf, we expect most test samples satisfying that rule to show agreement.[6] To account for any exceptions to the rule and/or parsing-related errors, we use a threshold that acts as proxy for evaluating whether the given triple denotes *required agreement*. We use a threshold of 0.95, and if $q_{f,t} > 0.95$ then we assign the test label $l_{\text{test},f,t}$ for that triple as *required-agreement*, and otherwise choose *chance-agreement*.[7] Similar to the human evaluation, we compute a score for each triple t marking feature f

$$\text{AS}_t = \mathbb{1}\begin{cases} 1 & l_{\text{test},f,t} = l_{\text{tree},f,t} \\ 0 & \text{otherwise} \end{cases}$$

then average scores across all annotated triples in T_f to get the ARM score for each feature f:

$$\text{ARM}_f = \frac{\sum_{t \in T_f} \text{AS}_t}{|T_f|}$$

4 Experiments with Gold-Standard Data

In this section, we evaluate the quality of the rules induced by our framework, using gold-standard syntactic analyses and learning the decision trees over triples obtained from the training portion of all SUD treebanks. As baseline, we compare with trees predicting all leaves as *chance-agreement*.

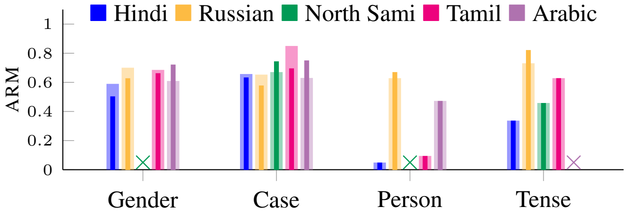

Figure 5: Our approach (shaded bars) outperforms the chance-agreement baseline (solid bars) in all cases where there exist agreement rules. Features not present in the language are marked with ×.

The extracted rules have an 0.574 ARM score (averaged across all treebanks and features), outperforming the baseline scores by 0.074 ARM points.[8] Of all the 451 decision trees across all treebanks and features, we find 78% trees outperforming the baseline trees. In Figure 4, we show the improvements over the baseline averaged across language families/genera. In families with extensive agreement systems such as Slavic and Baltic our models clearly outperform the baseline discovering correct rules, as they do for the other Indo-European genera, Indo-Aryan and Germanic. For mood and tense, the *chance-agreement* baseline performs on par with our method. This is not surprising because there is little agreement observed for these features given that only verbs and auxiliary verbs mark these features. We find that for both tense and mood in the Indo-Aryan family, our model identifies *required-agreement* primarily for conjoined verbs, which mostly need to agree only if they share the same subject. However, subsequent analysis revealed that in the treebanks nearly 50% of the agreeing verbs do not share the same subject but do agree by chance.

Agreement for Indo-European languages like Hindi and Russian is well documented (Comrie, 1984; Crockett, 1976) and is reflected in our large improvements over the baseline (Figure 5). Similarly, Arabic exhibits extensive agreement on noun phrases including determiners and adjectives (Aoun et al., 1994). We find that for Arabic gender the lower ARM scores of our method are an artifact of the small test data.

North Sami is an interesting test bed: as a Uralic language, case agreement would be somewhat unexpected and indeed our model's predictions are not better than the baseline. Nevertheless, with our interface we find patterns of rare positive paratactic constructions with required agree-

---

[6] There are exceptions: e.g. when the head of dependent is a multiword expression (MWE), in which case dependency parsers might miss or pick only one of its constituents as head/dependent, or if the MWE is syntactically idiosyncratic.

[7] We keep a 5% margin to account for any exceptions or parsing errors based on the feedback given by the annotators.

[8] Individual scores for each treebank are in Appendix A.5.

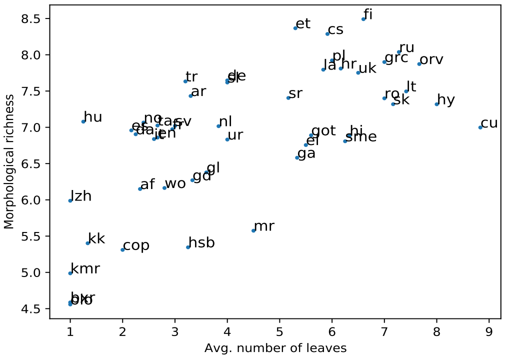

Figure 6: Correlation between size of the decision trees constructed by our framework and morphological complexity of languages.

ment where demonstrative pronouns overwhelmingly agree with their heads.[9] The case decision tree also uncovers interesting patterns of 100% agreement on Tamil constructions with nominalized verbs (Gerunds) where the markings propagate to the whole phrase.

Conciseness of Extracted Rules We further analyze the decision trees learnt by our framework for conciseness and find that the trees grow more complex with increasing morphological complexity of languages as seen in Figure 6. To compute the morphological complexity of a language, we use the word entropy measure proposed by Bentz et al. (2016) which measures the average information content of words and is computed as follows:

$$H(D) = -\sum_{i \in V} p(w_i) \log p(w_i)$$

where V is the vocabulary, D is the monolingual text extracted from the training portion of the respective treebank, $p(w_i)$ is the word type frequency normalized by the total tokens. Since this entropy doesn't account for unseen word types, Bentz et al. (2016) use the *James-Stein shrinkage* estimator (Hausser and Strimmer, 2009) to calculate $p(w_i)$:

$$p(w_i) = \lambda p^{\text{target}}(w_i) + (1 - \lambda) p^{\text{ML}}(w_i)$$

where $\lambda \in [0, 1]$, p^{target} denotes the maximum entropy case given by the uniform distribution $\frac{1}{V}$ and p^{ML} is the maximum likelihood estimator which is given by the normalized word type frequency. Languages with a larger word entropy are considered to be morphologically rich as they pack more information into the words. In Figure 6 we plot the morphological richness with the average number of leaves across all features and find these to be highly correlated.

Manual Evaluation Results We conduct an expert evaluation for Greek (el), Russian (ru) and Catalan (ca) as described in Section §3.2. For a strict setting, we consider both *Sometimes agree* and *Need not agree* as *chance-agreement* and report the human evaluation metric (HRM) in Figure 7. Overall, our method extracts first-pass grammar rules achieving 89% accuracy for Greek, 78% for Russian and 66% for Catalan.

In most error cases, like person in Russian, our model produces *required-agreement* labels, which we can attribute to skewed data statistics in the treebanks. In Russian and Greek, for instance, conjoined verbs only need to agree in person and number if they share the same subject (in which case they *implicitly* agree because they both must agree with the same subject phrase). In the treebanks, though, only 15% of the agreeing verbs do indeed share the same subject – the rest agree by chance. In a reverse example from Catalan, the overwhelming majority (92%) of 8650 tokens are in the third-person, causing our model to label all leaves as chance agreement despite the fact that person/number agreement is required in such cases. Similarly for tense in Catalan, our framework predicts *chance-agreement* for auxiliary verbs with verbs as their dependent because of overwhelming majority of disagreeing examples. We believe this is because of both annotation artifact and the way past tense is realized.

To demonstrate how well the automated evaluation correlates with the human evaluation protocol, we compute the Pearson's correlation (r) between the ARM and HRM for each language under four model settings: *simulate-50, simulate-100, baseline* and *gold. simulate-x* is a simulated low-resource setting where the model is trained using x gold-standard syntactically analysed data.[10] The *baseline* setting is the one where all leaves predict *chance-agrement* and under the *gold* setting we train using the entire gold-standard data. We compute the ARM and HRM scores for the rules learnt under each of the four settings and report the Pearson's correlation, averaged across all features. Overall, we observe a moderate correlation for all three languages, with $r = 0.59$ for Greek, r=0.41 for Russian and r=0.38 for Catalan. The correla-

[10] More details on the experimental setup in § 5.1.

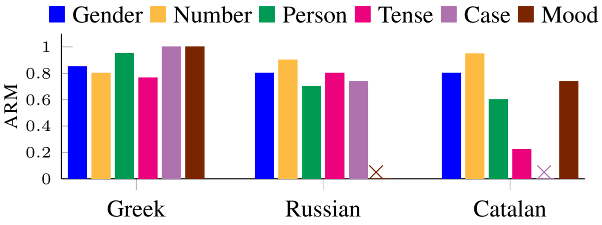

Figure 7: Annotation accuracy for Greek, Russian and Catalan per each morphological feature.

tions are very strong for some features such as Gender (r_{el}=0.97, r_{ru}=0.82, r_{ca}=0.98) and Number (r_{el}=0.97, r_{ru}=0.69, r_{ca}=0.96) where we expect to see extensive agreement.

5 Low-Resource Experiments

5.1 Simulated Zero-/Few-Shot Experiments

It is not always possible to have access to gold-standard syntactic analyses. Therefore, in order to investigate how the quality of rules are affected by the quality of syntactic analysis, we conduct simulation experiments by varying the amount of gold-standard syntactically analysed training data. For each language, we sample x fully parsed sentences from the its treebank out of L training sentences available. For the remaining $L - x$ sentences, we use *silver* syntactic analysis i.e., we train a syntactic analysis model on x sentences and use the model predictions for the $L - x$ sentences.

Data and Setup: We experiment with Spanish, Greek, Belarusian and Lithuanian. For transfer learning, we use Portuguese, Ancient Greek, Ukrainian and Latvian treebanks respectively. The data statistics and details are in Appendix A.2.

We train `Udify` (Kondratyuk and Straka, 2019), a parser that jointly predict POS tags, morphological features, and dependency trees, using the x gold-standard sentences as our training data. We generate model predictions on the remaining $L - x$ sentences. Finally, we concatenate the x gold data with the $L - x$ automatically parsed data from which we extract the training data for learning the decision tree. We experiment with $x = [50, 100, 500]$ gold-standard sentences. To account of sampling randomness, we repeat the process 5 times and report averages across runs.

To further improve the quality of the automatically obtained syntactic analysis, we use cross-lingual transfer learning where we train the `Udify` model by concatenating x sentences of the target language with the entire treebank of the related language. We also conduct zero-shot experiments under this setting where we directly use the `Udify` model trained only on the related language and get the model predictions on L sentences. As before, we train five decision trees for each x setting and report the average ARM over the test data.

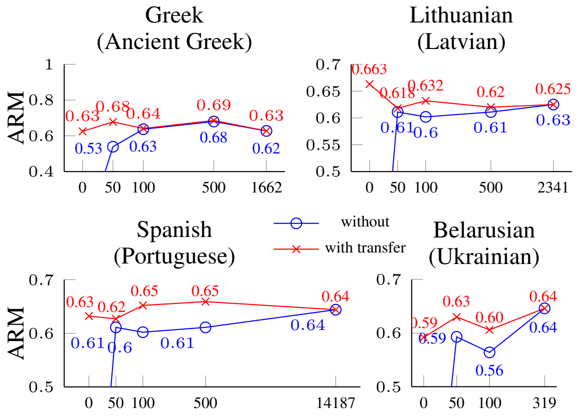

Figure 8: Comparing the (avg.) ARM score for `Number` agreement with and without cross-lingual transfer learning (transfer language in parenthesis). x-axis in log space. The higher the ARM the better.

[Relation, Head, Dependent]	correct label	gold	zero-shot
det, NOUN, DET.	almost always	required	required
mod, NOUN, ADJ	almost always	required	required
flat, PROPN, PROPN	almost always	required	chance
mod, PROPN, PROPN	almost always	required	chance
appos, PROPN, PROPN	sometimes	required	chance
comp:aux@pass, AUX, VERB	need not	chance	required
conj, PROPN, PROPN	need not	required	chance
ARM score over the test set:		0.644	0.632

Table 1: The Spanish gender rules extracted in a zero-shot setting are generally similar to the ones extracted from the gold data (93%). We highlight the few mistakes that the zero-shot tree makes.

Results We report the results for Number agreement in Figure 8. Similar plots for other languages and features can be found in the Appendix A.5. We observe that using cross-lingual transfer learning (CLTL) already leads to high scores across all languages even in zero-shot settings where we do not use any data from the gold-standard treebank. Taking Spanish gender as an example, 93% of the rule-triples extracted from the gold-standard tree (which are overwhelmingly correct) are also extracted by the zero-shot tree. The zero-shot tree only makes a few mistakes (shown in Table 1 and reflected in its overall ARM score) on certain proper noun and auxiliary verb constructions. Interestingly, using CLTL, training with just 50 gold-standard target language sentences is almost equivalent to training with 100 or 500 gold-standard sentences. This opens new avenues for language documentation: with as few as 50 expertly-annotated syntactic analysis of a new language and CLTL our framework can produce decent first-pass agreement rules. Needless to say, in most cases the extracted rules improve as we increase the number of gold-standard sentences and CLTL further helps bridge the data availability gap for low-resource settings.

5.2 Real Zero-Shot Experiments

Some languages like Breton, Buryat, Faroese, Tagalog and Welsh have test data only; there is no gold-standard training data available, which presents a *true* zero-shot setting. In such cases, we can still extract grammar rules with our framework using zero-shot dependency parsing.

Data and Setup: We collect raw text for the above languages from the Leipzig corpora (Goldhahn et al., 2012). Data statistics are listed in Appendix A.2. We parse these sentences using the "universal" `Udify` model that has been pre-trained on all of the UD treebanks, as released by (Kondratyuk and Straka, 2019). As before, we use these automatically parsed syntactic analyses to extract the rules which we evaluate with ARM over the gold standard test data of the corresponding SUD treebanks.

Results: We report the ARM scores in Figure 9. Averaged over all rules, our approach obtains a ARM of 0.566, while the naive all-chance baseline only achieves 0.506. The difference appears to be small, but we still consider it significant, because these languages do not actually require agreement for many grammatical features. Tagalog and Buryat are the most distant languages that we test on (no Philippine and Mongolic language is present in our training data) and yet we observe our method being at par with the baseline and even outperforming in case of Tagalog. Breton and Welsh, on the other hand, are an interesting test bed: Celtic languages are to some degree outliers among Indo-European languages (Borsley and Roberts, 2005), and we suspect that as a result the parser performs generally worse. Despite that, our approach has an ARM of 0.730 for Welsh gender agreement, as opposed to the mere 0.615 that the baseline achieves.

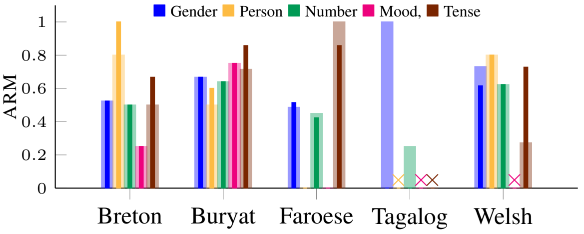

Figure 9: In most cases our framework (shaded bars) extracts a good first-pass specification for *true* zero-shot settings. Solid bars indicate the baseline.

6 Related Work

Bender et al. (2014) use interlinear glossed text (IGT) to extract lexical entities and morphological rules for an endangered language. They experiment with different systems which individually extract lemmas, lexical rules, word order and the case system, some of which use hand-specified rules. Howell et al. (2017) extend this to work to predict case system on additional languages. Zamaraeva (2016) also infer morphotactics from IGT using k-means clustering. To the best of our knowledge, our work is the first to propose a framework to extract first-pass grammatical agreement rules directly from raw text in a statistically-informed objective way. A parallel line of work (Hellan, 2010) extracts a *construction profile* of a language by having templates that define how sentences are constructed.

7 Future Work

While we have demonstrated that our approach is effective in extracting a first-pass set of agreement rules directly from raw text, it focuses only on agreement between a pair of words and hence might fail to capture more complex phenomena that require broader context or operate at the phrase level. Consider this simple English example: "John and Mary love their dog". Under both UD and SUD formalisms, the coordinating conjunction "and" is a dependent, hence the verb will not agree with either of the (singular) nouns ("John" or "Mary"). Also, deciding agreement based on only POS tags is insufficient to capture *all* phenomena that may influence agreement for e.g. mass nouns such as 'rice' do not follow the standard number agreement rules in English. We leave a more expressive model and evaluation on more languages as future work. We also plan to expand our methodology for extracting grammar rules from raw text to other aspects of morphosyntax, such as argument structure and word order phenomena.

Acknowledgments

The authors are grateful to the anonymous reviewers who took the time to provide many interesting comments that made the paper significantly better, and to Josep Quer, Ekaterina Vylomova and Maria Ryskina, for participating in the human annotation experiments. This work is sponsored by the DARPA grant FA8750-18-2-0018 and by the National Science Foundation under grant 1761548.

A Appendix

A.1 Decision Tree Hyperparameters

We perform a grid search over the following hyperparameters of the decision tree:

- `criterion` = [gini, entropy]
- `max depth` = [6,15]
- `min impurity decrease` = $1e^{-3}$

The best parameters are selected based on the validation set performance. For some treebanks which have no validation set we use the default cross-validation provided by `sklearn` (Buitinck et al., 2013). Average model runtime for a treebanks is 5-10mins depending on the size of the treebank.

A.2 Dataset Statistics

For the true low-resource experiments, the dataset details are in Table 2.

LANGUAGE	TRAIN / TEST
Breton-KEB	30000 / 888
Buryat-BXR	10000 / 908
Faroese-OFT	50000/ 1208
Tagalog-TRG	30000 / 55
Welsh-CCG	30000 / 956

Table 2: Dataset statistics. Training data is obtained by parsing the Liepzig corpora (Goldhahn et al., 2012) and test data is obtained from the respective treebank. Each cell denotes the number of sentences in train/test.

A.3 Evaluation

A.4 Annotation Interface for Expert Evaluation

In Figure 10, we show the annotation interface used for verifying `Gender` agreement rules in Catalan. For each triple, we display 10 randomly selected examples from the training portion of the treebank.

A.5 Low-resource Experiment Results

For the simulation experiments, the dataset details are in Table 3.

A.5.1 Udify (Kondratyuk and Straka, 2019) Model Details

We used the `Udify` model for automatically annotating the raw text with part-of-speech (POS), dependency links and morphological features. For each of the simulation experiment we report the `udify` parsing performance on the test data in Table 4. We used the same hyperparameters for training with a related languages as specified by the authors.[11]. In the configuration file, we only change the parameters `warmup steps=` 100 and `start-step=` 100, as recommended by the authors for low-resource languages.

A.5.2 Results and Discussion

For each language and feature, we plot the ARM score with and without transfer learning in Figure 12-14. Similar to our findings for `Gender` in Figure 5, we find that cross-lingual transfer leads to a better score across all languages in the zero-shot setting. As we increase the number of gold-standard sentences, the quality of extracted rules improve. Although, for Belarusian we observe the opposite trend for `Person` agreement. On closer inspection we find that it is because person applies only to non-past finite verb forms (VERB and AUX) as an inflectional feature and to pronouns (PRON) as a lexical feature which means that in many cases person is not explicitly marked, even though it implicitly exists [12].

A.6 Experiments with Gold-Standard Data

We present the ARM scores for all treebanks and features in Tables 5-11. We also report the validation results in the same tables for our best setting which uses the *Statistical Threshold*. In Section 2.2, we proposed using two types of thresholds for retaining the high probability agreement rules. In order to compare which threshold is the best for all treebanks, we manually inspect some of the learnt decision trees. We find that for the trees learnt from the *hard threshold* often over-fit on the training data causing to produce leaves with very few examples. In Figure 15 we compare the trees constructed for number agreement with the two thresholds for Marathi. One reason why *Statistical-Threshold* performs better for low-resource languages is because there are more leaves with fewer samples overall causing the *Hard Threshold* to have more false positives. Whereas the *Statistical Threshold* uses *effect size* with the significance test which takes into account the sample size within a leaf leading to better leaves. Therefore, we choose to use *Statistical-Threshold* for all our simulation experiments.

In Figure 11, we report that (avg.) number of leaves in the decision trees grouped by language

Table 3: Dataset statistics. Train/Dev/Test denote the number of sentences in the respective treebank used for the target language.

family. Overall, `Gender` and `Case` tend to have more complex trees. For `Case`, it is probably because languages have more number of cases making it harder for the decision tree to model them.

A.7 SUD treebanks

Figure 16 presents a comparison of UD and SUD-style trees for the German sentence, “Ich werde lange Bücher lesen.". The SUD tree has the function word ‘werde’ as the syntactic head to the content word ‘lesen’.

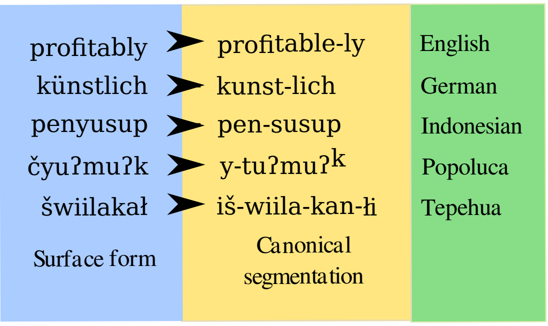
Abstract

Canonical morphological segmentation consists of dividing words into their standardized morphemes. Here, we are interested in approaches for the task when training data is limited. We compare model performance in a simulated low-resource setting for the high-resource languages German, English, and Indonesian to experiments on new datasets for the truly low-resource languages Popoluca and Tepehua. We explore two new models for the task, borrowing from the closely related area of morphological generation: an LSTM pointer-generator and a sequence-to-sequence model with hard monotonic attention trained with imitation learning. We find that, in the low-resource setting, the novel approaches outperform existing ones on all languages by up to 11.4% accuracy. However, while accuracy in *emulated* low-resource scenarios is over 50% for all languages, for the *truly* low-resource languages Popoluca and Tepehua, our best model only obtains 37.4% and 28.4% accuracy, respectively. Thus, we conclude that canonical segmentation is still a challenging task for low-resource languages.

1 Introduction

Morphological segmentation denotes the task of dividing words into their constituting morphemes, i.e., their smallest meaning-bearing units, and has been studied extensively in natural language processing (NLP) (Ruokolainen et al., 2016). The most common form of segmentation consists of separating morphemes at the surface level. However, this is not always well suited: in fusional languages, morphemes are merged during word formation and, thereby, change their surface forms. Thus, in this paper, we tackle the task of canonical segmentation (Cotterell et al., 2016b), which consists of segmenting a word while restoring the original forms of its morphemes. Considering, e.g., the English word *collision*, its surface segmentation is *collis+ion*, while its canonical segmentation is *collide+ion*. Figure 1 provides examples for all five languages we experiment on.



Surface form	Canonical segmentation	
profitably	profitable-ly	English
künstlich	kunst-lich	German
penyusup	pen-susup	Indonesian
čyuʔmuʔk	y-tuʔmuʔ^{k}	Popoluca
šwiilakał	iš-wiila-kan-ɬi	Tepehua

Figure 1: Canonical segmentation examples for all languages in our experiments.

Neural models have shown to perform well on this task when large amounts of training data are available (Kann et al., 2016; Ruzsics and Samardzic, 2017). Nevertheless, datasets with morphological annotations are difficult to obtain, since they require expert annotators. Furthermore, many languages with complex morphology are spoken by a limited number of people or are listed as endangered languages (Mager et al., 2018), which reduces the possible annotator pool even more. However, morphological segmentation is important for downstream tasks like machine translation (Conforti et al., 2018; Vania and Lopez, 2017), dependency parsing (Seeker and Çetinoğlu, 2015; Vania et al., 2018), or semantic role labeling (Sahin and Steedman, 2018). Moreover, high performance on these tasks can yield more language independent NLP models (Gerz et al., 2018).

Here, we focus on low-resource canonical segmentation. We propose two new models for the task, which have recently been successfully applied to a related morphological generation task called *morphological inflection*. The approaches we in-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5237–5250,
November 16–20, 2020.

vestigate are (i) an LSTM pointer-generator model (Sharma et al., 2018a), and (ii) a neural transducer trained with imitation learning (IL; Makarov and Clematide, 2018a). Since both canonical segmentation and morphological inflection are character-level string transduction tasks, we hypothesize that models which can learn one from limited data, will also be able to do so for the other.

We experiment on three benchmark datasets in German, English, and Indonesian, but simulate a low-resource scenario by reducing the number of training examples. We further evaluate our models on datasets for two *truly* low-resource languages: Popoluca and Tepehua. We find that our new models indeed outperform previous approaches on all languages. For additional insight, we also evaluate the performance of all models for varying amounts of training data from the high-resource languages and find that the neural-transducer with imitation learning outperforms all other models in all but one setting with up to 600 training examples. Using the entire training set for English, German, and Indonesian, the state-of-the-art LSTM sequence-to-sequence model performs best. However, the difference to our proposed models is below 3.3% accuracy for all languages and models.

Contributions. (i) Inspired by recent advances in the area of morphological generation, we propose two new models for the task of low-resource canonical segmentation, which outperform all baselines. (ii) We introduce two canonical segmentation datasets for the *truly* low-resource languages Popoluca and Tepehua. (iii) We compare all models under multiple different conditions, highlighting their strengths and shortcomings, and conduct an analysis of the errors made by all neural models.

2 Related Work

The task of morphological segmentation was introduced by Harris (1951). Most work has considered the surface segmentation task, for which unsupervised methods like LINGUISTICA (Goldsmith, 2001) and MORFESSOR (Creutz and Lagus, 2002, 2007; Poon et al., 2009) played an important role. The latter was further extended to a semi-supervised version (Kohonen et al., 2010; Grönroos et al., 2014).

Over the last years, supervised methods have attracted more attention: Ruokolainen et al. (2013) cast the task as a sequence labeling problem using conditional random fields (CRFs; Lafferty et al., 2001). A similar approach was suggested by Wang et al. (2016), who employed a long short-term memory network (LSTM; Hochreiter and Schmidhuber, 1997) for tagging. Semi-Markov CRFs were also proposed (Cotterell et al., 2015). Kann et al. (2018) modeled the task as a sequence-to-sequence problem. Supervised methods for surface segmentation were shown to perform acceptably even in the low-resource setting (Grönroos et al., 2019). Recent work also included context to improve morphological disambiguation (Can and Manandhar, 2018; Sakakini et al., 2017). Yang et al. (2019) proposed a pointer network to find surface segmentation boundaries.

For fusional languages, surface segmentation is not very effective. Therefore, restoring morphemes to their canonical form was previously discussed in linguistics (Kay, 1977) as well as in the NLP literature. Previous approaches include unsupervised (Naradowsky and Goldwater, 2009), as well as joint models for segmentation and transduction (Cotterell et al., 2016b) and neural encoder-decoder models (Kann et al., 2016; Ruzsics and Samardzic, 2017). However, up to now, supervised models have only been explored in the high-resource setting. We aim at closing this gap.

For low-resource morphological segmentation, rule-based approaches have been used frequently, since they do not need large amounts of data. They have been developed, e.g., with finite state transducer (FST) tools like FOMA (Hulden, 2009) or HFST (Lindén et al., 2011). However, this kind of system requires both time and linguistic knowledge. Our aim is to explore data-driven approaches for the low-resource setting in order to overcome this limitation.

In recent years, the area of morphological generation has experienced substantial progress, with a variety of methods that can be used for the canonical segmentation task. Kann et al. (2016) used a sequence-to-sequence model to inflect a word given a set of morphological tags. Sharma et al. (2018a) proposed a pointer-generator model, which was more suitable for the low-resource setting. Aharoni and Goldberg (2017) proposed a neural transducer with hard monotonic attention. Makarov et al. (2017) extended this approach and added a copy operation, and Makarov and Clematide (2018a) proposed imitation learning (Daumé et al., 2009) for training it. Here, we explore the applicability of the models by Sharma et al. (2018a) and Makarov

and Clematide (2018a) to low-resource canonical segmentation.

3 Datasets for Popoluca and Tepehua

We release two new datasets for low-resource canonical segmentation in Popoluca and Tepehua[1]. In this section, we briefly introduce the languages, before describing our datasets. We use these two languages to shed light on polysynthetic languages that also exhibit fusional phenomena. The high-resource datasets introduced by (Cotterell et al., 2016a) cover fusional (German), analytic (English), and agglutinative (Indonesian) languages.

3.1 Languages

In addition to experimenting on high-resource datasets for English, German and Indonesian (Cotterell et al., 2016b), we introduce datasets for two low-resource languages from Mexico: Popoluca and Tepehua. This enables us to evaluate our models in real low-resource settings.

Popoluca. Popoluca of Texistepec (language code: POQ[2]) is part of the Mixe-Zoquean family. Its morphology is classified as polysynthetic, and it mostly follows a verb, subject, object (VSO) word order (Dryer and Haspelmath, 2013). This language is almost extinct with only one native speaker alive reported in 2005 (Gordon Jr, 2005). However, attempts for language revival have been reported (INEGI, 2008). Efforts made for language revitalization can benefit from advances in NLP.

	>3Morph.	Surf.	Canon.	NoSeg.	M./W.	Ch./W.

Table 2: Statistics for all five canonical segmentation datasets. Percentages of words with more than 3 morphemes (>3 Morph.), surface segmentation (Surf.), canonical segmentation (Canon.), and without segmentation (NoSeg.), as well as the average number of morphemes per word (M./W.) and characters per word (Ch./W.).

Thus, the creation and development of accurate models for those languages is of high importance.

Here we show an example of canonical segmentation in Popoluca, together with its English gloss. The plus symbol is part of the alphabet of the language. We use a '-' as morpheme delimiter.

kki:mba: → ky-k+:m-ba:
You are small

Tepehua. Tepehua (language code: TPP) belongs to the Totonacan language family. It is spoken in three Mexican regions: in the northeastern part of the state of Hidalgo (around 3000 speakers), in the villages of Pisaflores (around 4000 speakers), and in Tlachichilco in the state of Veracruz (around 3000 speakers) (Gordon Jr, 2005). It is also polysynthetic. Tepehua permits free word order, but has a preference for a subject, verb, object (SVO) configuration (Dryer and Haspelmath, 2013).

An example for canonical segmentation is

iklakadíkdi → ik-laka-tikti
I am small

The variant of the language used in our dataset is the one spoken in Pisaflores, Veracruz.

3.2 Datasets

We collect words for our datasets from two books belonging to the Archive of Indigenous Languages (ALI-Colmex) of the College of Mexico (*Colegio de México*). For Popoluca we used the book by Wichmann (2007) and for Tepehua that by MacKay and Trechsel (2010). We include segmentable as well as non-segmentable words in order to avoid oversegmentation by our systems. For both languages a set of Spanish sentences are used to elicit the data. This set of sentences is the same across the entire ALI-Colmex collection. For each language

---

[1] Te dataset is available at `http://turing.iimas.unam.mx/wix/canseg`

[2] We use the languages codes defined in the ISO 639-3 standard.

the authors of the books asked native speakers to translate the sentences into the respective languages (elicited data). Afterwards, they performed a glossing of the translated text. For more details we refer the reader to the original books.

In Table 2, we show statistics for all five datasets used in this paper. Importantly, the German dataset only contains multi-morpheme words. Additionally, we observe that most of the Indonesian words only require surface segmentation, while English is the language with the highest ratio of words that do not require any segmentation. On the other hand, Popoluca and Tepehua have the highest proportion of words that require both splitting and restoration of the canonical forms. Moreover, both languages have a high amount of words that contain more than 3 morphemes per word, and also have the highest morphemes-per-word rate. Adding to these facts, the small amount of data available for these languages makes morphological segmentation even harder. To get a better understanding of the underlying morphemes seen in each language, we extract the 15 most common ones for each dataset. These morphemes, together with their relative frequency in our datasets, are shown in Table 1.

4 Models

Inspired by recent successes of two models for low-resource morphological inflection, we propose to apply these architectures to canonical segmentation with limited training data. In this section, we introduce the models.

4.1 Pointer-Generator Network

Motivation. The first model we apply to low-resource canonical segmentation is a pointer-generator network (See et al., 2017), i.e., a sequence-to-sequence model with a mechanism to copy input elements over to the output. Our intuition is that this should make the learning problem easier and help in settings with limited training data. The pointer-generator network can be considered a hybrid between an attention-based sequence-to-sequence model (Bahdanau et al., 2015) and a pointer network (Vinyals et al., 2015).

Model description. Our pointer-generator network consists of a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) encoder and a unidirectional LSTM decoder with an attention mechanism. We cast the task of canonical segmentation as a character-based sequence-to-sequence problem, with the characters of the original word as the input and the characters of the restored morphemes in combination with segment boundary markers as the output. Both our encoder and decoder operate on the character level.

The pointer-generator network differs from the standard sequence-to-sequence architecture in that the decoder calculates a probability for copying an element from the input over to the output instead of generating. Here, we follow Sharma et al. (2018b) and use two separate encoders: one for the lemma and one for the morphological tags. The decoder then computes the probability distribution of the output at each time step as a weighted sum of the probability distribution over the output vocabulary and the attention distribution over the input characters. The weights can be seen as the probability to generate or copy, respectively, and are computed by a feedforward network. For details, we refer the reader to Sharma et al. (2018b).

Hyperparameters. All encoder and decoder hidden states are 100-dimensional, and our embeddings are of size 100. For training, we use Adam (Kingma and Ba, 2014) with a learning rate of 0.001 and a mini-batch size of 32. To avoid overfitting, we use dropout (Srivastava et al., 2014) with a coefficient of 0.3 for the high-resource setting and 0.5 for the low-resource setting. We train our model for 100 and 300 epochs and use early stopping with a patience of 10 and 100 for the high-resource and the low-resource setting, respectively.

4.2 Neural Transducer with Imitation Learning

Motivation. Hard monotonic attention networks (Aharoni and Goldberg, 2017) have shown to perform well on morphological generation in the low-resource setting. These systems use a nearly-monotonic alignment between the source characters and the output characters. For our second model, we employ the variant proposed by Makarov and Clematide (2018c), which makes use of imitation learning for end-to-end training and, thus, avoids error propagation.

Model description. This model is a sequence-to-sequence model with hard monotonic attention (Aharoni and Goldberg, 2017), which transduces an input sequence of characters into an output sequence by performing edit operations. Following Makarov and Clematide (2018b), it can perform three operations: insertion, deletion and copy. However, instead of using maximum likelihood estimation (MLE), training is done with imitation learning. The idea is to train a model to imitate an expert policy that maps the training configurations to a set of optimal actions. We aim to minimize the sequence-level loss and an action level loss.

The training is composed of two steps: a roll-in and a roll-out stage. In the roll-in stage, the model gather actions by sampling from the expert policy. This process returns a set of decoder outputs called configurations. For the roll-out stage: a sequence-level loss is computed for each valid action per configuration. For that, the action is executed and is compared to the optimal action sequence of the expert. This loss is defined in terms of Levenshtein distance (Levenshtein, 1966) between the prediction and the target and the cost of the actions. The cost function uses the information from a character aligner. After calculating the sentence-level loss, this is fed into an action-level loss. This loss expresses how much a certain action suffers relative to the optimal action under the current policy. This is done by minimizing the negative marginal log-likelihood of all optimal actions (Makarov and Clematide, 2018b).

Hyperparameters. For the encoder and the decoder of this model, we use one layer with a 200-dimensional size, with a dropout of 0.5. For optimization we use ADADELTA (Zeiler, 2012) with a learning rate of 0.1. As the RNN unit, we use an LSTM. We train the model for 30 epochs, with a patience of 10 epochs. For IL training, we use an inverse sigmoid, and a decay rate of 12. For decoding, we employ beam search with a beam of width 4.

5 Experiments

We now describe the experiments we conduct to explore the performance of our models both in the high-resource and in the low-resource setting.

5.1 Data

The canonical segmentation datasets for English (ENG), German (DEU) and Indonesian (IND) by Cotterell et al. (2016b) each consist of 8000 training, 1000 development, and 1000 test examples. We consider the complete training set to be high-resource. The datasets feature a splitting into 10 folds for cross-validation. For our low-resource experiments, we randomly take a subset of words from each training fold, but keep the development and test sets unchanged.

The high-resource datasets cover three languages: English, German, and Indonesian. English is an analytic language from the Indo-European family (Konig and Van der Auwera, 2013), German exhibits fusional typology (Hawkins, 2015), while Indonesian is an agglutinative language whose morphology involves the use of affixation, reduplication and cliticization (Hiroki Nomoto and Bond, 2018).

We additionally experiment with two polysynthetic low-resource languages: Tepehua and Popoluca (cf. Section 2). As those datasets are small (900 words for each language), we divide the datasets into 9 folds, each containing 100 training, 100 development, and 700 test examples.

5.2 Baselines

We compare the neural-transducer with imitation-learning (`IL`) and the pointer-generator network (`PGNet`) to three strong baselines, including the current state of the art for the canonical segmentation task.

Encoder-Decoder (`s2s`). Our first baseline is a character-based encoder-decoder recurrent neural network (RNN) architecture with attention as proposed by Kann et al. (2016). It defines (in combination with a reranker which we omit here since it is orthogonal to our work) the state of the art on the high-resource datasets. To perform experiments in the low-resource setting, we re-implement this model using OpenNMT (Klein et al., 2017). The hyperparameters suggested by Kann et al. (2016) are as follows: the RNNs of the encoder and decoder have 100 hidden units each; the embedding size is 300. For optimization we use ADADELTA (Zeiler, 2012) with a minibatch size of 20.

Semi-Markov CRF (`semiCRF`). Our first non-neural baseline is the ChipMunk (Cotterell et al., 2015) implementation of a semi-Markov CRF (Sarawagi and Cohen, 2005). Although the system is able to make use of additional complementary information like morphological tags or dictionaries, we decide to not include those, in order to make our results comparable across all languages and systems.

Joint log-linear model (`joint`) As a second non-neural system we use a log-linear model which

	English			German			Indonesian		
	Acc.	ED	F1	Acc.	ED	F1	Acc.	ED	F1
`SemiCRF`	64.7	64.3	76.6	41.9	108.3	74.1	70.4	46.3	84.3
`joint`	72.0	98.0	76.0	59.0	101.0	76.0	90.0	15.0	80.0
`s2s`	♦**78.0**	**41.2**	88.4	♦**77.1**	**47.8**	**89.3**	♦**94.3**	**7.6**	**97.9**
`PGNet`	77.5	42.4	**88.5**	74.8	52.1	88.2	92.9	10.0	97.5
`IL`	76.7	42.9	87.2	73.8	52.3	87.2	93.4	8.4	97.6

Table 3: Results for `semiCRF`, `joint`, `s2s`, `PGNet`, and `IL` for the high-resource setting of English, German and Indonesian. Lower scores in the ED columns are better. For accuracy, ♦ indicates statistical significance at $p < .01$.

jointly segments and generates underlying representations of the input words (Cotterell et al., 2016b). For segmentation it uses the `semiCRF` previously described, and for transduction of the underlying forms it uses a probabilistic final state transducer (Cotterell et al., 2014).

5.3 Training Details

We choose the hyperparameters for all models following the mentioned previous work. All neural models and the `semiCRF` were trained on a server with 2 Intel(R) Xeon(R) CPU v4@ 2.20GHz, with 4 Nvidia GTX 1080ti graphic cards. To train the joint log-linear model a MacBook Pro 2009 laptop was used. Links to the repositories we use are listed in the complementary material.

5.4 Metrics

For evaluation, we use three metrics. The first one is **accuracy**, i.e., the proportion of entirely correctly segmented words, to get a better understanding of partially right segmentation. To get more information about subword-level errors, we also employ **edit distance** on the character level. This is particularly useful to penalize big mistakes in a single word. We also use $\mathbf{F}_1$ **score** on the morpheme level, to measure the overlap between morphemes. Precision corresponds to the proportion of morphemes in the prediction that occur in the gold standard, and recall is the proportion of morphemes in gold that appear in the system's prediction. This will ensure that morphemes that are predicted without appearing in the gold standard are penalized, as well morphemes that are in the gold standard but are omitted in the prediction.

5.5 Results

Low-resource *simulation*. Figure 2 shows the accuracy of all systems for different low-resource training set sizes (100, 200, 300, 400, 500 and 600 examples) for English, German, and Indonesian. To ensure statistical significance we use McNemar's test (McNemar, 1947) for all accuracy results (Tables 3 and 4, Figure 2) comparing the best and the second best systems. All results are significant at $p < 0.01$. The scores of all systems vary across languages. However, `IL` consistently is among the two best systems in terms of accuracy in all settings. For 100 training examples `IL` is the second-best performing system with 50.99% for English, just behind the `semiCRF` with 52.87%. For German 51.49% `IL` slightly outperforms `Joint` (51.33%) and obtains the best score for Indonesian with 61.14%, where the second best system is `semiCRF` (58.82%). Moreover, from 300 examples up to 600, `IL` strongly outperforms all other systems, including non-neural ones.

If we compare the performance of our two proposed systems with `s2s`, `PGNet` strongly outperforms `s2s` with improvements of 22.27%, 17.84%, and 25.66% absolute accuracy for English, German, and Indonesian, respectively, in the setting with 100 training examples; while `IL` have even bigger gains with improvements of 30.65%, 32.1% and 35.73% of accuracy respectively.

Looking on the learning curves for each model for increasing training set sizes, we can see that both proposed systems show monotonically increasing performance: they take advantage of more data well, but still achieve decent performance in the low-resource setting, even outperforming all non-neural systems in some settings. On the contrary, the non-neural models `joint` and `semiCRF` have in many cases a good start, but only benefit to a limited extends from additional data. A table listing all individual results for this experiment is included in the supplementary material.

	Tepehua			Popoluca		
Model	Acc.	ED	F1	Acc.	ED	F1
`SemiCRF`	21.9	285.3	35.9	26.0	215.0	41.4
`joint`	11.2	335.4	29.5	14.6	393.6	36.8
`s2s`	4.1	532.4	7.7	13.2	309.4	23.3
`PGNet`	17.2	321.7	29.3	27.0	211.0	42.5
`IL`	♦**28.4**	**242.6**	**44.0**	♦**37.4**	**158.8**	**54.7**

Table 4: Results for the low-resource languages Popoluca and Tepehua. For accuracy, ♦ indicates statistical significance at $p < .01$.

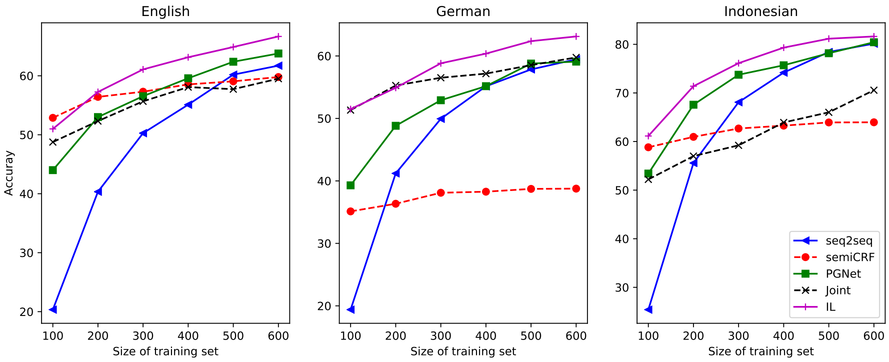

Figure 2: Accuracy for different simulated low-resource settings for our high-resource languages.

Low-resource *languages*. Results for Popoluca and Tepehua are shown in Table 4 and confirm most of the tendencies seen in our low-resource simulation experiment. `s2s` barely predicts any correct segmentation for Tepehua, and only obtains 4.14% absolute accuracy and 13.19 F_1 score. Similarly, for Popoluca, `s2s` reaches only 13.19% accuracy. The performance of `IL` is consistently better on all metrics, with substantial gains for Tepehua of 6.5% accuracy over the closest system (`semiCRF`) and 10.4% accuracy over `PGNet`.

The performance of `PGNet` is consistently better than that of `s2s`, with gains of 13.03% and 13.77% accuracy for Tepehua and Popoluca, respectively. `joint` surprisingly shows a low performance for our two low-resource languages, obtaining a 17.2% lower accuracy than the best model for Tepehua (`IL`), and a 22.8% lower accuracy than the best system for Popoluca (`IL`).

Overall, all systems perform notably worse for Tepehua and Popoluca than for the high-resource languages. This could be due to their high morphological complexity, as shown in Table 2.

High-resource setting. Table 3 shows results for `IL`, `PGNet`, `s2s`, `joint`, and `semiCRF` for the high-resource experiment. The `s2s` model gets the best results in this setting with 78.02%, 77.06%, and 94.30% accuracy for English, German, and Indonesian, respectively. However, it only obtains a slightly higher accuracy than `PGNet` and the differences in F_1 scores are similarly small. Overall, the pointer-generator network achieves results that are comparable with the state of the art in the high-resource setting. In contrast to the good performance for low-resource settings, `IL` under-performs on all metrics compared to `s2s` and `PGNet`. The `joint` model is the best non-neural system and performs clearly worse than both neural systems. Compared to `PGNet`, its accuracy is 5.54% lower for English, 15.80% lower for German, and 2.90% lower for Indonesian. `semiCRF` performs even worse.

6 Error Analysis

To get a better understanding of the results obtained with our neural models, we perform an error analysis on the output for the development sets of all folds. By manual inspection, we identify five not mutually exclusive types of errors: **Oversegmentation (Overseg.)** arises when the number of morpheme boundaries in the prediction is higher than in the gold standard annotation. **Undersegmentation (Underseg.)** occurs when the number of morpheme boundaries is lower than in the gold

	Oversegmentation
Input	internationalisierung
Gold	internationale isier ung
Error	internationale *is i er* ung
Description	The morpheme `isier` is segmented wrongly into three morphemes.
	Undersegmentation
Input	internationalisierung
Gold	internationale isier ung
Error	internationale *isieung*
Description	The morphemes `isier` and `ung` are lacking of a segmentation boundary.
	Restoration Error
Input	internationalisierung
Gold	internationale isier ung
Error	*international* isier ung
Description	The system did not perform the needed restoration for the stem `internationale`.
	Overrestoration
Input	internationalisierung
Gold	internationale isier ung
Error	internationaler *isierer* ung
Description	The systems perfomed a restoration on a morpheme that is not supposed to be restored.
	Wrong segmentation
Input	internationalisierung
Gold	internationale isier ung
Error	internationale *isi erung*
Description	The segmentation was done with the exact number of morphemes as in gold, however, the segmentation points are wrongly placed. In this error count all instances that do not match the exact segmentation boundaries.

Table 5: Examples of error types. Wrong parts are marked in italics.

standard. **Restoration error (Res.)** occurs when the prediction does not match the gold annotation, and the predicted word without boundaries does not match the input. These are errors that occur to words that undergo orthographic changes during word-formation. **Overrestoration (Overres.)** refers to outputs with errors where the correct output needs only segmentation and a copy of the input to the output. **Wrong segmentation (Wrong seg.)** arises when the morpheme boundaries in the prediction are not the same as in gold. From each segmented word, we extract the indices within the word where the segmentation is performed. If the segmentation indices from the gold standard and the prediction are not equal, it counts as this error.

Table 6 shows the percentage of errors in all languages for both experimental settings (100 examples in the low-resource setting). For the high-resource experiments, the results for oversegmentation and undersegmentation errors are mixed: for English, `s2s` avoids to generate too many segmentation boundaries, but this also has the drawback of not segmenting sufficient when it is needed. The opposite happens for German, where `IL` performs better as well, with respect to oversegmentation but fails regarding undersegmentation. `PGNet` shows no strong wins or problems regarding these errors, except for English, where it performs better for undersegmentation. `s2s` performs better for restoration errors with the exception of English, where again `PGNet` improves. With respect to oversegmentation errors, `IL` wins on all languages when compared to the other neural systems. As Indonesian has a relatively regular morphology, all error types are much less frequent for this language. If we only consider the exact segmentation point prediction, `s2s` performs better for all languages. However, the differences between the observed error rates are relatively small between `s2s` and `PGNet` models. Overall, wrong segmentation errors are the most common error type for all languages in the high-resource setting.

In the low-resources experiments, `IL` excels over all other models for oversegmentation and overrestoration, and for all languages with except to Indonesian for wrong segmentation errors. This low error rate explains the important gains that this model shows for low-resource languages. `PGNet` shows, however, better performance avoiding undersegmentation errors in all languages. It also performs better for Popoluca and Tepehua for restoration errors, while `s2s` has the lowest restoration errors for English, German, and Indonesian.

Finally, we also perform an error analysis of `joint` (cf. supplementary material). In our low-resource simulation experiments, we notice a surprisingly good performance of `joint` for German.

		Overseg.			Underseg.			Res.			Overres.			Wrong seg.		
		`IL`	`PGNet`	`s2s`	`IL`	`PGNet`	`s2s`	`IL`	`PGNet`	`s2s`	`IL`	`PGNet`	`s2s`	`IL`	`PGNet`	`s2s`

Table 6: Error types found in the development set. The high resource configuration includes three languages, while the low-resourced setting refers to model performance using 100 training examples. This error analysis was done for all five languages.

The data for this language is special since all words contained in the set are segmentable. We find that `joint` has no undersegmentation errors at all. Also, it makes very few copy errors (9.5%, compared to 21.7% of `PGNet`). For our new datasets, this model obtains a high rate of wrong segmentation (88.87% for Popoluca and 91.57% for Tepehua). It further seems to not easily be able to decide which words should or should not be segmented. This is shown by the high undersegmentation rate (50.14% for Popoluca and 62.43% for Tepehua). Thus, the low performance of `joint` on those languages can be explained by this error type and the high morphemes-per-word rate of those languages as shown in Table 2.

7 Conclusion

We proposed two new models for the task of canonical segmentation in the low-resource setting: an LSTM pointer-generator model and a neural transducer trained with imitation learning. We evaluated the performance of both models against multiple state-of-the-art baselines on five languages of different morphological typology: English, German, Indonesian, Tepehua, and Popoluca. In emulated low-resource settings with up to 600 training examples, our best proposed model outperformed all baselines in all but one setting. We obtained a similar picture for experiments on the truly low-resource languages Popoluca and Tepehua: our best approach outperformed the best baseline by 11.4% and 6.5% accuracy. For large training sets, our systems performed close to the state of the art. However, we find a large gap between the *emulated* and the *real* low-resource scenarios: while accuracy is above 50% for all high-resource languages even with reduced amounts of training data, for Popoluca and Tepehua, our best model only obtains 37.4% and 28.4% accuracy, respectively.

Acknowledgments

We would like to thank Hilaria Cruz, Jaime Gonzalez and Ekta Sood for their valuable feedback. We also want to thank all the anonymous reviewers for their valuable comments and suggestions. This project has benefited from financial support to Manuel Mager and Özlem Çetinoğlu by DFG via project CE 326/1-1 "Computational Structural Analysis of German-Turkish Code-Switching" and to Manuel Mager by DAAD Doctoral Research Grant.

IGT2P: From Interlinear Glossed Texts to Paradigms

Sarah Moeller Ling Liu Changbing Yang Katharina Kann Mans Hulden
University of Colorado
`first.last@colorado.edu`

Abstract

An intermediate step in the linguistic analysis of an under-documented language is to find and organize inflected forms that are attested in natural speech. From this data, linguists generate unseen inflected word forms in order to test hypotheses about the language's inflectional patterns and to complete inflectional paradigm tables. To get the data linguists spend many hours manually creating interlinear glossed texts (IGTs). We introduce a new task that speeds this process and automatically generates new morphological resources for natural language processing systems: IGT-to-paradigms (IGT2P). IGT2P generates entire morphological paradigms from IGT input. We show that existing morphological reinflection models can solve the task with 21% to 64% accuracy, depending on the language. We further find that (i) having a language expert spend only a few hours cleaning the noisy IGT data improves performance by as much as 21 percentage points, and (ii) POS tags, which are generally considered a necessary part of NLP morphological reinflection input, have no effect on the accuracy of the models considered here.

1 Introduction

Over the last few years, multiple shared tasks have encouraged the development of systems for learning morphology, including generating inflected forms of the canonical form—the lemma—of a word. NLP systems that account for morphology can reduce data sparsity caused by an abundance of individual word forms in morphologically rich languages (Cotterell et al., 2016, 2017a, 2018; McCarthy et al., 2019; Vylomova et al., 2020) and help mitigate bias in training data for natural language processing (NLP) systems (Zmigrod et al., 2019). However, such systems have often been limited to languages with publicly available structured data, i.e. languages for which tables containing inflectional patterns can be found, for example, in online dictionaries like Wiktionary.[1] This limits the development of NLP systems for morphology to languages for which morphological information can be easily extracted.

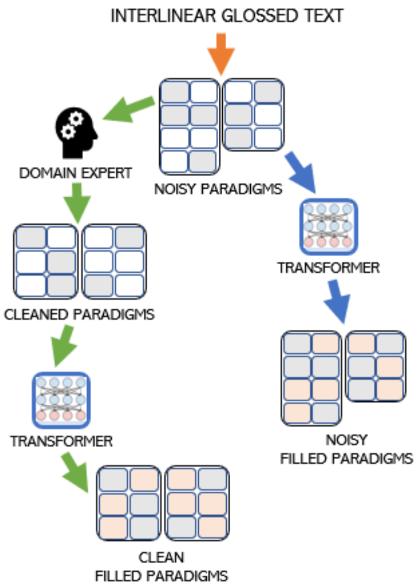

Figure 1: Inflected word forms attested in interlinear glossed texts (IGT) train transformer encoder-decoder to generalize morphological paradigmatic patterns and generate word forms when given known morphosyntatic features of missing paradigm cells. Noisy paradigms are automatically constructed from IGT and a language expert creates "cleaned" paradigms. Both sets are tested on the same missing word forms and the results are compared.

Here, we propose to instead make use of a resource which is much more common, especially for low-resource languages: we explore how to leverage interlinear glossed text (IGT)—a common artifact of linguistic field research—to generate unseen forms of inflectional paradigms, as illustrated in Figure 1. This task, which we call **IGT-to-paradigms** (IGT2P), differs from the ex-

November 16–20, 2020.

isting *morphological inflection* (Yarowsky and Wicentowski, 2000; Faruqui et al., 2016) task in three aspects: (1) inflected forms extracted from IGT are noisier than curated training data for morphological generation, (2) since lemmas are not explicitly identified in IGT, systems cannot be trained on typical lemma-to-form mappings and, instead, must be trained on form-to-form mappings, and (3) part-of-speech (POS) tags are often unavailable in IGT. IGT2P can thus be seen as a noisy version of morphological *re*inflection (Cotterell et al., 2016), but without explicit POS information. Our experiments show that morphological reinflection systems following preprocessing are strong baselines for this task.

We further perform two analyses:

(i) Part-of-speech (POS) tags are usually considered necessary inputs for learning morphological generation. However, they are frequently missing from IGT, since they result from a later step in a linguist's pipeline. Thus, we ask: are POS tags necessary for morphological generation? Surprisingly, we find that POS tags are of little use for morphological generation systems.

(ii) How much does manual cleaning of IGT data by a domain expert improve performance? As expected, cleaning the data improves performance across the board with a transformer model: by 1.27% to 16.32%, depending on the language.

We examine which inflection model performs better on noisy and cleaned IGT data and how the performance varies across languages and data quality or size.

2 A New Morphological Task: IGT2P

2.1 Background: Morphological Generation

An inflectional paradigm is illustrated in tables, such as Table 1. Paradigms can be large; for example, Polish verbs paradigms can have up to 30 cells and other languages may have several more. Here we define the notation related to morphological inflection systems for the remainder of this paper.

We denote the paradigm of a lemma ℓ as:

$$\pi(\ell) = \left\langle f(\ell, \vec{t}_\gamma) \right\rangle_{\gamma \in \Gamma(\ell)} \quad (1)$$

where $f : \Sigma^* \times \mathcal{T} \rightarrow \Sigma^*$ defines a mapping from a tuple consisting of the lemma and a vector $\vec{t}_\gamma \in \mathcal{T}$ of morphological features to the corresponding inflected form. Σ is an alphabet of discrete symbols, i.e., the characters used in the natural language. $\Gamma(\ell)$ is the set of slots in lemma ℓ's paradigm. We will abbreviate $f(\ell, \vec{t}_\gamma)$ as $f_\gamma(\ell)$ for simplicity. Using this notation, we now describe the most important generation tasks from the computational morphology literature.

	present		**past**	
	sing.	**pl.**	**sing.**	**pl.**
1 person	am	are	was	were
2 person	are	are	were	were
3 person	is	are	was	were

Table 1: The inflectional paradigm of the English verb "to be". This verb has more inflected forms than any other English lemma, but is quite small compared to paradigms in many other languages.

Morphological inflection. The task of morphological inflection consists of generating unknown inflected forms, given a lemma ℓ and a feature vector $\vec{t}_\gamma$. Thus, it corresponds to learning the mapping $f : \Sigma^* \times \mathcal{T} \rightarrow \Sigma^*$.

Morphological reinflection. Morphological *re*inflection is a generalized version of the previous task. Here, instead of having a lemma as input, system are given some *inflected form* $f(\ell, \vec{t}_{\gamma_1})$ – optionally together with $\vec{t}_{\gamma_1}$ – and a target feature vector $\vec{t}_{\gamma_2}$. The goal is then to produce the inflected form $f(\ell, \vec{t}_{\gamma_2})$.

Paradigm completion. The task of paradigm completion consists of, given a *partial* paradigm $\pi_P(\ell) = \left\langle f(\ell, \vec{t}_\gamma) \right\rangle_{\gamma \in \Gamma_P(\ell)}$ of a lemma ℓ, generating all inflected forms for all slots $\gamma \in \Gamma(\ell) - \Gamma_P(\ell)$. Training data for this task consists of entire paradigms.

Unsupervised morphological paradigm completion. For the *unsupervised* version of the paradigm completion task, systems are given a corpus $\mathcal{D} = w_1, \ldots, w_{|\mathcal{D}|}$ with a vocabulary V of word types $\{w_i\}$ and a lexicon $\mathcal{L} = \{\ell_j\}$ with $|\mathcal{L}|$ lemmas belonging to the same part of speech. However, no explicit paradigms are observed during training. The task of unsupervised morphological paradigm completion then consists of generating the paradigms $\{\pi(\ell)\}_{\ell \in \mathcal{L}}$ of all lemmas $\ell \in \mathcal{L}$.

2.2 IGT-to-Paradigms

The task we propose, IGT-to-paradigms (IGT2P), can be described as the paradigm completion problem above, with an additional step of inference regarding which of the attested forms is associated with which lemma.

Formally, systems are given IGTs consisting of words with – potentially empty – morphological feature vectors: $\mathcal{D} = (w_1, \vec{t_1}) \ldots, (w_{|\mathcal{D}|}, \vec{t}_{|\mathcal{D}|})$ and a list $\mathcal{U} = \{u_j\}$ with $|\mathcal{U}|$ inflected words, $u_j = f(\ell_j, \vec{t}_{\gamma_j})$. The goal of IGT2P is to generate the paradigms $\{\pi(\ell_j)\}_{f(\ell_j, \vec{t}_{\gamma_j}) \in \mathcal{U}}$.

Similar to unsupervised paradigm completion, we do not assume information about the lemma to be explicit. Similar to morphological reinflection, the input includes word forms with features, and a system has to learn to generate inflections from other word forms and morphological feature vectors. IGT2P is further similar to paradigm completion in that we aim at generating *all* inflected forms for each lemma.[2]

2.3 Why IGT2P?

Descriptive linguistics aims to objectively analyze primary language data in new languages and publish descriptions of their structure. This work informs our understanding of human language and provides resources for NLP development through academic literature, which informs projects such as UniMorph (Kirov et al., 2016), or through crowdsourced effort such as Wiktionary. Yet with most descriptive work performed manually with very little NLP assistance, language resources for thousands of under-described languages remain limited. This includes languages with millions of speakers, such as Manipuri in India.

However, there exists a type of labeled data that is available in nearly all languages where a linguist has undertaken any scientific endeavor: *interlinear glossed texts* (IGT), illustrated in Table 2. They are the output of early steps in a field linguist's pipeline which consist of recording natural speech, transcribing it, and then identifying minimal meaningful units—the morphemes—and using internally consistent tags to label the morphemes' morphosyntactic features. IGTs serve as vital sources of morphological, syntactic, and higher levels of linguistic information. They are often archived in long-term repositories, and openly accessible for non-commercial purposes, yet they are rarely utilized in NLP.

IGT2P has potential benefits for NLP (by increasing available resources in low-resource languages) but also for linguistic inquiry. First, since machine-assistance has been shown to increase speed and accuracy of manual linguistic annotation with just 60% model accuracy (Felt, 2012), such a model could assist the initial analysis of morphological patterns in IGT. Second, by quickly learning morphological patterns from word forms attested in IGT, IGT2P generates forms that fill empty cells in a lemma's paradigm. Since IGTs are unlikely to contain complete paradigms of lemmas, an accompanying step in fieldwork is that of elicitation of inflectional paradigms for selected lemmas. Presenting candidate words to a native speaker for acceptance or rejection is often easier than asking the speaker to grasp the abstract concept of a paradigm and to generate the missing cells in a table. With the help of IGT2P, linguists could use the machine-generated word forms to support this elicitation process. IGT2P then becomes a tool for the discovery of morphological patterns in under-described and endangered languages.

3 Related Work

IGT for NLP. The AGGREGATION project (Bender, 2014) has used IGT to automatically construct *grammars* for multiple languages. This includes inferring and visualizing systems of morphosyntax (Lepp et al., 2019; Wax, 2014). Much of their data comes from the Online Database of INterlinear Text (Lewis and Xia, 2010, ODIN) which is a collection of IGTs extracted from published linguistic documents on the web. Published IGT excerpts, such as those in ODIN, differ from IGTs produced by field linguists such as those used in our experiments. First, noise is generally removed from the published examples. Second, the amount of glossed information in published IGT snippets can vary widely depending on the phenomenon that is the main focus of the publication.

Computational morphology. Our work is further related to and takes inspiration from research on the tasks described in Section 2.1.

Most recent work in the area of computational morphology which was concerned with generation (as opposed to analysis) has focused on morpholog-

---

[2] We currently approximate this during evaluation, since we do not have gold standard paradigms for the languages. Also, our list $\mathcal{U}$ consists of words in $\mathcal{D}$, which we exclude from the input.

ical inflection or reinflection. Approaches include Durrett and DeNero (2013); Nicolai et al. (2015); Faruqui et al. (2016); Kann and Schütze (2016); Aharoni and Goldberg (2017). Partially building on these, other research has developed models which are more suitable for low-resource languages and perform well with limited data (Kann et al., 2017b; Sharma et al., 2018; Makarov and Clematide, 2018; Wu and Cotterell, 2019; Kann et al., 2020a; Wu et al., 2020). These are the most relevant approaches for our work, since we expect IGT2P to aid documentation of low-resource languages. Accordingly, we use the systems by Wu and Cotterell (2019) and Wu et al. (2020) in our experiments.

Work on paradigm completion – or the *paradigm cell filling problem* (PCFP; Ackerman et al., 2009) – includes Malouf (2016), who trained recurrent neural networks for it, and applied them successfully to Irish, Maltese, and Khaling, among other languages. Silfverberg and Hulden (2018) also trained neural networks for the task. Kann et al. (2017a) differed from other approaches in that they encoded multiple inflected forms of a lemma to provide complementary information for the generation of unknown forms of the same lemma. Finally, Cotterell et al. (2017b) introduced neural graphical models which completed paradigms based on principal parts. The unsupervised version of the paradigm completion task (Jin et al., 2020) has been the subject of a recent shared task (Kann et al., 2020b), with the conclusion that it is exremely challenging for current state-of-the-art systems. Here, we propose to, instead of generating paradigms from raw text, generate them from IGT, a resource available for many under-studied languages.

4 To POS Tag or Not to POS Tag

In addition to the lemma and the morphological features of the target form, part-of-speech (POS) tags are by default a part of the input to neural morphological reinflection systems. POS tags are assumed to carry valuable information, since, for example, morphemes that are otherwise identical (e.g. "seat") may use one set of inflectional morphemes as nouns (e.g. "many seats") and another as verbs ("be seated").

Since POS tags are typically annotated at a later stage than morpheme boundaries and glosses, IGTs often do not contain POS tags for all words. This makes large parts of the IGT unusable for state-of-the-art reinflection systems if POS tags are assumed necessary. However, the assumption that POS tags improve morphological generation performance has never been empirically verified for recent state-of-the-art systems. We hypothesize that, in fact, POS tags might not be necessary, since they might be implicitly defined by either the morphological features or the input word form. Thus, we ask the following research question: *Are POS tags a necessary or beneficial input to a morphological reinflection system?*

4.1 Experimental Setup

To answer this question, we train morphological reinflection systems twice on 10 languages that have been released for the CoNLL-SIGMORPHON 2018 shared task (Cotterell et al., 2018), once with and once without POS tags as input. In order to obtain generalizable results, our selected languages belong to different families and are typologically diverse with regards to morphology, as shown in Table 3.[3] We kept the original training/validation/test splits, and experiment on the three training set sizes: 10,000, 1000, and 100 examples for the *high*, *medium*, and *low* setting, respectively.

4.2 Models

We experiment with two state-of-the-art neural models for morphology learning: the transformer model for character-level transduction (Wu et al., 2020) and the LSTM sequence-to-sequence model with exact hard monotonic attention for character-

---

[3] The language family and morphological typology for each language is on the UniMorph official website (`https://unimorph.github.io`).

Language	POS	transformer model (%)			Exact hard mono model (%)		
		high Δ	medium Δ	low Δ	high Δ	medium Δ	low Δ
Adyghe	N, ADJ	0.0	-0.3	1.7	0.2	-0.3	-0.5
Arabic	N, V, ADJ	-0.1	0.0	-0.5	-0.5	1.2	0.0
Basque	V	-0.2	0.0	-2.8	-0.3	2.1	-0.4
Finnish	N, V, ADJ	0.6	-0.5	0.2	-0.7	4.4	0.0
German	N, V	0.6	-0.6	-1.6	-0.1	0.0	-0.7
Persian	V	0.0	-1.5	-0.2	-0.3	-0.9	1.2
Russian	N, V, ADJ	0.1	1.3	-0.4	0.0	-0.6	-0.9
Spanish	N, V	-0.1	0.9	0.7	1.0	4.2	-0.3
Swahili	N, V, ADJ	0.0	0.0	0.0	0.0	3	1.0
Turkish	N, V, ADJ	-0.2	0.0	1.5	0.2	3.2	-0.1

Table 3: SIGMORPHON languages, their inflected parts of speech used to test the helpfulness of POS tags to neural reinflection tasks, and the difference in accuracy (%) between using and not using POS for the transformer model and the LSTM seq2seq model with exact hard monotonic attention in different training data size settings. Negative scores means that removing POS tags decreased performance.

level transduction (Wu and Cotterell, 2019).[4]

4.3 Results

Table 3 illustrates the performance difference when including and not including POS tags for all three training data sizes. The largest difference is a decrease of 4.4 percentage points when POS tags are removed for Finnish at the medium setting using hard monotonic attention. The average difference is about 0.2 percentage points. We therefore conclude that a lack of POS tags does not make a significant difference in the reinflection task.

5 IGT2P

5.1 Language data

We used IGTs that were primarily transcribed from naturally-occurring oral speech in low-resource and endangered languages. They represent a wide range of projects, which is reflected in the size and quality of the data. The amount of usable data (i.e. glossed words) ranges from approximately 90,000 tokens in Arapaho to about 5,000 in Manipuri. The five languages (see Table 4) are spoken by communities across five continents. They represent different language families and morphological complexity, though all are agglutinating to some degree. Other than the IGT, there is very limited resources for these languages.

Language	ISO	Family	Tokens
Arapaho	arp	Algonquian	90k
Lezgi	lez	Nakh-Daghestanian	18.7k
Manipuri	mni	Tibeto-Burman	5k
Natügu	ntu	Austronesian	14k
Tsez	ddo	Nakh-Daghestanian	53k

Table 4: Languages with IGT used in this experiment, their ISO 639-3 identifying codes, and the approximate number of tokens in the database that are interlinearized (i.e. segmented into morphemes and glossed).

5.2 Issues specific to IGT

The most notable issue with IGT is the "noise". An inevitable cause is the dynamic nature of ongoing linguistic analysis. As the linguist gains a better understanding of the language's structure by doing interlinearization, early decisions about morpheme shapes and glosses differ from later ones. Another cause is that limited budget and time means IGT are often only partially completed. Another source of noise comes when the project is focused on annotating one particular phenomenon. For example, frequently only one morphosyntactic feature in Manipuri was glossed in each word, meaning different inflected forms looked like they had the same morphosyntactic features. Another source of noise is imprecision introduced by human errors or choices made for convenience to speed tedious annotation. One example of imprecision is glossing different stem morphemes with the same English word. For example, Lezgi has several copula verbs which can

---

[4] It is theoretically possible that the other baselines can outperform these models once we limit our experiments to words with POS information. However, based on our preliminary experiments using POS tags, this seems unlikely.

Figure 2: Lezgi paradigms were automatically constructed from IGT (left columns) and have typos or incorrect paradigms clusters. Experts filtered or corrected these issues, resulting in “clean” paradigms (middle). These can be compared with the published description (right column) which includes historic forms that are rarely used today.

be narrowly translated as ‘be in’, ‘be at’, etc., but most were merely glossed as ‘be’. So all copula verbs were initially grouped into one paradigm. A similar situation happened with Arapaho: nuances of meaning were not often distinguished in the glosses; thus, different verb stems are glossed simply as ‘give’, when, in reality they should be divided into ‘hand to someone’ in one case, ‘give as a present’ in another case, and ‘give ceremonially, as an honor’ in third case.

Another issue is that IGT annotators do not usually differentiate between different types of morphemes. Thus, we do not always distinguish between them. Derivational and inflectional morphemes were only differentiated where we were able to easily identify and eliminate derivational glosses. For example, in Arapaho we were able to group derived stems into separate paradigms because they were glossed distinctly. Also, clitics are often not distinguished from affixes. This means that the morphological patterns that the models learn are not always, strictly speaking, inflectional paradigms, but it does mean that the models learn all attested forms related one lemma.

5.3 Approach

As a first step, partial inflectional paradigms were automatically extracted from the IGT. Words were organized into paradigms based on the gloss of the stem morpheme. Then, these stem glosses were removed, leaving only the affix glosses which serve as morphosyntactic feature tags.

Step 1: Preprocessing paradigms. The automatically extracted paradigms were preprocessed in two ways. The resulting data is publicly available.[5] In the first preprocessing method, a language domain expert was asked to “clean” the automatically extracted paradigms. Example results are in shown Figure 2. Experts reorganized words into correct inflectional paradigms, for example, by regrouping Lezgi copula verbs. They also completed missing morphosyntatic information; for example, adding PL (plural) or SG (singular) where the nouns were otherwise glossed identically. Finally, they removed any words that are not inflected in the language. This usually included words that are morphologically derived from another part of speech but not inflected. For example, an affix might derive an adverb from a noun root, and if the adverbializing affix was glossed, then the word form would have been extracted automatically, resulting in more noise since it displays derivational morphology and no inflectional morphology. Experts were asked to spend no more than six hours on the cleaning task.

For the second preprocessing method, the automatically extracted paradigms were surveyed by a non-expert. Since non-experts could not be expected to identify and correct most issues, they simply removed obvious mistakes such as glosses of stem morphemes that were misidentified as affix glosses and word forms with obviously incomplete glosses or ambiguous glosses (due to identi-

Table 5: Data sizes for noisy extracted paradigms and paradigms cleaned by experts. The columns show the total number of inflectional paradigms extracted from the IGT, the number of paradigms with only a single word entry, the number of three-tuples (source, target, features) in the train/validation/test sets before adding unannotated forms and finally the number of additional unannotated/uninflected word forms.

cal glosses on one or more word forms). For some languages, this cleaning-by-removal made these paradigms smaller than the "cleaned" dataset.

Step 2: Preparing reinflection data. The typical morphological reinflection data is in tuple format of `(source form, target form, target features)`. We convert the paradigm data into this format in preparation for reinflection. Table 5 presents the data sizes.

For each language, we prepare the validation and test sets by using the the expert-cleaned data language in the following way: If the paradigm has more than one form, pick a random form as the source form and select the remaining forms in the paradigm with a probability of 0.3 to be "unknown", i.e. to be predicted from the first form. Half of the "unknown" data transformed in this way is used for validation and the other half for testing. The validation and test sets for each language is shared across all the experiments we conduct for that language.

To prepare the training data from the noisy and clean paradigms, we first map each form in the data to itself and add them to the training data. Paradigms with a single entry have only self-to-self mapping. If a paradigm has more than one form, all possible pairs of forms in a paradigm are generated and added to the training data, excluding those that are part of testing or validation set, i.e. "unknown".

Step 3: Reinflection models and experimental setup. We experiment with two state-of-the-art models for morphological reinflection, the transformer model for character-level transduction (Wu et al., 2020) and the LSTM sequence-to-sequence model with exact hard monotonic attention for character-level transduction (Wu and Cotterell, 2019). For all the models, we used the implementation of the SIGMORPHON 2020 shared task 0 baseline (Vylomova et al., 2020),[6] and our hyperparameters are the same as the shared task baseline.

After paradigms are extracted and preprocessed, we conduct two experiments to generate "unknown" inflected forms. We then expand those experiments by two data augmentation techniques. First, we add all unannotated/uninflected words from the IGT data to the training data. When tokens that were either unannotated or uninflected are added, they are self-mapped as the source and target forms (as we do with single-entry paradigms), and their morphosyntactic features are annotated with a special tag: `XXXX`. Second, we augment the training data by generating 10,000 artificial instances with the implementation in the SIGMORPHON 2020 shared task 0 baseline of the data hallucination method proposed by (Anastasopoulos and Neubig, 2019). Finally, we combine both additions. These augmentations are intended to overcome data scarcity.

All models and techniques were tested on the same held-out set chosen randomly from multi-

entry paradigms in each language.

5.4 Results

We compared results when training on the noisy paradigms and on the expertly cleaned paradigms and found that the limited involvement of experts always improved results. We also found the transformer outperformed the LSTM with hard monotonic attention on cleaned data in all instances and on noisy data overall. When comparing results from augmenting the data by artificial and uninflected/unannotated tokens, we find varied results. The results are displayed in Table 6.

There is no clear correlation between accuracy and the total number of annotated tokens or training paradigms (see Tables 4 and 5). Tsez and Arapaho [arp] achieved over 60% accuracy and these languages do have more training data (35K and 283K triples, respectively) than the others (less than 10K). However, even though Arapaho has considerably more training data, its accuracy is lower than Tsez. A slight correlation between accuracy and amount of multi-entry paradigms does exist. Languages with a higher proportion of multi-entry paradigms tend to have better results. Fewer single-entry paradigms may indicate more complete paradigm information.

Any correlation between results and linguistic factors such as language family or morphological type is uncertain because of the limited number of testing languages. Tsez [ddo] gave best results overall. This could be due to its limited allomorphy and very regular inflection which may explain why its relative Lezgi [lez] perform better than languages with more data. Arapaho's poorer performance could be due to its polysynthetic morphology (Cowell and Moss, 2008) which is more complex than the fairly straightforward agglutination in Tsez (Job, 1994) and Lezgi (Haspelmath, 1993). The models do seem less sensitive in recognizing the word structure in Arapaho. When the front part of a stem is incidentally the same as a common inflection affix, the stem is often generated incorrectly.

The factor that seems most clearly correlated with accuracy is the consistency and thoroughness of IGT annotations. The Arapaho, Tsez, and Natügu [ntu] corpora were noticeably more complete (i.e. most morphemes were glossed) and polished. This probably explains why Tsez not only had the best results but also showed the smallest improvements after cleaning. Interestingly, augmentation techniques also helped these languages the least (only artificial data augmentation helped Tsez slightly). It seems, therefore, that results are highest and data augmentation is most helpful when original manual annotations are least consistent or complete.

As might be expected with limited data, errors were most common with irregular or rare forms. For example, the best performing model incorrectly inflected many Lezgi pronouns which have an inflection pattern identical to nouns except for a unpredictable change in the stem vowel. Perhaps related to this, the model also misidentified some epenthetic vowels in several Lezgi nouns. Another interesting pattern involved unique Nakh-Daghestanian (Tsez and Lezgi) case-stacking, where nominal affixes concatenate, rather than substitute each other, to form several peripheral cases such as SUPERELATIVE or POSTDIRECTIVE. The more common affixes in the concatenation string were often generated correctly but the less common concatenated affixes were not. Allomorphy also causes difficulty. Models struggle generating the right form when multiple forms are possible. For example, in Arapaho the third person singular inflection has variations (e.g. -oo, -o, or -'). On the other hand, models learned regular inflectional patterns well enough to correctly inflect forms even where the expert had left misspellings of that form in the clean data.

Finally, we clearly see expert cleaning improved performance across the board (with two negligible exceptions for Tsez and Lezgi on the hard monotonic attention model). Experts were asked to spend no more than six hours and actually spent up to seven but as little as two hours on each language. This indicates that expert labor is well worth its "cost".

6 Conclusion

We proposed a new morphological generation task called IGT2P, which aims to learn inflectional paradigmatic patterns from interlinear gloss texts (IGT) produced in linguistics fieldwork. We experimented with neural models that have been used for morphological reinflection and new preprocessing steps as baselines for the task. Our experiments show that IGT2P is a promising method for creating new morphological resources in a wide range of low-resource languages.

Table 6: Accuracy percentages of reinflection task for transformer model (T) and the LSTM seq2seq model with exact hard monotonic attention (mono) with/out artificial data augmention (+aug), unannotated/uninflected word forms (+uninfl) and both together. Boldface indicates best result; italics indicate best result on noisy paradigms.

With sufficient IGT annotations, IGT2P obtains reasonable performance from noisy data. We investigated the effect of manual cleaning on model performance and showed that even very limited cleaning effort (2-7 hours) drastically improves results. The inherent noisiness in IGT and other linguistic field data can be overcome with limited input from domain experts. This is a significant contribution considering the extensive effort—on the order of months and years—to produce the curated structured data normally used to train NLP models. In languages with the noisiest data performance is improved even further by data augmentation techniques. Finally, since field data does not often include POS annotation, we investigated the usefulness of POS tags for morphological reinflection and find that, surprisingly and in contrast to common assumptions, they are not beneficial to recent state-of-the-art systems. This is a useful discovery for researchers who wish to optimize their inflection systems.

There is room for future improvement. Better techniques for further cleaning might be useful since accuracy seems to have close related to data quality. However, at some point more cleaning will return less improvement. Upper bounds could be established by comparing results on languages with gold standard inflection tables, although polysynthetic languages like Arapaho would make this difficult since their tables do not always include noun incorporation. Better use of experts' time might involve identification of lemmata that could be used to train a lemma-to-form model, rather than the form-to-form mapping used here. Another approach would be to compare improvements between manual-only cleaning and cleaning done by a linguist working with someone who can write scripts to automatically correct repeated patterns of noise.

IGT2P also has implications for the documentation of endangered languages and addressing digital inequity of speakers of marginalized languages. It could be integrated into linguists' workflow in order to improve the study of inflection and increase IGT data. For example, the generated inflected forms could be used for automated glossing of raw text. IGT2P could speed the discovery and description of a language's entire morphological structure. An elicitation step with native speakers could be added to strategically augment data. This would integrate well with linguists' workflow. IGT2P results could serve as to prompt speakers for forms that are rare in natural speech. It might also be integrated into linguistic software such as FLEx.

Acknowledgments

We are obliged to Drs. Brenda Boerger, Shobhana Chelliah, Bernard Comrie, and Andy Cowell, as well as Chuck Donet, and Andrew Brumleve for generously sharing their field data and to Mary Burke, Drs. Boerger and Cowell, and Andrew Brumleve who did expert cleaning of the data. Also, to anonymous reviewers for their insightful comments.

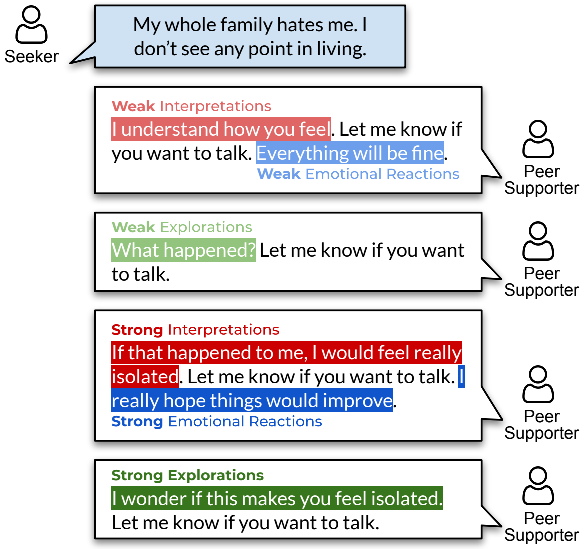
Abstract

Empathy is critical to successful mental health support. Empathy measurement has predominantly occurred in synchronous, face-to-face settings, and may not translate to asynchronous, text-based contexts. Because millions of people use text-based platforms for mental health support, understanding empathy in these contexts is crucial. In this work, we present a computational approach to understanding how empathy is expressed in online mental health platforms. We develop a novel unifying theoretically-grounded framework for characterizing the communication of empathy in text-based conversations. We collect and share a corpus of 10k (post, response) pairs annotated using this empathy framework with supporting evidence for annotations (rationales). We develop a multi-task RoBERTa-based bi-encoder model for identifying empathy in conversations and extracting rationales underlying its predictions. Experiments demonstrate that our approach can effectively identify empathic conversations. We further apply this model to analyze 235k mental health interactions and show that users do not self-learn empathy over time, revealing opportunities for empathy training and feedback.

1 Introduction

Approximately 20% of people worldwide are suffering from a mental health disorder (Holmes et al., 2018). Still, access to mental health care remains a global challenge with widespread shortages of workforce (Olfson, 2016). Facing limited in-person treatment options and other barriers like stigma (White and Dorman, 2001), millions of people are turning to text-based peer support platforms such as TalkLife (`talklife.co`) to express emotions, share stigmatized experiences, and receive peer support (Eysenbach et al., 2004). However, while peer supporters on these platforms are motivated and well-intentioned to help others seeking support (henceforth *seeker*), they are untrained and typically unaware of best-practices in therapy.



My whole family hates me. I don't see any point in living.

I understand how you feel. Let me know if you want to talk. Everything will be fine.

What happened? Let me know if you want to talk.

If that happened to me, I would feel really isolated. Let me know if you want to talk. I really hope things would improve.

I wonder if this makes you feel isolated. Let me know if you want to talk.

Figure 1: Our framework of empathic conversations contains three empathy communication mechanisms – *Emotional Reactions*, *Interpretations*, and *Explorations*. We differentiate between no communication, weak communication, and strong communication of these factors. Our computational approach simultaneously identifies these mechanisms and the underlying rationale phrases (highlighted portions). *All examples in this paper have been anonymized using best practices in privacy and security (Matthews et al., 2017).*

In therapy, interacting empathically with seekers is fundamental to success (Bohart et al., 2002; Elliott et al., 2018). The lack of training or feedback to layperson peer supporters results in missed opportunities to offer empathic textual responses. NLP systems that understand conversational empathy could empower peer supporters with feedback and training. However, the current understanding of empathy is limited to traditional face-to-face, speech-based therapy (Gibson et al., 2016; Pérez-Rosas et al., 2017) due to lack of resources and methods for new asynchronous, text-based inter-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5263–5276,
November 16–20, 2020.

actions (Patel et al., 2019). Also, while previous NLP research has focused predominantly on empathy as reacting with emotions of warmth and compassion (Buechel et al., 2018), a separate but key aspect of empathy is to communicate a cognitive understanding of others (Selman, 1980).

In this work, we present a novel computational approach to understanding how empathy is expressed in text-based, asynchronous mental health conversations. We introduce EPITOME,[1] a conceptual framework for characterizing communication of empathy in conversations that synthesizes and adapts the most prominent empathy scales from speech-based, face-to-face contexts to text-based, asynchronous contexts (§3). EPITOME consists of three communication mechanisms of empathy: *Emotional Reactions*, *Interpretations*, and *Explorations* (Fig. 1).

To facilitate computational modeling of empathy in text, we create a new corpus based on EPITOME. We collect annotations on a dataset of 10k (post, response) pairs from extensively-trained crowdworkers with high inter-rater reliability (§4).[2] We develop a RoBERTa-based bi-encoder model for identifying empathy communication mechanisms in conversations (§5). Our multi-task model simultaneously extracts the underlying supportive evidences, *rationales* (DeYoung et al., 2020), for its predictions (spans of input post; e.g., highlighted portions in Fig. 1) which serve the dual role of (1) explaining the model's decisions, thus minimizing the risk of deploying harmful technologies in sensitive contexts, and (2) enabling rationale-augmented feedback for peer supporters.

We show that our computational approach can effectively identify empathic conversations with underlying rationales ($\sim$80% acc., $\sim$70% macro-f1) and outperforms popular NLP baselines with a 4-point gain in macro-f1 (§6). We apply our model to a dataset of 235k supportive conversations on TalkLife and demonstrate that empathy is associated with positive feedback from seekers and the forming of relationships. Importantly, our results suggest that most peer supporters do not self-learn empathy with time. This points to critical opportunities for training and feedback for peer supporters to increase the effectiveness of mental health support (Miner et al., 2019; Imel et al., 2015). Specifically, NLP-based tools could give actionable, real-time feedback to improve expressed empathy, and we demonstrate this idea in a small-scale proof-of-concept (§7).

2 Background

2.1 How to measure empathy?

Empathy is a complex multi-dimensional construct with two broad aspects related to emotion and cognition (Davis et al., 1980). The "emotion" aspect relates to the emotional stimulation in reaction to the experiences and feelings expressed by a user. The "cognition" aspect is a more deliberate process of understanding and interpreting the experiences and feelings of the user and communicating that understanding to them (Elliott et al., 2018).

Here, we study *expressed empathy* in text-based mental health support – empathy *expressed* or *communicated* by peer supporters in their textual interactions with seekers (cf. Barrett-Lennard (1981)).[3] Table 1 lists existing empathy scales in psychology and psychotherapy research. Truax and Carkhuff (1967) focus only on communicating cognitive understanding of others while Davis et al. (1980); Watson et al. (2002) also make use of expressing stimulated emotions.

These scales, however, have been designed for in-person interactions and face-to-face therapy, often leveraging audio-visual signals like expressive voice. In contrast, in text-based support, empathy must be expressed using textual response alone. Also, they are designed to operate on long, synchronous conversations and are unsuited for the shorter, asynchronous conversations of our context.

In this work, we adapt these scales to text-based, asynchronous support. We develop a new comprehensive framework for text-based, asynchronous conversations (Table 1; §3), use it to create a new dataset of empathic conversations (§4), a computational approach for identifying empathy (§5; §6), & gaining insights into mental health platforms (§7).

2.2 Computational Approaches for Empathy

Computational research on empathy is based on speech-based settings, exploiting audio signals

[2] Our dataset can be accessed from `https://bit.ly/2Rwy2gx`.

[3] Note that *expressed* empathy may differ from the empathy *perceived* by seekers. However, obtaining perceived empathy ratings from seekers is challenging in sensitive contexts and involves ethical risks. Psychotherapy research indicates a strong correlation of expressed empathy with positive outcomes and frequently uses it as a credible alternative (Robert et al., 2011).

		Context	Applicable to text-based peer-support	Communication Mechanisms		
				Emotional Reactions	Interpretations *(Cognitive)*	Explorations *(Cognitive)*
Scales	Truax and Carkhuff (1967)	Face-to-face therapy	✗	✗	✓	✓

	EPITOME	Text-based, asynchronous support	✓	✓	✓	✓

Table 1: EPITOME incorporates both emotional and cognitive aspects of empathy that were previously only studied in face-to-face therapy and never computationally in text-based, asynchronous conversations. *Rashkin et al. (2019) implicitly enable empathic conversations through grounding in emotions instead of communication.

like pitch which are unavailable in text-based platforms (Gibson et al., 2016; Pérez-Rosas et al., 2017). Moreover, previous NLP research has predominantly focused on empathy as reacting with emotions of warmth and compassion (Buechel et al., 2018). For mental health support, however, communicating cognitive understanding of feelings and experiences of others is more valued (Selman, 1980). Recent work also suggests that grounding conversations in emotions implicitly makes them empathic (Rashkin et al., 2019). Research in therapy, however, highlights the importance of expressing empathy in interactions (Truax and Carkhuff, 1967). In this work, we present a computational approach to (1) understanding empathy expressed in textual, asynchronous conversations; (2) address both emotional and cognitive aspects of empathy.

3 Framework of Expressed Empathy

To understand empathy in text-based, asynchronous, peer-to-peer support conversations, we develop EPITOME, a new conceptual framework of expressed empathy (Fig. 1). In close collaboration with clinical psychologists, we adapt and synthesize existing empathy definitions and scales to text-based, asynchronous context. EPITOME consists of three communication mechanisms providing a comprehensive outlook of empathy – *Emotional Reactions*, *Interpretations*, and *Explorations*. For each of these mechanisms, we differentiate between – (0) peers not expressing them at all (*no communication*), (1) peers expressing them to some weak degree (*weak communication*), (2) peers expressing them strongly (*strong communication*).

Here, we describe our framework in detail using the following seeker post as context for all example responses: *I am about to have an anxiety attack.*

Emotional Reactions. Expressing emotions such as warmth, compassion, and concern, experienced by peer supporter after reading seeker's post. Expressing these emotions plays an important role in establishing empathic rapport and support (Robert et al., 2011). A **weak communication** of emotional reactions alludes to these emotions without the emotions being explicitly labeled (e.g., *Everything will be fine*). On the other hand, **strong communication** specifies the experienced emotions (e.g., *I feel really sad for you*).

Interpretations. Communicating an understanding of feelings and experiences inferred from the seeker's post. Such a cognitive understanding in responses is helpful in increasing awareness of hidden feelings and experiences, and essential for developing alliance between the seeker and peer supporter (Watson, 2007). A **weak communication** of interpretations contains a mention of the understanding (e.g., *I understand how you feel*) while a **strong communication** specifies the inferred feeling or experience (e.g., *This must be terrifying*) or communicates understanding through descriptions of similar experiences (e.g., *I also have anxiety attacks at times which makes me really terrified*).

Explorations. Improving understanding of the seeker by exploring the feelings and experiences not stated in the post. Showing an active interest in what the seeker is experiencing and feeling and probing gently is another important aspect of empathy (Miller et al., 2003; Robert et al., 2011). A **weak exploration** is generic (e.g., *What happened?*) while a **strong exploration** is specific and labels the seeker's experiences and feelings which the peer supporter wants to explore (e.g., *Are you feeling alone right now?*).

Consistent with existing scales, responses that only give advice (*Try talking to friends*), only provide factual information (*mindful meditation overcomes anxiety*), or are offensive or abusive (*shut the f**k up*)[4] are not empathic and are characterized as no communication of empathy in our framework.

4 Data Collection

To facilitate computational methods for empathy, we collect data based on EPITOME.

4.1 Data Source

We use conversations on the following two online support platforms as our data source:

(1) TalkLife. TalkLife (`talklife.co`) is the largest global peer-to-peer mental health support network (`talklife.co/about`). It enables seekers to have textual interactions with peer supporters through conversational threads. The dataset contains 6.4M threads and 18M interactions (seeker post, response post pairs) on TalkLife between May 2012 to Jan 2019.

(2) Mental Health Subreddits. Reddit (`reddit.com`) hosts a number of sub-communities aka *subreddits* (e.g., *r/depression*). We use threads posted on 55 mental health focused subreddits (Sharma et al. (2018)). This publicly accessible dataset contains 1.6M threads and 8M interactions on Reddit between Jan 2015 to Jan 2019.

We use the entire dataset for in-domain pre-training (§5) and annotate a subset of 10k interactions on empathy. We further analyze empathy on a carefully filtered dataset of 235k mental health interactions on TalkLife (§7).

4.2 Annotation Task and Process

Empathy is conceptually nuanced and linguistically diverse so annotating it accurately is difficult in short-term crowdwork approaches. This is also reflected in prior work that found it challenging to annotate therapeutic constructs (Lee et al., 2019). To ensure high inter-rater reliability, we designed a novel training-based annotation process.

Crowdworkers Recruiting and Training. We recruited and trained eight crowdworkers on identifying empathy mechanisms in EPITOME. We leveraged Upwork (`upwork.com`), a freelancing platform that allowed us to hire and work interactively with crowdworkers. Each crowdworker was trained through a series of phone calls (30 minutes to 1 hour in total) and manual/automated feedback on 50-100 posts. Refer Appendix A for more details.

	Data Source	No	Weak	Strong	Total
Emotional Reactions	TalkLife	3656	2945	461	7062
	Reddit	2034	899	148	3081
Interpretations	TalkLife	5533	178	1351	7062
	Reddit	1645	115	1321	3081
Explorations	TalkLife	5137	767	1158	7062
	Reddit	2600	104	377	3081

Table 2: Statistics of the collected empathy dataset. The crowdworkers were trained on EPITOME through a series of phone calls and manual/automated feedback on sample posts to ensure high quality annotations.

Annotating Empathy. In our annotation task, crowdworkers were shown a pair of (seeker post, response post) and were asked to identify the presence of the three communication mechanisms in EPITOME (Emotional Reactions, Interpretations, and Explorations), one at a time. For each mechanism, crowdworkers annotated whether the response post contained no communication, weak communication, or strong communication of empathy in the context of the seeker post.

Highlighting Rationales. Along with the categorical annotations, crowdworkers were also asked to highlight portions of the response post that formed rationale behind their annotation. E.g, in the post "*That must be terrible! I'm here for you*", the portion "*That must be terrible*" is the rationale for it being a strong communication of interpretations.

Data Quality. Overall, our corpus has an average inter-annotator agreement of 0.6865 (average over pairwise Cohen's κ of all pairs of crowdworkers; each pair annotated $>$50 posts in common) which is higher than previously reported values for the annotation of empathy in face-to-face therapy ($\sim$0.60 in Pérez-Rosas et al., 2017; Lord et al., 2015).[5] Our ground-truth corpus contains 10,143 (seeker post, response post) pairs with annotated empathy labels from trained crowdworkers (Table 2).

Privacy and Ethics. The TalkLife dataset was sourced with license and consent from the TalkLife platform. All personally identifiable information (user and platform identifiers) in both the datasets were removed. This study was approved by University of Washington's Institutional Review Board.

---

[4] Our approach is focused on supporting peers who are trying to help seekers. This is different from toxic language identification tasks. Such content can be independently flagged using existing techniques (e.g., `perspectiveapi.com`)

[5] We achieve an inter-annotator agreement of 0.69 for emotional reactions, 0.61 for interpretations, and 0.76 for explorations.

In addition, we tried to minimize the risks of annotating mental health related content by providing crisis management resources to our annotators, following Sap et al. (2020). This work does not make any treatment recommendations or diagnostic claims.

5 Model

With our collected dataset, we develop a computational approach for understanding empathy.

5.1 Problem Definition

Let $\mathbf{S}_i = s_{i1}, ..., s_{im}$ be a seeker post and $\mathbf{R}_i = r_{i1}, ..., r_{in}$ be a corresponding response post. For the pair $(\mathbf{S}_i, \mathbf{R}_i)$, we want to perform two tasks:

Task 1: Empathy Identification. Identify how empathic $\mathbf{R}_i$ is in the context of $\mathbf{S}_i$. For each of the three communication mechanisms in EPITOME (Emotional Reactions, Interpretations, Explorations), we want to identify their level of communication (l_i) in $\mathbf{R}_i$ – no communication (0), weak communication (1), or strong communication (2).

Task 2: Rationale Extraction. Extract rationales underlying the identified level $l_i \in \{$no, weak, strong$\}$ of each of the three communication mechanism in EPITOME. The extracted rationale is a subsequence of words x_i in $\mathbf{R}_i$. We represent this subsequence as a mask $m_i = (m_{i1}, ..., m_{in})$ over the words in $\mathbf{R}_i$, where $m_{ij} \in \{0, 1\}$ is a boolean variable: 1 – rationale word; 0 – non-rationale word. Correspondingly, $x_i = m_i \odot \mathbf{R}_i$.

5.2 Bi-Encoder Model with Attention

We propose a multi-task bi-encoder model based on RoBERTa (Liu et al., 2019) for identifying empathy and extracting rationales (Fig. 2). We multi-task over the two tasks of empathy identification and rationale extraction and train three independent but identical architectures for the three empathy communication mechanisms in EPITOME (§3). The bi-encoder architecture (Humeau et al., 2019) facilitates a joint modeling of $(\mathbf{S}_i, \mathbf{R}_i)$ pairs. Moreover, the use of attention helps in providing context from the seeker post, $\mathbf{S}_i$. We find that such an approach is more effective than methods that concatenate $\mathbf{S}_i$ with $\mathbf{R}_i$ with a `[SEP]` token to form a single input sequence (§6).

Two Encoders. Our model uses two independently pre-trained transformer encoders from RoBERTa$_{\text{BASE}}$ – S-Encoder & R-Encoder – for encoding seeker post and response post respectively.

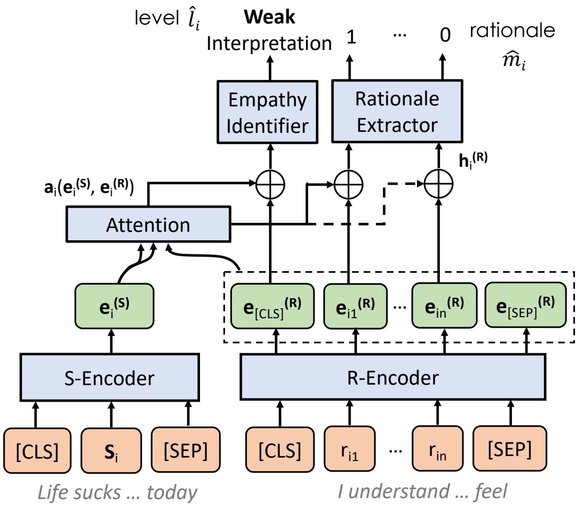

Figure 2: We use two independently pre-trained RoBERTa-based encoders for encoding seeker post and response post respectively. We leverage attention between them for generating seeker-context aware representation of the response post, used to perform the two tasks of empathy identification and rationale extraction.

S-Encoder encodes context from the seeker post whereas R-Encoder is responsible for understanding empathy in the response post.

$$\mathbf{e}_i^{(\mathbf{S})} = \text{S-Encoder}(\texttt{[CLS]}, \mathbf{S}_i, \texttt{[SEP]}) \quad (1)$$

$$\mathbf{e}_i^{(\mathbf{R})} = \text{R-Encoder}(\texttt{[CLS]}, \mathbf{R}_i, \texttt{[SEP]}) \quad (2)$$

where `[CLS]` and `[SEP]` are special start and end tokens adapted from BERT (Devlin et al., 2019).

Domain-Adaptive Pre-training. Both the S-Encoder and R-Encoder are initialized using the weights learned by RoBERTa$_{\text{BASE}}$. We further perform a domain-adaptive pre-training (Gururangan et al., 2020) of the two encoders to adapt to conversational and mental health context. For this additional pre-training of the two encoders, we use the datasets of 6.4M seeker posts (182M tokens) and 18M response (279M tokens) posts respectively sourced from TalkLife (§4). We use the masked language modeling task for pre-training (3 epochs, batch size = 8).

Attention Layer. We use a single-head attention over the two encodings for generating seeker-context aware representation of the response post. Using the terminology of transformers (Vaswani et al., 2017), our query is the response post encoding $\mathbf{e}_i^{(\mathbf{R})}$, and the keys and the values are the seeker post encoding $\mathbf{e}_i^{(\mathbf{S})}$. Our attention is computed as:

$$\mathbf{a}_i(\mathbf{e}_i^{(\mathbf{R})}, \mathbf{e}_i^{(\mathbf{S})}) = \text{softmax}\left(\frac{\mathbf{e}_i^{(\mathbf{R})} \mathbf{e}_i^{(\mathbf{S})}}{\sqrt{d}}\right) \mathbf{e}_i^{(\mathbf{S})} \quad (3)$$

Table 4: Rationale extraction task results. We evaluate both at the level of tokens (T-f1) and spans (IOU-f1).

where $d = 768$ (hidden size in RoBERTa$_{\text{BASE}}$). We sum the encoded response $\mathbf{e}_i^{(\mathbf{R})}$ with its representation transformed through attention $\mathbf{a}_i(\mathbf{e}_i^{(\mathbf{R})}, \mathbf{e}_i^{(\mathbf{S})})$ to obtain a residual mapping (He et al., 2016) – $\mathbf{h}_i^{(\mathbf{R})}$, which forms the final seeker-context aware representation of the response post.

Empathy Identification. For the task of identifying empathy, we use the final representation of the `[CLS]` token in the response post ($\mathbf{h}_i^{(\mathbf{R})}$`[[CLS]]`) and pass it through a linear layer to get the predictions of the empathy level $\hat{l_i}$ (0, 1, or 2) of each empathy communication mechanism. Note that we train three independent models for the three communication mechanisms in EPITOME (§3).

Extracting Rationales. For extracting rationales y_i underlying the predictions, we use final representations of the individual tokens in $\mathbf{R}_i$ ($\mathbf{h}_i^{(\mathbf{R})}[r_{i1}, ..., r_{in}]$) and pass them through a linear layer for making boolean predictions, $\hat{m_i}$.

Loss Function. We use cross-entropy between the true and predicted labels as the loss functions of our two tasks. The overall loss of our multi-task architecture is: $\mathcal{L} = \lambda_{\mathbf{EI}} * \mathcal{L}_{\mathbf{EI}} + \lambda_{\mathbf{RE}} * \mathcal{L}_{\mathbf{RE}}$.

Experimental Setup. We split both datasets into train, dev, and test sets (75:5:20). We train our model for 4 epochs using a learning rate of $2\text{e}{-5}$, batch size of 32, $\lambda_{\mathbf{EI}} = 1$, and $\lambda_{\mathbf{RE}} = 0.5$ (Refer Appendix B for fine-tuning details).

6 Results

Next, we analyze how effectively we can identify empathy with underlying rationales using our computational approach.

6.1 Overall Results

We compare the performance of our approach with a range of models popularly used in related tasks (e.g., sentiment classification, conversation analysis). We quantify how challenging identifying empathy with underlying rationales is, how well do existing models perform, and what performance is achieved by our proposed approach.

Baselines. Our baselines are: **1.** Log. reg. (logistic regression over tf.idf vectors); **2.** RNN (two-layer recurrent neural network); **3.** HRED (hierarchical recurrent encoder-decoder, often used for modeling conversations (Sordoni et al., 2015)); **4.** BERT$_{\text{BASE}}$ (Devlin et al., 2019); **5.** GPT-2 (typically used for language generation (Radford et al., 2019)); **6.** DialoGPT (GPT-2 adapted to asynchronous conversations (Zhang et al., 2020)); and **7.** RoBERTa$_{\text{BASE}}$ (Liu et al., 2019).

Empathy Identification Task. Table 3 reports the accuracy and macro-f1 scores of the three communication mechanisms (random baseline for each is 33% accurate; three levels). Log. reg., RNN, and HRED struggle to identify empathy with noticeably low macro-f1 scores indicative of failures to distinguish between the three levels of communication. Among the baseline transformer architectures, we obtain best performance using RoBERTa but observe substantial gains over them with our approach

Table 5: Ablation results. Most of our gains are due to context provided through attention and seeker post; higher gains for the rationale extraction task. *Note that rationales cannot be predicted after removing them from training.

(+1.73 acc., +4.02 macro-f1 over RoBERTa). We analyze the sources of these gains in §6.2.

Rationale Extraction Task. We perform both token level and span level evaluation for this task. We use two metrics, commonly used in discrete rationale extraction tasks (DeYoung et al., 2020): **1.** T-f1 (token level f1); **2.** IOU-f1 (intersection over union overlap of predicted spans with ground truth spans; threshold of 0.5 on the overlap for finding true positives and the corresponding f1). We find that GPT-2 and DialoGPT perform better than BERT and RoBERTa likely due to appropriateness to the related task of generating free-text rationales (Table 4). Our approach obtains gains of +2.58 T-f1 and +6.45 IOU-f1 over DialoGPT, potentially due to the use of attention and seeker post (§6.2).

6.2 Ablation Study

We next analyze the components and training strategies in our approach through an ablation study.

No Attention. Instead of using attention, we concatenate the seeker post encoding ($\mathbf{e}_i^{(\mathbf{S})}$) with the response post encoding ($\mathbf{e}_i^{(\mathbf{R})}$) and use the concatenated representation as input to the linear layer.

No Seeker Post. We train without the S-Encoder, i.e., by only encoding from the R-Encoder.

No Rationales. We set $\lambda_{\mathbf{RE}}$ to 0 and only train on the empathy identification task.

No Domain-Adaptive Pre-training. We initialize by only using model weights from RoBERTa$_{\text{BASE}}$.

Results. Our most significant gains come from using attention and the seeker post (Table 5) which greatly benefits the rationale extraction task (+4.88 T-f1, +5.74 IOU-f1). Also, using rationales and pre-training only leads to small performance improvements.

6.3 Error Analysis

We qualitatively analyze the sources of our errors. For the empathy identification task, we found that the model sometimes failed to identify short expressions of emotions in responses that otherwise contained a lot of instructions (e.g., *Sorry to hear that! Try doing ...*). Also, certain responses trying to universalize the situation (e.g., *You are not alone*) got incorrectly identified as strong interpretations. Furthermore, a source of error for explorations was confusions due to questions that were not an exploration of seeker's feelings or experiences (e.g., offers to talk - *Do you want to talk?*).

For the rationale extraction task, the model accurately extracts phrases that are commonly used for expressing empathy (e.g., *this might be tough*), but also sometimes incorrectly extracts single words from sentences indicating errors in disambiguating word usage (e.g., 'what' in *Tell them what you need* gets extracted as an exploration, likely because *what* is really common in explorations as in *what happened?*).

7 Model-based Insights into Mental Health Platforms

We apply our model to study how empathy impacts online peer-to-peer support dynamics. To only focus on conversations related to significant mental health challenges and filter out common social media interactions (e.g., *Merry Christmas*), we carefully select 235k mental health related interactions on TalkLife using a seeker-reported indicator.[6]

---

[6] We focus analyzing TalkLife alone as Reddit lacks rich publicly available signals such as seeker liking the response.

Seeker Post	Original Response	Re-written Response
I cannot do anything without getting blamed today. This day is getting worse and worse.	Days end, tomorrow is a fresh start.	**I'm sorry that today sucks**, but tomorrow is a fresh start.
An hour ago i was happy an hour later i'm sad. Am i getting mad now?	Try mindful meditation which can control anxiety	**That's something I've struggled with too**, and **it really pains me to hear that you're dealing with the same thing. Have you considered trying meditation?** I've found it to be very helpful.

Table 6: Example re-written responses with our model-based feedback. Participants increased empathy from 0.8 to 3.0. **blue** = Strong emo. reactions, **light red**/**dark red** = Weak/Strong Interpretations, **green** = Strong explorations.

We investigate (1) the levels of empathy on the platform, its variation over time, and examine the relationship of empathy with (2) conversation outcomes, (3) relationship forming, and (4) gender.

(1) Peer supporters do not self-learn empathy over time. Overall, we observe that empathy expressed by peer supporters on the platform is low (avg. total score[7] of 1.09 out of 6). In addition, we find that the emotional reactivity of users decreases over time (36% decrease over three years) and their levels of interpretations and explorations remain practically constant (Fig. 3a). Further analyzing whether a user individually improves, worsens, or remains constant in their expression of empathy, we find that 69% users either worsen or stay constant in their empathy expressions and only 10% improve by at least one point (i.e. one level in our framework). This is also reflected in prior work on therapy that shows that without deliberate practice and specific feedback, even trained therapists often diminish in skills over time (Goldberg et al., 2016). We find this trend robust to potential confounding factors (new users, user dropout) and users of different groups (low vs. high activity users, moderators; Appendix C). This indicates that most users do not self-learn empathy and highlights the need of providing them feedback.

(2) High empathy interactions are received positively by seekers. We analyze the correlation of empathic conversations with positive feedback, concretely with seeker "liking" the post. We find that strong communications of empathy are received with 45% more likes by seekers than no communication (Fig. 3b). Strong explorations get 44% less likes but receive 47% more replies than no explorations, leading to higher engagement.

(3) Relationship forming more likely after empathic conversations. Psychology research emphasizes the importance of empathy in forming alliance and relationship with seekers (Watson, 2007). Here, we operationalize relationship forming as seeker "following" the peer supporter after a conversation (within 24hrs). We find that seekers are 79% more likely to follow peer supporters after an empathic conversation (total score of 1+ vs. 0) than after a non-empathic one (Fig. 3c).

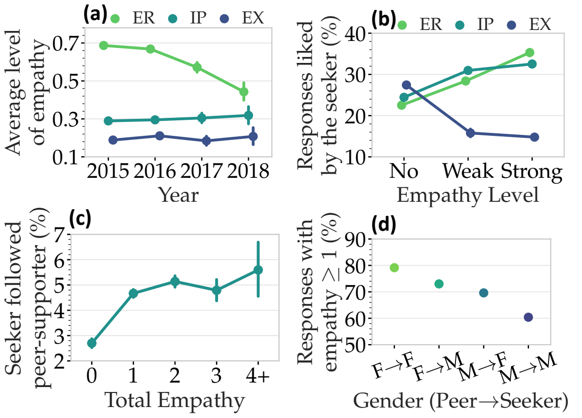

Figure 3: (a) Peer-supporters do not self-learn empathy over time. Only users who joined in 2015 were included but similar trends hold for other user groups; (b) Stronger communications of emotional reactions and interpretations are received positively by seekers. Stronger explorations get 47% more replies; (c) A lot more seekers follow peers after empathic interactions; (d) Females are more empathic towards females.

(4) Females are more empathic with females than males are with males. Previous work has shown that seekers identifying as females receive more support in online communities (Wang and Jurgens, 2018). Here, we ask if empathic interactions are affected by the self-reported gender of seekers and peer supporters. We find that female peer supporters are 32% more empathic towards female seekers than males are towards male seekers (Fig. 3d). Also, females are 6% more empathic towards males than males are towards females.

Implications for empathy-based feedback. These results suggest that our approach not only successfully measures empathy according to a

---

[7] Total empathy score is obtained by adding the level of communication across the three mechanisms.

principled framework (§3), but that the measured empathy components are important to online supportive conversations as indicated by the positive reactions from seekers and meaningful reflections of social theories. However, peer supporters on the platform express empathy rarely and this does not improve over time. This points to critical opportunities for empathy-based feedback to peer supporters for making their interactions with seekers more effective. Here, we demonstrate the potential of feedback in a simple proof-of-concept. When providing three participants (none are co-authors) simple feedback (Appendix D) based on EPITOME and our best-performing model, they were able to increase empathy in responses from 0.8 to 3.0 (total empathy across the three mechanisms). Table 6 shows two such examples of re-written responses that improve in communicating cognitive understanding (*today sucks*) and are also better with emotional reactions (*I'm sorry, it pains me*) and explorations (*Have you considered trying mindful meditation?*).

8 Further Related Work

Previous work in NLP for mental health has focused on analysis of effective conversation strategies (Althoff et al., 2016; Pérez-Rosas et al., 2019; Zhang and Danescu-Niculescu-Mizil, 2020), identification of therapeutic actions (Lee et al., 2019), and language development of counselors (Zhang et al., 2019). Researchers have also analyzed linguistic accommodation (Sharma and De Choudhury, 2018), cognitive restructuring (Pruksachatkun et al., 2019), and self-disclosure (Yang et al., 2019). We extend these studies and analyze empathy which is key in counseling and mental health support. Previous research has analyzed empathy in health communities (Khanpour et al., 2017), face-to-face therapy (Gibson et al., 2016), motivational interviewing (Pérez-Rosas et al., 2017), and emotionally-grounded conversations (Rashkin et al., 2019). Small-scale studies on manually annotated datasets have also been conducted (Morris and Picard, 2012; Lord et al., 2015). Our work develops a computational method for identifying empathy in text-based, asynchronous mental health support which is grounded in psychology and psychotherapy research and provides deeper insights into mental health platforms. Recent work has also developed proof-of-concept prototypes, such as ClientBot (Huang et al., 2020), for training users in counseling. Our approach is aimed towards developing empathy-based feedback and training systems for peer supporters (consistent with calls to action for improved treatment access and training (Miner et al., 2019; Imel et al., 2015; Kazdin and Rabbitt, 2013)).

9 Conclusion

We developed a new framework, dataset, and computational method for understanding expressed empathy in text-based, asynchronous conversations on mental health platforms. Our computational approach effectively identifies empathy with underlying rationales. Moreover, the identified components are found to be important to mental health platforms and helpful in improving peer-to-peer support through model-based feedback.

Acknowledgments

A Data Collection Details

A.1 Annotation Instructions

For each (seeker post, response post) pair, the annotators were asked the following four questions:

1. **(Mental Health Related)** Is the seeker talking about a mental health related issue or situation in his/her post?[8]
   - Yes
   - No
2. **(Emotional Reactions)** Does the response express or allude to warmth, compassion, concern or similar feelings of the responder towards the seeker?
   - No
   - Yes, the response alludes to these feelings but the feelings are not explicitly expressed
   - Yes, the response has an explicit mention of these feelings
3. **(Interpretations)** Does the response communicate an understanding of the seeker's experiences and feelings? In what manner?
   - No
   - Yes, the response communicates an understanding of the seeker's experiences and/or feelings

   If the answer to the above question was "Yes", the annotators were further asked to annotate one or more of the following:

   - The response contains conjectures or speculations about the seeker's experiences and/or feelings
   - The responder has reflected back on similar experiences of their own or others
   - The responder has also described similar experiences of their own or others
   - The response contains paraphrases of the seeker's experiences and/or feelings
4. **(Explorations)** Does the response make an attempt to explore the seeker's experiences and feelings?
   - No
   - Yes, but the exploration is generic
   - Yes, and the exploration is specific

The detailed instructions can be found at https://mhannotate-test.cs.washington.edu/annotate/readme.html.

A.2 Interactive Training of Crowdworkers

The crowdworkers on Upwork were initially provided with our entire annotation instructions and an interactive training system[9] containing ten examples. After this initially automated training, we scheduled a 1hour long phone call with them to discuss our annotation instructions and annotation interface. During the phone call, crowdworkers also asked questions on the annotation guidelines which greatly helped in addressing potential ambiguities. After the phone call, we assigned them 20 tasks each (randomly chosen; different for each crowdworker). We manually evaluated the annotations on those 20 tasks. Based on the evaluation, we either decided to discontinue with the crowdworker (there were two such crowdworkers) or we provided them further manual feedback. Throughout the process, crowdworkers actively asked questions through the chat feature on Upwork. After the initial training phase, we also did spot checks on quality (at least two times for each crowdworker; ≥ 20 posts each) to provide them further feedback.[10]

B Reproducibility

B.1 Implementation Details

Code. Our codes are based on the huggingface library (`https://huggingface.co/`). We make them publicly available at `https://github.com/behavioral-data/Empathy-Mental-Health`.

Seed Value. For all our experiments, we used the seed value of 12.

B.2 Hyperparameter Fine-tuning

We searched through the following space of hyperparameters for fine-tuning our model:

- learning rate = 1e-5, 2e-5, 5e-5, 1e-4, 5e-4
- $\lambda_{\mathbf{EI}} = 1$
- $\lambda_{\mathbf{RE}} = 0.1, 0.2, 0.5, 1$

---

[8] We use this question for filtering non-mental related posts from the data collection process

[9] This system contained prompts of manually written feedback for both correct and incorrect annotations.

[10] Crowdworkers only needed minor feedback on these posts.

B.3 Runtime Analysis

Domain-Adaptive Pre-training Time. We conducted domain-adaptive pre-training on four RTX 2080 Ti GPUs. Pre-training S-Encoder took around 22 hours. Pre-training R-Encoder took around 38 hours. Both are pre-trained for three epochs.

Model Training Time. We trained our model on one RTX 2080 Ti GPU. The training approximately takes five minutes. Our model is trained for four epochs.

B.4 Train, Dev, Test Splits

We split both the datasets into train, dev, and test sets in the ratio of 75:5:20. Table 7 contains the statistics of the train, dev, and test splits.

B.5 Number of Parameters

The total number of parameters of our model = 2 * number of parameters of $\text{RoBERTa}_{\text{BASE}}$ + parameters in the linear layers $\approx$ 2*125M + 2 * .5M = 251M

B.6 Reddit dataset

The entire Reddit dataset can be accessed through its archive on Google BigQuery at `https://bigquery.cloud.google.com/table/fh-bigquery:reddit_comments.2015_05?pli=1`

C Potential confounding factors in analysis of variation of empathy over time

We note that such an analysis can be affected by several confounding factors such as old vs. new users, user dropout, and low activity of several users. To account for these factors, we stratify users by the year in which they started supporting on the platform (2015, 2016, 2017) and analyze the average levels of empathy during subsequent years in each stratum. We further filter users with < 10 posts and only consider users who stay on the platform for at least a year.

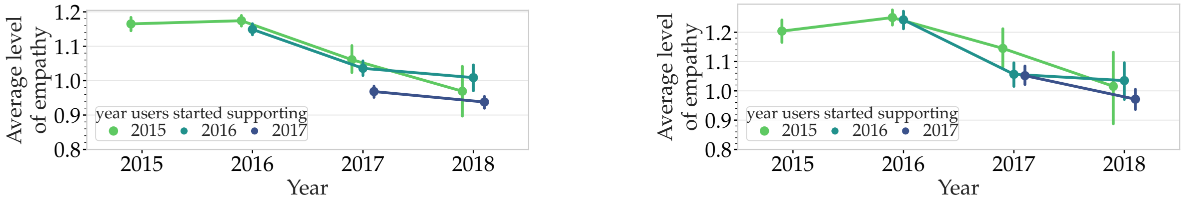
In addition, we analyze various user groups but observe similar trends (Fig. 4).

D Proof-of-Concept Details: model-based feedback for making responses empathic

We work with three computer science students with no training in counseling and give them (seeker post, response post) pairs identified low in empathy by our approach (total empathy score ≤ 1). We show them – (1) the levels of empathy predicted by our model, (2) extracted rationales, (3) a templated feedback explaining where the response lacks and how it can be made more empathic (based on the predicted levels, extracted rationales, definitions and examples in EPITOME). A sample feedback is shown below:

- **Seeker Post:** I'm hurt so much that I don't really have feelings anymore
- **Response Post:** Yeah, I felt it once
- **Feedback:**
    1. The response communicates an understanding of the seeker's post to a weak degree in the portion "I felt it once". The communication can be made stronger by talking about the seeker's feelings or experiences that you interpret after reading the post. Typically, they are expressed by saying "This must be terrible", "I know you are in a tough situation".
    2. It also lacks expressions of emotions of warmth, compassion, or concern and also does not attempt to explore the seeker's emotions or feelings. Typically, they are expressed by saying "I am feeling sorry for you", "What makes you feel depressed?"

We ask them to rewrite the response post making use of the templated feedback. Overall, the participants were comfortable to rewrite the responses with an average difficulty of 1.92 out of 5 (most difficult is 5) and found the feedback useful in the rewriting process with an average usefulness rating of 3.5 out of 5 (highly useful is 5).



(a) Users with $\geq$ 10 posts (b) Users with $\geq$ 50 posts

(c) Users with $<$ 10 posts (d) Moderators

Figure 4: Empathy over time analysis of various user groups. We find similar trends across multiple groups.

snigdha@cs.unc.edu

Abstract

Emotions and their evolution play a central role in creating a captivating story. In this paper, we present the first study on modeling the emotional trajectory of the protagonist in neural storytelling. We design methods that generate stories that adhere to given story titles and desired *emotion arcs* for the protagonist. Our models include Emotion Supervision (EmoSup) and two Emotion-Reinforced (EmoRL) models. The EmoRL models use special rewards designed to regularize the story generation process through reinforcement learning. Our automatic and manual evaluations demonstrate that these models are significantly better at generating stories that follow the desired emotion arcs compared to baseline methods, without sacrificing story quality.

1 Introduction

Stories are an integral part of human culture. They allow us to express emotions, share knowledge, and to shape our perspective of the world (McKee, 2003). Stories are made interesting through emotions that connect the characters, their motivations, goals, and achievements (Vonnegut, 1981).

Cognitive scientists have pinpointed the central role of emotions in storytelling (Parkinson and Manstead, 1993; Hogan, 2011). Early automatic storytelling systems based on symbolic planning also showed that addressing character emotions for plot construction resulted in more diverse and interesting stories (Theune et al., 2004; Pérez y Pérez, 2007; Méndez et al., 2016). However, these studies were rule-based and limited to small-scale data. The advent of deep learning has shifted computational storytelling efforts towards neural methods (Martin et al., 2018; Yao et al., 2019). However, despite the broad recognition of its importance, neural story generation methods have not explored the modeling of emotional trajectory.

Title (input): Raw burger
Emotion arc (input): joy → anger → sadness
Story (output): Tom went to a burger place with his friends. He ordered a burger. When he got it , he noticed that it was raw. Tom yelled at the waiter for it being raw. He was really disappointed.

Figure 1: An example story generated by our model for a given title and emotion arc of the protagonist. Story segments are highlighted with the emotions the protagonist (Tom) experiences.

In this paper, we present the first study to take into account the emotional trajectory of the protagonist in neural story generation. Research in cognitive science has shown that while comprehending narratives, readers closely monitor the protagonist's emotional states (Komeda and Kusumi, 2006; Gernsbacher et al., 1992). However, emotions experienced by the protagonist might differ from the general emotions expressed in the story. For example, the general emotion of *"My boss was very angry and decided to fire me."* is *anger*, but the narrator's emotional reaction would be to feel *upset*. At any point in a story, we represent the protagonist's emotions using a set of *basic emotions*. The theory of basic emotions is well-accepted in psychology, but there is little consensus about the precise number of basic emotions. Plutchik (1982) proposed 8 primary emotions, and Ekman (1992) first proposed 7 and then changed to 6 basic emotions. Following recent theories (Jack et al., 2014; Gu et al., 2016), we choose *anger, fear, joy*, and *sadness*, to describe the protagonist's emotions. We additionally include *neutral* to account for cases with no strong emotions. We refer to these 5 emotions as *basic emotions*.

Moreover, emotions evolve within a narrative. For modeling the evolving emotions of the protagonist, we define an *emotion arc* for a story. Our definition is inspired by Prince's change-of-state

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5277–5294,
November 16–20, 2020.

formalization (Prince, 2009), which asserts that stories are about change. According to this theory, a story has three components: a starting state; an ending state; and events that translate the starting into the ending state. Motivated by this, we define the *emotion arc* as a sequence of three *basic emotions* that describe the starting, body, and ending emotional states of the protagonist.

Given a story title and the emotion arc of the protagonist as inputs, our goal is to generate a story about the title that adheres to the given emotion arc. Fig. 1 shows an example story generated by our model, where the protagonist's emotion evolves from *joy* to *anger* and then *sadness*.

To address this problem, we present three models based on GPT-2 (Radford et al., 2019) that incorporate the protagonist's emotion arc as a controllable attribute while preserving content quality: an Emotion Supervision (EmoSup), and two Emotion-Reinforced (EmoRL) models based on reinforcement learning. The EmoRL models use two Emotion-Consistency rewards, EC-EM and EC-CLF. EC-EM uses semantically enhanced emotion matching to encourage the model to adhere to the given emotion arc. It infers the protagonist's emotions in the generated stories using *Commonsense Transformers*, COMET (Bosselut et al., 2019). EC-CLF achieves the same goal using a classifier to infer the protagonist's emotions.

In the absence of a training corpus of stories labeled with the protagonist's emotions, we automatically annotate a large-scale story corpus using COMET. Our automatic and manual evaluations show that our models can not only express the desired emotion arcs but also produce fluent and coherent stories. Our contributions are:

- We present the first study on modeling the *emotion arc* of the protagonist for neural story generation.
- We propose two Emotion-Consistency rewards designed to enforce the desired emotion arcs using reinforcement learning.
- We track the protagonist's emotions in a story (1) using a commonsense knowledge model based pipeline; and (2) through an emotion classifier trained using transfer learning from out-of-domain data.
- We empirically demonstrate that our models can effectively generate stories that follow the desired emotion arc. We also illustrate how these models can find novel applications.

2 Related Works

Early story generation systems relied on symbolic planning (Lebowitz, 1987; Pérez y Pérez and Sharples, 2001; Porteous and Cavazza, 2009; Riedl and Young, 2010) or case-based reasoning (Gervás et al., 2005). Although these systems could ensure long-term coherence, they could only operate in predefined domains and required manual engineering. These problems have been somewhat alleviated by recent seq2seq storytelling models (Roemmele, 2016; Jain et al., 2017), some of which are based on intermediate representations (Martin et al., 2018; Xu et al., 2018; Fan et al., 2018b; Yao et al., 2019; Fan et al., 2019).

Recent approaches have also used large-scale language models (LMs) based on Transformers (Vaswani et al., 2017), such as GPT-2 (Radford et al., 2019). Being trained on large amounts of data, these models can generate highly fluent text and find applications in story generation (Qin et al., 2019; Guan et al., 2020) and dialogue systems (Budzianowski and Vulić, 2019; Wolf et al., 2019). However, they lack the ability to dictate any auxiliary objective for the generated text, such as expressing specific attributes.

To address this, approaches such as conditional training or weighted decoding have been proposed to control different properties of the generated text such as sentiment, tense, speaker style, and length (Kikuchi et al., 2016; Hu et al., 2017; Ghazvininejad et al., 2017; Wang et al., 2017; Fan et al., 2018a). Tambwekar et al. (2019) use reinforcement learning for generating goal-driven story plots, which are sequences of event tuples. Dathathri et al. (2020) propose PPLM, which uses an attribute classifier to steer text generation without further training the LM.

More closely related to our work is generating automatic responses with a specific sentiment or emotion (Zhou et al., 2018; Huang et al., 2018; Zhou and Wang, 2018; Song et al., 2019). Modeling characters (Bamman et al. (2013), Bamman et al. (2014), Vala et al. (2015), Iyyer et al. (2016), Kim and Klinger (2019), Krishnan and Eisenstein (2015) *inter alia*) and sentiment trajectory (Chaturvedi et al. (2017), Chen et al. (2019) *inter alia*) has been shown to be useful for story understanding, in general. However, there are limited works on incorporating characters or sentiment for story generation. Previous work model characters but not sentiment (Clark et al., 2018; Liu et al., 2020). Weber et al. (2020) is a contemporary and unpublished work that incorporates sentiment while "filling in" a narrative. Peng et al. (2018) and Luo et al. (2019) control the overall sentiment for story ending generation. These works are limited to coarse-grained sentiments and/or only target the ending sentence. Instead, we model the emotional trajectory of the protagonist as the story progresses, which is more central to storytelling than the overall sentiment.

3 Emotion-aware Storytelling

We first explain how our models can track the protagonist's emotional trajectory (§3.1). We then define the problem statement (§3.2) and followed by an introduction to our base storytelling model (§3.3), which is used as the backbone of our three proposed models (§3.4 and §3.5)[1].

3.1 Tracking Protagonist's Emotions

In this work, we define the *protagonist* as the most frequently occurring character in a narrative (Morrow, 1985). Our two rewards for the EmoRL models (§3.5) need to track the protagonist's emotions to guide the generation. For this, we obtain their emotions at various stages in the story using one of the following two approaches:

Commonsense Transformer Our Ec-Em reward uses a commonsense knowledge model to reason about the implicit emotional states of the protagonist. We use COMET (Bosselut et al., 2019), a knowledge base construction model trained on ATOMIC *if-then* knowledge triples (Sap et al., 2019). It contains information about everyday events and their causes and effects. Given an event and a relation, COMET can generate commonsense inferences about the relation. For tracking emotions, we use relations `xReact` and `oReact` that correspond to emotional reactions to events (more details on this in §4.1).

Emotion Classifier Our Ec-Clf reward captures the protagonist's emotions using an emotion classifier. For this, we adapt the pre-trained BERT$_{large}$ for multi-label classification over 5 *basic emotions*: *anger, fear, joy, sadness,* and neutral. Following Devlin et al. (2019), we use a fully-connected layer over the final hidden representation corresponding to the special classification token (`[CLS]`). We train this classifier in two steps.

First, we train this classifier on a human-annotated dataset for emotion identification in tweets (Mohammad et al., 2018), consisting of $6,857$ tweets, with binary labels for 11 emotions, among which we only focus on our *basic emotions*. On this dataset, the classifier achieves better or comparable performance to state-of-the-art results (Kant et al., 2019) (see Appendix B.1 for detailed results).

Next, in order to identify the protagonist's emotions from a given story-text, we further fine-tune the classifier on story training data that is automatically annotated with the protagonist's emotions using the pipeline described in §4.1. To evaluate the classifier, we obtain manual annotations for the protagonist's emotions on Amazon Mechanical Turk for a subset of 50 randomly selected stories (250 sentences) from our story corpus. Each sentence was annotated by 3 judges. Workers agreed with our emotion classifier 70% of the time (random agreement would be 20%). See Appendix B.2 for more details about these annotations.

3.2 Problem Statement

We formulate the emotion-aware storytelling task as follows: given a story title as a sequence of tokens $\boldsymbol{t}=\{t_1, t_2, ..., t_m\}$, and an emotion arc for the protagonist as a sequence of *basic emotions* $\boldsymbol{a}=\{e_1, e_2, e_3\}$, the task is to generate a story as a sequence of tokens $\boldsymbol{y}=\{y_1, y_2, ..., y_n\}$ that adheres to the title and emotion arc.

3.3 Transformer-based Storytelling Model

Our models are built upon a base storytelling model that can generate a story consistent with a given prompt (e.g., title). We choose GPT-2 (medium) (Radford et al., 2019) because our initial experiments demonstrated that it outperforms other state-of-the-art story generation models, in general (§5.1). GPT-2 uses multiple Transformer blocks of multi-head self-attention and fully connected layers (the left box in Fig. 2). Since it was trained on a broad range of domains, we fine-tune it on a dataset of stories (§4.1) by minimizing the negative conditional log-likelihood:

$$\begin{aligned} \mathcal{L}_{ML} &= -\sum_{i=m}^{m+n} \log p(y_i|y_{<i}, \boldsymbol{t}) \\ p(y_i|y_{<i}, \boldsymbol{t}) &= \text{softmax}(h_i^L W^T) \qquad (1) \\ h_i^l &= \text{block}(h_{<i}^{l-1}), l \in [1, L] \\ h_i^0 &= W_i + P_i \end{aligned}$$

---

[1] Code at: `https://github.com/fabrahman/Emo-Aware-Storytelling`

where m and n denote the number of tokens in the title and story respectively. h_i^l is the l-th layer's output at the i-th position computed through transformer block with the masked multi-head self attention mechanism, and h_i^0 is a summation of *token embedding* W_i and *position embedding* P_i for the i-th token. $y_{<i}$ indicates left context.

3.4 Emotion Supervision (EmoSup) Model

The underlying idea behind our Emotion Supervision (EmoSup) model is to provide the emotion arc as an additional input similar to conditional training (Fan et al., 2018a; Kikuchi et al., 2016). Specifically, each title has the corresponding emotion arc prepended at the beginning, separated by a delimiter token (<$>). This way, emotion arcs receive special treatment (Kobus et al., 2017), since they are propagated to all of the story and the model learns to maximize $p(y_i|y_{<i}, \boldsymbol{t}, \boldsymbol{a})$.

3.5 Emotion-Reinforced (EmoRL) Models

The emotion arc guides the generation in EmoSup as an initial input. However, we want to continually supervise the model *during* the generation process. This motivates us to use a reinforcement learning framework. To deal with exposure bias, many previous works have optimized the evaluation measures (e.g., BLEU, ROUGE, CIDEr) as rewards (Rennie et al., 2017; Paulus et al., 2018). Here, we propose two Emotion Consistency rewards, Ec-Em and Ec-Clf, which optimize adherence to the desired emotion arc.

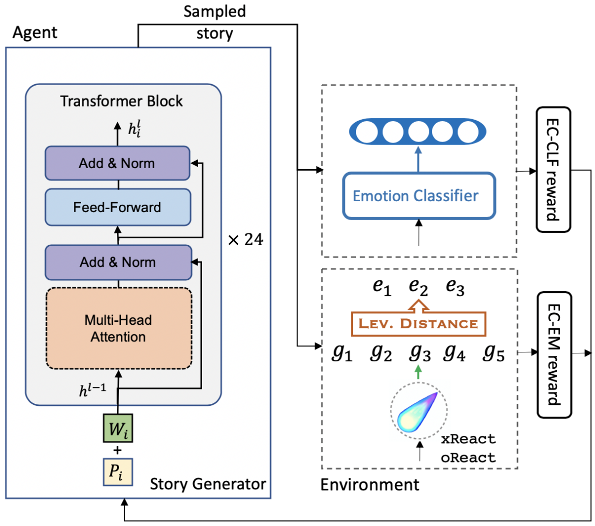

Figure 2: Transformer block architecture (left) and emotion-reinforced storytelling framework (right)

Ec-Em Reward This reward quantifies the alignment of the emotion arc of the generated story to the desired arc using the commonsense knowledge model, COMET. For an N-sentence-long generated story, we use COMET to obtain the protagonist's emotional reaction for each sentence, resulting in a sequence of emotion-phrases $\boldsymbol{a}^g$=$\{g_1, g_2, ..., g_N\}$[2]. We then define the reward as a modified Levenshtein distance (Levenshtein, 1966) between the generated reactions $\boldsymbol{a}^g$ and the desired emotion arc $\boldsymbol{a}^*$=$\{e_1, e_2, e_3\}$. This modification allows only two operations: (1) Deletion of an emotion-phrase (in $\boldsymbol{a}^g$), and (2) Replacement of an emotion-phrase with a basic emotion at a cost proportional to semantic similarity between the two (e.g., *happy to help* and *joy*). Semantic similarities are computed using cosine similarity between the averaged GloVe embeddings (Pennington et al., 2014) [3]. The reward is defined as:

$$r_{em} = \text{lev}(\boldsymbol{a}^g, \boldsymbol{a}^*) \tag{2}$$

where lev denotes the modified Levenshtein distance. We refer to the model that uses this reward as **Rl-Em**.

Ec-Clf Reward This reward infers the protagonist's emotions in a given text using our emotion classifier (§3.1). We first divide the generated story into segments: beginning, body, and ending[4]. Then, for each segment, we use the classifier to obtain the probability of the desired emotion. The reward is defined as the probabilities of the desired emotions averaged across the segments:

$$r_{clf} = \frac{1}{k}\sum_{j=1}^{k} p_{\text{clf}}(e_j^*|\boldsymbol{x}_j) \tag{3}$$

where k is the number of tokens in the emotion arc (here, k=3), and e_j^* denotes the desired emotion for j-th segment $\boldsymbol{x}_j$. We refer to the model that uses this reward as **Rl-Clf**.

Policy Gradient For training, we use the REINFORCE algorithm (Williams, 1992) to learn a generation policy p_θ of the storytelling model with

---

[2] N=5 for our dataset. Also, COMET's outputs, g_is, are phrases representing emotional reactions. Details on obtaining emotional reactions during training are provided in Appendix A.1.

[3] We experimented with contextualized representations from pre-trained BERT but opted for static embeddings because (1) they yielded better results, and (2) enabled us to focus on semantics of the individual emotion tokens/phrases rather than context-sensitive representations.

[4] We generate 5-sentence long stories similar to our training corpus and segment them into the beginning, body, and ending in 1:3:1 ratio.

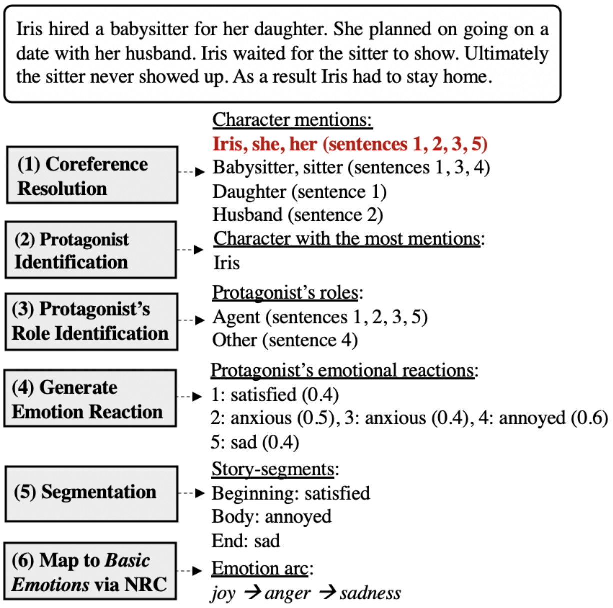

Figure 3: Annotation pipeline for *emotion arc*.

parameters θ. Here, the model generates a sample story $\boldsymbol{y}^s$ from the model's output distribution, and the goal is to minimize the negative expected reward, which is approximated by:

$$\mathcal{L}_{RL} = -(r(\boldsymbol{y}^s) - r(\hat{\boldsymbol{y}})) \sum_{i=k+m}^{k+m+n} \log p_\theta(y_i^s | y_{<i}^s) \quad (4)$$

We follow the self-critical training approach (Rennie et al., 2017), and take the reward of the greedily decoded story $\hat{\boldsymbol{y}}$ as the baseline reward $(r(\hat{\boldsymbol{y}}))$. This ensures that with better exploration, the model learns to generate stories $\boldsymbol{y^s}$ with higher rewards than the baseline $\hat{\boldsymbol{y}}$. Optimizing only with the RL loss mentioned above using the emotion-consistency rewards may increase the expected rewards, but at the cost of fluency and readability of the generated story. Therefore, we optimize the following mixed loss (Paulus et al., 2018):

$$\mathcal{L}_{mixed} = \gamma \mathcal{L}_{RL} + (1 - \gamma) \mathcal{L}_{ML} \quad (5)$$

where γ is a hyper-parameter balancing the two loss functions. Our emotion-reinforced storytelling framework is depicted in Fig. 2.

4 Experimental Setup

4.1 Dataset and Annotation Pipeline

We use the *ROCStories* corpus (Mostafazadeh et al., 2016) for our experiments. It contains $98,162$ five-sentence stories, designed to have a clear beginning and ending, thus making it a good choice for our emotion-aware storytelling task. We held out 10% of the stories each for validation and test sets, respectively.

For training our models, we need stories annotated with emotion arcs of the protagonists. We annotated the stories in our dataset automatically using the multi-step annotation pipeline shown in Fig. 3. In step 1, we identify all characters and their mentions in a story using coreference resolution. In step 2, we identify the character with the most mentions as the *protagonist* (e.g., 'Iris' who is mentioned in 4 sentences). Then, in step 3, in each sentence of the story, we identify the protagonist's role as *Agent* or *Other* using its dependency parse[5]. The protagonist is an *Agent* if he/she is the subject of the main verb in the sentence and *Other* otherwise (e.g., Iris's role is *Other* in sentence 4 and *Agent* in all other sentences). Next, in step 4, we obtain the emotional reaction of the protagonist in each sentence using COMET. Given a context, c, and relation type, r, COMET can yield the emotional reaction of the *Agent* (r=`xReact`) and *Others* (r=`oReact`). Depending on the protagonist's role in the sentence, we use the appropriate relation to get their emotional reaction, g, and COMET's confidence in the prediction, φ_g. In sentences without an explicit mention of the protagonist, his/her role is assigned as *Other*, and we use `oReact` since the event in that sentence will affect all characters of the story, including the protagonist (e.g., sentence 4 in Fig. 3).

Step 4 gives the protagonist's emotions for each sentence of the story, but the emotion arc has to represent them for the three segments: beginning, body, and end. The stories in our corpus are 5-sentence long, and following previous work on this corpus (Chaturvedi et al., 2017), we segment them in 1:3:1 ratio. For the protagonist's emotion in the body (middle 3 sentences), we take the emotion of the sentence in which COMET was most confident (e.g., 'annoyed' for the body of the running example in Step 5).

Note that since COMET's outputs, gs, are open-ended emotion-phrases, in step 6, we need to map these phrases to one of the 5 *basic emotions* using NRC Affect Intensity Lexicon (Mohammad, 2018). The lexicon is a list of words with their real-valued intensities for 4 non-*neutral* basic emotions. We represent the likelihood of g getting mapped to

---

[5] We use AllenNLP (Gardner et al., 2018) for coreference resolution and dependency parsing: `https://github.com/allenai/allennlp`

each of the basic emotions, e, as $score_e$(e). For mapping, we first tokenize, lemmatize, and filter stop words from g. Then we find exact matches of g's tokens to words in the lexicon (along with the match-intensities). For each match, we increase $score_g$(e) by the match-intensities. Finally, g is mapped to the basic emotion with the maximum score. An emotion-phrase with no matching tokens is mapped to *neutral*.

Note that we also experimented with the emotional reactions generated by COMET to constitute the *emotion arc* without mapping them to *basic emotions*. However, with more than 500 unique emotional reactions, the space of possible arcs became too large with too few training examples for each which prevented the models from effectively learning the pattern. The smaller set of *basic emotions* also made it more natural and manageable for the user to provide a desired emotion arc as input.

4.2 Implementation Details

We follow the training and inference settings of medium-size GPT-2 as in Radford et al. (2019) (for completion, we provide full details in Appendix A.2). Our models are implemented with the Texar toolkit (Hu et al., 2019).

4.3 Evaluation Measures

Automatic We adopt several automatic measures to evaluate the generated stories both on content quality and emotion faithfulness.

For evaluating the content quality, we use the following measures: (1) **Perplexity** as an indicator of fluency. A smaller value is better[6]. (2) **BLEU**, which is based on n-gram overlaps (Papineni et al., 2002). Following Guan et al. (2020), since BLEU scores become extremely low for large n, we used n=$1, 2$. (3) **Distinct-n** (with n=$1, 2, 3$) measure the percentage of unique n-grams (Li et al., 2016). A high ratio indicates a high level of lexical diversity. (4) **Repetition-4** is the percentage of generated stories that repeat at least one 4-gram (Shao et al., 2019). A high value indicates redundancy in the generated text.

For evaluating the emotion faithfulness of a generated story, we adapt lexical measures (1) **Seg-word** and (2) **Arc-word** (Song et al., 2019). Given a desired emotion arc for a story, Seg-word is the percentage of the story's segments that contain emotion words corresponding to desired emotion. Correspondingly, Arc-word for a story is a binary score indicating if *all* of its segments contain emotion words corresponding to the desired emotions. We also define (3) **Seg-acc** and (4) **Arc-acc** for a generated story. Seg-acc for the story is the fraction of generated segments for which the emotion (as determined by the emotion classifier) exactly matches the desired emotion. Similarly, Arc-acc for a story is a binary score indicating if its emotion arc (as determined by the emotion classifier) exactly matches the desired emotion arc. We also use the reward functions, (5) **EC-CLF** and (6) **EC-EM**, to score a generated story. For all these measures, we report averaged scores across all stories generated by a model.

Manual We also conduct a manual evaluation of generated stories using Amazon Mechanical Turk. Following Song et al. (2019), workers are asked to evaluate pair of stories on a 0-3 scale (3 being very good) from two different perspectives: (1) **emotion faithfulness** to assess whether it follows the desired emotion arc for the protagonist, and (2) **content quality** to indicate whether a story is fluent, logically coherent, and on-topic (related to the given title). Workers were also asked to indicate their **overall preference** by choosing the better story of the two while considering both aspects, or indicate that they are of equal quality. More details about evaluation measures are provided in Appendix A.3.

5 Results and Discussion

We first describe our experiments on choosing the base storytelling model (§5.1) followed by evaluation of the proposed models (§5.2).

5.1 Base Storytelling Model Results

As noted before, our models build upon a base storytelling model (GPT-2). We compared GPT-2 with the following state-of-the-art story generation models, given the title as input. (1) *S2S* (Bahdanau et al., 2015), (2) *ConvS2S* (Gehring et al., 2017), (3) *Fusion* (Fan et al., 2018b), (4) *Plan&Write* (Yao et al., 2019), (5) *Decom-Event* (Fan et al., 2019).

Using various evaluation measures described earlier, our experiments showed that fine-tuned GPT-2 outperforms all baselines, indicating that it can serve as good base storytelling model. This is in-line with the observations made in Guan et al.

---

[6] For comparison, we compute *word-level* perplexity for GPT-2 based models. That is, we normalize the total negative log probability by the number of *word*-level tokens, not the number of BPE tokens.

Models	PPL (↓)	BLEU-1 (↑)	BLEU-2 (↑)	Dist-1 (↑)	Dist-2 (↑)	Dist-3 (↑)	Repet-4 (↓)
Fusion + Emo	24.02	21.10	2.61	66.18	90.88	96.91	23.30
Plan&Write + Emo	17.43	22.46	3.03	66.32	90.47	95.59	28.61
PPLM-3	–	20.36	2.37	71.37	93.90	98.19	13.36
PPLM-5	–	20.61	2.47	71.47	93.99	98.21	14.02
GPT-2 + FT*	12.16	22.68	3.10	72.93	94.24	98.28	12.10
EmoSup	**11.10**	22.70	3.23	71.44	93.75	98.10	13.94
RL-EM	11.98	22.52	3.15	**73.32**	**94.76**	**98.56**	**10.09**
RL-CLF	11.31	**22.78**	**3.26**	71.16	93.65	98.05	13.34

Models	Arc-word	Seg-word	Arc-acc	Seg-acc	EC-CLF	EC-EM
Fusion + Emo	6.32	38.89	29.89	62.59	60.06	73.59
Plan&Write + Emo	5.61	32.98	26.38	60.99	58.13	72.46
PPLM-3	7.11	36.10	23.97	57.01	56.02	73.19
PPLM-5	7.74	37.64	27.30	60.60	59.51	74.43
GPT-2 + FT*	4.46	33.28	17.32	48.69	47.93	69.00
EmoSup	7.33	40.86	31.25	64.26	62.88	74.10
RL-EM	8.85	43.77	33.56	65.13	63.93	**76.59**
RL-CLF	**10.14**	**45.42**	**37.58**	**68.90**	**67.55**	75.87

Table 1: Automatic evaluation of content quality (top) and emotion faithfulness (bottom). For content quality, RL-CLF and RL-EM outperform all baselines for BLEU and diversity/repetition scores respectively ($p < 0.05$). For emotion faithfulness, RL-CLF outperforms all baselines ($p < 0.05$). * indicates absence of emotion arc as input.

(2020). Since this is not our focus, we report full results and details in Appendix B.3.

5.2 Emotion-Aware Storytelling Results

Baselines We use the following baselines in our experiments: (1) GPT-2+FT, our base GPT-2 model fine-tuned on the ROCStories corpus, for which emotion arcs are not provided as inputs; (2) *Fusion+Emo* and (3) *Plan&Write+Emo*, which are two of the strongest storytelling baselines (we prepended emotion arcs to titles in our experiments); and (4) *PPLM* (Dathathri et al., 2020) which can be extended to accept emotion arcs for controlling story generation. *PPLM-3* and *PPLM-5* indicate 3 and 5 iterations respectively[7].

Automatic Evaluation For automatic evaluation, we used the titles and automatically extracted emotion arcs of the stories in our test set as input.

The evaluation results on content quality are shown in the top half of Table 1. Interestingly, even though the proposed models only aim to control emotion arc, they outperform GPT-2+FT on perplexity indicating better fluency. Among the proposed models, EmoSup obtains the best perplexity score mainly because that is what its loss function optimizes (as opposed to the mixed loss in EmoRL models). Overall, all of our proposed models outperform all baselines. In particular, RL-CLF has the highest BLEU scores, and RL-EM has the highest diversity and lowest repetition scores. All improvements over baselines are statistically significant (approximate randomization (Noreen, 1989), $p < 0.05$).

The evaluation results on emotion faithfulness are shown in the bottom half of Table 1. We see that, as expected, all models outperform GPT-2+FT, which is not provided the emotion arcs as inputs. Our proposed models also achieve significant improvements over all baselines (app. randomization, $p < 0.05$). In particular, RL-CLF achieves the best performance on almost all measures.

We also compare various models on the most common emotion arcs in our corpus. Fig. 4 shows the Arc-acc of various models on the 10 most common arcs. We can see that all models perform very well on "joy $\rightarrow$ joy $\rightarrow$ joy" as compared to other emotion arcs. This is because this is the most common emotion arc (34% of the training data) in our corpus, which results in availability of significant number of training examples for this arc. Nevertheless, for all arcs, RL-CLF consistently outperforms all other models indicating a better control over the desired emotion arc.

These results indicate that while all proposed

---

[7] We use the HuggingFace implementation: `https://github.com/huggingface/transformers/tree/master/examples/text-generation/pplm`. For a fair comparison, we used GPT-2 fine-tuned on stories as the underlying generation model.

	Specific Criteria		**Overall Preference**
	Emotion Faithfulness	Content Quality	Better / Worse / Tie (%)
RL-CLF vs. RL-EM	+0.20 ($1.77 \pm 0.91, 1.57 \pm 0.95$)	+0.15 ($1.73 \pm 0.78, 1.58 \pm 0.85$)	**52.33** / 38.00 / 9.66
RL-CLF vs. GPT-2+FT	+0.76 ($2.24 \pm 0.80, 1.48 \pm 0.98$)	+0.25 ($2.25 \pm 0.82, 2.00 \pm 0.88$)	**60.00** / 22.00 / 18.00
RL-CLF vs. EmoSup	+0.28 ($1.97 \pm 1.00, 1.69 \pm 1.05$)	+0.14 ($1.93 \pm 0.94, 1.79 \pm 0.97$)	**50.33** / 34.00 / 15.66
RL-CLF vs. PPLM-5	+0.48 ($2.10 \pm 0.86, 1.62 \pm 0.94$)	+0.34 ($2.21 \pm 0.90, 1.87 \pm 0.96$)	**61.00** / 25.66 / 13.33

Table 2: Manual evaluation results. For each criteria, we report the average improvements as well as the absolute scores for the two models, separated by a comma. RL-CLF is preferred over other methods ($p < 0.05$).

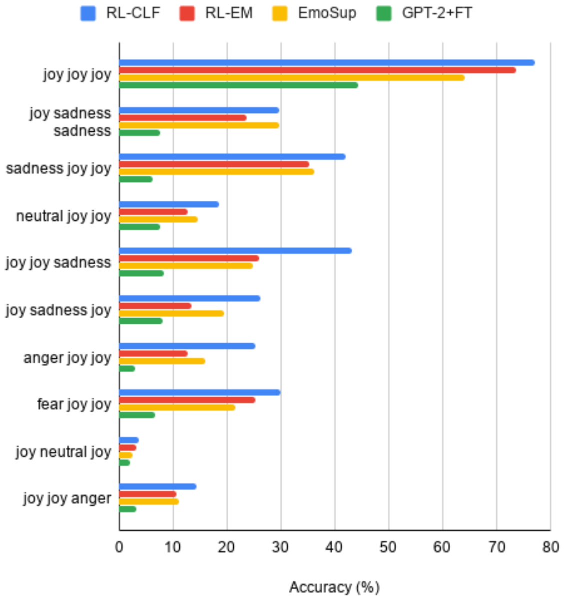

Figure 4: Arc-acc of various models on the 10 most common arcs in our corpus. RL-CLF outperforms other models for almost all arcs.

Title: fire injuries

joy - sadness - joy	My friends and I went camping this summer. We got in my van and went to the woods. We decided to light a campfire. While driving around , our tire popped and the fire started. We had to call the fire department for help and they were able to put out the fire.
sadness - sadness - joy	The fire department was called to a house in the woods. The house was engulfed in flames. There were two people inside. One person was taken to the hospital by air ambulance. Luckily, the other person was treated for non-life threatening injuries.

Title: dance

fear - joy - joy	Kelly was worried about her dance recital. She had practiced her dance for weeks. She decided to try out for the school's dance team. Kelly was nervous but knew she could do well. She was so excited she gave her best impression!
sadness - joy - joy	I was very depressed. I went to a dance class with a friend of mine. We tried out some different moves. We got stuck dancing for a long time. The next day I tried out some new moves and got a standing ovation.

Table 3: For a given title, our model can generate different stories for different emotion arcs. Story segments with corresponding emotions are highlighted.

models can control the emotion arc of generated stories, RL-CLF achieves a good balance between both content and emotion quality.

Manual Evaluation Since concerns have been raised about automatic evaluation of language generation, we also conduct a manual evaluation on Amazon Mechanical Turk. For this, we randomly sampled titles and emotion arcs of 100 instances from our test set, and generated stories using the models being evaluated. We compared five models, and so overall, there were 500 stories. We conduct pairwise comparisons of generated stories, and each pair was evaluated by 3 judges. Table 2 reports the average improvements as well as absolute scores for emotion faithfulness and content quality (evaluated independently) and also the overall preference of the judges. We first compare our two EmoRL models (Row 1). We see that RL-CLF improves over RL-EM on both emotion faithfulness and content quality. Overall, it is judged to be better than RL-EM 52.33% of the time and worse in only 38.00% cases. We then compare the better of the two, RL-CLF, with the uncontrolled GPT-2+FT (Row 2). We see that on average, RL-CLF model is not only better at adhering to the emotion arc by +0.76 points but also generates better content (improvement of +0.25 points) and its stories are preferred 60% of the times by humans. We observe similar results for comparison with EmoSup and PPLM-5. All improvements are statistically significant (app. randomization, $p < 0.05$).

Case Studies Since the proposed models can generate stories conditioned on the protagonist's *emotion arc*, they can be used to unfold a story in diverse situations for a given title. We demonstrate this capability in Table 3. It shows two examples where for the same title, our model (RL-CLF here) can generate stories that follow different emotion

Input story: There was a girl called Cinderella who did all the work for her mean, ugly step sisters. One day, she got an invitation to go to a ball at the palace. A fairy Godmother appeared an made her a beautiful dress and a lovely carriage. After Cinderella left the ball, the prince looked everywhere for her. He eventually found her and they got married and lived happily ever after.
Automatically extracted emotion arc: sadness → joy → joy
Input Title: The wedding
Output story: Ryan had been feeling really lonely lately. He decided he needed a way to make a friend. He decided to go to a wedding. When he got there he met a beautiful girl. Ryan had made a new friend that day !

Table 4: Given a story, our model can generate another story with similar emotion arc.

arcs for the protagonists.

Alternatively, given a story, the models can also be used to generate another story with a similar emotion arc (after automatically extracting the protagonist's emotion arc in the given story using the pipeline described in §4.1). For example, in Table 4 we show how RL-CLF can be used to generate a novel story in which the protagonist follows the same emotion arc as in the 'Cinderella' story. Note that the goal here is not necessarily to generate a similar narrative but a story that follows the same emotional trajectory.

We provide more qualitative examples in Appendix Figure 8.

6 Conclusion

In this paper, we proposed the emotion-aware storytelling task for modeling the emotion arc of the protagonist. To this goal, we designed two emotion-consistency rewards using a commonsense transformer and an emotion classifier. Experiments demonstrated that our approach improved both content quality and emotion faithfulness of the generated stories. We also presented two case studies, which show interesting use cases of our model. In general, such models can have educational applications by enabling children to explore creative writing at an early age and addressing the literary learning needs of learners with disabilities.

This paper is a step towards future research directions on planning emotional trajectory while generating stories. Using commonsense inferences about the effect of the events on emotional states of various characters of the story has the potential of generating more coherent, realistic, and engaging stories. In this work, we focused only on the protagonist, but future works can explore modeling motivations, goals, achievements, and emotional trajectory of all characters. Our approach is general and provides a blueprint for similar works going forward and can be used outside emotion-aware storytelling, e.g., for generating other emotional content or text with other attributes or properties.

The various assumptions and choices made in this paper and the specific characteristics of the dataset we chose can introduce biases and errors. For example, COMET is a discourse-agnostic model, and separately extracting emotional reactions for each sentence may fail to maintain emotional consistency with the rest of the narrative. Such sources of errors and biases need further systematic investigation.

A Training and Experiment Setup

A.1 Obtaining Emotion Reactions During RL-EM Training

During self-critical training, for each training instance, two stories are generated: $\boldsymbol{y}^s$ which is sampled from the model's probability distribution, and $\hat{\boldsymbol{y}}$ which is greedily decoded. Then for each sampled or greedy story, the value of the reward is computed. For computing the EC-EM reward, we need to identify and track the protagonist and obtain his/her emotional reactions for each sentence of the sampled or greedy story. This requires identifying the protagonist and determining his/her role, *Agent* or *Other*, in every sentence so that the appropriate argument for COMET (`xReact` or `oReact`) can be chosen. In principle, this can be done using the annotation pipeline described in §4.1 of the main paper. However, doing this is computationally prohibitive during training as the pipeline requires running dependency parsing for each sentence and coreference resolution for every sampled or greedy story. To this end, upon analyzing our corpus and some generated stories, we devised several heuristics that approximate the tasks (i.e. identifying protagonists and their roles) with high accuracy. We describe these heuristics below.

For identifying the protagonist, we use the following heuristics. The first heuristic is based on the observation that if the narrator features in a story, the story primarily focuses on the narrator and his/her experiences, thus making him/her the protagonist. So our first heuristic is that if first person pronouns (I, We) appear in the story, they are considered the protagonist. Our second heuristic is based on the observation that the protagonist is usually introduced fairly early in the story. Especially, in our case, where the stories are 5-sentence long, the protagonist appears mostly in the first couple of sentences of the story. With this in mind, we define the first noun that appears in a lexicon of common protagonists as the protagonist of the story. This lexicon consists of terms for `Male_Char`, `Female_Char`, `Social_Group`, `Generic_People`, and the NLTK name corpus. Example of these terms are shown in Table 5. This also let's us identify the gender of the protagonist (using the lexicon category that the protagonist belongs to) and hence the pronouns that will be used in the following sentences to refer to the protagonist. This combination of protagonist's mentions and pronouns lets us track him/her throughout the story.

For identifying the role of the protagonist, if the first noun that occurs in a sentence matches the protagonist or his/her corresponding pronoun, we assume that the protagonist's role is *Agent*, otherwise the role is *Other*. Depending on this role, we use `xReact` or `oReact` when obtaining protagonist's emotional reaction in that sentence using COMET.

`Male_Char`	husband, father, dad, dady, brother, grandpa, granddad, son, nephew, man, boy, boyfriend
`Female_Char`	wife, mother, mom, momy, sister, grandma, grandmom, niece, daughter, nana, woman, girl, girlfriend
`Social_Group`	family, parents, grandparents, children, kids, couple, friends, boys, girls, band
`Generic_People`	cousin, friend, fiance, boss, manager, assistant, doctor, nurse

Table 5: Predefined terms used for tracking the protagonist.

A.2 Training Hyper-parameters

Our proposed models follow the setting of medium-sized GPT-2 (Radford et al., 2019) (345 million parameters) that used a 24-layer decoder-only transformer, 1024-dimensional hidden states, and 16 attention heads. The stories are encoded using BPE with vocabulary size of 50,257. We set the maximum sequence length to 128 tokens, as it is large enough to contain complete stories and additional inputs. We use Adam optimization (Kingma and Ba, 2015) with an initial learning rate of 10^{-5} and minibatch of size 4. For stability, we first pre-train the models with teacher forcing until convergence, then fine-tune them with the mixed loss. Hyper-parameter $\gamma = 0.97$ is tuned manually on the validation set. All models were trained until there was no improvement on the validation set performance. We use a NVIDIA GTX 1080 Ti GPU machine to train our models. At inference time, we generate stories using top-k sampling scheme (Fan et al., 2018b) with k=40 and a softmax temperature of 0.7. It took about 3 hours to generate stories for our test set of size 9,796.

For generating commonsense inferences about the protagonist's emotions using COMET, we use greedy decoding algorithm since it has been shown to have superior performance as evaluated by humans (Bosselut et al., 2019).

Models	Domain	Accuracy (Jaccard)	Mico F1	Macro F1
Meisheri and Dey (2018)	tweets	0.582	0.694	0.534
Baziotis et al. (2018)	tweets	0.595	0.709	0.542
Kant et al. (2019)	tweets	0.577	0.690	0.561
BERT$_{large}$ (ours)	tweets	0.595	0.708	0.522
BERT$_{large}$ (ours)	stories	0.617	0.650	0.557

Table 6: Emotion classification results on the tweets dataset (upper block), and the automatically annotated story corpus (lower block).

A.3 Evaluation Measures

In this section we provide details about the automatic and manual measures used to evaluate our models.

Automatic To compute Arc-word and Seg-word measures, we use NRC Affect Intensity Lexicon (Mohammad, 2018). This lexicon contains words with corresponding emotion-intensities for different *basic emotions*. To find emotionally expressive words in a given piece of text (e.g., a story segment), we create a dictionary of words with emotion intensity higher than 0.5 for each of our *basic emotions*.

Manual During the manual evaluation, we conducted pairwise comparison of the models on Amazon Mechanical Turk (AMT). To ensure high quality of evaluation, we selected turkers that had an approval rate greater than 97%, had at least 1,000 approved HITS, and were located in the U.S. For each pairwise annotation, we showed the inputs (title and emotion arc) and two stories generated using the two models being compared. In order to avoid biases, we randomly shuffled the order in which the stories from the two models were shown to the turkers. We provided instructions to the turkers explaining the annotations and also provided examples. Following this process, each pair of stories was annotated by three turkers. Fig. 6 shows a screenshot of our setup on AMT.

B Supplementary Results

B.1 Emotion Classification

Our EC-CLF reward captures the protagonist's emotions using our emotion classifier. In this section we provide details about its evaluation.

We first evaluate the classifier on the tweets corpus (Mohammad et al., 2018)[8] by comparing it with

---

[8] `https://competitions.codalab.org/competitions/17751`

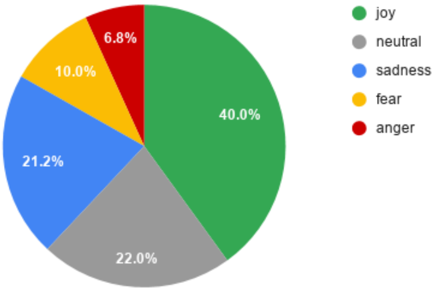

Figure 5: Label distribution of human annotated set.

several strong baselines (Kant et al., 2019). For this comparison, we trained all models on the training set of the corpora and tested them on a held-out test set. The models were evaluated using Jaccard Index based accuracy, and Micro and Macro F1 scores. This evaluation set-up (train-validation-test splits and choice of evaluation metrics) is as suggested in the challenge that provided the corpus (SemEval Task1:E-c challenge). The results of this comparison is shown in the top half of Table 6. We can see that our emotion classifier, BERT$_{large}$, is superior or competitive with other models.

The results reported above show that the model performs well for emotion classification in tweets. However, our goal is to design a model that can be used to track protagonist's emotions in stories. As described in the main paper, we further fine-tuned this classifier on our automatically annotated story corpora (described in the paper in §4.1). We also evaluated the classifier on a held-out portion of this story corpora consisting of about $1,201$ stories ($6,005$ sentences in total). The results are reported in the last row of Table 6. The classifier achieves a (Jaccard Index) accuracy of 61.75% and micro and macro F1 scores of 0.650 and 0.557 respectively. Note that this is different from the evaluation reported in the paper, which was conducted on a subset of stories annotated by humans.

B.2 Manual Annotation for Protagonist's Emotions

As described in the paper (§3.1), the emotion classifier was also evaluated on a subset of 50 randomly selected stories (250 sentences) manually annotated for the emotions experienced by their protagonists. This annotation was done on Amazon Mechanical Turk. To ensure good quality of the annotations, we selected turkers who had an approval rate greater than 97%, had at least $1,000$ approved HITS, and were located in the U.S. Fig. 7 shows a screenshot of our setup. The Fleiss kappa (inter-annotator agreement) was also moderate ($\kappa = 0.55$). We also analyzed the annotations to identify major sources of disagreements between the turkers. We found that most disagreements occurred between *neutral* and *joy*; and also between *sadness* and *anger*. The overall label distribution for this human annotated set is shown in Fig 5.

B.3 Base Storytelling Model

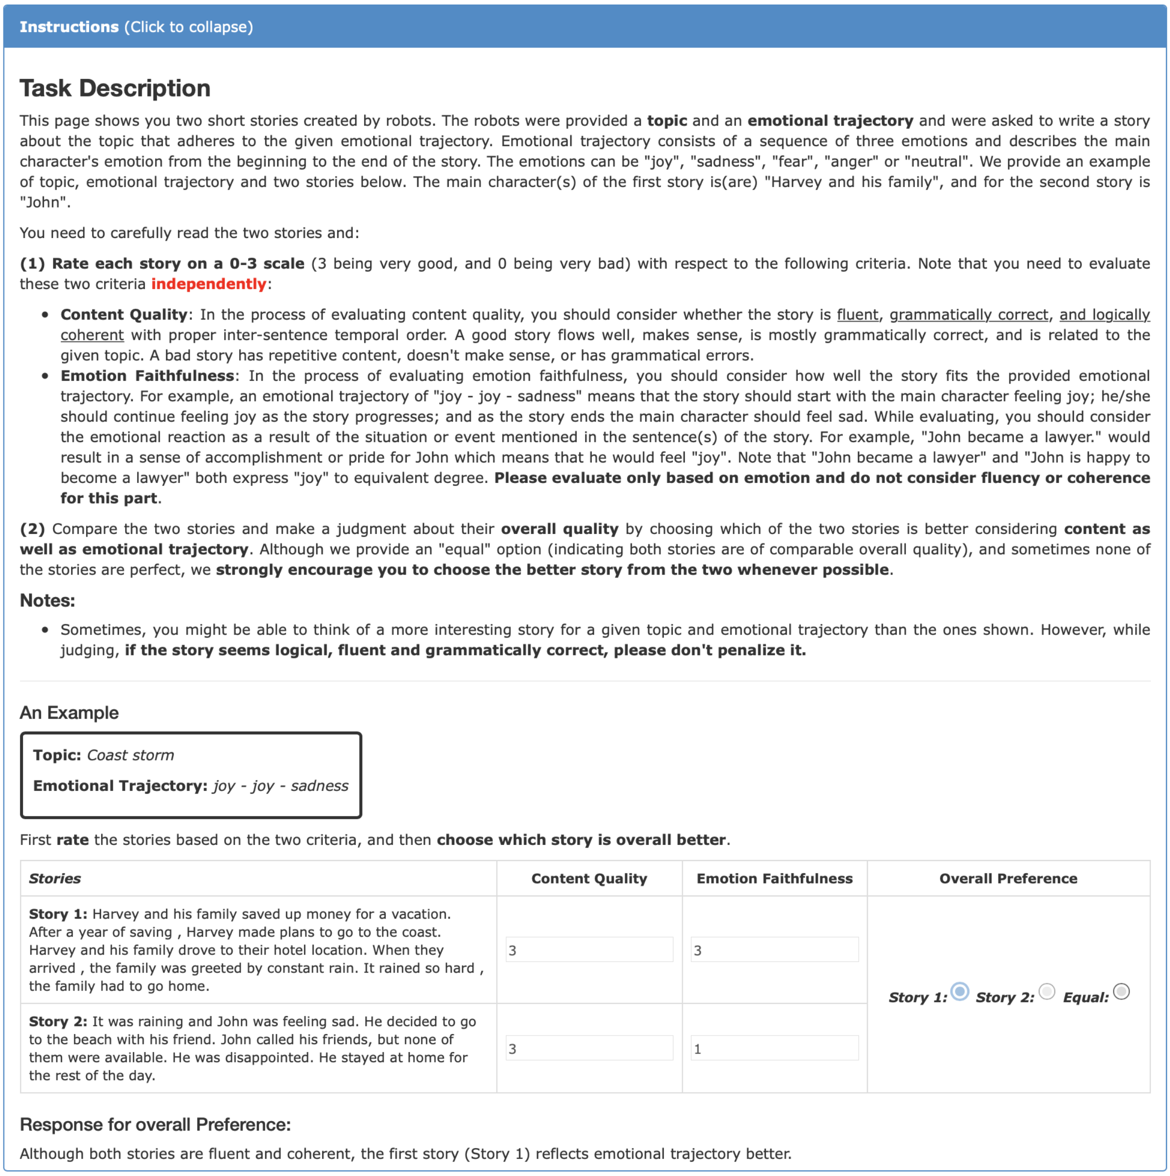
Baselines We compare our base storytelling model, GPT-2, with following state-of-the-art models:

1. *S2S*, an LSTM-based seq2seq model with attention (Bahdanau et al., 2015)
2. *ConvS2S*, a convolutional seq2seq model (Gehring et al., 2017) with decoder self-attention.
3. *Fusion*, a storytelling model that first pretrains a convolutional seq2seq model, then fixes the trained model and passes it to the second clone model with fusion mechanism (Fan et al., 2018b).
4. *Plan&Write*, another storytelling model that, given a title, first generates a plot as a sequence of keywords, and then conditioned on the plot it generates the text of the story (Yao et al., 2019).
5. *Decom-Event*, Fan et al. (2019) proposes to decompose the generation to two steps: generating successive events as the story plots, and generating story by surface realization of the plots. Events are represented by 4-tuples $<s, v, o, m>$, where s and o are the subject and object of verb v, and m is the modifier.

All of these models are trained, validated and tested on the same data splits described in §4.1.

Results The models are evaluated on content quality using the automatic measures described in the paper in §4.3. For comparison with other baselines, we compute *word-level* perplexity (PPL) for GPT-2+FT. That is, we normalize the total negative log probability of the target text by the number of *word*-level tokens (similar to the baselines), not the number of BPE tokens.

Table 7 describes the results of this evaluation. We can see that fine-tuned GPT-2 performs better



Instructions (Click to collapse)

Task Description

This page shows you two short stories created by robots. The robots were provided a **topic** and an **emotional trajectory** and were asked to write a story about the topic that adheres to the given emotional trajectory. Emotional trajectory consists of a sequence of three emotions and describes the main character's emotion from the beginning to the end of the story. The emotions can be "joy", "sadness", "fear", "anger" or "neutral". We provide an example of topic, emotional trajectory and two stories below. The main character(s) of the first story is(are) "Harvey and his family", and for the second story is "John".

You need to carefully read the two stories and:

(1) Rate each story on a 0-3 scale (3 being very good, and 0 being very bad) with respect to the following criteria. Note that you need to evaluate these two criteria **independently**:

- **Content Quality**: In the process of evaluating content quality, you should consider whether the story is fluent, grammatically correct, and logically coherent with proper inter-sentence temporal order. A good story flows well, makes sense, is mostly grammatically correct, and is related to the given topic. A bad story has repetitive content, doesn't make sense, or has grammatical errors.
- **Emotion Faithfulness**: In the process of evaluating emotion faithfulness, you should consider how well the story fits the provided emotional trajectory. For example, an emotional trajectory of "joy - joy - sadness" means that the story should start with the main character feeling joy; he/she should continue feeling joy as the story progresses; and as the story ends the main character should feel sad. While evaluating, you should consider the emotional reaction as a result of the situation or event mentioned in the sentence(s) of the story. For example, "John became a lawyer." would result in a sense of accomplishment or pride for John which means that he would feel "joy". Note that "John became a lawyer" and "John is happy to become a lawyer" both express "joy" to equivalent degree. **Please evaluate only based on emotion and do not consider fluency or coherence for this part**.

(2) Compare the two stories and make a judgment about their **overall quality** by choosing which of the two stories is better considering **content as well as emotional trajectory**. Although we provide an "equal" option (indicating both stories are of comparable overall quality), and sometimes none of the stories are perfect, we **strongly encourage you to choose the better story from the two whenever possible**.

Notes:

- Sometimes, you might be able to think of a more interesting story for a given topic and emotional trajectory than the ones shown. However, while judging, **if the story seems logical, fluent and grammatically correct, please don't penalize it.**

An Example

Topic: *Coast storm*

Emotional Trajectory: *joy - joy - sadness*

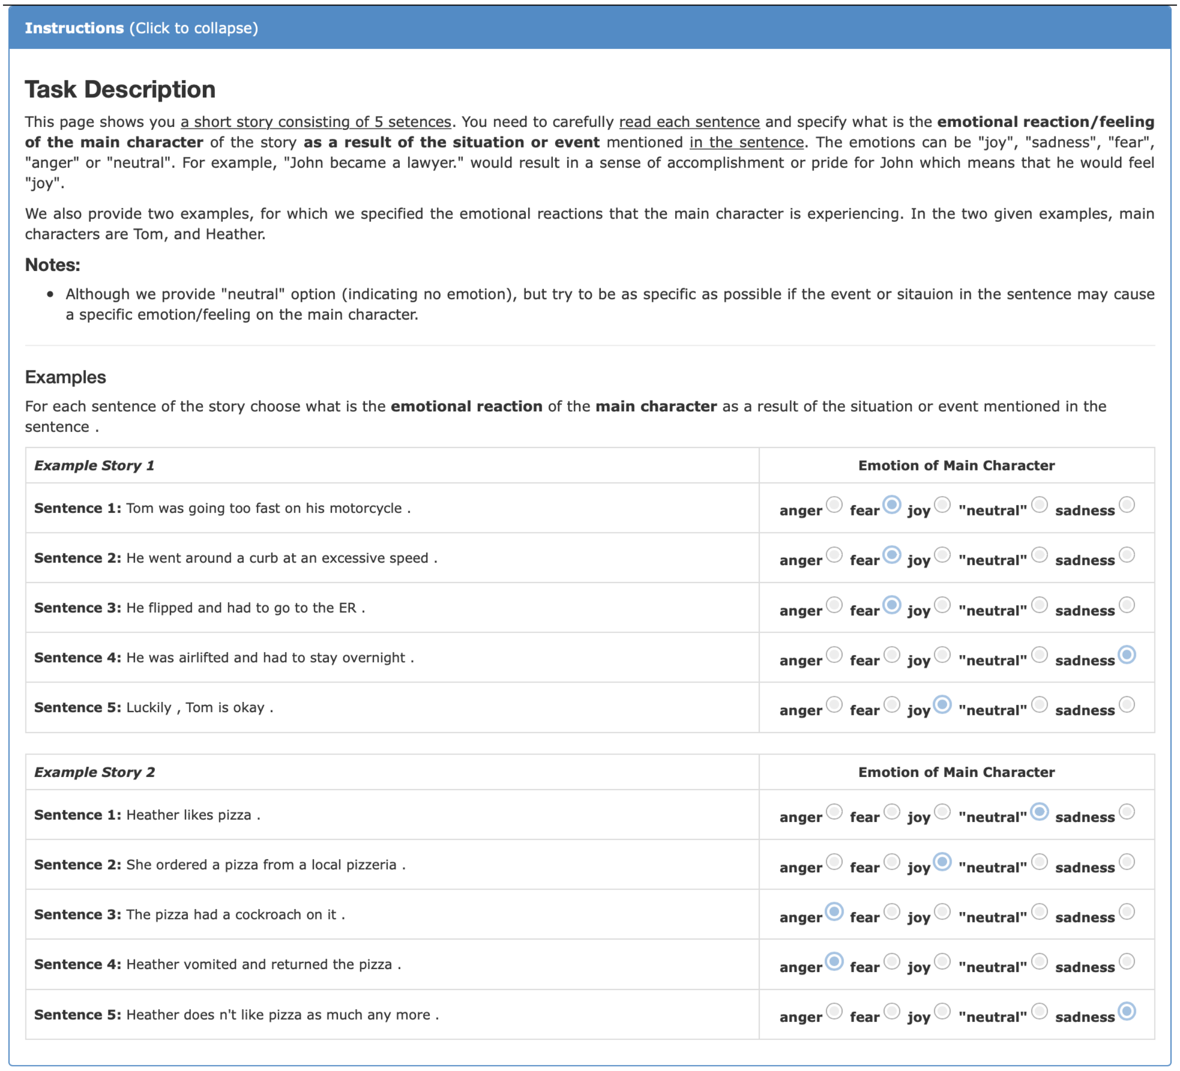
First **rate** the stories based on the two criteria, and then **choose which story is overall better**.

Stories	**Content Quality**	**Emotion Faithfulness**	**Overall Preference**
Story 1: Harvey and his family saved up money for a vacation. After a year of saving , Harvey made plans to go to the coast. Harvey and his family drove to their hotel location. When they arrived , the family was greeted by constant rain. It rained so hard , the family had to go home.	3	3	***Story 1:*** ● ***Story 2:*** ○ ***Equal:*** ○
Story 2: It was raining and John was feeling sad. He decided to go to the beach with his friend. John called his friends, but none of them were available. He was disappointed. He stayed at home for the rest of the day.	3	1	

Response for overall Preference:

Although both stories are fluent and coherent, the first story (Story 1) reflects emotional trajectory better.

Figure 6: An screenshot of manual evaluation on AMT.



Instructions (Click to collapse)

Task Description

This page shows you a short story consisting of 5 setences. You need to carefully read each sentence and specify what is the **emotional reaction/feeling of the main character** of the story **as a result of the situation or event** mentioned in the sentence. The emotions can be "joy", "sadness", "fear", "anger" or "neutral". For example, "John became a lawyer." would result in a sense of accomplishment or pride for John which means that he would feel "joy".

We also provide two examples, for which we specified the emotional reactions that the main character is experiencing. In the two given examples, main characters are Tom, and Heather.

Notes:

- Although we provide "neutral" option (indicating no emotion), but try to be as specific as possible if the event or sitauion in the sentence may cause a specific emotion/feeling on the main character.

Examples

For each sentence of the story choose what is the **emotional reaction** of the **main character** as a result of the situation or event mentioned in the sentence .

Example Story 1	**Emotion of Main Character**
Sentence 1: Tom was going too fast on his motorcycle .	**anger** ○ **fear** ● **joy** ○ **"neutral"** ○ **sadness** ○
Sentence 2: He went around a curb at an excessive speed .	**anger** ○ **fear** ● **joy** ○ **"neutral"** ○ **sadness** ○
Sentence 3: He flipped and had to go to the ER .	**anger** ○ **fear** ● **joy** ○ **"neutral"** ○ **sadness** ○
Sentence 4: He was airlifted and had to stay overnight .	**anger** ○ **fear** ○ **joy** ○ **"neutral"** ○ **sadness** ●
Sentence 5: Luckily , Tom is okay .	**anger** ○ **fear** ○ **joy** ● **"neutral"** ○ **sadness** ○

Example Story 2	**Emotion of Main Character**
Sentence 1: Heather likes pizza .	**anger** ○ **fear** ○ **joy** ○ **"neutral"** ● **sadness** ○
Sentence 2: She ordered a pizza from a local pizzeria .	**anger** ○ **fear** ○ **joy** ● **"neutral"** ○ **sadness** ○
Sentence 3: The pizza had a cockroach on it .	**anger** ● **fear** ○ **joy** ○ **"neutral"** ○ **sadness** ○
Sentence 4: Heather vomited and returned the pizza .	**anger** ● **fear** ○ **joy** ○ **"neutral"** ○ **sadness** ○
Sentence 5: Heather does n't like pizza as much any more .	**anger** ○ **fear** ○ **joy** ○ **"neutral"** ○ **sadness** ●

Figure 7: A screenshot of human annotation for protagonist's emotions.

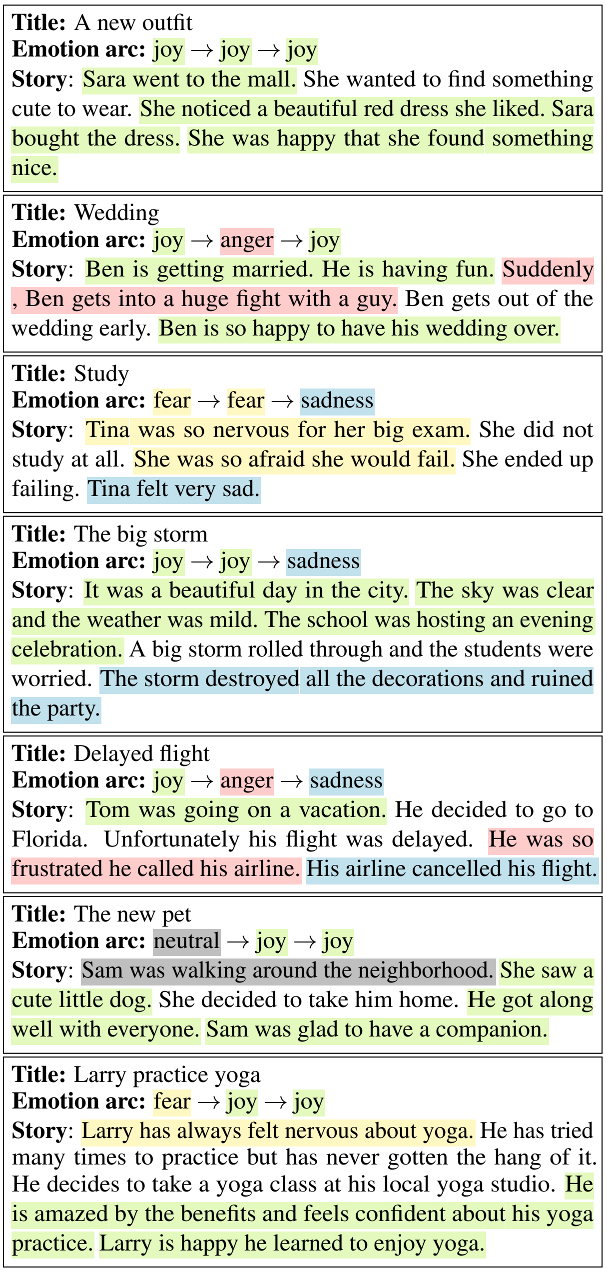
Models	PPL (↓)	BLEU-1 (↑)	BLEU-2 (↑)	Dist-1 (↑)	Dist-2 (↑)	Dist-3 (↑)	Repet-4 (↓)
S2S	22.60	21.98	2.82	64.00	87.07	93.90	36.57
ConvS2S	23.90	20.37	2.63	66.98	91.22	95.68	19.29
Fusion	22.34	20.44	2.66	67.05	91.26	95.71	19.26
Plan&Write	$21.11^{\dagger}$	22.27	3.03	65.18	88.45	95.11	30.43
Decom-Event	$18.16^{\dagger}$	18.14	1.69	68.82	92.39	97.40	20.52
GPT-2 + FT	**12.16**	**22.68**	**3.10**	**72.93**	**94.24**	**98.28**	**12.10**

Table 7: Base Storytelling model: Automatic evaluation. The scores marked with † indicate models that have access to extra ground-truth information besides title (keywords and event tuples).

than all baselines for all measures. This demonstrates that it can be used as a good base storytelling model upon which our models are built.

B.4 Emotional-Aware Storytelling

Supplementary qualitative examples We provide more qualitative examples in Fig 8. In the figure we show stories generated by our model for a given title and emotion arc for the protagonist.



Title: A new outfit
Emotion arc: joy → joy → joy
Story: Sara went to the mall. She wanted to find something cute to wear. She noticed a beautiful red dress she liked. Sara bought the dress. She was happy that she found something nice.

Title: Wedding
Emotion arc: joy → anger → joy
Story: Ben is getting married. He is having fun. Suddenly , Ben gets into a huge fight with a guy. Ben gets out of the wedding early. Ben is so happy to have his wedding over.

Title: Study
Emotion arc: fear → fear → sadness
Story: Tina was so nervous for her big exam. She did not study at all. She was so afraid she would fail. She ended up failing. Tina felt very sad.

Title: The big storm
Emotion arc: joy → joy → sadness
Story: It was a beautiful day in the city. The sky was clear and the weather was mild. The school was hosting an evening celebration. A big storm rolled through and the students were worried. The storm destroyed all the decorations and ruined the party.

Title: Delayed flight
Emotion arc: joy → anger → sadness
Story: Tom was going on a vacation. He decided to go to Florida. Unfortunately his flight was delayed. He was so frustrated he called his airline. His airline cancelled his flight.

Title: The new pet
Emotion arc: neutral → joy → joy
Story: Sam was walking around the neighborhood. She saw a cute little dog. She decided to take him home. He got along well with everyone. Sam was glad to have a companion.

Title: Larry practice yoga
Emotion arc: fear → joy → joy
Story: Larry has always felt nervous about yoga. He has tried many times to practice but has never gotten the hang of it. He decides to take a yoga class at his local yoga studio. He is amazed by the benefits and feels confident about his yoga practice. Larry is happy he learned to enjoy yoga.

Figure 8: Qualitative examples of generated stories given a title and an emotion arc.

Help! Need Advice on Identifying Advice

Abstract

Humans use language to accomplish a wide variety of tasks – asking for and giving advice being one of them. In online advice forums, advice is mixed in with non-advice, like emotional support, and is sometimes stated explicitly, sometimes implicitly. Understanding the language of advice would equip systems with a better grasp of language pragmatics; practically, the ability to identify advice would drastically increase the efficiency of advice-seeking online, as well as advice-giving in natural language generation systems.

We present a dataset in English from two Reddit advice forums – r/AskParents and r/needadvice – annotated for whether sentences in posts contain advice or not. Our analysis reveals rich linguistic phenomena in advice discourse. We present preliminary models showing that while pre-trained language models are able to capture advice better than rule-based systems, advice identification is challenging, and we identify directions for future research.

1 Introduction

Humans use language in the real world to achieve many goals – communicate intents and desires, to argue and convince, and to ask for and give advice. In recent years, people have increasingly looked to the internet to find advice; advice forums like BabyCenter and r/needadvice have hundreds of thousands of members; studies also showed that people increasingly seek health advice online (Fox and Duggan, 2013; Chen et al., 2018). However, finding the right solution to a problem is difficult, since advice may be spread over multiple posts and pages online. Even within the same post, not all sentences contain relevant advice, like in the following (truncated) reply to a question titled *Is it too late to start a hobby/activity at 12?*:

(1) *..you can always pick anything up you think is interesting and giving it a shot.* You never know what you are good at until you try new things! *Idk if you have a budget or maybe borrow tools but you can try woodworking?* It's fun and frustrating (in a good way) at the same time

Only the italicised sentences are advice to the question asked. Both sentences that follow the advice sentences lend support to the advice, rather than containing advice towards a course of action themselves. People also give advice in different ways (Abolfathiasl and Abdullah, 2013), often implicitly like in the following reply to a question titled *Parenting with a history of depression?*, where advice is implicitly conveyed via personal experience:

(2) I took my meds the whole time. I used the tools I learned in therapy. I talked on Reddit with others to get support and ideas.

Automatic identification of advice in text would thus be extremely useful. Yet, as we see above, it would also require a deep understanding of semantics and discourse pragmatics. In recent years, NLP systems based on large-scale pre-trained language models have shown impressive gains on several linguistic benchmarks (Devlin et al., 2019; Clark et al., 2020; Yang et al., 2019). However, these same models have been found to struggle at tasks that require higher-level processing (Ettinger, 2020), including giving advice (Zellers et al., 2020).

This work aims to advance both our understanding of how people give advice, as well as to provide resources for learning to identify advice. First, we construct a dataset of annotations of advice in English from two advice-focused Reddit commu-

November 16–20, 2020.

nities – r/AskParents and r/needadvice, totalling 18456 sentences across 684 posts (§3). These two subreddits are different in a number of respects. r/needadvice is a general advice forum, while r/AskParents targets a specific audience—parents—who are often active seekers of advice. r/needadvice is more strongly moderated than r/AskParents. In addition, our analysis shows that r/AskParents contains more implicit, narrative advice than r/needadvice (§4). Through this dataset we provide the first-of-its-kind resources to explore the breadth of advice-giving strategies, and testbeds for modeling advice.

We establish benchmarks for this task with BERT (Devlin et al., 2019), a large pre-trained language model, to identify sentences that constitute advice. We find that it is substantially better than a rule-based approach (§5). In an in-depth analysis, we find that BERT re-discovers some linguistic rules that have been previously proposed for identifying advice, but struggles with advice that is more implicit, for example in the form of a narrative, like in (2) (§7). Our results also show that r/AskParents is more challenging for advice identification, despite the fact that r/needadvice has a wider range of topics. We make all of our data and code available online[1].

2 Related Work

Advice Strategies There has been sociological and pragmatic work analysing how people navigate the task of engaging in advice discourse. People weigh interactional costs when giving and asking for advice (Shaw and Hepburn, 2013), and they engage in various strategies to persuade their interlocutor and achieve their goals. Effective advice givers were found to engage in roles that extended beyond giving advice – they help advice seekers clarify their problem, list possible solutions and sort through them, offer support and reassurance, and more (DeCapua and Dunham, 1993). While there has been work by Fu et al. (2019) looking at how people use personal narratives to *ask for* advice online, no work thus far has looked at the discourse of advice *giving* online.

SemEval SemEval-2019 introduced a pilot task on suggestion mining (Negi et al., 2019), recognizing the growing importance of identifying whether a text contains a suggestion towards a course of action or not. The dataset only considers sentences that *explicitly* include suggestions – that is, where one can infer without context that a sentence is a suggestion – while we always give the annotators the wider context of the entire post and question, and ask them to evaluate which sentences are advice based on this wider context. For instance, (2) is advice in the context of the question, but that same narrative could also be support for advice, given a different question. Additionally, suggestions are not synonymous with advice, and can include tips and recommendations (although none of these terms are mutually exclusive). For example, *You should try the food at Italian restaurant* might be construed as a tip or a recommendation, rather than advice.

SemEval-2019 Task 9 provides two datasets – one from a software suggestions forum and another from a hotel reviews website. While the dataset and the suggestion mining models are useful for understanding suggestions, we find that the definition of suggestion is too constrained – explicit suggestions will not include many implicit instances of advice, which we are interested in studying. Secondly, we find the domain of their datasets to be somewhat restricted, and not representative of the wide range of online advice-seeking behavior. We chose to construct datasets based on subreddits devoted to asking for advice related to parenting and general issues, since we want to understand how to model general human advice-seeking interactions. We target parenting as parents frequently seek and give advice online, and express it in linguistically diverse forms. For general advice, r/needadvice has clear grouping mechanisms (“flairs”) that inform us with the topic of advice, which we use during analysis.

TuringAdvice Contemporaneous work from Zellers et al. (2020) introduces a new framework to evaluate the performance of language models. `TuringAdvice` challenges models to generate advice that is at least as helpful to the advice seeker as human generated advice. They introduce a new dataset called REDDITADVICE, which scrapes posts from a wide variety of advice subreddits. Annotators on Mechanical Turk were presented with a Reddit post seeking advice, along with two replies to the post, and were asked to choose which reply constitutes the more helpful advice.

However, as (1) shows, the entirety of a response to a question rarely constitutes advice. In contrast,

---

[1] `https://github.com/venkatasg/Advice-EMNLP2020`

our work annotates and identifies explicit and implicit advice *within* a reply to an advice-seeking posts and finds that less than 40% of sentences in a reply are actually advice (Table 3). Moreover, we focus on *understanding* how people give advice linguistically, and to what extent pre-trained language models are able to identify advice. We believe our approach of analyzing what constitutes advice at the semantic and discourse level complements the motivation of Zellers et al. (2020).

3 Data Collection

3.1 Data sources

In this section, we describe the data pipeline that we used to collect annotations. We sourced our data from Reddit – an online forum composed of many communities dedicated to specific topics (called subreddits). We gathered our data from two subreddits – r/AskParents, which is a forum for parents seeking advice on how to raise their children, and r/needadvice, a general advice forum, where users (or moderators) also have the ability to tag their advice-seeking posts with a specific flair (i.e. category). r/AskParents and r/needadvice were chosen for their respective narrow and wide domains (and audience), and also because we believed we might see differences in how advice is communicated based on our pilot studies. r/needadvice is also more highly moderated than r/AskParents, having more rules for users to follow for posting and replying to posts. We believe all of these factors contribute to two different "styles" of advice-giving.

For r/needadvice, we study posts which contain the following highly frequent flairs: "Education", "Career", "Mental Health", "Life Decisions", and "Friendships". Some flairs were not considered due to the lack of variety in responses. For example, in the "Medical" flair, replies often consisted of telling the original poster to see the doctor.

3.2 Annotation Task

We crowdsource advice annotations from Amazon Mechanical Turk. Despite the inherent noise due to crowdsourcing (Parde and Nielsen, 2017), recent work showed that when designed carefully, *aggregated* crowdsourced annotations are trustworthy even for complex tasks (Nye et al., 2018).

As (1) illustrates, not all sentences in a response to an advice-seeking question constitute advice. Thus, we want annotators to highlight which parts of the response to a question are advice, and which are not. We also want to find instances of implicit advice, i.e., advice that is given indirectly, like in (2). To ensure that annotators can also identify advice that might be marked using contextual cues, we provide annotators with sufficient context.

Dataset	Sentences	κ_{maj}	κ_{DS}
AskParents	203	0.620	0.669
needadvice	110	0.680	0.681

Table 1: Gold annotator agreement on the internal task.

In our task, we present annotators with an advice-seeking post and the post's corresponding replies. Given the hierarchical structure of forum replies, we show workers comment-trees, where a comment-tree is a comment and all of its replies[2]. Annotators are instructed (with examples) to highlight instances of both direct and indirect (implicit) advice within these comment trees. The highlighting interface, setup using the third-party tool BRAT (Stenetorp et al., 2012), asks annotators to highlight the longest contiguous span of text that they deem to be advice that addresses the question in the post.

Preprocessing We recruited annotators on Amazon Mechanical Turk who were from the USA, had a minimum approval rating of 95%, and had completed at least 500 HITS. To ensure that the posts on which annotators worked were substantive, we chose posts from both subreddits that were at least 3 days old and had at least 3 comments with 10 or more tokens. Comments made by the original poster or moderators usually did not contain any advice, so they were excluded[3]. To keep the task load reasonable for annotators, any posts with a submission title and body exceeding one standard deviation above the average length of posts (421 tokens) were filtered out; we restricted comment-trees to a depth of 2 and constructed HITS to contain at most 5 top-level comments to an advice-seeking post. Each HIT was annotated by 5 annotators for $0.15 per HIT. We perform a final round of preprocessing on our dataset to ensure quality (Cachola et al., 2018), by removing annotations from workers whose Spearman correlation against the sum of labels within a HIT was below 0.2.

---

[2] The order of comment-trees are determined by Reddit's ranking algorithm. We ordered by "top" comments

[3] If the original poster makes a reply to an existing comment, we only annotate posts that appear *before* that reply.

Dataset	Acc	P	R	F1
AskParents	83.71	76.86	79.62	73.14
needadvice	85.99	85.71	79.99	79.55

Table 2: Average inter-annotator agreement for all workers against DS labels

Dataset	Train	Dev	Test
AskParents	8701(.29)	802(.33)	1091(.26)
needadvice	6148(.37)	816(.34)	898(.37)

Table 3: Sentence metrics in our dataset, with fraction DS-labeled as advice.

3.3 Annotator agreement

We use *sentences* as our processing unit for advice identification. While BRAT does not restrict highlights to be along sentence boundaries, we observed that when a sentence contains highlights, 77.9% of the tokens are highlighted, and that using sentences as units avoids fine-grained annotator variability resulting from the free-form highlighting interface.

Label aggregation Following Nye et al. (2018), we use the Dawid-Skene algorithm (Dawid and Skene, 1979) to obtain aggregated labels, henceforth referred to as Dawid-Skene (DS) labels[4]. This is an EM based algorithm that estimates the label with the maximum estimated posterior probability by iteratively computing annotator competencies and type probabilities. The algorithm ensures that competent annotators are given higher weight, and we show below that it is preferable to majority vote aggregation.

Expert annotation To evaluate the reliability of the DS labels, pilot annotations were done internally by three authors, two of whom are trained linguists. They also constructed an "expert" annotation of a randomly selected subset of posts, containing 203 sentences for r/AskParents and 110 sentences for r/needadvice. Cohen's Kappa (Cohen, 1960) was 0.529 for r/AskParents and 0.572 for r/needadvice, indicating moderate agreement. Disagreements in expert annotations were subsequently adjudicated to construct the gold annotations on the subset of posts.

Agreement Table 2 evaluates the agreement between annotators in terms of micro-averaged accuracy, precision, recall and F1 between each worker and the DS labels. These numbers, although moderately high, show that there is disagreement among workers. However, Nye et al. (2018) found that despite the internal noise with complex tasks, the aggregated labels can still align well with experts. Table 2 also shows that agreement scores are higher on r/needadvice than on r/AskParents.

Table 1 reports the Kappa values of the resolved expert labels against either the DS labels or majority vote. We find that DS labels have substantial agreement with expert labels, and that the agreement is higher than majority vote. This result confirms that the aggregated DS labels are reliable.

A note on posts with deleted question bodies We observed after collecting annotations that 69 of 407 posts in r/AskParents and 98 of 277 posts in r/needadvice had been deleted by users or removed by moderators, meaning the submission bodies were missing and only the titles and comment-trees remained. However, most of the titles of these question posts are highly informative, and provide ample context for advice annotation, as shown below:

(3) How can I enjoy my loneliness?

(4) If I quit a grocery store job after two shifts, will I have to report it for employement history?

We identified 19 deleted posts whose titles failed to provide annotators with enough context. However, since we found no discrepancy with the the agreement scores for any annotations from these posts, we don't exclude them from the dataset. We report the agreement scores within deleted posts for both subreddits in Table 12 in the Appendix.

3.4 Corpus

Our final dataset consists of annotations of 407 posts in r/AskParents (by 95 workers) and 277 posts in r/needadvice (by 64 workers). Table 3 gives an overview of the sentence metrics in our dataset, along with the fraction of sentences DS-labeled as advice. We used a train/development/test split of 80-10-10 on posts rather than sentences so as to retain context for sentences in the same post.

4 Preliminary Analysis

4.1 How is advice expressed?

As noted previously, r/AskParents and r/needadvice differ with respect to their styles of moderation, but they are also different communities that may

---

[4] We used Get-Another-Label to generate DS labels

Subreddit	**Other (%)**	**Personal Narrative (%)**
r/AskParents	83.6	16.4
r/needadvice	93.67	6.33
-Career	100	0
-Mental Health	81.82	18.18
-Friendships	100	0
-Education	95.4	4.6
-Life Decisions	88.9	11.1

Table 4: Modes of discourse for advice sentences in each flair/subreddit

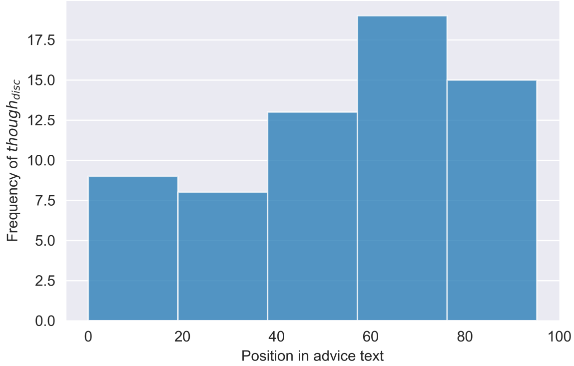

Figure 1: Frequency of discourse connective *though*. X-axis: Frequency, Y-axis: Percentage progress through a reply, 0 is beginning and 100 is end of reply.

engage in giving advice differently. To understand how this impacts the structure of replies to posts, we manually analyzed 10 different posts from r/AskParents, and 4 different posts each from the flairs of r/needadvice.

We observed that people often give advice by alluding to their personal experience, for example:

(5) I did the classic Ferberizing : check on baby after 5 mins , then 10 mins , then 20 mins , etc , until asleep .

Otherwise, a range of pragmatic strategies are adopted as noted by Abolfathiasl and Abdullah (2013), including the use of questions, imperatives, conditionals, etc.:

(6) Have you tried a calm spray ?

(7) Figure out why they like them , and then recommend those ones for those reasons .

(8) If he does n't want therapy , maybe an antidepressant would help .

Personal narratives are particularly interesting because it can be used to express advice indirectly, as in example (2). Table 4 reports the percentage of advice sentences that contain personal narratives. We analyzed 213 sentences DS-labelled as advice from 13 posts for whether they contained personal narratives. We observe that r/AskParents has a higher percentage (16.4%) of personal narrative sentences than r/needadvice overall (6.33%), though *Mental Health* posts in r/needadvice have a high percentage of sentences that expressed personal narratives, at 18.18%. These statistics, as well as the lower agreement statistics for r/AskParents which we report in Table 2, suggest that r/AskParents is in general a harder dataset to work with.

Personal narrative versus other advice-giving strategies demonstrates distinctions in *discourse modes* of advice. Smith (2003) recognizes 5 different discourse modes – narrative, descriptive, report, information and argumentative – which roughly identify a text's contribution through clusters of linguistic features including temporal progression, stative vs. generic sentences, etc. We found that personal narrative is often expressed in the *narrative* discourse mode, as shown in example (5) above. For non-personal-narrative advice, the *argumentative* discourse mode is highly prevalent, as shown in example (7) above. Additionally, we have also observed the *information* discourse mode, where the advice-giver expresses known facts in a general stative:

(9) Just a bit of female health advice, having a late period is very normal

Finally, we noticed that advice-givers will tend to hedge their advice towards the end with a condition or possible consequences of following their advice, or as a form of reassurance. Take the following example from our dataset:

(10) **Q**: Help. Accidentally fed one month old 4oz of baby water... Will she be okay? **A**: She will absolutely be fine . Water is n't bad for a baby , *though* obviously formula / breast milk is best.edit : You 're a good mom for being concerned *though* .

The discourse marker "though" is frequently used for signalling concession and contrast (Prasad et al., 2003). This intuition is confirmed by an analysis of the discourse connective "though" among all posts we collected, which revealed a clear tendency towards the end of a reply, as illustrated in Figure 1.The lexical discourse marker "though" was found by splitting a large collection of posts and replies from r/AskParents into Elementary Discourse Units (Mann and Thompson, 1988), using a neural discourse segmenter (Wang et al., 2018).

	Advice	Non-advice
r/AskParents	book if take something help then you might talk need down can etc play find show or great also give buy big watch diaper car about else minute spend baby	luck sorry shit however dog crazy teenager op die eventually three wish weird daughter yeah brother example miss gender anyway anymore comment morning lol boyfriend girl younger hope drive mine
r/needadvice	he phone night adult stay set big game doctor fun bring less show love depend activity eat normal put teacher family etc minute teach allow home they area	luck degree company college interview hobby student field mental course op sorry job dog anxiety hire eventually position path shit comment human online community shoe thanks note exercise depression slowly

Table 5: Top 30 lemmas ranked by logodds ratio

4.2 Non-advice sentences in advice posts

Table 3 shows that the majority of sentences in replies to an advice-seeking post do not actually contain advice. To understand this phenomenon, we looked into sentences that are annotated as non-advice in our dataset. We found several distinctive phenomena, some of which are described with examples below (non-advice text is italicised):

(11) Expressing sentiment: I also found being fully prepared for an interview calmed me down …*Good luck on your interviews and fingers crossed* .

(12) Providing support to advice: Look for smaller outfits , they 're more likely to be willing to give you some time . *Most professionals - if they have the time - are more than happy to talk to a student about what they do , especially if the student is interested in the same field* .

(13) Reasoning about the situation: *Yes , no one will ever know the big answers to the big questions* . What is the only thing that if shared , will grow larger in size?Answer : Love . Let that define your actions in life .

These non-advice sentences suggest a highly dynamic way in which advice-giving is structured into a coherent discourse. They also indicate that context can play a role in identifying advice.

4.3 Lexical Analysis

To motivate that the language of advice varies systematically from non-advice, we quantify how strongly individual lemmas are associated with advice versus non-advice text. We use the log-odds ratio as a metric of comparison (Nye and Nenkova, 2015). To counteract the tendency of log-odds scores to highlight infrequent lemmas (Monroe et al., 2017), we filter out lemmas that occurred less than 20 times in the train and validation set of our corpus.

Table 5 shows the top 30 lemmas (excluding punctuation characters and numbers) from advice and non-advice sentences for each subreddit ranked by their log-odds ratio. We observe that there are fewer verbs among non-advice lemmas than advice lemmas, and that lemmas which are generally used in expressing sentiment (*luck*, *sorry*, *thanks*) are more likely to be found in non-advice sentences. Combined with our observations in §4.2, this shows that language varies systematically between advice and non-advice sentences.

5 Models

Task setup We have constructed a dataset from the subreddits r/needadvice and r/AskParents as a general purpose resource for studying the breadth of advice-giving strategies. Our modelling experiments aim to establish baseline performance for rule-based models and language models at identifying advice, as well as explore how their performance varies with domain and provided context. We model advice identification as a binary classification task – given a sentence, predict whether the sentence is advice or not.

Baselines We test the baseline rule-based model and the top performing rule-based submission (**NTUA-IS**; Potamias et al., 2019) from SEMEVAL Task 9 2019 on our dataset, and use the results of these rule based models as baselines against which to gauge the performance of more advanced ones based on pre-trained language models.

The baseline model provided by Negi et al. (2019) uses search patterns to identify suggestions, including words (*suggest, recommend*), phrases (.*would\slike.*if.*), and part-of-speech (POS) tags (*modals, past tense verbs*).

However, some of these rules are naive and not intepretable – such as classifying a sentence as a suggestion if it contains a modal or the base form of a verb. Potamias et al. (2019) improve upon this baseline with more keywords and phrases, searching for more rigorous POS patterns within clauses rather than sentences, and assigning different confidence scores for keyword and POS matches[5]. A sentence is classified as a suggestion if it exceeds a preset confidence score.

Since there is broad overlap between the purposes of their task and our analysis, we believe the results of these rule-based models are good baselines for our dataset. Moreover, the lexical and linguistic rules provide avenues of analysis for interpreting how our models make predictions.

Utilizing pre-trained language models Pre-trained language models based on the Transformer architecture (Vaswani et al., 2017) subsequently finetuned on a dataset relevant to the downstream task of interest have proven to be immensely successful in NLP. Therefore, we consider two model architectures based on BERT (Devlin et al., 2019). We finetune models separately on r/AskParents and r/needadvice.

BERT has been pretrained for classification tasks with a special [CLS] token appended at the beginning of the sentence. We use this token's final hidden layer representation exclusively for classification. We experiment with 3 different ways of passing inputs to the pre-trained language model, varying the presence of some form of context:

1. $\textbf{BERT}_{\textbf{sent}}$: We only use the sentence as input.
2. $\textbf{BERT}_{\textbf{sent+q}}$: BERT has also been pretrained for question-answering tasks with a CLS token followed by two spans of text with a separation ([SEP]) token between them, like so: [CLS] SENTENCE A [SEP] SENTENCE B. We set SENTENCE A as the sentence being classified and SENTENCE B as the title and last three sentences of the corresponding advice-seeking post.
3. $\textbf{BERT}_{\textbf{sent+c}}$: In addition to using the advice-seeking post as context for the sentence, we experiment with using the rest of the reply as context. We set SENTENCE B as the remainder of the reply by that user.

We also present results for non-finetuned BERT embeddings ($\textbf{BERT}_{\textbf{noft}}$), where we only finetune the parameters of the classifier on top of the BERT model.

	Model	**P**	**R**	**F1**
r/AskParents	SEMEVAL	32.7	70.2	44.6
	NTUA-IS	31.4	64.9	42.3
	$\text{BERT}_{\text{noft}}$	62.6 (1.2)	14.9 (1.0)	24.0 (1.4)
	$\text{BERT}_{\text{sent}}$	54.9 (2.4)	49.5 (4.4)	**51.9** (1.9)
	$\text{BERT}_{\text{sent+c}}$	54.2 (2.1)	49.9 (4.0)	51.9 (2.2)
	$\text{BERT}_{\text{sent+q}}$	61.0 (13.4)	33.1 (11.9)	37.4 (8.1)
r/needadvice	SEMEVAL	44.5	80.3	57.2
	NTUA-IS	43.0	70.9	53.5
	$\text{BERT}_{\text{noft}}$	82.9 (0.5)	44.6 (1.4)	58.0 (1.2)
	$\text{BERT}_{\text{sent}}$	79.7 (3.8)	76.3 (3.9)	**77.8** (0.3)
	$\text{BERT}_{\text{sent+c}}$	80.4 (4.4)	75.3 (4.4)	77.6 (0.7)
	$\text{BERT}_{\text{sent+q}}$	83.4 (4.8)	64.7 (7.4)	72.5 (3.5)

Table 6: Classification results on test set.

Generalizability We explore the generalizability of models finetuned on r/AskParents and r/needadvice by taking the best performing model on each dataset and analyze the predictions of the model on the other dataset. Since our r/AskParents dataset is larger, we also experiment with training on a subset of r/AskParents that is similar in size to r/needadvice.

Implementation We use the *bert-base-cased* pretrained embeddings from HuggingFace's Transformers module (Wolf et al., 2019). All models are optimized with AdamW (Loshchilov and Hutter, 2019) and fine tuned for a maximum of 6 epochs with early stopping. We used a batch size of 32, and set weight decay to 0 and learning rate to `1e-5`.

Evaluation We report precision, and recall and F1 scores for all models. The results for the finetuned BERT-based models are averaged over 5 random restarts during finetuning, and presented along with their standard deviation in parentheses.

6 Results

Baseline The performance of the baseline models and the finetuned language models are given in Table 6. Surprisingly, we find that our baseline rule-based models perform reasonably well – they outperform non-finetuned BERT embeddings at recall. However, as noted previously, many of the keyword and POS pattern rules are simplistic, which explains their high false positive rate.

r/AskParents vs r/needadvice We observe that all of the models perform better on the r/needadvice dataset, providing further evidence that r/AskParents is a more challenging dataset. As already discussed, this is likely due to a combination of factors – r/AskParents is less moderated

---

[5] Due to the lack of availability of code from Potamias et al. (2019), we attempted to reverse engineer all of their rules to the best of our ability.

Model	P	R	F1
AP → AP	54.9 (2.4)	49.5 (4.4)	51.9 (1.9)
AP_p → AP	59.1 (3.5)	44.4 (4.1)	50.5 (1.8)
NA → AP	61.9 (4.9)	39.7 (3.5)	48.1 (1.3)
NA → NA	79.7 (3.8)	76.3 (3.9)	77.8 (0.3)
AP → NA	74.0 (4.0)	79.3 (2.9)	76.5 (0.9)
AP_p → NA	76.9 (3.8)	75.5 (4.7)	76.0 (1.1)

Table 7: Generalizbility results on test set. AP=r/AskParents, AP_p = AP subset, NA =r/needadvice

than r/needadvice, and contains a higher proportion of narrative compared to argumentative discourse modes.

$\text{BERT}_{\text{sent+c}}$ We observe that adding context to a post does not improve model performance. This could be because the architecture we used to add context to the model, [CLS] SENT [SEP] CONTEXT [SEP], may not be conducive to retrieving contextual information necessary to identify advice.

$\text{BERT}_{\text{sent+q}}$ Curiously, appending information from the question using the same architecture leads to a noticeable loss in model performance along with high variability. This could be because the question and the sentence are written by different users, leading to discourse incoherence which might confuse the model. For instance, while $\text{BERT}_{\text{sent}}$ classified the following sentence correctly, appending the question title and last 3 sentences of the question body lead it to go astray:

(14) **Sentence**:You don't actually have to tell her anything of any substance. **Question**: Why is my Mother so negative over my new job? The end Rant over, thank you all

We experimented with only appending the question title, as well as excluding posts that had deleted post bodies, and found similar loss in performance along with variability.

We have illustrated that context from the question (like in (2)) and from the rest of the reply (like those in §4.2) can help in identifying advice. However, neither of our models with context outperforms the model without context. Future work needs to work on building better models that can extract relevant information from these contextual cues to inform advice identification.

Generalizability Table 7 shows that while testing on another advice domain leads to lower performance on both subreddit datasets, the model trained on r/AskParents, a more niche subreddit, performs well on the more general r/needadvice subreddit. Our model results suggest that data from both subreddits is sufficiently generalizable for models to learn some general features of what constitutes advice. Moreover, training on a subset of the r/AskParents data (71% randomly sampled) doesn't lead to substantial degradation of performance on r/AskParents (or r/needadvice). This result indicates that models find it harder to learn from our r/AskParents dataset, since more data doesn't seem to lead to substantial improvements in performance.

Flair	P	R	F1
Friendships	85.5 (5.7)	93.8 (0.0)	89.2 (2.9)
Mental Health	75.6 (3.5)	74.7 (3.6)	75.0 (0.6)
Education	86.8 (2.9)	67.4 (6.2)	75.7 (3.1)
Career	75.9 (5.1)	78.0 (3.8)	76.7 (1.3)
Life Decisions	82.4 (4.4)	82.8 (3.5)	82.4 (0.7)

Table 8: Flair results on test set.

Flairs Table 8 reports per-flair results (of the $\text{BERT}_{\text{sent}}$ model) on r/needadvice. We observe that the lowest performance is in the flairs Mental Health and Career. We had shown previously (Table 4) that Mental Health had a high proportion of personal narrative discourse, which we can see tends to lead to lower performance. For Career, the reasons are less clear.

7 Analysis

We chose the $\text{BERT}_{\text{sent}}$ model – the best performing model on both datasets, and analyzed the attention weights to see if they show some of the patterns we used in the baseline models. The attention weights were visualized using BertViz (Vig, 2019).

Attention Analysis Transformer based language models utilize multiple self-attention heads to learn higher order and long distance relationships among words in a sentence. In Figure 2, we visualize the distribution of attention weights from the final hidden layer, with each color representing a different attention head. The [CLS] token is observed to attend to the modals that the baseline rule based models have explicitly encoded in them.

The model is also robust to noise in our annotation protocol. The sentence in Figure 3, was improperly annotated as not advice, as was the aggregated DS label. However in Figure 3, which visualizes the attention distribution in the penultimate layer, we observe that the model attends to

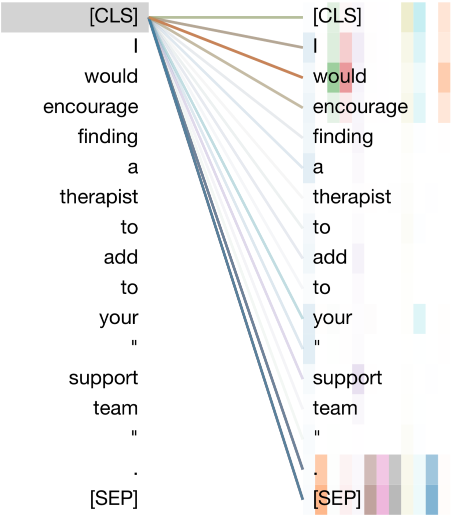

Figure 2: Attention distribution of a reply to a post titled *Parenting with a History of Depression?*.

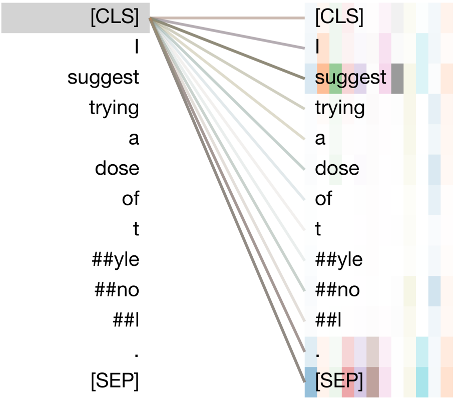

Figure 3: Attention distribution of a reply to a post titled *Why will my 10 month old not stop crying?*.

suggest, and correctly predicts this sentence to contain advice. This is promising, since it shows that finetuned language models are latching onto surface level syntactic and lexical cues that we know to be indicative of advice.

Narrative Discourse Narrative discourse is known to contain higher instances of advice that is given implicitly (Abolfathiasl and Abdullah, 2013). For instance, the following is a different reply to the same post dicussed in Figure 2:

(15) I talked on Reddit with others to get support and ideas .

The user is implicitly suggesting to the advice-seeker that they should talk with others on Reddit, since it helped them. This span was annotated as advice, but our model predicts otherwise. To understand if the model struggles with personal narratives, we analysed its performance on sentences that contain the personal pronouns *me*, *my* or *we* which we take as indicative of personal narrative. A cursory analysis of the validation sets found 109 such sentences in r/AskParents, 81 of which we consider to be personal narratives, and 100 such sentences in r/needadvice, 66 of which we consider to be personal narratives.

Dataset	P	R	F
AP	54.9 (2.4)	49.5 (4.4)	51.9 (1.9)
AP_{pers}	43.4 (4.3)	31.7 (5.7)	32.2 (7.7)
NA	79.7 (3.8)	76.3 (3.9)	77.8 (0.3)
NA_{pers}	61.2 (16.3)	37.9 (6.9)	45.9 (6.9)

Table 9: Performance of model on test set comprising only personal narrative sentences. AP=r/AskParents, NA=r/needadvice

Table 9 shows that the model performance suffers on sentences that are approximated to contain personal narratives. We also observe a higher variability in the performance of the models, which indicates that the model is also highly uncertain of its predictions in such contexts. Future work on advice identification needs to look into how this can be improved using discourse level information.

8 Conclusion

We introduce a new dataset on advice given on the online platform Reddit, specifically r/AskParents and r/needadvice that differ in audience and level of moderation. We find that advice language consists of various pragmatic strategies and discourse structures. We find that fine-tuned BERT discovers certain surface-level features indicative of advice, but struggles to disambiguate instances of implicit advice conveyed through personal narrative. Future work needs to look into how question and reply context can improve automatic identification of advice.

Acknowledgments

We thank the anonymous reviewers for their valuable feedback. We are grateful to family and friends who supported the authors personally during the COVID-19 pandemic. Quantifying Intimacy in Language

Abstract

Intimacy is a fundamental aspect of how we relate to others in social settings. Language encodes the social information of intimacy through both topics and other more subtle cues (such as linguistic hedging and swearing). Here, we introduce a new computational framework for studying expressions of the intimacy in language with an accompanying dataset and deep learning model for accurately predicting the intimacy level of questions (Pearson's r=0.87). Through analyzing a dataset of 80.5M questions across social media, books, and films, we show that individuals employ interpersonal pragmatic moves in their language to align their intimacy with social settings. Then, in three studies, we further demonstrate how individuals modulate their intimacy to match social norms around gender, social distance, and audience, each validating key findings from studies in social psychology. Our work demonstrates that intimacy is a pervasive and impactful social dimension of language.

1 Introduction

Intimacy is a vital ingredient in the hierarchy of human needs (Maslow, 1981; Erikson, 1993; Sullivan, 2013), playing key roles in development (Harlow and Zimmermann, 1959) and well-being (Sneed et al., 2012). Language provides multiple means of conveying intimacy in a social context as individuals make decisions on the topic of conversation, phrasing, and markers relating the speaker to the world. Much like how social status and power are constructed and expressed, individuals negotiate intimacy in language to fulfill fundamental and strategic needs, while respecting social norms about the appropriate intimacy (Chaikin and Derlega, 1974; Korobov and Thorne, 2006). In this paper, we aim to quantify the intimacy expressed in language and demonstrate how this intimacy is constructed and employed across diverse social settings.

While sociolinguistics and social psychology have long pointed to how people shape their language to convey social information (Labov, 1972; Brown and Levinson, 1978; Clark and Schunk, 1980; Weber, 2008; Locher and Graham, 2010), only recently, have computational models focused on making this information explicit (Choi et al., 2012; Danescu-Niculescu-Mizil et al., 2013; Bak et al., 2014). In particular, works on social status and power have shown how individuals use lexical cues and linguistic strategies like accommodation to express their perceived status in relation to others (Danescu-Niculescu-Mizil et al., 2013; Prabhakaran et al., 2014). Much like status in society, intimacy is a natural concept describing how an individual relates to their audience in their perceived interdependence, warmth, and willingness to personally share (Perlman and Fehr, 1987). Our work provides the first model of intimacy in language and tests its implications.

In this paper, we examine the intimacy of questions. As requests for information, questions provide a natural mechanism for studying how people shape the intimacy of their questions in response to the social context (Clark and Schunk, 1980; Jordan and Roloff, 1990). Questions serve a fundamental role in dialogues for interpersonal exchange (Athanasiadou, 1991), and increasingly intimate questions are known to foster deep social ties (Aron et al., 1997; Kashdan et al., 2011). Our work starts from a new dataset of 2,397 questions rated for intimacy using Best-Worst-Scaling (Louviere et al., 2015; Kiritchenko and Mohammad, 2016). We use this dataset to train a deep learning model that obtains high correlation with human judgment on both in-domain and out-domain settings. Using this model, we rate 80,484,458 questions across Reddit, Twitter, literature, and film.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5307–5326,
November 16–20, 2020.

Through this massive dataset, we demonstrate how individuals actively construct their social context through linguistic choices that signal the acceptability of a question's intimacy. Given the role of intimacy in social interactions, we examine the social perspective of intimacy in conversations in three settings. First, we show that the intimacy level of language reflects cultural norms of masculinity and femininity, which our study shows persist across real and imagined settings—and even across other gender's perceptions of the norms. Second, even online, individuals reserve their most intimate questions for close friends and strangers, mirroring offline observations, where the risk of social capital loss is greatest for acquaintances. Finally, online communication affords a new communication mechanism—complete anonymity—for communicating, which we demonstrate is used as a strategy to ask more intimate questions. Both the model and datasets used in this paper are released at `https://blablablab.si.umich.edu/projects/intimacy/`.

2 Theories of Intimacy

As a natural concept in social settings (Helgeson et al., 1987), intimacy has been widely explored in interpersonal, behavioral, and social domains (Prager, 1995; Weber, 2008; Locher and Graham, 2010). Studies of intimacy in communication have primarily focused on the exchange of personal information as a measure of intimacy (Miller and Lefcourt, 1982; Descutner and Thelen, 1991). Yet, intimacy in language is revealed more than just through disclosure, as individuals select topics, phrasings, and styles to indicate their intimacy with another within the social context. Here, we study the role of intimacy in language and argue that intimacy is a natural component of language similar to politeness (Brown and Levinson, 1978). Following, we discuss the theoretical background of intimacy in social psychology and linguistics.

The Concept of Intimacy The concept of intimacy has long been proposed by psychologists with various definitions. While intimacy generally refers to the closeness and interdependence of partners, the extent of self-disclosure, and the warmth or affection experienced within the relationship (Perlman and Fehr, 1987), the concept of intimacy is not restricted to the closeness or interactions between people in intimate relationships, as even people who are not in intimate relationships can have intimate interactions in a certain space and time (Wynne and Wynne, 1986). Therefore, a widely-accepted conceptualization of intimacy is to distinguish between intimate interactions and intimate relationships (Hinde, 1981). The former refers to dyadic communicative exchanges, while the latter is the history and future expectations of intimate contact over time (Prager, 1995). Intimate interactions and intimate relationships are interrelated in the following way: while intimate interactions are necessary in the formation of intimate relationships and are regular within them (Prager, 1995), intimate relationships also build expectations for the depth and types of interactions between people (Chelune and Chelune, 1979).

In this work, we focus on the language aspect of intimate interactions as dialogue is one of the core forms of intimate interactions (Hinde, 1981) and certain ways of communications can facilitate the experience of interpersonal closeness (Aron et al., 1997).

Intimacy in Interpersonal Communication Language is one of the core aspects of intimate interactions (Hinde, 1981) and multiple branches of linguistics have studied aspects of communications in social relationships which relate to intimacy, including interactional sociolinguistics (Gumperz, 2015), conversational analysis (Hutchby and Wooffitt, 2008), and discourse analysis (Johnstone, 2018).

Most notably, works in interpersonal pragmatics have analyzed the relational aspect of interactions between people that both affect and are affected by their understandings of culture, society, and their own and others' interpretations (Locher and Graham, 2010). One closely-related branch of interpersonal pragmatics is the study of politeness (Brown and Levinson, 1978), which demonstrates how people change their expressions to construct politeness with respect to different social settings to signal relative power. Analogously, intimacy in language can also be constructed with intentional pragmatic choices to signal the perceived intimacy between speakers. However, while psychologists have deeply explored people's behavior of self-disclosure (Cozby, 1973) as one of the major components of verbal intimacy (Fitzpatrick, 1987), intimacy in language is not just conveyed by the degree of self-disclosure. The style of the language can indicate the intimacy of the speaker (Bell, 1984), e.g., through adjustments to formality, use of specific terms of address ("dear"), or using in-group vocabulary. While prior computational work has studied the language of power and politeness for assessing hierarchies between speakers (e.g., Bramsen et al., 2011; Prabhakaran et al., 2012; Danescu-Niculescu-Mizil et al., 2013; Sap et al., 2017), little prior work on the language of intimacy exists, with most focusing on self-disclosure (Bak et al., 2012, 2014), which captures only a part of the concept of intimacy. In this study, we test the roles of two linguistic devices in intimate communication (§5), hedging (Hyland, 2005) and swearing (Stapleton, 2010), whose usages theory suggests should change relative to people's expressions of intimacy.

Social Norms in Intimate Communications Group and sociocultural norms may strongly constrain the kinds of behaviors that are acceptable and desirable within certain situations (Allan, 1993). Frequently, these norms specify the acceptable levels of intimate interactions between people in specific social relationships and circumstances (Davies et al., 2013), where violations of these norms lead to loss of face and social capital (Caltabiano and Smithson, 1983). While types of relationships and closeness between people naturally build the expectations that certain levels of interactions are reserved for only selected social ties (Chelune and Chelune, 1979), intimate behaviors and experience may not happen between people who are in close relationships (Hinde, 1981) and are thus regulated by larger social norms like gender. Societal views of gender roles significantly constrain the use of intimate communication, with specific expectations not only of the individual on the basis of their gender (Caltabiano and Smithson, 1983) but dyadic effects depending on the gender identities present (Derlega and Chaikin, 1976).[1] However, individuals are less adherent to these norms as they perceive themselves to be anonymous or when interacting with an individual whom they perceive they will not interact with again (Rubin, 1983; Wynne and Wynne, 1986; Dindia et al., 1997); without the potential loss of face or social capital in such circumstances, individuals are more likely to engage in more intimate communication. Thus, the norms of a social context and expectations around the loss of social capital for violations of these norms act as primary drivers of selecting the degree of intimacy expressed in a given context. Here, we test how intimacy varies across different types of social settings by varying dyadic gender composition in interactions (§6), social distance (§7), and perceived anonymity (§8).

3 Quantifying Language Intimacy

Questions provide a natural mechanism to study the intimacy of language. In conversation, questions are frequently used to request information (Athanasiadou, 1991), providing the interlocutor with the opportunity to respond at a desired level of intimacy. This interactive questioning process can lead to the formation of intimate relationships as the subject matter and nature of disclosure increase over time (Aron et al., 1997). In this study, we aim to quantify intimacy in questions as a continuous variable because people naturally perceive intimacy along a continuum (Schaefer and Olson, 1981). Following, we describe the dataset and annotation process for rating questions by intimacy.

Data Questions are drawn from 41 manually selected question-centered subreddits, e.g., `r/AskReddit`, which encompass a wide variety of topics and conversation styles. The initial set of questions is derived from all post titles made in 2018 containing one question mark. Then for each raw question, we remove Reddit-specific markup, e.g., "[17M]" or address terms to the community, e.g., "Members of r/AskScience, ...", replaced common abbreviations, e.g., "AITA (Am I the Asshole)" with their full expressions. To ensure questions are self-contained, we require the question to be the entire post title and be a single sentence with at least four words. In total, this process yielded 3,212,969 questions; Appendices A and G contain the list of selected subreddits and question cleaning process. From this dataset, we select 2,247 questions to annotate, balancing across months.

Annotation Rating the precise intimacy of question is a challenging task due to the potentially subjective nature of the question and the relative expectations of intimacy. Rather than directly estimating an intimacy value through scale-based annotation, we treat intimacy as a latent variable to be inferred from relative comparisons between questions. Following prior work in NLP on annotating social aspects of language (Kiritchenko and Mo-

---

[1] For example, prior studies have found that males who disclose very personal (intimate) information to other men are viewed as less well-adjusted (Derlega et al., 1976) and are less well-liked (Lazowski and Anderson, 1990).

hammad, 2016), we adopt a Best-Worst-Scaling (BWS) (Louviere et al., 2015) scheme to estimate the latent intimacy values of questions. Here, four questions are shown as a tuple, and annotators are asked to identify the most intimate and least intimate questions of the tuple. As questions could be interpreted in multiple ways depending on the context, annotators were instructed to consider their judgments according to the expected intimacy if the question is asked in a scenario appropriate to its usage. Each tuple annotation generates five pair-wise comparisons between questions' intimacy values that act as constraints when inferring the latent value on a continuous scale.

Prior to annotation, two annotators went through three rounds of training and discussed all disagreements. Following, annotators labeled an initial 212 tuples to assess exact agreement and subsequently, all other tuples were divided up between the two for annotation; these 8,563 tuples included 2,397 questions comprising 2,247 Reddit questions and an additional 150 questions from books, movies and Twitter for generalizability tests. Each question was presented in at least 12 tuples to ensure an accurate approximation. To infer the latent intimacy values of all questions, we use Iterative Luce Spectral Ranking (Maystre and Grossglauser, 2015) to convert the pair-wise comparisons into real-valued scores ranging from -1 (least intimate) to 1 (most intimate).

To test the reliability of the ranked scores, we follow best practices (Kiritchenko and Mohammad, 2017; Mohammad, 2018) and compute the Split Half Ranking (SHR) by randomly splitting all the tuples into two sets, compute the intimacy scores within each, and compare the rankings; note that as the same questions appeared in both annotators' sets of tuples, the inferred ranks in each split reflect the judgments of both annotators. The Pearson's r between the two sets' ranking scores is 0.776, which demonstrates high reliability in the annotations. See Appendices H and I for annotation guidelines and data samples.

Additionally, annotators attained Krippendorff's α=0.548 on 212 tuples. While this α is moderate as inter-annotator agreement (IAA) is normally measured, in BWS, lower agreement is expected when annotators encounter tuples where all four items are perceived to have essentially the same value, e.g., four factual questions asking nothing intimate; in such settings, annotators are likely to arbitrarily select the best and worst, which ultimately leads the items to have similar scores in the BWS scalar conversion process (as intended) but penalizes IAA. As a result, SHR is a better estimate of annotation quality and annotator reliability.

Model	MSE	Pearson's r
Mean-value Predictor	0.08625	0.0000
LR + Bag of Words	0.06532	0.5127
LR + Topic Model	0.05476	0.6211
RoBERTa (base)	0.02855	0.8232
RoBERTa (fine-tuned)	**0.02106**	**0.8719**

Table 1: Question Intimacy Prediction Performance

4 Predicting the Intimacy of Questions

Question intimacy is predicted using model-based regressors. We test two baseline models and two deep-learning regressors based on neural language models. As baselines, we include two linear regression models with L2 regularization separately trained on either (1) bag of words features or (2) topic features. Bag of words features are constructed with unigrams, bigrams and trigrams. The second model uses an LDA model trained with 50 topics using Mallet[2] over a sample of 1M questions that includes the annotated questions; each question is then represented using its topic distribution for regression. Our neural regressors use the RoBERTa (Liu et al., 2019) language model as a base. We include two variants: one which is fine-tuned on 3M unannotated questions on a masked language modeling task, and a second which uses the default parameters in RoBERTa. Training uses only the 2,247 annotated Reddit questions, split 8:1:1 into training, validation, and test. Model settings and validation performance are listed in Appendix E.

Results Table 1 shows that our best model, the fine-tuned RoBERTa model, attains a high correlation with human judgments as measured by Pearson's r. RoBERTa model with question fine-tuning outperforms the RoBERTa base model while both the RoBERTa models outperform all the other baselines. The topic model baseline is still able to attain moderate performance, matching the intuition that some topics are more intimate (e.g., romance) while others are less (e.g., mobile phones). However, as shown in Appendix J, Figure 8, many topics span the range of intimacies, demonstrating that

---

[2] `http://mallet.cs.umass.edu/`

estimating intimacy from topic alone is insufficient.

Final Dataset To study question intimacy, we apply our fine-tuned RoBERTa regressor to our four different question datasets from Reddit, Twitter, books, and movies. For Reddit data, we apply the same question extraction procedure to all content written in 2018 and extract all questions in posts and comments that receive a reply. This process yielded 16.6M post and 60.8M comment questions.

Twitter questions were collected from a 10% sample of tweets from Jan 2018 to April 2020, where the tweet text was a single English question and was made as a direct message to a single person (i.e., reply or mention). We follow a similar question selection process as described in Section 3. Twitter questions were further processed by replacing all mentioned users (e.g., @StephenCurry30) with their screen names e.g., Stephen Curry), removing all emojis, and removing all URLs. After removing duplicates and self-replies, this process yielded 1.04M questions.

Book questions were collected from 51,224 English books on Project Gutenberg (Hart, 1992). BookNLP (Bamman et al., 2014) is used to identify characters' quotes and we identify 2.02M quotes ending with a question mark and having at least four words. We keep the full quote as a question, as the extended context was deemed necessary for correct interpretation.

Movie questions were extracted from the Cornell movie dialogue dataset (Danescu-Niculescu-Mizil and Lee, 2011), where all dialog lines ending with a question mark and at least four words are treated as questions, which yields 53,507 questions.

To test the generalizability of our model on these domains, the annotated data included 50 questions from each non-Reddit source, which were not included in the training data. Over this external dataset, our best-performing model achieved 0.6684, 0.6602, and 0.5233 Pearson's r correlations on the intimacy ratings for book, Twitter, and movie questions, respectively. These moderately-high correlations demonstrate the generalizability of our model on outer domain data.

These four datasets allow detailed study on intimacy in language and social factors due to their variety of content and social setting. Reddit and Twitter are social media data that contains real human messages, while book and movie data are imagined conversations that reflect social norms. Moreover, Twitter questions can be overlaid on its social network data to study the relationships between intimacy in language and social distance.

To test the reliability of our model prediction, the same annotators further annotated 300 question pairs sampled from the final dataset to reflect ranges of differences in their intimacy. Pairs of questions were grouped according to their difference in intimacy using a 0.1 range per group. 30 questions were sampled from each group. Annotators selected which of the two questions was more intimate, or a third option if they had the same level of intimacy. Annotators attained Krippendorff's α=0.70, indicating moderately-high agreement, with most disagreements happening for questions with small differences in intimacy as estimated by the model. Ultimately, 89% of the question pairs have the same order for model prediction and human annotation, indicating the model's estimates of intimacy do match human judgments.

5 Intimacy and Pragmatic Choices

In language, individuals can construct intimacy through stylistic choices that signal their view of the world and personal relationship to the proposed ideas (Bell, 1984). When questions carry the risk of losing face—e.g., broaching more intimate topics beyond what is socially acceptable in the current context—individuals reduce their commitment to the act through linguistic mitigation (Fraser, 1980). Here, we connect interpersonal pragmatics to the language of intimacy, showing how individuals perform pragmatic acts in their questions to mitigates risk as intimacy increases, much like how politeness is employed to save face (Brown et al., 1987). In particular, we examine pragmatic choices in questions around (i) the speaker's certainty, expressed in hedges from Hyland (2005) (ii) the speaker's belief of the social distance, expressed in swearing. To analyze these choices, we compare the mean intimacy ratings in questions relative to whether a specific strategy is employed; to ease comparison across datasets, we first standardize intimacy ratings within each domain.

Certainty Hedging is a marker of intentional vagueness (Lakoff, 1975) and aims to reduce risks in interpersonal communications (Caffi, 1999). Expressing uncertainty in a question can allow people to ask more intimate questions without the risk of inappropriateness. For example, in the following two questions, the hedge (i.e., might) serves to allow the respondent to answer with uncertainty

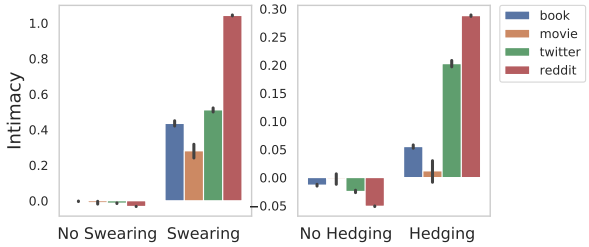

Figure 1: Relative levels of intimacy for questions containing socoiopragmatic markers show that individuals use swearing in intimate settings likely as a way of indicating closeness and hedge when asking intimate questions to decrease risk. Intimacy values are standardized within domain for comparability.

or vagueness, reducing the risk from forcing an overly-intimate answer.

(a) What **might be** your best childhood memory?

(b) What is your best childhood memory?

Figure 1 (Right) shows that questions containing hedging words are generally more intimate than other questions, which is highly consistent across different domains. This result indicates people regularly employ hedging as a strategy to reduce risk when asking more intimate questions.

Social Distance While the use of swear words explicitly transgresses social norms (Andersson and Trudgill, 1990; Monaghan et al., 2012), the act of swearing can express the speaker's perceived solidarity with the audience (Stapleton, 2010, p. 296). In this discursive act, the intentional act of swearing emphasizes in-group status with the audience and normalizes the use of words that would be taboo to out-group members (Fägersten, 2012, p. 99). Therefore, when asking questions, swearing may be employed to construct the perception of stronger social ties that would license more intimate questions. Large-scale analysis across domains also supports this hypothesis. Figure 1 (left) shows that questions containing swear words are far more intimate than others. This finding is consistent in both real conversations (Twitter, Reddit) and imagined conversations (movies, books).

6 Gender Norms in Language Intimacy

Gender is one of the earliest learned social norms for individuals (West and Zimmerman, 1987; Martin and Ruble, 2010), with strong gender expectations around intimacy in conversation (Caltabiano and Smithson, 1983). Social psychologists have found that women show more interest in verbal intimacy than men (Blumstein and Schwartz, 1983; Engel and Saracino, 1986), and are more likely to initiate intimate verbal interactions in marriages (Markman and Kraft, 1989). Even in friendship, female friendships typically involve more intimate self-disclosures than male friendships (Aries and Johnson, 1983; Davidson and Duberman, 1982; Lewis, 1978).

Our four datasets provide an ideal setting for testing theories of gender expectations of intimacy along two fronts. First, relatively-anonymous social media like Reddit provide few social cues about the identity of the person; in these deindividuated settings, do gender norms persist? Second, film and literature reflect imagined conversations that require authors to "do gender" (West and Zimmerman, 1987) from their internalized expectations around intimacy, which is not regulated by actual loss of face for norm violations. In these imagined settings, do authors perform gender expectations on their characters, and are expectations consistent for authors of a different gender?

Methods A user's gender[3] in social media is inferred from their username using GenderPerformer (Wang and Jurgens, 2018), which was trained to operate on social media like Reddit and only returns a gender label for usernames that strongly perform male or female. In movie scripts, we use both the gender labels provided for 3,015 characters in the Cornell movie dialogue dataset (Danescu-Niculescu-Mizil and Lee, 2011) and a second approach to infer gender for another 2,872 characters using a name database based on US baby names from 1930-2015. For questions in books, BookNLP (Bamman et al., 2014) is used to identify the speaker of each question using coreference resolution to identify a canonical name; the speaker's name is then matched using US census names and checked against gendered titles (e.g., Mr.) or roles ("mother"). Additional details on the matching process are provided in Appendix B.

To test for differences in intimacy norms for authors, we construct separate mixed-effect regressions to predict the intimacy of the question for

---

[3] Gender is a complex social construct beyond male and female and we acknowledge the known presence of a small number of nonbinary and transgender individuals in our fictional works, as well as their likely presence in Twitter and Reddit. However, we were regrettably unable to reliably identify these gender identities using current techniques.

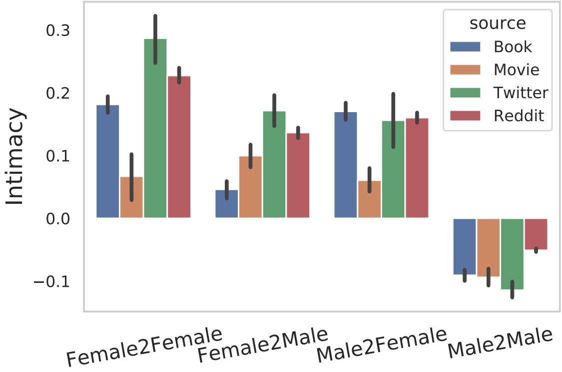

Figure 2: Relative levels of intimacy for questions show that male-to-male conversations hold the least intimacy among four gender dyads. This pattern persists across both real social media data and imagined conversations in books and movies, which indicates a strong social norm of masculinity.

male and female authors. Each domain may have its own level of intimacy, therefore we standardize all intimacy scores within domain to compare z-scores across domain when examining the effect of dyadic gender composition. Each regression includes a fixed effect for the gender of the speaker and audience and nested random effects for the author and book. These random effects effectively control for idiosyncratic differences in authors' perceptions of intimacy, relative differences across genres, and the time period in which the book was written. From this regression, we estimate the average marginal effect on intimacy for depicting a particular gender composition of the dyad, using female-female as the reference category.

Results Dyadic interactions in all four datasets—real and imagined—follow expected social norms for gender and intimacy (Figure 2). Although the relative intimacy levels differ across datasets, female-female questions were the most intimate and the presence of a female audience licenses males to ask more intimate questions, on par with those of females. In contrast, male-male dyadic interactions follow the low-intimacy hegemonic norms of masculinity, where men are supposed to be strong, rational, and inexpressive of personal emotions (Edwards, 2004; Donaldson, 1993).

Do female authors also perpetuate gendered intimacy norms of males or are the trends in Figure 2 driven by male authors only? Shown in Figure 3, these norms persist regardless of whether the interaction is described by a male or female author: male-male interactions have the lowest intimacy in conversation. This result suggests that despite female authors not having direct experience with such interactions, normed expectations around gender intimacy are so firmly established that they persist across gender in imagined settings—even when controlling for genre and time period. However, the disparity between male-male interactions and others is highest for male authors, suggesting these authors reinforce this norm more strongly. Full regression details are in Appendix F.

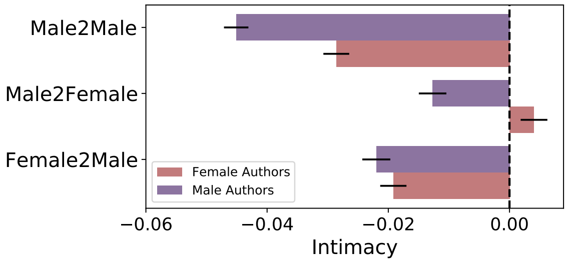

Figure 3: Averaged marginal effect of different gender dyads on intimacy grouped by author gender. Female-to-Female is the dashed baseline here. Both male and female authors write less intimate male-to-male language, which mirrors expectations of lower intimacy.

7 Social Distance and Intimacy

The appropriateness of a specific level of intimacy and associated cost for transgressing expectations vary depending on the social expectations. Among close friends, intimate questions are a natural form of discourse and carry low social risk (Dosser et al., 1983; Miller, 1990). However, people may also share very intimate information with strangers (Simmel, 1950; Rubin, 1975), commonly referred to as the *strangers on a train* effect (Rubin, 1983). Individuals in these encounters have little likelihood of future interactions, removing the consequences for violating intimacy norms around increased disclosure (Thibaut, 2017; Wynne and Wynne, 1986). In contrast to both friends and strangers, individuals are least intimate with casual acquaintances for which there are some expectations of potential future interaction and, therefore, longer-term consequences for norm violations. Together these behaviors point to a hypothesized U-shaped relationship between intimacy and social distance in in-person settings (Rubin, 1975). In social media, individuals come in contact with all three of these cohorts and have the potential to regularly connect individuals with complete strangers. Here, we ask whether these offline behaviors trans-

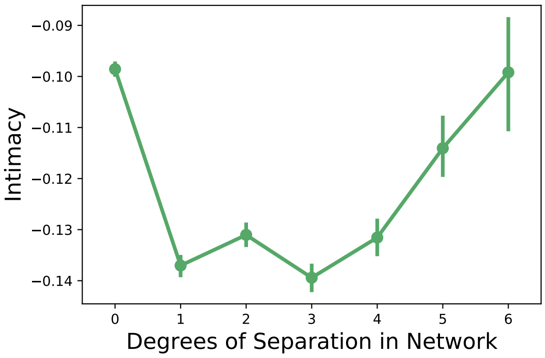

Figure 4: Intimacy in language and the social distance between users. The most intimate interactions happen between close friends or total strangers.

late to a "strangers on the internet" phenomenon.

Data and Methods To estimate familiarity and expected future contact between individuals, we construct a social graph from Twitter of all mentions from a 10% sample of tweets made from January 2013 to April 2020. Following common practice (e.g., Jurgens, 2013; Myers et al., 2014; Faralli et al., 2015), individuals are considered to have a relationship if they both mention each other. The resulting graph contains 1.1B edges.

For each question tweet in our dataset, we measure the degrees of separation (path length in the graph) between the question-asker and recipient. Recipients with an immediate social relationship have a degree of 0. As the network is constructed from a 10% sample, our estimates of degree contain Type II bias and may overestimate the degree (e.g., by not seeing an interaction); however, many individuals do ask questions to complete strangers through encounters on shared discussions (e.g., around a hashtag). To minimize confounds due to user popularity (e.g., celebrities and politicians), we remove all tweets directed to verified accounts or those with $\geq$5000 followers.

Results As shown in Figure 4, intimacy behavior on Twitter mirrors the U-shaped curve predicted from offline experiences (Simmel, 1950; Rubin, 1975), where people ask the most intimate questions to close ties and complete strangers, with a trough for acquaintances where norm violations have the highest cost. Further, individuals ask strangers questions with the same level of intimacy as friends, but these strangers must be very distant in the network; our results suggest that individuals are highly sensitive to the perceived risk of future interaction with lower intimacy rates even four degrees of separation away. In in-person settings, psychologists have largely been unable to measure the exact degree of separation between people due to the cost and difficulty of such a large-scale experiment; using a global social network, our result provides the first quantitative estimate of the relationship between distance and intimacy.

8 Anonymity as Audience Design

Social media creates a new affordance for sidestepping the norms around intimacy: anonymity. By communicating through an anonymous account, an individual ensures that they are viewed as a stranger, removing the social cost of norm transgressions around intimacy for gender and social distance. Prior work has shown that the use of anonymous accounts is not necessarily driven by their willingness to publicly disclose, but rather around perceived anonymity and privacy as a way of performing identity and boundary management (De Choudhury and De, 2014; Leavitt, 2015).

Individuals shift their language based on the expected audience, with Bell (1984, p. 185) noting that these shifts can "simulate or create intimacy with a stranger;" social media complicates this audience design process through its context collapse (Marwick and Boyd, 2011) where individuals must choose content and style to simultaneously match the norms and expectations of their different social circles (Androutsopoulos, 2014). Given an audience of an unknown composition, individuals may be inhibited from style-shifting into more intimate language due to the perceived risk of social capital loss. However, full anonymity could free the speaker from the penalty of norm violations, allowing them to shift to a desired intimacy level without risk. Following, we test to what degree does anonymity facilitate increased intimacy.

Methods Anonymous accounts were collected by identifying posts made in 2018 on Reddit by usernames containing *throwaway* or *anonymous*, which are recognized markers of intentional anonymity on Reddit (Leavitt, 2015). The intimacy of language by **Anonymous** accounts is compared relative to three groups: (1) accounts containing a first name in the username, e.g., `SamIsCool`, as these potentially signal a closer association with personal identity, which we refer to as **Name Containing**; (2) accounts without any explicit demographic or identity marker, e.g., `atomiccyle`,

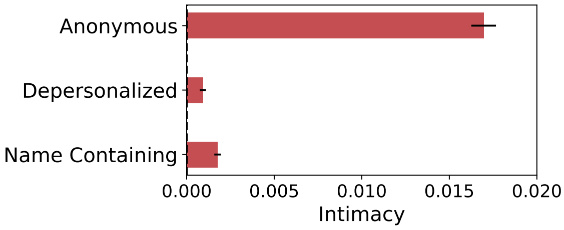

Figure 5: Averaged marginal effect on intimacy in language for specific types of Reddit accounts, relative to all other accounts as the reference category, shows that anonymous accounts have higher intimacy in their language than other accounts in the same communities.

which are referred to as **Depersonalized**, and (3) all other accounts within a subreddit. Details on name and demographic matching are provided in Appendix C. A total of 12,528,813 questions were collected across 117,526 subreddits. We fit a mixed-effect regression to predict the intimacy of the question from the identity presentation of the author, using random effects for each subreddit to control for different levels of intimacy in each; the all-other category of names is treated as the reference group in categorical coding.

Results Anonymous users ask substantially more intimate questions than any other types of accounts (Figure 5), even when controlling for the social context of those questions (via subreddit random effect). However, all other users ask substantially less-intimate questions, even if their username is effectively anonymous; model coefficients are listed in Appendix F. This result points to the perceived loss of face even for otherwise-anonymous users who may have a reputation on the platform. Only through explicit anonymity (e.g., a throwaway account) do users substantially violate the contextual social norms around intimacy in a community. From a linguistic perspective, creating a separate anonymous identity to ask intimate questions can be viewed as a special strategy of audience design. Rather than changing the style of the expression to match an audience, anonymity enables changing the social cost of the desired style.

9 Discussion and Ethics

This work has focused on analyzing intimacy in language through questions, showing consistent findings across four studies of how individuals modulate intimacy in their communication with respect to the norms of their social surroundings. Although questions are only one part of language, they represent a natural starting point due to their interpersonal nature and our findings open the door to broader studies on other types of communication. Further, our work has applications in many NLP settings. For example, intimacy measurements can provide a useful metric for context-sensitive offensive language detection; given an ongoing conversation, a question that is substantially more intimate than normal suggests that it might be offensive (or at least violate social norms). Our models would allow tracking intimacy changes to separate offensive questions from those in conversations that gradually become more intimate. As a second example, dialog systems can benefit from intimacy models through adjusting their language to match user preferences—or potentially encourage interactions that lead to more intimate topics.

The study of intimacy in language necessitates a discussion of ethical choices and implications. All experiments were performed on public data, in accordance with terms of service; as users of social media have contextual expectations of privacy, all examples of questions and usernames in this paper have been paraphrased to preserve anonymity. One risk posed by our technology is using these models to seek out especially-intimate questions from users in order to abuse or embarrass them. As one potential mitigation, platforms might use this same technology to prompt users to switch to a throw-away account when asking the question.

10 Conclusion

This paper represents a step towards a full understanding of the social information in language through new data and models for studying intimacy in language. By developing a high-quality dataset of questions rated for their intimacy and a corresponding model that closely correlates with human judgments, we study 80.5M questions across social media, books, and movies to reveal how individuals shape and react to their social setting through selecting the intimacy of their language. In four studies, we show that the intimacy of language is not only a personal choice, where people may use different linguistic strategies for the expressions of intimacy but reflects constraints from social norms, including gender and social distance. Our study provides strong evidence for existing findings in social psychology and also enriches the study of computational sociolinguistics in NLP community.

A List of Question Centered Subreddits

For data annotation and language model finetuning, we use questions sampled from the following subreddits:

OutOfTheLoop IWantToLearn whatisthisthing answers NoStupidQuestions amiugly whatsthisbug SampleSize TooAfraidToAsk whatsthisplant IsItBullshit morbidquestions ask AskReddit shittyaskscience TrueAskReddit AskScienceFiction AskWomen AskMen askgaybros AskRedditAfterDark asktransgender AskMenOver30 askscience AskHistorians AskCulinary AskSocialScience AskEngineers askphilosophy AskDocs explainlikeimfive ExplainLikeImCalvin relationships relationship_advice legaladvice bestoflegaladvice Advice AmItheAsshole MechanicAdvice needadvice dating_advice

B Gender Inference

User gender in social media (i.e. Twitter and Reddit) is inferred from the username using GenderPerformer (Wang and Jurgens, 2018), which was trained to operate on social media like Reddit. In movie scripts, we use both the gender labels provided for 3,015 characters in the Cornell movie dialogue dataset (Danescu-Niculescu-Mizil and Lee, 2011) and a second approach to infer gender for another 2872 characters using name database based on US baby names from 1930-2015. [4] Such a strategy has been widely used in previous works (West et al., 2013; Prabhakaran et al., 2014). For questions in books, BookNLP (Bamman et al., 2014) is used to identify the speaker of each question, and we follow the similar name matching strategy for movie questions to recognize the gender of speakers. For recipients, we look for addressee information using regular expressions. For example, for the question ”What is this, Tom?”, we first extract `Tom` using regular expressions to match words between “,” and “?”, and then use the gender name database to identify the gender. If the word is not found in the database, we secondly check gender special words (e.g., he, wife, sister) for book questions.[5]

Please note that we believe non-binary genders and transgenders are also vitally important and valuable for intimacy research. However, for this current work, we only identify binary genders following common practices and leave the study of other non-binary genders and transgenders in future research.

C Identity Lexicon

Anonymous accounts contain strings indicating anonymous identity including: `anonymous`, `anon` and `throwaway`. For `anon` we also require the username to end with digits. We use regular expressions to mach all the usernames meeting the criteria above.

Name Containing accounts contain real-world names,[6] which are treated as a marker of identity. Here, we restrict names to be CamelCased or containing special symbols (i.e. - and _). Moreover, some names in the database might be primarily used as other functions instead of names (e.g. `rainbow` and `my`), to eliminate the potential bias, we manually checked 500 most frequently matched names and removed those might be used in context other than names.

---

[4] https://www.ssa.gov/oact/babynames/limits.html

[5] Male: man, he, Mr., boy, husband, him, uncle, guy, sir, brother, father; Female: woman, she, Mrs., Miss, girl, madam, her, aunt, wife, sister, mother

[6] US baby names in 2016 https://www.ssa.gov/oact/babynames/limits.html

Depersonalized accounts are those without common demographic markers including: gender, age, socioeconomic info, religion and political identity. We select accounts marked as ungendered by GenderPerformer.[7] Then we further remove account names whose suffix likely denotes some form of age information by identifying usernames ending with 4 digits from 1950 to 2005 and 2 digits from 50 to 99. After this, we also removed accounts containing lexicons from three other categories using regular expressions. For lexicons containing less than 4 letters, we ensure that only when they are a subsplit of CamelCased string or usernames connected by _ will they be identified. Here is the list of identity lexicons.

1. Political: briebart, rightwing, imstillwithher, im_still_with_her, left_wing, lockherup, obama, bernie_sanders, maga, leftie, leftwing, neocon, liberal, republicans, republican, libtard, democrap, democrats, trump, conservative, im_with_her, imwithher, bernie, neo conright_wing, democratic, lock_her_up, democrat, clinton
2. Religions: allah, lutheran, atheist, bible, buddah, jewish, christ, muslim, islamic, buddhism, jesus, shariah, catholic, buddhist, quran, torah, buddha, methododist, christianity, athiest, athiesm, judaism, koran, jew
3. Socioeconomic: mdphd, phd, dumb_hick, ghetto_fabulous, hillbilly, boondocks, hill_billy, yokel, yokels, lawyer, ghetto, hillbillies, hayseed, hayseeds, rednecks, professor, backwoods, beer_drinkin, ghettofabulous, bumpkins, prof, dphil, red_neck, redneck, beerdrinkin, beerswillin, bumpkin, doctor, dds, bubbas

While these lexicons are by no means exclusive to the types of identities a person might signal in their username, they still provide some utility for contrasting the behaviors of users who do chose to identify these sociodemographic signals with those that do not (e.g., pizzamagic).

D Hedge Words and Swear Words

The linguistic analysis of intimacy in Section 5 of the main paper uses two existing lexicons. For hedge words, we use the list provided by Hyland (2005), which comprises 100 common hedge words in scientific writing. For swear words, we use the swear word list[8] used by Google, which covers a wide range of swear words.

Model	MSE	Pearson r	Training time
Mean-value Predictor	0.08625	0.0000	< 1s
LR + Bag of Words	0.06532	0.5127	< 1s
LR + Topic Model	0.05476	0.6211	< 1s
RoBERTa (base)	0.02855	0.8232	< 10s/epoch
RoBERTa (fine-tuned)	**0.02106**	**0.8719**	< 10s/epoch

Table 2: Performance on the validation set at estimating intimacy and the training times for each model.

E Model Details

We use scikit-learn version 0.23.1 to build the linear regression model (Pedregosa et al., 2011). Specifically, for the linear model, we use ridge regressor with default settings. The built-in CountVectorizer of scikit-learn is used to vectorize the unigram, bigram and trigram of each input question. The size of the bag-of-words feature vector is set as 10000.

For all the RoBERTa models (Liu et al., 2019), we use Hugging Face[9] transformers and set the batch size as 128 and learning rate as 0.0001. We set $max\_len = 50$. Adam (Kingma and Ba, 2014) is used for optimization. All the other hyperparameters and the model size are the same as the default `roberta-base` model.[10] We train both the model for 30 epoches and choose the model with lowest MSE on validation set. For the question fine-tuning process, we simply follow all the default settings recommended by Hugging Face. Regarding hyperparameter trials, we only tuned the learning rate as 0.001, 0.0001 and 0.00001. We found that 0.001 didn't lead to a good performance while 0.0001 and 0.00001 both achieved good scores regarding MSE and Pearson r. So we simply go with 0.0001 for both the RoBERTa models. All the code, datasets and parameters of our best-performing model are released and one could easily reproduce all the experiments.

F Additional Regression Results

Here, we show the regression results of two analyses for the intimacy in different gender compo-

sitions of a dyad (Table 3) and how the relative anonymity of one's account name predicts the intimacy of the question that is asked (Table 4). These tables show the model coefficients and standard errors for the mixed-effect regressions described in the main paper; the figures in the paper reflect the bootstrapped average marginal effects of the relevant categorical variable.

G Question Cleaning Rules

Reddit questions can potentially contain significant noise from Markdown, Reddit-specific jargon, or the otherwise-noisy nature of social media. To avoid training our model on such data, we adopted the following pipeline, shown in Table 5, to either exclude or modify questions prior to inclusion. Table 5 also includes examples of the resulting modifications.

	Dependent variable:
	intimacy
Anonymous	0.017^{***} (0.001)
Depersonalized	0.001^{***} (0.0002)
Name Matched	0.002^{***} (0.0002)
intercept	-0.213^{***} (0.0005)
Observations	12,528,813
Log Likelihood	3,076,780.000
Akaike Inf. Crit.	−6,153,549.000
Bayesian Inf. Crit.	−6,153,463.000
Note:	*p<0.1; **p<0.05; ***p<0.01

Table 4: Fixed effect regression analysis of different types of Reddit accounts regarding question intimacy, controlled for subreddit; usernames categorized as Other are used as the reference category. Anonymous accounts are asking more intimate questions than other accounts, indicating an anonymous identity is in part of the users' audience design to initiate more intimate interactions. All the results are statistically significant.

H Annotation Guidelines and Preparation

Each annotator is asked to choose the question that could "lead to the Most/Least INTIMATE, DEEP and PERSONAL response in the APPROPRIATE SETTING" among four randomly selected questions. Figure 6 shows the user interface of our web-based annotation tool. The authors conducted several rounds of pilot annotation trials among seven annotators, prior to beginning annotation for the current study's data. In initial pilot studies, annotators were asked to choose the "most intimate questions in each tuple." However, this phrasing led to some confusion along two points: (1) lack of an intuitive definition of intimacy that was applicable in many contexts, and (2) how to determine what type of context the question might be asked in. The latter point was important as some questions could be interpreted as more or less intimate when asked in unusual contexts. Based on this feedback, the instructions were revised to (1) de-

Rule	**Example**	**Result**
Remove multiple sentences or sentence without ending marker	SO many chaos	*Removed*
Remove sentences without question mark	You are not saying this	*Removed*
Replace multiple markers with one question marker	Why are you doing this !!!!?	Why are you doing this ?
Remove inserted meta-information in questions	My husband[30M] ...	My husband ...
Replace special abbreviations with its full expressions	AITA in doing this?	Am I the Asshole in doing this ?
Replace html symbols	$\&amp$	and
Remove questions with fewer than four words	That thing?	*Removed*

Table 5: The sequential set of rules applied top to bottom for determining if a question asked in Reddit is included in our dataset.

scribe intimacy with three adjectives, “intimate, deep, or personal” which led to easier judgments, and (2) qualify the question as being asked “in the appropriated setting,” which helped annotators focus less on unusual or abnormal circumstances where a question might be asked. These changes were discussed with pilot annotators and ultimately helped to improve the agreement in further pilot trials. Further, two of the annotators (the authors) were selected to finish all the following annotation tasks. The final annotators first conducted several rounds of training to standardize their judgments and rationale between them. During the training, they independently annotated a small list of tuples and then discussed to resolve the disagreements. After training, the two annotators performed the annotation process as described in the main paper.

I Data Samples

We show the distribution of our annotated question intimacy dataset in Figure 7 and present data samples in Table 7. As shown in Figure 7, the score distribution across different splits of our dataset is balanced. Further, one can observe the data is slightly skewed to the less intimate (left) side.

J Topic Analysis

The topic of a question is likely related to the intimacy of a question, with some topics being more taboo and therefore more intimate in nature. To test for this, we trained an LDA topic model using Mallet[11] to use a question’s topic distribution as features for predicting intimacy, as described in Section 4 of the main paper. Here, we report additional experiments on different numbers of topics: 20, 50, 100 and 200 topics. Performance of linear regressors with different numbers of topics are reported in Table 6, with the main paper reporting the best-performing of these models. Figure 8 shows the kernel density distribution of intimacy scores for each topic in the 50-topic model, ordered by their mean intimacy. This plot reveals that while some topics are concentrated along specific ranges of intimacy, many span a large range (e.g., finances or weight loss) and thus topic alone is often insufficient for estimating intimacy. Indeed, even questions with the most intimate topic (on average) that focuses on regretful situations can be asked in less-intimate ways.

Model	**MSE**	**Pearson’s r**
LR + 20 topics	0.06038	0.5629
LR + 50 topics	**0.05476**	**0.6211**
LR + 100 topics	0.05508	0.6055
LR + 200 topics	0.06136	0.5302

Table 6: Question Intimacy Prediction Performance

K Pairwise Annotation

As an additional validation on the trained model, both annotators who labeled the initial dataset labeled an additional 300 pairs of questions from the full dataset. Questions were first sorted by their difference in predicted intimacy and binned at 0.1 ranges (e.g., those with distances in $[0.3, 0.4)$); then, 30 questions were sampled from each bin to test how sensitive annotators were to each distance. Annotators were asked to select the most intimate of the two question, or if the two questions were too close in similarity to meaningfully describe a difference, to select “same intimacy.” Figures 9 shows Krippendorff’s α for the judgments within each bin. Annotators had lower agreement for small differences in intimacy; however, the low values are also in part due to the relatively rare frequency of the same-intimacy label, which strongly penalizes α. Figure 10 shows the bootstrapped percentage of times the annotators agreed with the models’ rank, suggesting that humans largely agree with the

Abstract

Communicating complex scientific ideas without misleading or overwhelming the public is challenging. While science communication guides exist, they rarely offer empirical evidence for how their strategies are used in practice. Writing strategies that can be automatically recognized could greatly support science communication efforts by enabling tools to detect and suggest strategies for writers. We compile a set of writing strategies drawn from a wide range of prescriptive sources and develop an annotation scheme allowing humans to recognize them. We collect a corpus of 128K science writing documents in English and annotate a subset of this corpus.[1] We use the annotations to train transformer-based classifiers and measure the strategies' use in the larger corpus. We find that the use of strategies, such as storytelling and emphasizing the most important findings, varies significantly across publications with different reader audiences.

1 Introduction

Communicating scientific discoveries to a general audience of readers is difficult. A researcher or writer interested in doing so is faced with the challenging task of translating complex scientific ideas in an engaging manner without misleading or overwhelming their audience. There are many guides to science communication (e.g., Blum et al., 2006), but they rarely offer empirical evidence for how their advice is used, or proven effective, in practice. The potential science communicator is then confronted with the additional hurdle of understanding how to implement these guidelines in their writing.

Effective science communication requires understanding the unique needs and expectations of different audiences and stakeholders in science (Nisbet and Scheufele, 2009). We envision natural language processing technologies that help science writers communicate more effectively. These technologies might automatically classify common strategies in a writer's own text, support writers to adapt language to specific readers, or guide readers through personalized article recommendations.

As a first step, we compile a set of strategies from a wide range of prescriptive science writing sources in English and develop an annotation scheme allowing humans to recognize these strategies in texts about science. We introduce a new corpus of 128K university press releases, science blogs, and science magazines and annotate a subset of 337 texts. We use the annotations to train transformer-based classifiers to explore the communicative goals of science writing by analyzing variations in the strategies' use across several scientific communication forums.

Our paper is the first computational analysis of writing strategies driven by science communication theory. We find that most strategies are prevalent throughout our corpus and that publication venues with varying audiences use strategies differently. For example, press releases emphasize the impacts of science more than magazine articles, which instead tell more stories about the science. We also find that higher quality newspaper articles, as rated by expert journalists, use more storytelling and analogies than lower quality articles.

2 Defining Science Communication Writing Strategies

The goal of general science communication is to increase public awareness, enjoyment, interest, and understanding about science (Burns et al., 2003). Based on the idea of compositionality in discourse theory (Bender and Lascarides, 2019), we can think of the communicative intent of science writing as being made up of smaller communication goals rep-

resented in particular passages of an article (Grosz and Sidner, 1986; Louis and Nenkova, 2013a). Our computational approach builds on this theoretical assumption by annotating sentences and letting an article inherit the attributes we find in its sentences.

Past work on science communication has taken a similar view (Louis and Nenkova, 2013a) by using syntactic relations to characterize an article's communicative goals, allowing them to emerge inductively rather than from a theory of science communication. Our complementary approach starts with science communication guides to construct theory-driven communicative goals (referred to as "writing strategies" and consisting of lexical to multi-sentence features), and explores their use in a diverse range of science communication text.

To define our writing strategies, we categorized and grouped advice from style guides for science communicators. These guides were a mix of online resources, books, and academic articles (see Table 5 in the appendix). We selected the guides based on discussions with three expert science communicators at a large research university's press department and through online searches. We stopped adding resources when we reached saturation (Holton, 2007), meaning that each new resource had fewer new strategies and suggesting that our resources provided good coverage.

Two authors open-coded (Holton, 2007) the suggestions from each guide by assigning each piece of advice in a resource a code that represented its high-level strategy (such as "avoid jargon"). The authors then looked at other resources to see whether the same advice appeared there. Each new piece of advice was added with a new code. After coding all resources, the authors grouped the codes into a set of 10 suggested writing strategies. Appendix A.1 provides additional details on the coding and categorization. The strategies are as follows (examples of each are given in Table 9 in the appendix):

LEDE A few sentences at the beginning of an article, called a lede (spelled "lede" for easier differentiation with its homograph "lead"), that draws a reader in and makes them want to read more.

MAIN Sentences describing the main findings being reported by the original paper in order to not overwhelm the reader with details.

IMPACT Writing about the real world impact of the science or findings being reported in order to excite readers. This can include future technologies, breakthroughs the findings might enable, or their societal implications.

EXPLANATION Explanations about scientific subjects to improve reader understanding. This could be explaining a certain topic or word, or what researchers did in a study and what the findings mean.

ANALOGY Analogies or metaphors used as a way to explain concepts or make ideas in the article more relatable.

STORY Stories to engage readers and make the reported science more interesting. This can include short story snippets, or coming back to an underlying story throughout an article.

PERSONAL Including personal details about researchers in order to make them more approachable and add depth to the story.

JARGON Avoiding specialized terminology or jargon as much as possible as it can overwhelm readers.

ACTIVE Using the active voice to make the writing more lively and engaging.

PRESENT Similar to ACTIVE, using present tense verbs also to make the writing more lively and engaging.

Some of these strategies are specific to science writing, such as emphasizing the real world impact of the findings (IMPACT), while others are often thought of as general rules for good writing, such as using the active voice (ACTIVE). Both types of strategies were commonly referenced in the resources we analyzed, which suggests that engaging science writing shares traits with engaging writing in other disciplines while also containing its own set of unique strategies.

3 Dataset

In order to study the use of these strategies by science writers and build classifiers for automatic identification, we collected a corpus of 128K documents from a variety of science communication sources. We focused on four major types of U.S.-based venues, representing a broad spectrum of science communication for different audiences: blog sites, popular science magazines, university press releases, and scientific journal magazines.

Table 1: Sites and number of articles in corpus after filtering.

Venue	**Site**	**#Articles**
Blogs	*Sciencedaily.com*	38,191
	Phys.org	74,732
Magazines	*The Atlantic*	2,771
	Scientific American	5,174
Press releases	*Harvard*	752
	Stanford	599
	Rochester	219
	Northwestern	197
Journals	*Science*	4,173
	Nature	1,445
Total		128,253

Past work has shown that blog sites usually write to scientifically literate and engaged readers (Ranger and Bultitude, 2016), while university press releases often write to other science journalists (Bratton et al., 2019; Sumner et al., 2014). We selected popular science magazines since they target a more general audience, and scientific journal magazines as they often write to those involved in research, though not necessarily in the same domain (Nielsen and Schmidt Kjærgaard, 2011). The choices of website or publication we collected from each venue category were based either on previous work covering those categories (e.g., blog posts; Vadapalli et al., 2018) or as a convenience sample based on what was widely available. One note is that while past work has used the blogs sites we selected as sources for high quality science blogs (*sciencedaily.com* and *phys.org*), these sites also source a large portion of their content from press releases, often only changing headlines and lede sentences.

We scraped articles from each of these sources for all of 2016–2019 using the Wayback Machine,[2] resulting in 137,828 articles. Appendix A.2 provides more details on site selection.

3.1 Filtering

To focus on science communication, specifically, we removed articles matching U.S.-centric political keywords such as *Trump*, *democrats*, and *Senate*. Appendix A.3 lists all filter keywords. We also removed all articles over 15,000 or under 1,500 characters, since these represented either multiple articles on the same page, article previews, or scraper errors. After filtering we had a total of 128,253 articles. In total 7% of documents were filtered (3.5% removed for political keywords and 3.5% for length). Table 1 details the sites for each venue and the number of articles after filtering. URLs for all scraped articles are available at `https://github.com/talaugust/scientific-writing-strategies`.

3.2 Annotation

Recall that our goal is to measure the use of strategies from Section 2 in our corpus. We sample 337 articles stratified across sites to gather a spread of articles and balance the articles across venues. Each article was given to two annotators who were trained on the writing strategies and instructed to annotate the use of strategies at the sentence level. Concretely, each "annotation" corresponds to a contiguous chunk of one or more sentences labeled with one of the seven strategies. A sentence can be labeled with multiple strategies. Three of the strategies, JARGON, ACTIVE, and PRESENT, were not annotated because we believe they can be reliably detected using existing methods based on lexical and syntactic features; see Section 5.1. Figure 5 (in the appendix) presents an example of an annotated excerpt and the task interface.[3]

We conducted annotation in sets of 50 articles. After each set, one author measured agreement and manually evaluated a subset of annotations by both annotators. This author then acted as a coordinator for the annotators, providing suggestions or revisions to annotation guidelines. Additionally, annotators were able to look at the other's annotations after completing an article. Figure 4 in the appendix plots Krippendorff's α after each batch of 50 articles.

3.3 Annotator Agreement

While our strategies emerged from prescriptive advice in guides, our annotators had to interpret these strategies in the context of real-world scientific writing. This, to our knowledge, has not been done systematically before, though we suspect editors do it frequently. Because writing strategies are somewhat subjective and we wanted our categorizations to be flexible to the different good-faith

[3] Code for the interface is available at `https://github.com/talaugust/scientific_article_annotation`.

Table 2: Simple agreement rates for each writing strategy at a sentence, paragraph, and document level. See Table 6 (in the appendix) for α statistics.

Strategy	Sentence	Paragraph	Document
LEDE	0.97	0.95	0.65
MAIN	0.89	0.85	0.96
IMPACT	0.92	0.90	0.68
EXPLANATION	0.69	0.70	0.84
ANALOGY	0.95	0.92	0.68
STORY	0.84	0.86	0.71
PERSONAL	0.90	0.86	0.66

Table 3: Number of sentences and average number of words per annotation span for each strategy across articles in our annotated dataset (337 articles).

Strategy	# Sentences	Avg. words
LEDE	595	34.1±20.6
MAIN	1,596	35.9±19.1
IMPACT	1,102	40.0±19.1
EXPLANATION	4,677	55.0±28.1
ANALOGY	410	33.6±17.3
STORY	1,736	74.4±60.9
PERSONAL	727	50.5±33.1
Total	10,843	48.7±32.7

interpretations of each strategy, we were not aiming to obtain perfect agreement on each strategy. Table 2 reports on simple agreement rates for the annotated strategies.

Previous work annotating spans of text for communicative goals, such as framing (Card et al., 2015), propaganda techniques (Da San Martino et al., 2019), hate speech (Sap et al., 2020), statement strength (Tan and Lee, 2014), and agency (Sap et al., 2017), have shown that reaching high agreement is difficult. While agreement measures differ across these annotations tasks due to differences in how spans were annotated (e.g., preselected sentences or open selection), past work has reported Krippendorff's α agreement levels ranging between $0.3 < \alpha < 0.7$, in which we fall along the lower to moderate end ($0.3 < \alpha < 0.5$). We discuss the use of α in Appendix A.4 and there Table 6 reports α agreement for each strategy.

The annotators identified a total of 10,843 sentences (316,263 tokens) with one of the seven strategies in 337 articles. Table 3 details the number of sentences and average number of words for each strategy annotation span.

3.4 Abandoned Strategies

Two categories that achieved low agreement (as measured by α) were EXPLANATION and PERSONAL, which we drop from further analyses for the following reasons. We found that annotator 1 (a_1) annotated many more EXPLANATION strategies than a_2 (3,402 vs. 1,275). While the majority of a_2's EXPLANATION annotations agreed with a_1's (886 out of 1,275), a_2 highlighted fewer in general, suggesting that this lower agreement was due to the annotators having different thresholds for the EXPLANATION strategy.

For PERSONAL, our discussions with both annotators revealed that a_2 had assumed PERSONAL strategies were any reference to the researchers in an article (e.g., "Professor X, head of the mutation lab at the Academy") while a_1 focused on personal aspects of a researcher (e.g., "Professor X, who has been in a wheelchair since birth"). While we tried to resolve this difference early on, annotators still had difficulty reaching agreement on PERSONAL strategies. This discrepancy lowered agreement but highlighted an interesting nuance in the PERSONAL strategy.

Because both strategies are still important for science communication, we report on their use in the corpus in Figures 6 and 7 in the appendix.

4 Hypotheses

Our annotated corpus allowed us to begin to explore how strategies relate to the communicative goals of different science communication venues. To do this, we introduce hypotheses informed by existing literature.

Hypotheses **H1–H4** are based on our expectations for how strategies can differentiate science writing venues in our corpus based on their underlying goals. For these hypotheses, we evaluate strategy use across our corpus.

Hypotheses **H5** and **H6** focus on how strategies might relate to other important issues in science communication. They build on past research in science communication exploring article quality (Louis and Nenkova, 2013b) and sensationalism (Sumner et al., 2014). These issues are introduced with their own annotated datasets, and since we have no strategy annotations for these datasets, we report only on the aggregated predictions of our classifiers.

H1: LEDE is used once or twice within an article, but consistently across our entire corpus. Because the LEDE strategy is well adopted as a common strategy in general journalism (Pöttker, 2003), and LEDE sentences are only used at the beginning of an article, we expect low but consistent use of LEDE across the corpus.

H2: Press releases use higher IMPACT than other venues. One goal of press releases is to encourage other science writers to pick up a story. Because a key component to selecting stories is impactful findings (Hayden et al., 2013), we expect that press releases will emphasize this more.

H3: Magazines use lower JARGON, higher ACTIVE and PRESENT and higher STORY than other venues. Magazines target a broader readership compared to other venues, making it likely they use these strategies that are common in prescriptive guides for general good writing (Strunk, 2007) to relate to a wider audience.

H4: Blog sites use higher JARGON and MAIN, and lower IMPACT compared to other sites. Blog sites predominantly focus on other science educated or interested readers (e.g., *phys.org* reports a readership of "5 million scientists, researchers, and engineers every month"[4]). This suggests that blogs' focus is less on attracting a broad readership (higher JARGON) or encouraging news uptake (lower IMPACT) and more on communicating the main point of a journal article (higher MAIN).

H5: Higher quality science news articles use more STORY and ANALOGY than lower quality articles. Past work on science news quality has suggested that features related to storytelling and figurative language (e.g., coherence and descriptive language) are associated with higher quality articles (Louis and Nenkova, 2013b).

H6: Press releases that sensationalize the claims of the original journal paper use higher IMPACT and MAIN than press releases that do not. While emphasizing the impact of findings is a useful tool in engaging readers, work has shown that press releases will sometime sensationalize the claims of the original journal article (Sumner et al., 2014). Sumner et al. (2014) categorized sensationalism into three categories: exaggerated advice (suggesting actions the original paper did not), exaggerated causal claims (making causal claims the paper did not), and inference to humans from animal research. These categories most nearly relate to our strategies on the findings of a paper: IMPACT and MAIN, and we hypothesize these strategies' overuse is related to sensationalism.

5 Strategy Classification

We used our collected corpus and annotations to automate recognition of writing strategies and to evaluate our hypotheses. We describe our methods for classifying strategies with rules and with human annotations (Sections 5.1 and 5.2). We then discuss methods for using these classifiers to estimate the use of strategies in our corpus and overall classifier performance (Section 5.3).

5.1 Rule-Based Strategies

As discussed earlier, three of the strategies could be reasonably identified using rules, and were not annotated.

JARGON We used common science jargon word lists drawn from Rakedzon et al. (2017) and Gardner and Davies (2013) to detect jargon use. The word list from Rakedzon et al. (2017) consists of 2,949 words common in scientific journal abstracts and articles while rare in common usage. We augmented this list with the core Academic Vocabulary List (AVL, Gardner and Davies, 2013). The AVL is a list of the top 3,000 word lemmas based on 120 million words of academic texts from the Corpus of Contemporary American English (Davies, 2009). High JARGON means higher use of these specialized terms, which is negatively associated with the strategy (i.e., since the recommended strategy is to avoid specialized terms).

ACTIVE We identified active and passive clauses by counting the 'nsubj' and 'nsubj:pass' words from a parse of each article using Stanford NLP's dependency labels in the Stanford NLP Pipeline.[5] We normalized all active clauses by the number of verbs in an article.

PRESENT For measuring present tense, we normalized the number of present tense verbs using Stanford NLP's Universal Features (similar to POS tags and part of the same Stanford NLP Pipeline; Manning et al., 2014) over all verbs in an article.

Table 4: Mean and standard deviation of strategy classifier performance, including calibration error, on held-out test set based on 5 random seeds. Baseline accuracy for most frequent class (MFC), which always predicts the negative class, is included.

Strategy	Prec.	Recall	F_1	Calibr. Err.	Acc.	MFC Acc.
LEDE	$.31_{.02}$	$.56_{.03}$	$.40_{.02}$	$.05_{.004}$	$.95_{.002}$	.95
MAIN	$.38_{.04}$	$.51_{.03}$	$.43_{.03}$	$.11_{.01}$	$.86_{.005}$	.86
IMPACT	$.40_{.03}$	$.55_{.03}$	$.46_{.02}$	$.09_{.01}$	$.91_{.004}$	.90
ANALOGY	$.52_{.04}$	$.60_{.02}$	$.55_{.03}$	$.04_{.01}$	$.96_{.001}$	.95
STORY	$.38_{.03}$	$.49_{.04}$	$.43_{.02}$	$.12_{.01}$	$.84_{.009}$	.84

5.2 Sentence Classifiers

For the remainder of our strategies, we trained classifiers based on the annotations collected to estimate the prevalence of each strategy in our corpus. Each classifier takes a single sentence as input and provides a binary label (present or absent) for a given strategy. Apart from pretraining, the classifiers were trained separately for each strategy. We base our classifiers off RoBERTa (Liu et al., 2019) as it is a high-performing contextual word representation learner that has achieved state-of-the-art results on multiple NLP benchmarks, and which comes pretrained. We use Huggingface's RoBERTa implementation.[6]

We start by continuing to pretrain RoBERTa on additional in-domain text to tailor the model more closely to our task. This additional pretraining followed two phases as in Gururangan et al. (2020): pretraining on 11.90M general news articles from REALNEWS (Zellers et al., 2019) for 12.5K steps (domain-adaptive pretraining), and then pretraining on a held-out subset of 100k documents from the unannotated portion of our own corpus for 10 epochs (task-adaptive pretraining). Appendix A.5 includes details for both pretraining steps.

Finally, we finetune our pretrained RoBERTa model on each sentence-level classification task separately, making 5 binary classifiers (LEDE, MAIN, IMPACT, ANALOGY, STORY). Our pretrained RoBERTa models were finetuned using a 80%, 10%, 10% train, validation, test setup using all annotated articles. Articles were randomly split across the sets, meaning no two sentences from the same article could occur across sets. Appendix A.6 includes additional finetuning details.

Using classifiers optimized for individual classification can lead to biases when estimating category proportions (Hopkins and King, 2010). Past work has suggested that using a **well-calibrated** classifier leads to better proportion estimation in large unlabeled corpora (Card and Smith, 2018). Calibration refers to the long-run accuracy of predicted probabilities, where a well-calibrated probabilistic classifier at the level μ is one that predicts class k with probability μ when the proportion of instances correctly assigned to k is also μ.

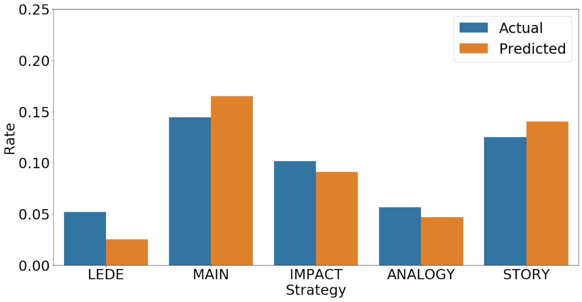

Figure 1: The rate of occurrence of predicted versus actual strategies on our human-annotated test set based on PCC and the classifiers.

Following Card and Smith (2018), we perform model selection based on calibration error on held-out data during hyperparameter tuning. We estimate calibration error using the adaptive binning procedure from Nguyen and O'Connor (2015). After picking our most well-calibrated classifiers, we measure the rate of each strategy across a collection of documents by averaging the classifiers' predicted posterior probabilities of a positive label. This is referred to as **Probabilistic Classify and Count** (PCC; Bella et al., 2010) and is a standard method for predicting label distributions in a corpus using a probabilistic classifier (Card and Smith, 2018).

5.3 Evaluation

We evaluate our classifiers in two ways: on individual examples (i.e., for reporting F_1), and in aggregate on a held-out annotated test set.

Our goal for the classifiers is to estimate aggregated proportions in our corpus, not to achieve perfect performance. For this reason, we report on classifier F_1 performance only to establish that the classifiers are reasonably able to detect strategies. Table 4 details the precision, recall, F_1 scores, average calibration error and accuracy of the trained classifiers, and baseline accuracies for the most frequent class predictions for each strategy. Our classifiers achieved F_1 scores between .40 and .55, which is comparable to other classifications of communicative goals, such as propaganda technique detection (e.g., F_1 scores between 0.39 and 0.61 in Da San Martino et al., 2019).

Because we are most interested in estimated proportions, we also compared the classifiers' predicted strategy rates in our held-out test set with the actual rates of the annotated strategies. Actual strategy rate is calculated as the number of sentences containing a strategy divided by the total number of sentences in the test set. Figure 1 illustrates this comparison. While we do see some discrepancies between actual rates and our predicted rates, these differences are small ($< .05$ rate difference, or less than 5% of sentences) and the trend of each strategy remains the same (e.g., STORY and MAIN are the most common, LEDE and ANALOGY are the least), suggesting that the classifiers estimate strategy rates with sufficiently high accuracy to begin comparing rates across strategies. Figure 6 in the appendix compares the predicted rate of strategies in the full dataset compared to actual rates of strategies in the test set broken down by site.

We additionally evaluated how accurate our automatic measures for JARGON, ACTIVE, and PRESENT were by randomly sampling 5 sentences from the top and bottom 10% of articles containing JARGON, ACTIVE, and PRESENT (as measured by our rule-based approaches) and manually inspecting them for correct word classifications. The rules for each measure are in line with our intuitions about JARGON, ACTIVE, and PRESENT with a large majority of words (Over 80% in the 30 sentences evaluated) being identified correctly as jargon, active voice, or present tense. Table 10 in the appendix provides examples of this evaluation.

6 Evaluating Strategy Applications

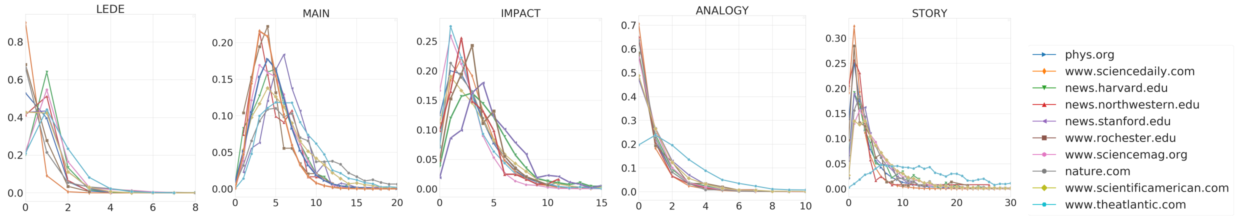
Evaluating our classifier output against gold-standard human annotations, as reported in Section 5.3, establishes the validity of our classifiers. We next turn to our hypotheses introduced in Section 4 to illustrate how we can use the strategies, classifiers, and corpus to explore the communicative goals of science writing. We introduce each hypothesis and report on its results separately.

H1: LEDE is used once or twice within an article, but consistently across our entire corpus. Figure 2a plots the estimated number of LEDE sentences per article across each site. Supporting **H1**, the majority of sites peak at either 0 or 1 LEDE sentences, with all sites tapering off quickly after that. *theatlantic.com* does have a higher number of predicted LEDE sentences (with 20% of articles containing more than 2 sentences). This might be due to *theatlantic.com* articles being longer (since they are full magazine articles) and therefore using more text to entice readers.

H2: Press releases use higher IMPACT than other venues. We find support for **H2**: press release sites like *news.harvard.edu*, *rochester.edu*, and *news.stanford.edu* have larger modes than other sites for IMPACT sentences in Figure 2c. For example, close to 15% of articles in *rochester.edu* have over 5 estimated IMPACT sentences, compared to 7 or 8% of articles in *scientificamerican.com* or *theatlantic.com* having that same number. This is especially striking because *scientificamerican.com* and *theatlantic.com* generally have much longer texts, since they are full magazines, compared to press releases.

H3: Magazines use lower JARGON, higher ACTIVE and PRESENT and higher STORY than other venues. Texts from *theatlantic.com* and *scientificamerican.com*, the two magazine sites, had the lowest and third lowest use of JARGON in the corpus with average rates below 0.2 (i.e., less than 20% of words), macro-averaged across articles (see Figure 6 in the appendix). Magazines also had the highest use of ACTIVE and some of the highest PRESENT. Additionally, *theatlantic.com* was the only site to have close to 5% of articles estimated to have more than an 15 STORY sentences (Figure 2e).

H4: Blog sites use higher JARGON and MAIN, and lower IMPACT compared to other sites.



(a) (b) (c) (d) (e)

Figure 2: Histogram of number of sentences per article (x-axis) estimated to use each strategy (proportions on y-axis). For an enlarged figure, see Figure 7 in the appendix. Figure 6 plots the estimated proportion of sentences using each strategy for all sites.

We find mixed support for **H4**: blog sites do use higher JARGON and MAIN, but not lower IMPACT compared to other sites. The two blog sites, *sciencedaily.com* and *phys.org*, used the highest and third highest amount of JARGON (both above 20%), and showed high levels of MAIN compared to other sites, especially *phys.org*, which had one of the highest rates of MAIN (close to 0.20, or 20% of sentences, see Figure 6 in the appendix). However, we do not find that these blog sites used lower IMPACT; in fact, we see the opposite. Blog sites use almost the same level of IMPACT as press releases. This might be due to some blog posts focusing on breaking science news, similar to press releases (Ranger and Bultitude, 2016), or due to rehosting press releases.

Delineating venues Based on our results for **H1–H4**, we see that strategies delineate different venues well. Blogs often focus on scientific terms and the main findings of a paper, press releases emphasize the impact of the findings, and magazines avoid complex scientific terms, instead telling stories and using active, engaging, writing.

We visualize these differences by representing each site as a vector of strategy rates (e.g., *phys.org* would be a vector of length eight) and calculate a single principal component from these vectors using principal component analysis.[7] Figure 3 plots each site along this axis, showing that the four venues we explore (blogs, press releases, magazines, and science journal magazines) group together clearly. The one overlap is science journal magazines, which fall between magazines and press releases. This is especially interesting because the goal of journal magazines is to both advertise research published in the journals (i.e., *nature.com* reports *Nature* findings) while also being closer in length to a magazine, making them a mixture of both press releases and magazines.

H5: Higher quality science news articles use more STORY and ANALOGY than lower quality articles. To evaluate this hypothesis, we use the corpus of *New York Times* science articles introduced by Louis and Nenkova (2013a).[8] The corpus consists of three labels of article quality: TYPICAL, VERY GOOD, and GREAT. These labels were drawn from whether the article appeared in that year's "Best American Science Writing" anthology (GREAT), was written by an author whose work had appeared in the year's anthology (VERY GOOD), or was neither (TYPICAL). The articles were drawn from the *New York Times* annotated corpus (Sandhaus, 2008) and filtered for science-related keywords (e.g., biology, biologist).

For a clear differentiation of article quality, we apply our strategy classifiers to only the GREAT and TYPICAL articles in the dataset. We select science articles from the years 2001 to 2007 for a total of 55 GREAT articles (6,211 sentences) and 15,532 TYPICAL articles (1,079,768 sentences).[9] To test for significance we perform χ^2 tests of independence and augment these with the ϕ coefficient, which is similar to Cohen's d as an effect size calculation for categorical variables (Fleiss, 1994).

Results: Sentences in GREAT articles use STORY and ANALOGY slightly but significantly more often than TYPICAL articles (STORY: 0.38 vs. 0.33, $p < 0.001$, $\phi = 0.01$, ANALOGY: 0.05 vs. 0.03, $p < 0.001$, $\phi = 0.01$), supporting **H5**. GREAT articles also used more ACTIVE and PRESENT than TYPICAL articles (ACTIVE: 0.73 vs. 0.67,

---

[7] We also considered calculating multiple components, but a single component covers the majority (65%) of the variance across the full vector.

[8] Available at `http://www.cis.upenn.edu/~nlp/corpora/scinewscorpus.html`

[9] We obtained similar results when uniformly sampling 55 TYPICAL articles.

Figure 3: All sites plotted along a their single principal component, which accounts for 65% of the total variance in strategies. Sites from left to right are: *sciencedaily.com*, *phys.org*, *news.northwestern.edu*, *nature.com*, *news.stanford.edu*, *news.harvard.edu*, *rochester.edu*, *scientificamerican.com*, *sciencemag.org*, and *theatlantic.com*.

$p < 0.001$, $\phi = 0.01$; PRESENT: 0.23 vs. 0.21, $p < 0.001$, $\phi = 0.004$).

H6: Press releases that sensationalize the claims of the original journal paper use higher IMPACT and MAIN than press releases that do not. Sumner et al. (2014) introduced a dataset of 462 press releases annotated for the three categories of sensationalism and their associated journal articles from 20 prominent U.K. universities.[10] We split press releases into 'sensationalized' and 'not sensationalized' for each area of sensationalism.

Results: **H6** is not supported. The difference in IMPACT and MAIN usage is small and not signficant for all types of sensationalism. Partly this is an encouraging result, as it suggests that using the strategies does not risk sensationalizing the science. Future work might explore strategies that help writers avoid sensationalism.

7 Related Work

We highlight additional areas of research relevant to our work beyond those already discussed.

Science communication. Over the past twenty years, science communication has shifted from improving scientific literacy to fostering participation in science (Hetland, 2014). A growing body of research shows that scientific literacy is only one of many factors that influence public decision making and cannot be divorced from cultural values (Nisbet and Scheufele, 2009; Bubela et al., 2009).

Scientific writing. There is a wealth of work exploring writing in scientific journals (i.e., when scientists communicate within their discipline). Because of the natural structure of scientific journal papers, much work has looked at ways of automatically identifying content in these papers (Liakata et al., 2010; Guo et al., 2010; Liakata et al., 2012). Kröll et al. (2014) examined the use of guidelines for science journal papers. Our work instead focuses on general science writing.

8 Future Work

We annotated writing strategies at the sentence level, but some strategies, such as STORY and ANALOGY, might be better annotated at the fragment level to account for longer or shorter use of strategies. Future work can explore more fine-grained analysis of these strategies (e.g., with metaphor detectors; Gao et al., 2018). We also hope to build on these findings by exploring how effective the strategies are at engaging different readers.

9 Conclusion

In this paper we compile writing strategies from theory and practical advice, collect a large corpus and annotate a subset of it to measure strategies' use. We observe how strategies covary with intended audience. For example, blog sites, which target researchers, use more jargon and focus on the main findings of a paper, while magazine articles, which target a much broader audience of readers, tell more stories and use more active voice. Our findings also suggest that science newspaper articles judged by experts to have higher quality use more metaphorical language and tell more stories. We expect that our strategy formulations, classifiers, annotations and dataset will enable NLP-powered tools to support effective science communication for different audiences.

Acknowledgments

We thank Kristin Osborne, Rebekka Coakley, and Sarah E. McQuate for their helpful input on science communication, the annotators for their work on the project and the anonymous reviewers and members of the UWNLP community for their helpful feedback. This work was supported in part by the Office of Naval Research under MURI grant N00014-18-1-2670.

---

[10] While these press releases were written in the U.K., we expect science writing to be more invariant to regional dialects than other genres of writing.

A Appendix

A.1 Open-Coding Details

Using the selected style guides, two authors open-coded (Holton, 2007) the guidelines from each guide and grouped these guidelines into suggested writing strategies. Some resources had lists of guidelines (e.g., "12 ways to…"), for which the authors coded each listed guideline as a separate strategy. For resources in prose (e.g., books and academic articles), the authors highlighted all guidance on writing strategies for science communication (e.g., "Have an engaging, new, first sentence."). Because the eventual goal was to identify these strategies in a document, the authors focused on document-specific strategies rather than process-specific strategies (e.g., "make sure to have a friend read the draft before sending it in."). Table 5 lists all resources used.

A.2 Corpus Collection

We selected universities based on the Carnegie Classification of Institutions of Higher Education[11] for large 4-year universities with doctoral programs and very high research activity (i.e., R1 institutions) in the US. We additionally filtered for STEM dominant research institutions. We randomly sampled 10 university websites from this filtered set of universities; however, many universities either did not have a single unified press department (e.g., each school handled press separately), or the majority of press was unrelated to research output. As Table 1 shows, a majority of articles came from blog sites, while few came from press releases. This is due to the fact that press releases focus on research coming from that particular institution, substantially limiting the number of articles produced by these sites.

A.3 Cleaning Keywords

We selected the following keywords for filtering based on inspection of politicized articles from the sites we scraped between 2016 and 2019. All keywords are lower cased: 'trump', 'president', 'republican', 'refugee', 'congress', 'country', 'obama', 'senate', 'white house', 'democrat', 'political', 'epa', 'attorney', 'politics'. An article was considered political if the title contained any of the keywords and the body contained at least 4 of the keywords. We inspected all articles selected for annotation (337) and found none that were political.

A.4 Annotation Agreement

Table 6 reports Krippendorff's α at the sentence level for each strategy. Because most strategies do not occur often (i.e., usually less than 10% of sentences), simple agreement rate skews high due to a majority of negative examples. α corrects for this skew by taking into account random chance of overlapping annotations.

A fresh approach to synthesizing ammonia from air and water

Ammonia is vital to society, but its manufacture is energy intensive, has a large carbon footprint and requires high initial capital outlays. An intriguing reaction now suggests that energy-efficient alternatives are possible.

Global food production requires ammonia-based fertilizers. The industrial transformation of atmospheric nitrogen gas (N2, also known as dinitrogen) into ammonia (NH3) is therefore essential for human life. Despite the simplicity of the molecules involved, the cleavage of the strong nitrogen–nitrogen triple bond (the N≡N bond) in dinitrogen and the concomitant formation of nitrogen–hydrogen (N–H) bonds poses a difficult challenge for catalytic chemistry, and typically involves conditions that are costly in terms of energy requirements: high reaction temperatures, high pressures or combinations of reactive reagents that are difficult to handle and energy-intensive to make. Writing in Nature, Ashida et al.1 demonstrate that a samarium compound mixed with water and combined with a molybdenum catalyst can promote ammonia synthesis from dinitrogen under ambient conditions. The work opens up avenues of research in the hunt for ammonia-making processes that operate under ambient conditions, and raises the question of what an ideal process should be.

Motivated by a looming global fertilizer shortage at the turn of the twentieth century, and later by munitions shortages (ammonia can be used

A.5 Pretraining Details

We followed the pretraining recommendations of Gururangan et al. (2020) and pretrain RoBERTa in two additional steps: domain- and task-adaptive pretraining. Both steps are to tailor the model to domain and task specific language. Domain adaptive pretraining was done on 11.90M articles from REALNEWS (Zellers et al., 2019) for 12.5k training steps and task adaptive pretraining was done on 100k articles from a held out portion of our corpus for 10 epochs. Hyperparameters for pretraining are in Table 7.

A.6 Finetuning Details

Articles were broken down into sentences for classification. We employed random search for hyperparameter tuning with 5-fold cross validation on the training set of the annotated articles. We ran a total of 10 search trials. Table 8 details the final

Table 7: Hyperparameters for domain- and task-adaptive pretraining. Based on pretraining in (Gururangan et al., 2020).

Hyperparameter	**Assignment**

Abstract

Subevents elaborate an event and widely exist in event descriptions. Subevent knowledge is useful for discourse analysis and event-centric applications. Acknowledging the scarcity of subevent knowledge, we propose a weakly supervised approach to extract subevent relation tuples from text and build the first large scale subevent knowledge base. We first obtain the initial set of event pairs that are likely to have the subevent relation, by exploiting two observations that 1) subevents are temporally contained by the parent event, and 2) the definitions of the parent event can be used to further guide the identification of subevents. Then, we collect rich weak supervision using the initial seed subevent pairs to train a contextual classifier using BERT and apply the classifier to identify new subevent pairs. The evaluation showed that the acquired subevent tuples (239K) are of high quality (90.1% accuracy) and cover a wide range of event types. The acquired subevent knowledge has been shown useful for discourse analysis and identifying a range of event-event relations[1].

1 Introduction

A subevent is the event that happens as a part of the other event (i.e., parent event) spatio-temporally (Glavaš and Šnajder, 2014). Subevents, which elaborate and expand an event, widely exist in event descriptions. For instance, when describing *election* events, people usually describe typical subevents such as "*nominate* candidates", "*debates*" and "people *vote*". Knowing typical subevents of an event can help with analyzing several discourse relations (such as expansion and temporal relations) between text units. Furthermore, knowing typical subevents of an event is important for understanding the internal structure of the event (what is the event about?) and its properties (is this a violent or peaceful event?), and therefore has great potential to benefit event detection, event tracking, event visualization and event summarization among many other applications.

While being in high demand, little subevent knowledge can be found in existing knowledge bases. Therefore, we aim to extract subevent knowledge from text and build the first subevent knowledge base covering a large number of commonly seen events and their rich subevents.

Little research has focused on identifying the subevent relation between two events in a text. Several datasets annotated with subevent relations (Glavaš et al., 2014; Araki et al., 2014; O'Gorman et al., 2016) exist, but they are extremely small and usually contain dozens to one/two hundred documents. Subevent relation classifiers trained on these small datasets are not suitable to use to extract subevent knowledge from text, considering that subevent relations can appear in dramatically different contexts depending on topics and events.

We propose to conduct weakly supervised learning and train a wide-coverage contextual classifier to acquire diverse event pairs of the subevent relation from text. We start by creating **weak supervision**, where we aim to identify the initial set of subevent relation tuples from a text corpus. With no contextual classifier at the beginning, it is difficult to extract subevent relation tuples because subevent relations are rarely stated explicitly. Instead, we propose a novel two-step approach to indirectly obtain the initial set of subevent relation tuples, exploiting two key observations that (1) subevents are temporally contained by the parent event, and thus can be extracted with linguistic expressions that in-

---

[1] Code and the knowledge base are available at `https://github.com/wenlinyao/EMNLP20-SubeventAcquisition`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5345–5356,
November 16–20, 2020.

dicate the temporal containment relationship[2], and (2) the definition of the parent event is useful to prune spurious subevent tuples away to improve the quality.

Specifically, we first use several preposition patterns (e.g., e_i *during* e_j) that indicate the temporal relation *contained_by* between events to identify candidate subevent relation tuples. Then, we conduct an event definition-guided semantic consistency check to remove spurious subevent tuples that often include two temporally overlapping but semantically incompatible events. For example, a news article may report a *bombing* event that happened in parallel during a *festival*, but the intense *bombing* event is not semantically compatible with the entertaining event *festival*, as informed by the common definition of *festival*:

> *A festival is an organized series of celebration events, or an organized series of concerts, plays, or movies, typically one held annually.*

Next, we identify sentences from the text corpus that contain an event pair, and use these sentences to train a contextual classifier that can recognize the subevent relation in text. We train the contextual subevent relation classifier by fine-tuning the pretrained BERT model (Devlin et al., 2019). We then apply the contextual BERT classifier to identify new event pairs that have the subevent relation.

We have built a large knowledge base of 239K subevent relation tuples. The knowledge base contains subevents for 10,318 unique events, with each event associated with 20.1 subevents on average. Intrinsic evaluation demonstrates that the learned subevent relation tuples are of high quality (90.1% of accuracy) and are valuable for event ontology building and exploitation.

The learned subevent knowledge has been shown useful for identifying subevent relations in text, including both intra-instance and cross-sentence cases. In addition, the learned subevent knowledge is shown useful for identifying temporal and causal relations between events as well, for the challenging cross-sentence cases where we usually have little contextual clues to rely on. Furthermore, when incorporated into a recent neural discourse parser, the learned subevent knowledge has noticeably improved the performance for identifying two types of implicit discourse relations, expansion and temporal relations.

In short, we made three main contributions: 1). We developed a novel weakly supervised approach to acquire subevent knowledge from text. 2). We have built the first large scale subevent knowledge base that is of high quality and covers a wide range of event types. 3). We performed extensive evaluation showing that the harvested subevent knowledge not only improves subevent relation extraction, but also improves a wide range of NLP tasks such as causal and temporal relation extraction and discourse parsing.

2 Related Work

Subevent Identification: Only a few studies have focused on identifying subevent relations in text. (Araki et al., 2014) built a logistic regression model to classify the relation between two events into full coreference (FC), subevent parent-child (SP), subevent sister (SS), and no coreference (NC). They improved the prediction of SP relations by performing SS prediction first and using SS prediction results in a voting algorithm. (Glavaš and Šnajder, 2014) trained a logistic regression classifier using a range of lexical and syntactic features and then used Integer Linear Programming (ILP) to enforce document-level coherence for constructing coherent event hierarchies from news. Recently, (Aldawsari and Finlayson, 2019) outperformed previous models for subevent relation prediction using a linear SVM classifier, by introducing several new discourse features and narrative features.

Subevent Knowledge Acquisition: Considering the generalizability issue of supervised contextual classifiers trained on small annotated data, our pilot research on subevent knowledge acquisition (Badgett and Huang, 2016) relies on heuristics, where we first identify sentences in news articles that are likely to contain subevents by exploiting a sentential pattern[3], and then, we extract subevent phrases from those sentences using a phrasal pattern[4]. In addition, this pilot work does not aim to acquire the parent event together with subevents, instead,

---

[2] While subevents are also spatially contained by the parent event, we did not use this observation to identify candidate subevent relations because the spatial *contained_by* relation between two events is not frequently stated in text.

[3] Subevents often appear in sentences that start or end with characteristic phrases such as "media reports" and "witness said".

[4] Subevent phrases often occur together in conjunction constructions as a sequence of subevent phrases.

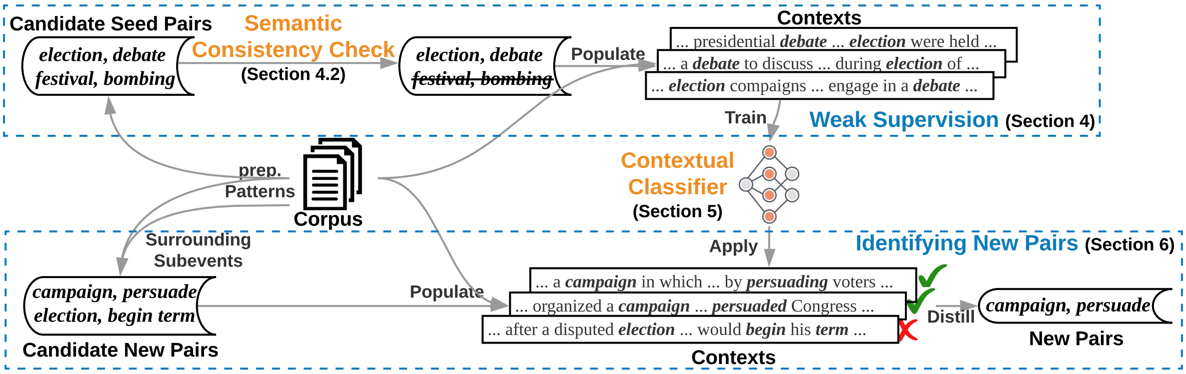

Figure 1: Overview of the Subevent Knowledge Acquisition System

it learns a list of subevent phrases from documents that are known to describe a certain type of event. Specifically, in this work, we only acquired 610 subevent phrases for one type of parent event, civil unrest events. The recent work (Bosselut et al., 2019; Sap et al., 2019) uses generative language models to generate subevent knowledge among many other types of commonsense knowledge.

We can potentially incorporate our learned subevent knowledge into a general event ontology to enrich subevent links in the ontology. For instance, the Rich Event Ontology (REO) (Brown et al., 2017) unifies two existing knowledge resources (i.e., FrameNet (Fillmore et al., 2003) and VerbNet (Kipper et al., 2008)) and two event annotated datasets (i.e., ACE (Doddington et al., 2004) and ERE (Song et al., 2015)) to allow users to query multiple linguistic resources and combine event annotations. However, REO contains few subevent relation links between events.

Identification and Acquisition of other Event Relations: Compared to relatively little research devoted to subevent identification and acquisition, significantly more research has been done for identifying and extracting several other types of event relations, especially temporal relations (Pustejovsky et al., 2003; Chklovski and Pantel, 2004; Bethard, 2013; Llorens et al., 2010; D'Souza and Ng, 2013; Chambers et al., 2014) and causal relations (Girju, 2003; Bethard and Martin, 2008; Riaz and Girju, 2010; Do et al., 2011; Riaz and Girju, 2013; Mirza and Tonelli, 2014, 2016).

3 Overview of the Weakly Supervised Approach

Figure 1 shows the overview of the weakly supervised learning approach for subevent knowledge acquisition. The key of this approach is to identify seed event pairs that are likely to be of the subevent relation in a two-step procedure (Section 4). We first use several temporal relation patterns (e.g., e_i *during* e_j) to identify candidate seed pairs since a child event is usually temporally contained by its parent event; and then, we conduct a definition-guided semantic consistency check to remove spurious subevent pairs that are semantically incompatible and are unlikely to have the subevent relation, e.g., (*festival, bombing*).

Next, we find occurrences of seed pairs in a large text corpus to quickly generate many subevent relation instances, we will also create negative instances to train the subevent relation classifier (Section 5). Then, the trained contextual classifier will be used to identify new event pairs of the subevent relation by examining multiple occurrences of an event pair in text (Section 6). We use the English Gigaword (Napoles et al., 2012) as the text corpus.

4 Weak Supervision

4.1 Seed Event Pair Identification

We use six preposition patterns (i.e., *during, in, amid, throughout, including*, and *within*) to extract candidate seed event pairs. Specifically, we use dependency relations[5] to recognize preposition patterns, and extract the governor word and dependent word of each pattern. We then check whether both words are event triggering words, and try to attach an argument to an event word to form an event phrase that tends to be more expressive and self-contained than a single event word, e.g., *sign agreement* vs *sign*, or, *attack on troops* vs *attack*. We consider both verb event phrases and

---

[5] We use Stanford dependency relations (Manning et al., 2014), e.g., *prep_during*.

noun event phrases (Appendix A provides more details). We further require that at least one argument is included in an event pair which may be attached to the first or the second event. In other words, we do not consider event pairs in which neither event has an argument.

To select seed subevent pairs, we consider event pairs that co-occur with at least two different patterns for at least three times. In this way, we identified around 43K candidate seed pairs from the Gigaword corpus. However, many candidate seed pairs identified by the preposition patterns only have the temporal *contained_by* relation but do not have the subevent relation. In order to remove such spurious subevent pairs, we present an event definition guided approach next to conduct semantic consistency check between the parent event and the child event of a candidate subevent relation tuple.

4.2 Definition-Guided Semantic Check

The intuition is that the definition of a parent event word describes important aspects of the event's meanings and signifies its potential subevents. For example, based on the definition of *festival*, events related to *"celebrations"*, such as *ceremony being held* and *set off fireworks*, are likely to be correct subevents of *festival*; however, *bomb explosion* and *people being killed* may be distinct events that only happen temporally in parallel with *festival*.

Specifically, we perform semantic consistency checks collectively for many candidate event pairs by considering similarities between events and similarities between the definition of an event and its subevents, and we cluster event phrases into groups so that any two event phrases within a group are semantically compatible. Therefore, when the clustering operation is completed, we will recognize an event pair as a spurious subevent relation pair if its two events fall into different clusters. Next, we describe details on graph construction and the clustering algorithm we used.

4.2.1 Graph Construction

Given a set of event pairs needing the semantic consistency check, we construct an undirected graph $G(V, E)$, where each node in V represents a unique event phrase. We connect event phrases with two types of weighted edges. First, for each candidate subevent relation tuple, we create an edge of weight 1.0 between the parent event and the child event. Second, we create an edge between any two event phrases if their similarity is greater than a certain threshold, and the edge weight is their similarity score. To calculate the similarity between two event phrases, we pair each word from one event phrase (either the event word or an argument) with each word from the other event phrase and calculate similarity between two word embeddings[6], then the similarity between two event phrases is the average of their word pair similarities. We set the similarity threshold as 0.3, after inspecting 200 randomly selected event pairs with their similarities. If two event phrases are already connected because they are a candidate subevent relation pair, we add their similarity score to the edge weight.

Next, we incorporate event definitions by adding new nodes and new edges to the graph. Specifically, for each event phrase that appears as the parent event in some candidate subevent relation tuples, we create a new node for its event word representing the event word definition. If the event word has multiple meanings and therefore multiple definitions, we consider at most five definitions retrieved from WordNet (Miller, 1995) and create one node for each definition, assuming each definition of the parent event will attract different types of children events. Then, we connect each definition node of a parent event with its children events, if their similarity is over the same similarity threshold used previously. The similarity between a definition node and a child event is calculated by exhaustively pairing each non-stop word from the definition sentence and each word from the child event phrase and taking the average of word pair similarities.

4.2.2 The Clustering Algorithm

We use a graph propagation algorithm called Speaker-Listener Label Propagation Algorithm (SLPA) (Xie et al., 2011). SLPA has been shown effective for detecting overlapping clusters (Xie et al., 2013), which is preferred because multiple types of events may share common subevents. For instance, *people being injured* is a commonly seen subevent of conflict events (e.g., *combat*) as well as disaster events (e.g., *hurricane*). In addition, SLPA is self-adapted and can converge to the optimal number of clusters, with no pre-defined number of clusters needed. Event clusters often become stable soon after 50 iterations, to ensure convergence, we ran the algorithm for 60 iterations.

After performing the semantic consistency

---

[6] We used word2vec word embeddings.

check, we retained around 30K seed event pairs. We find occurrences of these event pairs in the Gigaword corpus and obtained around 388K[7] sentences containing an event pair. These sentences will be used as positive instances to train the contextual classifier.

5 The Contextual Classifier Using BERT

Recently, BERT (Devlin et al., 2019) pretrained on massive data has achieved high performance on various NLP tasks. We fine-tune a pretrained BERT model to build the contextual classifier for subevent relation identification.

BERT model is essentially a bi-directional Transformer-based encoder that consists of multiple layers where each layer has multiple attention heads. Formally, given a sentence with N tokens, each attention head transforms a token vector t_i into query, key, and value vectors q_i, k_i, v_i through three linear transformers. Next, for each token, the head calculates the self-attention scores for all other tokens of the input sentence against this token as the softmax-normalized dot products between two query and key vectors. The output o_i of each attention head is a weighted sum of all value vectors:

$$o_i = \sum_{j=1}^{N} w_{ij} v_j, \; w_{ij} = \frac{\exp(q_i^T k_j)}{\sum_{l=1}^{N} \exp(q_i^T k_l)}$$

In this way, we can obtain N contextualized embeddings $\{o_i\}_{i=1}^{N}$ for all words $\{w_i\}_{i=1}^{N}$ in a sentence using the BERT model. To enforce the BERT encoder to look at context information other than the two event trigger words of a subevent pair, e.g., *war, person battle*, we replace the two event trigger words in a sentence with a special token `[MASK]` as the original BERT model did for masking. The contextualized embeddings at two event triggers' positions (two `[MASK]`'s positions) are concatenated and then fed into a feed-forward neural network with a softmax prediction layer for three-way classification, i.e., to predict two subevent relations (parent-child and child-parent relations depending on the textual order of two events) and no subevent relation (Other).

In our experiments, we use the pretrained BERT$_{\text{base}}$ model provided by (Devlin et al., 2019) with 12 transformer block layers, 768 hidden size and 12 self-attention heads[8]. We train the classifier using cross-entropy loss and Adam (Kingma and Ba, 2015) optimizer with initial learning rate 1e-5, 0.5 dropout, batch size 16 and 3 training epochs.

5.1 Negative Training Instances

High-quality negative training instances that can effectively compete with positive instances are important to enable the classifier to distinguish subevent relations from non-subevent relations. We include two types of negative instances to fine-tune the BERT classifier.

First, we randomly sample sentences that contain an event pair different from any seed pair or candidate pair (Section 6.1) as negative instances. We sample such negative sentences equal to five times of positive sentences, considering that most sentences in a corpus do not contain a subevent relation. Second, we observe that the subevent relation is often confused with temporal and causal event relations because a subevent is strictly temporally contained by its parent event. Therefore, to improve the discrimination capability of the classifier, we also include sentences containing temporally or causally related events as negative instances. Specifically, we apply a similar strategy - using patterns[9] to extract temporal and causal event pairs and then search for these pairs in the text corpus to collect sentences that contain a temporal or causal event pair. Event pairs that co-occur with temporal or causal patterns for at least three times are selected for population. We collected 63K temporally related event pairs and 61K causally related event pairs, which were used to identify 371K sentences that contain one of the event pairs. In total, we obtained around 1.8 million negative training instances.

6 Identifying New Subevent Pairs

We next apply the contextual BERT classifier to identify new event pairs that express the subevent relation. It is unnecessary to test on all possible pairs of events since two random events that co-occur in a sentence have a small chance to have the subevent relation. In order to narrow down the search space, we first identify candidate event pairs that are likely to have the subevent relation.

---

[7] Some event pairs appear very frequently in the corpus, to encourage diversity of the training data, we keep at most 20 sentences that contain the same event pair.

[8] Our implementation was based on `https://github.com/huggingface/transformers`.

[9] Three temporal patterns - "following", "before", "after" and seven causal patterns - "lead to", "result in", "result from", "cause", "cause by", "due to", "because of" are used.

Then, we apply the contextual classifier to examine instances of each candidate event pair in order to determine valid subevent relation pairs.

6.1 Candidate Event Pairs

We consider two types of candidate event pairs. First, the preposition patterns used to identify seed subevent relation tuples are again used to identify candidate event pairs, but with less strict conditions. Specifically, we consider event pairs that co-occur with any pattern for at least two times as candidate event pairs. In this way, we identified 1.4 million candidate event pairs from the Gigaword corpus.

Second, when a subevent relation tuple appears in a sentence, it is common to observe other subevents of the same parent event in the surrounding context. Therefore, we collect sentences that contain a seed subevent relation tuple, and identify additional subevents of the same parent event in the two preceding and two following sentences. Furthermore, we observe that the additional subevents often share the subject or direct object with the subevent of the seed tuple, as a consequence, we only consider such event phrases found in the surrounding sentences and pair them with the parent event of the seed tuple to create new candidate event pairs. Using this method, we extracted around 89K candidate event pairs from the Gigaword corpus.

6.2 New Subevent Pair Selection Criteria

We identify a candidate event pair as a new subevent relation pair only if the majority of its sentential contexts, specifically more than 50% of them, were consistently labeled as showing the subevent relation by the BERT classifier. In addition, we disregard rare event pairs and require that at least three instances of an event pair have been labeled as showing the subevent relation.

The full weakly supervised learning process acquires 239K subevent relation pairs, including 30K seed pairs and 209K classifier identified pairs. The subevent knowledge base has 10,318 unique events shown as parent events, and each parent event is associated with 20.1 children events on average.

6.3 An Example Subevent Knowledge Graph

The initial exploration of the learned subevent knowledge shows two interesting observations of event hierarchies. Figure 2 shows an example event graph. First, we can draw a partition of the event space at multiple granularity levels by grouping events based on subevents they share, e.g., the upper and the lower sections of the example event graph illustrate two broad event clusters sharing no subevent, and within each cluster, we see smaller event groups (colored) that share subevents extensively within a group while sharing fewer subevents between groups. Second, subevents encode event semantics and reveal different development stages of the parent events, e.g., subevents of natural disaster events (top left corner) reflect disaster *response* and *recovery* stages.

Seed Pairs	P/R/F1
Before Semantic check	44.9/25.3/32.4
After Semantic check	**55.9/26.2/35.7**

Table 1: Performance of the Contextual Classifier.

7 Intrinsic Evaluation

7.1 Precision of the Contextual Classifier

The contextual classifier is a key component of our learning approach. We evaluate the performance of the BERT contextual classifier on identifying subevent relations against several other types of event-event relations (e.g., temporal, causal relations, etc.), using the Richer Event Description (RED) corpus (O'Gorman et al., 2016) that is comprehensively annotated with rich event-event relations. Since the contextual classifier mainly performs at the sentence level, we only consider to identify intra-sentence subevent relations in the RED dataset[10].

Table 1 shows the comparisons between two training settings - the BERT classifier trained on seed pairs before vs after applying the semantic check (43k vs 30k seed pairs) and their identified training instances. Conducting the semantic check improves the precision of the trained classifier by 11% with no loss on recall. Without using any annotated data, the classifier achieves the precision of 55.9%. While the precision on predicting each sentential context is not perfect, note that we retain a candidate subevent relation pair only if the majority and more than three of its sentential contexts show the subevent relation.

7.2 Accuracy of Acquired Subevent Pairs

We randomly sampled around 1% of acquired subevent pairs, including 300 from seed subevent pairs and 2,090 from newly learned subevent pairs,

---

[10] RED has 2635 intra-sentence event relations, 530 of them are subevent relations.

and asked two human annotators to judge whether the subevent relation exists between two events. The two annotators labeled 250 event pairs in common and agreed on 93.6% (234) of them, and the remaining subevent pairs were evenly split between the two annotators. According to human annotations, the accuracy of seed pairs is 91.6% and the accuracy of newly learned event pairs is 89.9%, with the overall accuracy of 90.1%.

7.3 Coverage of Acquired Subevent Pairs

To see whether the acquired subevent knowledge has good coverage of diverse event types, we compare the unique events appearing in the acquired subevent relation tuples with events annotated in two datasets, ACE (Doddington et al., 2004) and KBP (Ellis et al., 2015), both with rich event types annotated and being commonly used for event extraction evaluation. We found that 73.8% (656/889) of events in ACE and 66.9% (934/1396) of events in KBP match with events in the acquired subevent pairs. Because we aim to evaluate the coverage on general event types instead of specific events, we ignore event arguments and only match event word lemmas.

In addition, we compare our learned 239K subevent pairs with the 30K ConceptNet subevent pairs. Interestingly, the two sets only have 311 event pairs in common, which shows that our learning approach extracts subevent pairs from real texts that are often hard to think of by crowd sourcing workers, the approach used by ConceptNet.

8 Extrinsic Evaluation

8.1 Subevent Relation Identification

To find out whether the learned subevent knowledge can be used to improve subevent relation identification in text, we conducted experiments on two datasets, RED[11] and HiEve[12] (Glavaš et al., 2014). In our experiments, we consider intra-sentence and cross-sentence event pairs separately. We randomly split data into five folds and conduct cross-validation for evaluation. We fine-tune the same BERT model using RED or HiEve annotations to

---

[11] RED has 530 intra-sentence and 415 cross-sentence subevent relations.

[12] HiEve annotated 3,200 event mentions and their subevents as well as coreference relations in 100 documents. We first extended the subevent annotations using transitive closure rules and coreference relations (Glavaš et al., 2014; Aldawsari and Finlayson, 2019), which produces 490 intra-sentence and 3.1K cross-sentence subevent relations.

Method	Macro	Acc	Comparison	Contingency	Expansion	Temporal

predict subevent relations vs others[13][14]. Note that for cross-sentence event pairs, we simply concatenate two sentences and insert in between the special token `[SEP]` used in the original BERT.

We propose two methods to incorporate the learned subevent knowledge. **1) Subevent links**. For a pair of events to classify in the RED or HiEve dataset, we check if they match with our learned subevent relation tuples. We ignore event arguments for matching events and only consider to match event word lemmas, for this reason, one pair of events might match with multiple learned subevent relations. We count subevent relations that match with a given event pair, (X, Y), in two directions (X $\overset{subevent}{\to}$ Y) and (Y $\overset{subevent}{\to}$ X) separately, and encode the log values of the two counts in a vector. **2) Event embedding**. Subevent relations can be used to build meaningful event embeddings to have the embeddings of a parent event and a child event preserve the subevent relation between them. Therefore, we train a BiLSTM encoder[15] to build event phrase embeddings, using the knowledge representation learning model TransE (Bordes et al., 2013)[16] such that $\mathbf{p} + \mathbf{r} \approx \mathbf{c}$ given a parent-child event pair (p, c) having the subevent relation r. We will use the trained BiLSTM encoder to obtain an embedding for an event phrase in the RED or HiEve dataset.

Finally, for subevent relation identification, we concatenate two event word representations obtained by the BERT encoder with either a subevent link vector or two event embeddings obtained using the above two methods. Results are shown in Table 2. We can see that compared to the basic BERT classifier, incorporating learned subevent knowledge achieves better performance on both datasets, for both intra-sentence and cross-sentence cases.

8.2 Temporal and Causal Relation Identification

Subevents indicate how an event emerges and develops, and therefore, the learned subevent knowledge can further be used to identify other semantic relations between events, such as temporal and causal relations. For evaluation, we use the same RED [17] dataset plus two more datasets, TimeBank v1.2[18] (Pustejovsky et al., 2003) and Event Storyline Corpus (ESC) v1.5[19] (Caselli and Inel, 2018),

---

[13] For the RED dataset, we consider all the annotated event-event relations in RED other than subevent relations as others.

[14] For the HiEve dataset, we exhaustively create event mention pairs among all the annotated event mentions in HiEve and consider all the mention pairs that were not annotated with the subevent relation as others. In this way, we generated 3.5K intra-sentence and 59.5K cross-sentence event mention pairs as others.

[15] The BiLSTM has the hidden size of 50 and uses max-pooling to encode an event phrase.

[16] We trained TransE for 20 iterations.

[17] RED has 1104 (1010) intra-sentence and 182 (119) cross-sentence temporal (causal) relations. We consider all the annotated event-event relations in RED other than temporal (causal) relations as others.

[18] TimeBank has 1,122 intra-sentence and 247 cross-sentence "before/after" temporal relations. We consider all the annotated event-event relations in TimeBank other than "before/after" relations as others.

[19] ESC has 1,649 intra-sentence and 3,952 cross-sentence causal relations. We exhaustively create event mention pairs

dedicated to evaluate temporal relation and causal relation identification systems respectively. We use the same experimental settings, including 5-fold cross-validations and evaluating predictions of intra- and cross-sentence cases separately. In addition, we repurpose the BERT model to predict temporal relations vs others or predict causal relations vs others, and we use the same two methods to incorporate the learned subevent knowledge.

Table 4 and 5 show results of temporal and causal relation identification. We can see that subevent knowledge has little impact for identifying intra-sentence temporal and causal relations that may heavily rely on local contextual patterns within a sentence. However, for identifying the more challenging cross-sentence cases that usually have little contextual clues to rely on, the learned subevent knowledge has noticeably improved the system performance on both datasets. This is true for both temporal relations and causal relations. Overall, the systems achieved the best performance when using the event embedding approach to incorporate subevent knowledge.

8.3 Implicit Discourse Relation Classification

We expect subevent knowledge to be useful for classifying discourse relations between two text units in general because subevent descriptions often elaborate and provide a continued discussion of a parent event introduced earlier in text. For experiments, we used our recent discourse parsing system (Dai and Huang, 2019) that easily incorporates external event knowledge as a regularizer into a two-level hierarchical BiLSTM model (Base Model) for paragraph-level discourse parsing. The experimental setting is exactly the same as in (Dai and Huang, 2019).

Table 3 reports the performance of implicit discourse relation classification on PDTB 2.0 (Prasad et al., 2008). Incorporating the acquired subevent pairs (239K) into the Base Model improves the overall macro-average F1-score and accuracy by 2.0 and 2.6 points respectively, which is non-trivial considering the challenges of implicit discourse relation identification. The performance improvements are noticeable on both the expansion relation and the temporal relation categories.

9 Conclusions

We have presented a novel weakly supervised learning framework for acquiring subevent knowledge and built the first large scale subevent knowledge base containing 239K subevent tuples. Evaluation showed that the acquired subevent pairs are of high quality (90.1% of accuracy) and cover a wide range of event types. We performed extensive evaluations showing that the harvested subevent knowledge not only improves subevent relation extraction, but also improve a wide range of NLP tasks such as causal and temporal relation extraction and discourse parsing. In the future, we would like to explore uses of the subevent knowledge base for other event-oriented applications such as event tracking.

A Event Representations

We consider both verb event phrases and noun event phrases.

Verb Event Phrases: To ensure good coverage of regular event pairs, we consider all verbs[20] as event words except possession verbs[21]. The thematic patient of a verb refers to the object being acted upon and is essentially part of an event, therefore, we first consider the patient of a verb in forming an event phrase[22]. The agent is also useful to specify an event especially for an intransitive verb event, which does not have a patient. Therefore, we include the agent of a verb event in an event phrase if its patient was not found. The patient or agent of a verb is identified using dependency relations[23]. If neither a patient nor an agent was found, we include a preposition phrase (a preposition and its object) that modifies a verb in the event representation to form an event phrase. Example verb event phrases are "agreement be *signed*" and "*occupy* territory".

Noun Event Phrases: We include a preposition phrase (a preposition and its object)that modifies a noun event in the event representation to form a noun event phrase. We first consider a preposition phrase headed by the preposition *of*, then a preposition phrase headed by the preposition *by*, lastly a preposition phrase headed by any other preposition. Example noun event phrases are "*ceremony* at location" and "*attack* on troops".

Note that many noun words do not refer to an event, therefore, we apply two strategies to quickly compile a list of noun event words. First, we obtain a list of deverbal nouns[24] (5028 event nouns) by querying each noun in WordNet (Miller, 1995) and checking if its root word form has a verb sense. Second, we identify five intuitive textual patterns, e.g., *participate in* EVENT, and extract their prepositional direct objects as potential noun events. The five patterns are: *participate in* EVENT, *involve in* EVENT, *engage in* EVENT, *play role in* EVENT and *series of* EVENT. We rank extractions first by the number of times they occur with these patterns and then by the number of unique patterns they occur with. We next quickly went through the top 5,000 nouns and manually removed non-event words, which results in 3154 noun event words.

Event Phrase Generalization: Including arguments into event representations generates event phrases that are too specific though. In order to obtain generalized event phrase forms, we replace named entity arguments with their entity types (Manning et al., 2014). We also replace personal pronouns with the entity type PERSON.

---

[20] We used POS tags to detect verb events.

[21] We determined that possession verbs, such as "own", "have" and "contain", mainly express the ownership status so we discarded these event phrases.

[22] In particular, we require a light verb (e.g., do, make, take etc.) to have a direct object because light verbs have little semantic content of their own.

[23] We use Stanford dependency relations (Manning et al., 2014). We identify the patient as the direct object of an active verb or the subject of a passive verb; we identify the agent as the subject of an active verb or the object of preposition *by* modifying a passive verb.

[24] Derivative nouns ending with suffixes -er, -or are discarded.

Biomedical Event Extraction as Sequence Labeling

Abstract

We introduce Biomedical Event Extraction as Sequence Labeling (BEESL), a joint end-to-end neural information extraction model. BEESL recasts the task as sequence labeling, taking advantage of a multi-label aware encoding strategy and jointly modeling the intermediate tasks via multi-task learning. BEESL is fast, accurate, end-to-end, and unlike current methods does not require any external knowledge base or preprocessing tools. BEESL outperforms the current best system (Li et al., 2019) on the Genia 2011 benchmark by 1.57% absolute F1 score reaching 60.22% F1, establishing a new state of the art for the task. Importantly, we also provide first results on biomedical event extraction *without* gold entity information. Empirical results show that BEESL's speed and accuracy makes it a viable approach for large-scale real-world scenarios.[1]

1 Introduction

Biomedical event extraction provides invaluable means for assisting domain experts in the curation of knowledge bases and biomolecular pathways (Ananiadou et al., 2010). While the task has received significant attention in research over the last decade, it remains challenging. Progress has been rather stagnating (see Figure 1).

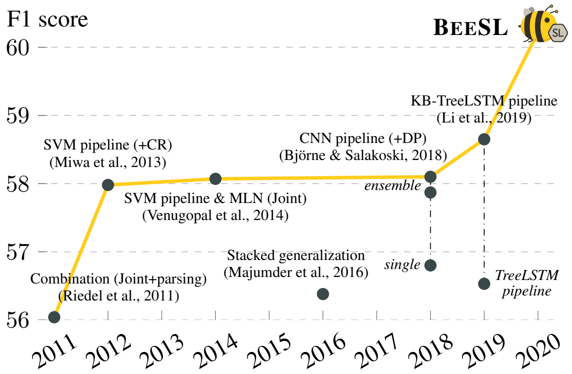

Figure 1: Performance of biomedical event extraction on the BioNLP Genia 2011 test set over time.

Events are typically highly complex and nested structures, which require deep contextual knowledge to resolve. This is particularly the case for biomedical NLP (Kim et al., 2011), where biomolecular events can be nested (Miwa et al., 2014) and long-distance arguments are frequent (Li et al., 2019). Figure 2 shows an example with four events. Each event consists of an event mention (*trigger*) and one or more *arguments*. For instance, there is a +REGULATION event triggered by the span "induced", with a PROTEIN entity (i.e., "IL-12") as CAUSE and a nested +REGULATION event (i.e., "activation") as THEME. Many state-of-the-art biomedical event extraction systems still work as a pipeline and extract event triggers and their arguments independently (Björne and Salakoski, 2018; Li et al., 2019). They typically employ dependency parsing as features in a CNN model ensemble (Björne and Salakoski, 2018) or in Tree-LSTMs with knowledge bases (Li et al., 2019).

We propose a new approach for biomedical event extraction by casting it as a sequence labeling task (BEESL). Our approach is conceptually simple: we convert the event structures into a representation suitable for sequence labeling, and leverage a multi-label aware decoder with BERT (Devlin et al., 2019) in a multi-task sequence labeling model. This reduces the problem to predicting a structured output for an input sequence to word-level tagging decisions. Compared to previous alternatives (cf. Section 7) which cast event extraction as syntactic or semantic tree- or graph-parsing task, this leads to a faster, joint model which also mitigates error propagation of locally-optimized classifier pipelines (Björne and Salakoski, 2018;

Above the text (*italicized*), mentions (triggers inside rounded boxes, and entities without rounded boxes) and argument roles are indicated. Bottom: our proposed encoding, where d, r and h represent the label parts for dependents, relations, and heads, respectively.

Li et al., 2019). Our empirical evaluation shows the effectiveness of BEESL for biomedical event extraction. A quantitative and qualitative analysis shows that BEESL is fast and effective. Despite the model's simplicity, BEESL outperforms the previous best model (Li et al., 2019) on most event categories.

Contributions To the best of our knowledge, we are the first to cast biomedical event extraction as sequence labeling. We demonstrate that BEESL is an attractive and efficient solution to extract biomedical events. We evaluate it on the BioNLP Genia 2011 benchmark, obtaining a new state of the art (cf. Figure 1), while gaining on efficiency. We additionally provide empirical results of the impact of alternative multi-task encodings, and to the best of our knowledge, the first results of biomedical event extraction *without* assuming gold entities.

2 Encoding Event Structures

This section introduces the event structures and how we encode them for sequence labeling.

2.1 Event structures

Events are structured representations which comprise multiple information units (Figure 2, top). An event is anchored to a *trigger*, a text span which indicates the presence of an event (Figure 2, rounded boxes). Each event has one or more arguments, namely *entities* or other events (Figure 2, end of arrows), which are assigned a *role* in the event (Figure 2, labels on arrows). For example, an EXPRESSION event is indicated in Figure 2 at "production" involving the PROTEIN "IL-10" as its argument. Nested structures are possible and frequent. For instance, the +REGULATION event centered on "activation" is both argument of the "induced"-anchored event as well as the "promote"-anchored event.

2.2 Sequence labeling encoding

Given $[x_1, ..., x_n]$ a sequence of n tokens, we encode event structures as token-level labels $[y_1, ..., y_n]$, to reduce the task to a sequence labeling problem. Adopting dependency parsing terminology, we encode the label y_i for each token x_i as a tuple $\langle d, r, h \rangle$, where d is the *dependent* and refers to the token and its mention type (either trigger, entity, or nothing), r is the *relation* and used to refer to its role, and *head* (h) denotes the event the token refers to (Figure 2, bottom). In more detail, to discriminate event heads with the same type in text, we encode the heads h as *relative head mention position*.[2] For instance, $h =$ +REG$_{+1}$ means the head is the first +REGULATION on the right of d in the relative surface order, whereas $h =$ +REG$_{-2}$ means it is the second +REGULATION on the left. In Figure 2 the label for "production" is $\langle$EXPRESSION, THEME, +REG$_{-1}\rangle$, denoting the token is an EXPRESSION trigger, THEME of the first +REGULATION event on the left.

As opposed to dependency parsing, tokens may have zero or multiple roots, and thus multiple heads and relations. This poses additional challenges. For instance, the "activation"-anchored event (Figure 2) is both THEME and CAUSE of "induced"- and "promote"-anchored event heads, respectively. As a result, both r and h are multi-label, and the label for "activation" is encoded as $\langle$+REGULATION, [THEME, CAUSE], [+REG$_{-1}$, +REG$_{+1}$]$\rangle$, where the order of r and h items is preserved.

3 Event Extraction as Sequence Labeling

Formally, we aim to learn a function $f : X \mapsto Y$ that assigns each token x_i a structured label y_i, i.e.,

---

[2] In preliminary experiments we found this mitigates the label sparsity problem of other positional encodings, e.g., relative positional encoding (Strzyz et al., 2019). We additionally found relative head mention positions ≥ 2 are rare in our data.

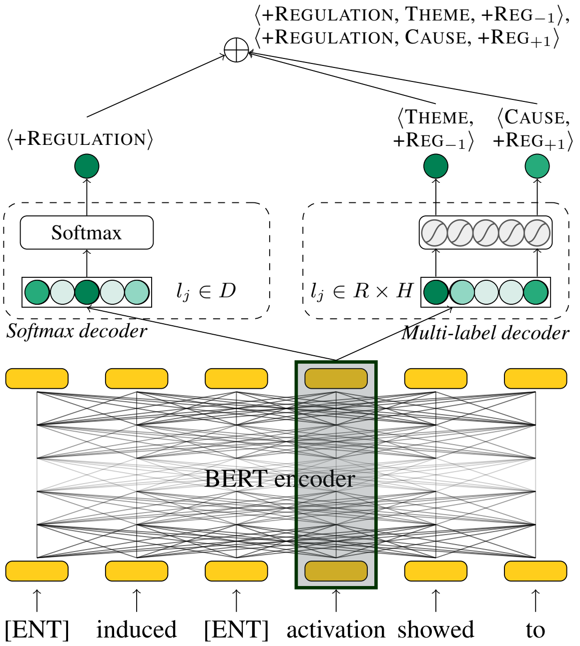

Figure 3: BEESL uses a multi-task multi-label model, using a BERT encoder with layer attention, and dedicated decoders for predicting the labels for each label sub-space, which are trivially merged.

$\langle d, r, h \rangle$. A straightforward solution is to predict the label y_i as an atomic entity (i.e., single label) in a single-task model. For BEESL, we instead propose to use multi-task learning (MTL) which allows to learn interdependencies while cutting down the label space, paired with multi-label prediction.

An overview of BEESL is shown in Figure 3. We use BERT (Devlin et al., 2019) as encoder, pretrained on biomedical texts (Section 4). We mask entity spans for better generalization (Alt et al., 2019). The first WordPiece (Schuster and Nakajima, 2012) of each token x_i is used for prediction, where the contextual hidden representation e_i of the token x_i is encoded with layer-wise attention over the BERT layers, similarly to (Peters et al., 2018; Kondratyuk and Straka, 2019). As decoders, we use standard softmax with a cross entropy loss unless otherwise specified, and introduce a multi-label decoder (Section 3.2) (Figure 3, upper right).

We empirically evaluate both single-task and multi-task setups, including several MTL encoding alternatives, discussing their limitations and benefits. In the following, we first introduce the multi-task setups, and then multi-label decoding.

3.1 Multi-task strategies

We denote the label spaces for each component of the labels as $d_i \in D$, $r_i \in R$, and $h_i \in H$. Further, we use $\mathcal{L}$ to refer to the maximum label space size.

Single-task A single-task (ST) setup is used as a baseline. It predicts a single label $y_i = \langle d, r, h \rangle$ for each input token x_i. The label space is up to $\mathcal{L} = |D| \times |R| \times |H|$.

Multi-task The label y_i for each token x_i is decomposed into parts (hereafter, sub-labels), each treated as a prediction task. The decomposition of the label space allows each sub-label space to be framed as a different task with its own private decoder, mitigating the output space sparsity (Vilares et al., 2019). Depending on the decomposition of the label $y_i = \langle d, r, h \rangle$, we have four multi-task learning options (pairs of tasks, or each subpart as a task, respectively) with the following properties:

1. $\langle d \rangle, \langle r, h \rangle$: up to $\mathcal{L} = |D| + |R| \times |H|$;
2. $\langle d, r \rangle, \langle h \rangle$: up to $\mathcal{L} = |D| \times |R| + |H|$;
3. $\langle d, h \rangle, \langle r \rangle$: up to $\mathcal{L} = |D| \times |H| + |R|$;
4. $\langle d \rangle, \langle r \rangle, \langle h \rangle$: up to $\mathcal{L} = |D| + |R| + |H|$.

Option 4 encodes each subpart as its own task. While this leads to the smallest label space, it decouples the problem into 3 separate tasks. Options 1-3 are pair-wise task setups. We hypothesize that BEESL benefits from disentangling mention detection from head labeling (option 1).

As illustrated in Figure 3, BEESL uses the predicted sub-labels to form the complete label tuple $\hat{y}_i = \langle \hat{d}, \hat{r}, \hat{h} \rangle$. In case r and h belong to different sub-label spaces (as is possible in options 2-4), we require that both predictions $\hat{r}$ and $\hat{h}$ are present (non-empty) to ensure well-formedness. This is a downside of these alternative options 2-4, as we will see empirically (Section 5).

During training, the MTL loss is computed as $L = \sum_t \lambda_t L_t$, where L_t is the loss for each task t, given by the respective decoder (see also Section 3.2), with λ_t a task-specific weighting parameter. In our experiments we kept $\lambda = 1.0$ for all, since preliminary experiments showed weighting sub-tasks differently was not beneficial. In the single-task setup, the loss reduces to $L = L_t$.

3.2 Multi-label decoder

The multi-label decoder is designed to handle multiple labels per token, thus being suitable for predicting relations and heads. Given a task with $l_j \in L$ labels, it models $P(l_j | e_i)$ for each label l_j. Differently from the single-label decoder, each label

Item	Train	Dev	Test
Documents	908	259	347
Sentences	8,664	2,888	3,363
Tokens	230,737	74,334	90,091
Entities	11,625	4,690	5,301
Events	10,310	3,250	4,487

Table 1: Statistics of the Genia 2011 event dataset.

is predicted with a sigmoid, where all contribute equally to the loss. Given the probabilities $P(l_j|e_i)$ for the $l_j \in L$ labels and a threshold τ, the token x_i is assigned all the labels l_j with probability $P(l_j|e_i) \geq \tau$. If no $P(l_j|e_i) \geq \tau$ is found, we take the highest scoring label l_j (which may also be empty) as a fallback.[3] We employ a binary cross-entropy loss, averaged across all batches.

4 Experimental Setup

We evaluate BEESL on the Genia 2011 benchmark (Kim et al., 2011), which comprises both abstracts and full-texts. The corpus consists of annotations for PROTEIN entities and 9 fine-grained event types. The Genia event extraction tasks expect both texts and entities as input, and complete events need to be predicted. Statistics on the dataset are shown in Table 1.

Event types can be categorized into simple, binding and complex events, related to the number and types of arguments. *Simple events* require a THEME only, *binding events* require one or more THEME arguments, while *complex events* take both THEME and CAUSE arguments, where both can in turn be other events, resulting in nested structures. Björne and Salakoski (2011) estimated that 37.2% of the events in the data are nested. We refer the reader to Appendix A.1 for formal event definitions.

BEESL is based on MaChAmp (van der Goot et al., 2020), a toolkit for multi-task learning and fine-tuning of BERT-like models. We extend MaChAmp to also handle multi-label sequence labeling. We experiment with BEESL in single- and different multi-task setups.

After sequence labeling, token-level labels are converted into the official BioNLP-ST standoff format for evaluation (Kim et al., 2011). We simply split the event arguments based on their formal definition, producing complete structures (e.g., an EXPRESSION event with k THEME arguments is split into k EXPRESSION events, with one THEME each). Similarly to previous work, we focus on sentence-level events. We used BioBERT-Base 1.1 as our BERT model for experiments, since it provides state-of-the-art performance across multiple biomedical information extraction tasks (Lee et al., 2019). For multi-label decoding, we tune the threshold τ for each setup (yielding $\tau_{MT} = 0.5$ and $\tau_{ST} = 0.7$). Other hyper-parameter values and tuning details are provided in Appendix A.2.

Evaluation In line with previous work, we evaluate BEESL in terms of precision (P), recall (R), and F1 score according to the approximate recursive span matching criterion (Kim et al., 2011) using the official BioNLP online evaluation service.[4] For early stopping during training, we employ the simpler span-based F1 score (as used in named entity recognition) as our proxy metric. We found it highly correlates with the approximate recursive span based F1 official metric.

No gold entities In biomedical event extraction, entities are typically given in advance. To evaluate BEESL in a setup with *predicted* entities (Section 6.3), we firstly employ our model as single-task sequence labeler for BIO-tagged entity mentions using default settings and a standard CRF decoder (Gardner et al., 2018). Note that for comparison purposes in all other experiments we assume entity mentions are gold-tagged. Then, we evaluate BEESL with raw texts and *predicted* entities as input, thus indirectly penalizing events that take over-predicted entities or that miss entities since they are under-predicted.

5 Results

First, we evaluate the MTL and multi-label decoding strategies on the development set to determine the best setup (Sections 5.1, 5.2). Then, we compare BEESL to the results obtained by the top performing systems on the official test set (Section 5.3). Finally, we gauge its speed (Section 5.4).

5.1 Multi-task settings

Table 3 (top) summarizes the main results for the MTL experiments. They confirm our hypothesis that $\langle d \rangle, \langle r, h \rangle$ (option 1) is the most viable representation; it leads to the highest F1 score, largely

---

[3] In case $\tau = 0 \vee \tau = 1$, we adopt the same strategy, since all or no labels would be potentially predicted, respectively.

with multi-label	71.84	59.42	**65.04**

Table 3: Performance of diverse settings for BEESL (multi-task and multi-label) on the development set.

outperforming the other MTL options, particularly in recall. These results show that a multi-task setup with separate tasks for mention detection and head labeling, respectively, is the most useful. Option 1, i.e., $\langle d\rangle, \langle r, h\rangle$ defaults to the multi-task option for BEESL (Figure 3) used in the following experiments.

5.2 Adding the multi-label decoder

We evaluate the multi-label decoder for both single-task (BEESL$_{ST}$) and multi-task (BEESL$_{MT}$) setups (Table 3, bottom). Multi-label decoding is beneficial, as the data contains many multi-headed tokens, and modeling them improves both setups. Single task performance increases substantially, from 61.13 to 63.34 F1 score. Similar significant performance gains are observed for multi-task learning, from 62.37 to 65.04 F1 score. Regardless of the multi-label modeling, the multi-task setup provides the highest overall performance.

5.3 Comparison to the state of the art

We now compare the multi-task multi-label BEESL to the top performing systems (hereafter, simply BEESL). As shown in Table 2, BEESL outperforms the state-of-the-art by a large margin, i.e., an absolute improvement of 1.57 points in F1 score over the KB-Tree LSTM model (Li et al., 2019) (hereafter, KBTL). It improves over both precision and recall, and yields a new state of the art with an F1 score of 60.22%, yet being conceptually simple.

Table 4 compares F1 scores of BEESL to the previous best model on a per-event level (precision and recall are provided in Appendix A.3). BEESL outperforms the KBTL approach (Li et al., 2019) overall on 7 out of the 9 event types. From a coarse-grained perspective, BEESL outperforms KBTL on simple, binding, and complex event categories. Particularly, improvements over KBTL on simple events are as large as +13% F1 score. Furthermore, noticeable are also the improvements for binding and nested, complex events, for which our model achieves 50.19% and 48.32% F1 score. From a closer look, the recall of BEESL on simple events is substantially higher than KBTL, which ease a correct identification of complex events.

Next, we look at performance per text type (i.e., abstract and full-text subsets). BEESL achieves 62.14% F1 score on abstracts-only documents,

Event type	BEESL	KBTL
Simple events	**79.31**	78.73
Gene expression	**80.90**	80.28
Transcription	69.46	**75.39**
Protein catabolism	**74.07**	60.87
Phosphorylation	**89.52**	84.36

Binding	**50.19**	44.10
Complex events	**48.32**	47.72
Regulation	**45.90**	43.52
Positive regulation	**49.41**	48.26
Negative regulation	47.17	**49.02**
All events	**60.22**	58.65

Table 4: Per-event performance of BEESL and KBTL (KB-driven TreeLSTM) (Li et al., 2019) on the test set.

	sents/min
TEES (*single*)	$255_{\pm 1}$
TEES (*ensemble*)	$101_{\pm 1}$
BEESL	$499_{\pm 3}$

Table 5: Speed comparison to TEES (Björne and Salakoski, 2018) single and ensemble models at inference time. Results are sents/min, averaged over 5 runs.

Setting	P	R	F1
BEESL	71.84	59.42	**65.04**
– multi-task	71.66	56.95	63.47
– multi-label	74.28	52.39	61.44

Table 6: Ablation study on BEESL when removing the multi-task capability (i.e., replacing MTL with independent classifiers) and the multi-label handling.

and 55.59% F1 score on full-texts. This confirms that full-texts are harder to process than abstracts, due to the differences in structural and content aspects (Cohen et al., 2010).

To sum up, BEESL handles events well, and unlike most prior work, does not use knowledge bases or dependency parsers as pre-processing step. BEESL uses multi-task learning with a contextual encoder and multi-label aware decoding, herewith bringing progress to the biomedical event extraction task as illustrated in Figure 1.

5.4 Speed comparison

We compare BEESL to TEES, the Turku Event Extraction System (Björne and Salakoski, 2018) to compare their speed at inference time on commodity hardware. TEES is the 2nd top-performing system (Figure 1), and its code is freely available. To the best of our knowledge, the source code of (Li et al., 2019) is not yet available.

Results in Table 5 show that BEESL is ∼2x faster and ∼5x faster on a consumer grade CPU[5] than TEES single and ensemble system, respectively. In terms of sentences per minute, BEESL processes ∼500 sents/min compared to 255 sents/min and 101 sents/min in TEES single (3.42% lower F1) and ensemble (2.12% lower F1), respectively.

6 Analysis and Discussion

To gain insights about BEESL, we shed more light on several aspects. Firstly, we analyze how much BEESL gains from multi-task learning, compared to using a powerful contextualized BERT encoder alone in a single-task learning setup and a formulation with two independent classifiers (Section 6.1). Then, we quantify the stability of the threshold τ of the multi-label decoder (Section 6.2). We also aim to get deeper insight on model performance without gold entities (Section 6.3), and qualitatively study the sources of prediction errors of BEESL (Section 6.4).

6.1 How important is multi-task learning?

As opposed to running one single model which models $\langle d \rangle$ and $\langle r, h \rangle$ jointly in a multi-task setup, we also compare to single-task (ST) and an experiment in which we formulate two classifiers which predict the two labels from the best MTL setup separately. This allows us to gauge the effectiveness of the multi-task learning approach compared to local classifiers which use strong BERT-based encoding, and compared to predicting an atomic label in ST.

Results in Table 6 confirm that leveraging a shared encoder and multi-task learning for both triggers and heads is crucial. Without multi-task learning and multi-label decoding, the F1 score drops to 61.44 (independent classifiers) and 61.13

---

[5] Intel Core i5-6360U (2 cores).

Setting	F1	Δ
BEESL$_{ST}$ (multi-label)	63.34	
with best-only prediction	62.87	-0.47
BEESL$_{MT}$ (multi-label)	**65.04**	
with best-only prediction	64.54	-0.50

Table 7: Ablation study on the threshold τ of the multi-label decoder ("with best-only predicion": $\tau = 1.0$).

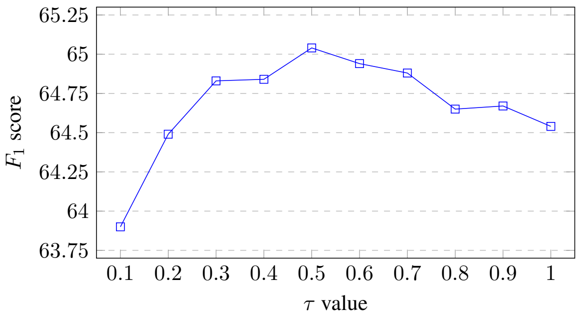

Figure 4: Stability of the threshold τ. Values in the range 0.3-0.7 only minimally alter BEESL scores.

(ST setup, BEESL$_{ST}$ in Table 3). Adding multi-label decoding helps, as expected. However, the full power of BEESL is only achieved by using *both* the multi-task and the multi-label approach, which leads to the novel state of the art.

6.2 How brittle is BEESL to the threshold τ?

As shown in Table 3, using a multi-label decoder largely increases the performance of a system with a single-label decoder (from 62.37 to 65.04 F1 score). However, what is left is how much the threshold τ impacts the performance. To get insights on it, we firstly performed an ablation study setting $\tau = 1.0$. As introduced in Section 3.2, this reduces to predicting the highest scoring label only – however, in a reduced label space induced by the multi-label aware decoder. We found only part of the improvement is due to the threshold τ in both multi-task and single-task settings (+0.50% and +0.47%, respectively) (Table 7).

Moreover, we evaluated BEESL with different τ values. As shown in Figure 4, a threshold in the range 0.3-0.7 only marginally alters the results, which are still better than predicting the highest scoring label only ($\tau = 1.0$).

6.3 What is the effect of using gold entities?

The standard in biomedical event extraction is to evaluate the performance of a system on gold entities. In real-world situations it is unlikely that the data is annotated for entities. We believe it is important to estimate the impact non-gold entities have on system performance (hereafter, *silver entities*). The performance of the entity prediction on the development set is 87.95 span-based F1 score.

	P	R	F1
BEESL	71.84	59.42	**65.04**
– gold entities	66.15	54.09	59.51

Table 8: Performance of BEESL with *no* gold entities.

Error type	Fraction
Trigger	
Under-prediction	31.43%
Over-prediction	28.57%
Wrong type	10.00%
Argument	
Under-prediction	22.86%
Over-prediction	7.14%
Wrong type	0.00%

Table 9: Error analysis on a random sample of 30 documents from the development set.

The results on the event extraction task using silver entities are shown in Table 8. The overall drop in F1 amounts to around 5%, and it is well-balanced across precision and recall. This shows that BEESL's performance is clearly affected, but that the system is relatively robust to noisy, non-gold *silver entities*. We believe that this performance gap can be further minimized by using jackknifing (Agić and Schluter, 2017) to reduce data mismatch, however, this requires to align the predicted entities with the existing events in the training data, which is non-trivial, and we leave this for future work.

6.4 What are the sources of errors?

We randomly sampled 30 documents (comprising 168 gold events) from the development set for a manual scrutiny for sources of errors. We classified errors into two broad categories, namely trigger and argument errors. Further, we classify them in fine-grained categories based on the type of error, namely under-prediction, over-prediction, and wrong type. Table 9 summarizes the results.

We notice the largest fraction of errors is due to trigger errors. From a closer look, under-predicted triggers account for 31.43% of the total, whereas over-predicted triggers for 28.57%. We investigated the reason for these errors, finding that over-predicted triggers are often due to generic words used very frequently to indicate specific trigger types. For instance, BEESL identifies the +REGULATION event anchored at "activated" in the following sentence: "*Tax [...] maximally activated HTLV-I-LTR-CAT and kappa B-fos-CA*" albeit the gold standard does not contain the event in this instance. However, from a semantic point of view we believe these errors are acceptable. Other cases include the words such as "detected" and "influences", which are often used as EXPRESSION and REGULATION event triggers, respectively.

Under-prediction of triggers is instead due to a variety of reasons. Both rare words (e.g., a +REGULATION event centered on "co-transfected") and uncertain events account for a large fraction of this error type. An example of uncertain event is represented by the +REGULATION trigger "importance" in the sentence "*[...] importance of NF-kappa B in LT gene expression*", that BEESL does not predict.

Wrongly typed triggers represent only 10% of the errors. An example is represented by ambiguous trigger types. In the sentence "*T cells upregulates A3G mRNA levels*", BEESL classifies "levels" as an EXPRESSION trigger, while the gold annotation indicates it is a TRANSCRIPTION trigger. By a closer look, we found some triggers in the corpora are annotated as EXPRESSION and TRANSCRIPTION types interchangeably. This is due to the fact a TRANSCRIPTION is a gene EXPRESSION.

Regarding the identification of arguments, over-predictions are quite uncommon. If erroneous, the main error we found may benefit from syntactic information, which we aim to integrate in a multi-task setup in future work. We found no misclassification of arguments in our document samples. Under-prediction of arguments are instead mostly due to under-predicted events.

7 Related Work

Biomedical event extraction has a long-standing tradition (Riedel et al., 2011; Miwa et al., 2012; Vlachos and Craven, 2012; Venugopal et al., 2014; Majumder et al., 2016). Current work has explored neural methods and uses multiple classification stages. Namely, first identifying trigger mentions, and then evaluating all entity pairs (Li et al., 2019; Björne and Salakoski, 2018). They come with the shortcomings of traditional pipeline methods. Many studies use dependency parsers to obtain features or for guidance of Tree-LSTMs (Li et al., 2019; Björne and Salakoski, 2018).

Recent work in syntactic parsing has shown that reducing parsing to sequence labeling is a viable alternative for both constituent and dependency parsing (Spoustová and Spousta, 2010; Gómez-Rodríguez and Vilares, 2018; Strzyz et al., 2019), which we took as inspiration. Moreover, earlier work framed biomedical event extraction as syntactic and semantic tree- or graph-parsing (McClosky et al., 2011; Rao et al., 2017). In particular, McClosky et al. (2011) do dependency parsing, followed by a second-stage parse reranker model for event extraction, and Rao et al. (2017) cast the problem as subgraph identification problem.

Joint learning for biomedical event extraction was explored in early work (Riedel and McCallum, 2011; Venugopal et al., 2014; Vlachos and Craven, 2012). Contemporary to our work, a very recent study proposes oneIE, a joint learning model for event extraction (Lin et al., 2020). It proposes a single end-to-end model for event extraction using 4 stages, paired with a beam search, obtaining good results on ACE data. Processing multiple heads has previously been done for relation extraction using multi-head selection (Bekoulis et al., 2018a,b), and sequence labeling has been employed for joint entity and relation classification (Dai et al., 2019) with inter-token attention. We employ it at the token-level for multi-label sequence labeling.

8 Conclusion

This paper proposes BEESL, a new end-to-end biomedical event extraction system which is both efficient and accurate. BEESL is broadly applicable to event extraction and other tasks that can be recast as sequence labeling. The system's strength comes from the joint multi-task modeling paired with multi-label decoding, which aids interdependencies between the tasks and is superior to alternative decoders based on strong contextualized BERT embeddings. BEESL is fast, and achieves state-of-the-art performance on the Genia 2011 event extraction benchmark without the need of external tools for features and resources such as knowledge bases. Our analysis shows that BEESL works very well across event types.

We release the code freely, to foster research on using BEESL for other NLP tasks as well, e.g., enhanced dependency parsing, fine-grained named entity recognition, and semantic parsing.

A Appendix

A.1 Data and formal event definitions

Events on the Genia 2011 benchmark follow the formal specification detailed in Table 10. The full data can be downloaded from the official portal.[6]

Event type	Arguments
Simple events	
Gene expression	Theme(P)
Transcription	Theme(P)
Protein catabolism	Theme(P)
Phosphorylation	Theme(P)
Localization	Theme(P)
Binding	Theme(P)+
Complex events	
Regulation	Theme(P/E), Cause(P/E)
Positive regulation	Theme(P/E), Cause(P/E)
Negative regulation	Theme(P/E), Cause(P/E)

Table 10: Formal definition of events. P: PROTEIN, E: any event type, +: 1 or more arguments.

A.2 Hyper-parameters

The list of hyper-parameter values and the search space are presented in Table 11, whereas the number of trainable parameters in BEESL is $\approx 110M$. For tuning, we started from the values reported in previous works on multi-task learning for NLP evaluation benchmarks, e.g., UDify (Kondratyuk and Straka, 2019). We performed 32 search trials via grid search, in which "batch size" and "base learning rate" have been coupled – $(32, 1e^{-}3)$ and $(64, 1e^{-}2)$. Additional 9 search trials have been performed for threshold τ selection for the BEESL multi-task multi-label model. We used the official approximate recursive span matching based F1 score for model selection, whereas the sum of span-based F1 scores of the tasks was employed to determine early stopping of the training process.

A.3 Miscellaneous

Technical details Texts have been tokenized and segmented using scispaCy 0.2.4 (Neumann et al., 2019). In our data it is uncommon that multiple contiguous triggers have the same type, so BIO encoding is not needed. In the rare case of overlapping event triggers of different types, we create a single label d concatenating their types. Similarly to previous work, for BINDING events with multiple THEME arguments we employ a simple heuristic to convert them into the BioNLP-ST standoff format (Vlachos and Craven, 2012). For speed experiments with TEES (Björne and Salakoski, 2018), we removed extra modules for a fair comparison.

Hyper-parameter	Value	Space
Optimizer	Adam	
β_1, β_2	0.9,0.99	
Weight decay	0.01	
Gradient clipping	10	
Dropout	0.5	0.1, 0.3, 0.5
BERT dropout	0.1	0.1, 0.2
Mask probability	0.1	0.1, 0.15, 0.2
Layer dropout	0.1	
Batch size	64	32, 64
Base learning rate	$1e^{-}2$	$1e^{-}3$, $1e^{-}2$
BERT learning rate	$5e^{-}5$	
Epochs	50	
Patience	5	
Multi-label threshold	0.5	0.1, 0.2, ..., 1.0

Table 11: Hyper-parameter values and search space.

Detailed per-event scores We present in Table 12 a complementary view of scores (i.e., with precision and recall) of BEESL and the previous state of the art (Li et al., 2019) on a per-event level.

	BEESL			KBTL		
Event type	**P**	**R**	**F1**	**P**	**R**	**F1**
Simple events	84.17	**74.98**	**79.31**	**85.95**	72.62	78.73
Gene expression	84.55	**77.54**	**80.90**	**87.24**	74.35	80.28
Transcription	72.50	66.67	69.46	**82.31**	**69.54**	**75.39**
Protein catabolism	83.33	**66.67**	**74.07**	**87.50**	46.67	60.87
Phosphorylation	**94.05**	**85.41**	**89.52**	87.28	81.62	84.36
Localization	**83.21**	59.69	**69.51**	80.28	59.69	68.47
Binding	**65.36**	**40.73**	**50.19**	53.16	37.68	44.10
Complex events	**58.54**	41.14	**48.32**	55.73	**41.73**	47.72
Regulation	**62.22**	36.36	**45.90**	53.61	**36.62**	43.52
Positive regulation	**60.14**	**41.93**	**49.41**	57.90	41.37	48.26
Negative regulation	**53.19**	42.38	47.17	52.39	**46.06**	**49.02**
All events	**69.72**	**53.00**	**60.22**	67.01	52.14	58.65

Table 12: Detailed per-event performance of BEESL and KBTL (KB-driven TreeLSTM) on the test set.

Upper bound of the encoding We quantified the upper bound of our encoding strategy by directly evaluating the performance of the encoded development set. Results (P: 95.76%, R: 91.30%, F1: 93.48%) indicate the goodness of our strategy, and that the $\approx 6\%$ missing is due to cross-sentence arguments we disregard, similarly to previous work.

Annotating Temporal Dependency Graphs via Crowdsourcing

Jiarui Yao[1], Haoling Qiu[2], Bonan Min[2], and Nianwen Xue[1]

Abstract

We present the construction of a corpus of 500 Wikinews articles annotated with *temporal dependency graphs* (TDGs) that can be used to train systems to understand temporal relations in text. We argue that temporal dependency graphs, built on previous research on narrative times and temporal anaphora, provide a representation scheme that achieves a good balance between completeness and practicality in temporal annotation. We also provide a crowdsourcing strategy to annotate TDGs, and demonstrate the feasibility of this approach with an evaluation of the quality of the annotation, and the utility of the resulting data set by training a machine learning model on this data set. This data set is publicly available[1].

1 Introduction

Understanding temporal relations between events in a text is an important part of understanding the "meaning" of text. With the wide adoption of machine learning methods in natural language processing, the ability to achieve a large-scale high-quality temporally annotated data set has been the bottleneck in advancing the state of the art in this area. Even though the first temporal annotation scheme, TimeML (Pustejovsky et al., 2003a; Saurí et al., 2006), was proposed over a decade ago, temporally annotated data is still relatively scarce. The largest data set that we are aware of is the data set used in TempEval-3 (UzZaman et al., 2013), and it consists of 276 articles from the TimeBank Corpus (Pustejovsky et al., 2003b) and the AQUAINT Corpus. This data set was later re-annotated by (Ning et al., 2018) to improve its annotation consistency using a crowdsourcing approach.

There are many challenges that have contributed to this state of affairs. Temporal relations are often confounded with modalities (How do you order an event that actually happened with one that might happen?). Some events are ambiguous between an instantaneous and stative reading (Does "marriage" refer to the start of the marriage or does it refer to the state when marriage is in effect?) and this complicates its temporal relation with other events. While these have all contributed to the difficulty in temporal annotation, the main challenge is a practical one. The general assumption in temporal annotation has been that the temporal relation between every pair of events in a text has to be specified in order to fully understand the temporal relations in a text. This amounts to constructing a fully connected graph in which every event is connected to another event. With this *pair-wise* approach, a text of n events has $\binom{n}{2}$ event pairs that need to be considered. As the value of n increases, the number of event pairs quickly becomes very large. In practice, attempts to achieve complete annotation often fell far short and had to settle with covering all event pairs within a short text window (e.g., within adjacent sentences). Even with this restriction, it is still difficult to produce a large data set. For example, there are only 36 articles in TimeBank-Dense (Cassidy et al., 2014). On the other end of the spectrum, approaches that allow the annotators to select a subset of the event pairs to annotate often end up with sparse and inconsistent annotation, as different annotators often select different event pairs to annotate. For example, while the TimeBank corpus has relatively more articles, but only annotates a relatively small number of temporal relations (6,418 in total). There are also efforts that report improved annotation consistency by focusing on specific syntactic constructions (Bethard et al., 2007) or one aspect of temporal annotation (Reimers et al., 2016), but this comes at the cost of incomplete annotation.

One promising recent approach to get out of this

---

dilemma is to focus on *dependencies* between time expressions, between time expressions and events, and between events (Zhang and Xue, 2018b), based on the observation that time expressions and events are often expressed in relative terms and their temporal location needs to be understood with a *reference time* in mind. Consider the examples in (1):

(1) a. He **left** on Friday. He left home at 9:00am.
b. The Pentagon **said** today that it would **re-examine** the question.
c. The Pentagon said today that it will **re-examine** the question.
d. Ricky New **entered** the store carrying a large stick, **demanded** money, **assaulted** the clerk with the stick, and **left** with an undisclosed amount of money.

In (1a), the interpretation of the time expression *9:00am* depends on another time expression *Friday*, which in turn depends on when the time this sentence is written, generally known as the document creation time (DCT). In (1b), the temporal location of *re-examine* can only be understood in relation to *said* (it happens after the saying event). Note that it does not depend on *today*, as it may or may not happen on that day. In contrast, in (1c), the temporal location of *re-examine* can only be understood with respect to the DCT, not *said*. Another example of one event depends on another event for its temporal interpretation is (1d), where the temporal interpretation of *demanded* depends on *entered* (it happened after *entered*), the temporal interpretation of *assaulted* depends on *demanded*, and the temporal interpretation of *left* depends on *assaulted*. This is a linguistic phenomenon known as *temporal anaphora* (Reichenbach, 1949; Partee, 1973, 1984; Hinrichs, 1986; Webber, 1988; Bohnemeyer, 2009) that has been extensively studied in computational linguistics. The working hypothesis of this *dependency-based* approach is that by annotating the dependencies, additional temporal relations can be inferred, via transitivity, or via common sense reasoning. This hypothesis seems to have been born out in (1d): Based on the dependencies, one can additionally infer that *assaulted* happened after *entered*, for example.

Zhang and Xue (2018b) made the assumption that there is exactly one reference time for each event or time expression. With this assumption, the temporal relations between time expressions and events in a text will form a *temporal dependency tree* (TDT). This means that each event or time expression only relates to one other event or time expression, making TDT a much scalable annotation problem in practice. However, there are reasons to believe that this assumption is too stringent, and in some cases, multiple reference times may be needed to properly interpret the temporal location of an event. In this paper, we extend the temporal dependency tree to *temporal dependency graph* (TDG), allowing each event to have a reference time expression, a reference event, or both. Compared with TDT, TDG does not substantially increase the number of temporal relations in a text that need to be annotated while improving its expressiveness.

We also investigate the feasibility of annotating TDGs from scratch via crowdsourcing, meaning we start with identifying events and time expressions, and then annotate the temporal relations between them. Previous work on crowdsourcing temporal annotations relies on the events and time expressions already identified in the TimeBank (Ning et al., 2018; Zhang and Xue, 2019), and this limits the possibility of expanding temporally annotated datasets beyond what already exist. We show that with a carefully designed annotation strategy, annotating TDGs via crowdsourcing is feasible. We annotated a corpus of 500 Wikinews articles with this approach, and created the largest corpus in terms of the number of articles and the number of event or time expression pairs.

The remainder of the paper is organized as follows. We provide a brief overview of the TDT representation and propose our extension in Section 2. We present our crowdsourcing strategy in Section 3. We present a quantitative analysis of our corpus in Section 4, and then evaluate the quality of our annotation in Section 5. In Section 6, we retrain a neural ranking parser (Zhang and Xue, 2018a) on this data set to demonstrate its utility and establish a baseline for fellow researchers. We discuss related work in Section 7, and conclude in Section 8.

2 From Temporal Dependency Tree to Temporal Dependency Graph

2.1 Temporal Dependency Tree

Zhang and Xue (2018b) defines a temporal dependency tree as a rooted directed edge-labeled tree in which nodes are events and time expressions as well as a few pre-defined meta nodes (e.g. DCT). The parent of each node is its reference time. The

Relations	Definitions
Before	A before B
After	A after B
Overlap	The temporal interval of A overlaps that of B. Applies only to events
Includes	Time expression A includes B

Table 1: Temporal relations used in TDT

temporal dependency tree obeys the following constraint: the reference time of a time expression can only be a time expression or a meta node and it cannot be an event. The reference time of an event, on the other hand, can be a time expression, a meta node or another event. For example, in (2), the reference time for the time expression *yesterday* is *DCT*, and the reference time for *went* and *had* is *yesterday*. The edges in the temporal dependency tree are labeled with temporal relations, which are simplified version of what is used in TimeML. The full set of temporal relations are presented in Table 1. The relation between time expressions and meta nodes is represented as "Depend-on".

(2) Yesterday, I **went** to the museum, then **had** dinner with my friends.

2.2 Temporal Dependency Graph

In a temporal dependency tree, each child node can only have one parent or one reference time. However, there are reasons to believe that this assumption is too stringent. In (2), for example, the reference time of the *had* event can be *went*, or the time expression *yesterday*. To precisely determine the temporal location of *had*, we need to say it happened *yesterday* and after *went*. To account for linguistic phenomena like this, we extend the temporal dependency tree to temporal dependency graph, where each event always has a reference time that is a time expression or a meta node. We call this the *reference timex*. Optionally it can also have another event as its reference time, and we call this the *reference event*. The reference event is optional because not all events have an reference event. For example, in (2), *went* does not have another event as its reference time and only has a reference timex. In TDG, the reference timex of an event is the most specific (i.e., the smallest) *narrative time* (Pustejovsky and Stubbs, 2011) that the event can be placed into. If such a narrative time is not available, this event should be anchored to DCT. The reference event of an event is the event that gives this event the most specific temporal location.

Figure 1 provides a contrast between the TDT and TDG for the example in (2). The solid lines indicate edges for TDT, and the dotted line indicates the additional edge in its TDG.

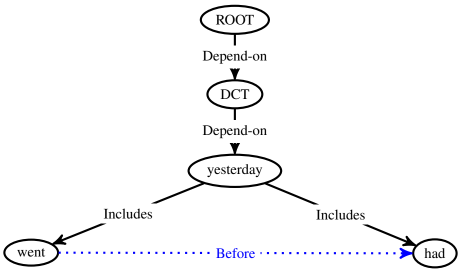

Figure 1: Temporal Dependency Structure for (2).

3 Crowdsourcing Strategy

Crowdsourcing is generally accepted as a cost-effective alternative to the traditional annotation approach where annotators are provided detailed guidelines and carefully trained to meet certain consistency threshold before productive annotation can start. In a crowdsourcing setting, we oftentimes hire a much larger set of annotators that are not professionally trained and may be only working on the task sporadically. Therefore, it is infeasible to ask them to follow detailed guidelines. As a result, successful crowdsourcing tasks tend to be simple and intuitive. To make crowdsourcing practical for TDGs, we adopt a divide-and-conquer strategy that decomposes the annotation of a TDG into five steps. A top-level flowchart of our annotation process is in Figure 2. After all annotation steps are completed, we assemble the TDG for each text, and an example that illustrates the step-by-step construction of the TDG of a text is provided in Figure 3.

In all steps, each annotation is completed by three crowd workers using the Amazon Mechanic Turk platform. Unless otherwise specified, the majority-voted answer is designated as the gold annotation. We explain each annotation step in greater detail in the rest of the section.

3.1 Step 1: Time Expression Identification

In the spirit of simplifying the task as much as possible, we present crowd workers a candidate time expression and ask them to decide if it is indeed a time expression instead of asking crowd workers to select time expressions from raw text directly. This makes this task a binary decision rather than an open-ended text selection. This means we

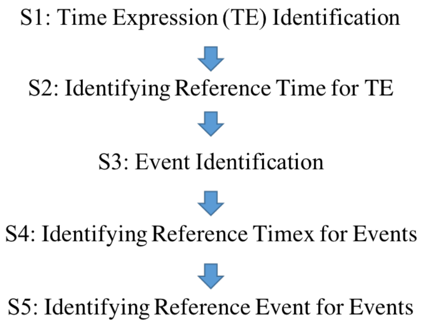

Figure 2: A top-level flow chart for the annotation tasks. S1, S2, ..., S5 refer to the steps 1-5.

need a reliable way to generate candidate time expressions without excluding true time expressions. To achieve this, we supplement candidate time expressions extracted with HeidelTime (Strötgen and Gertz, 2013) with numeric expressions extracted with regular expression patterns.

3.2 Step 2: Identifying Reference Time for Time Expressions

With the assumption that the reference time for a time expression can only be another time expression, the search space for the reference time of a time expression is greatly reduced. Following the practice of (Zhang and Xue, 2018b), we classify time expressions into different types: *locatable* time expressions that can be placed on a timeline and *unlocatable* time expressions. Locatable time expressions include concrete *absolute* time expressions (e.g., "2020"), concrete *relative* time expressions (e.g., "this year") and *vague* time expressions (e.g., "nowadays"). Unlocatable time expressions include durations (e.g., "two months"), set (e.g., "every month"). Concrete absolute time expressions do not need a reference time to be resolved, and they are directly attached to the root of the dependency graph without going through an annotation process. Vague time expressions belong to a closed set and they can be anchored to pre-defined meta nodes (Present/Past/Future_reference) in a deterministic manner. Unlocatable time expressions cannot be resolved with reference times and are ignored. The focus is on identifying the reference time for concrete relative time expressions, which can be another concrete time expression (absolute or relative) or the DCT. To classify the time expressions, we use regular expression patterns in the case of absolute time expressions and dictionaries when there is a closed set of expressions for that particular type.

As many concrete relative time expressions can be resolved to DCT, we further split this step into two subtasks. In the first subtask, we ask crowd workers if a time expression can be resolved to DCT. If the answer is "No", in the second subtask, crowd workers will be asked to find the reference time for this time expression. However, it turned out that in most cases the reference time is the DCT. After the first subtask was completed, we found that only for fewer than 200 time expressions (less than 10% of all time expressions), their reference time is not DCT. We decide that it is not worth setting up another crowdsourcing task and to have experts annotate the second subtask.

3.3 Step 3: Event Identification

Following the same approach with time expression identification, we give crowd workers an event candidate and ask them if that is an event. To collect event candidates, we first construct a list of common event trigger words[2]. Then, we parse the raw text with Stanford CoreNLP dependency parser (Chen and Manning, 2014; Manning et al., 2014) and add the verbs of each sentence as well as the root of its dependency parse as event candidates. We exclude modal events, negative events and stative events in this work. In total, we collected 27,487 event candidates.

3.3.1 Quality Control for Step 3

We set up a qualification test for this pass. Crowd workers have to achieve at least 70% accuracy in order to be eligible to work on this task. In addition, 5 questions with gold answers are inserted into each HIT. If a crowd worker's accuracy on the 5 test questions drops below 60%, he or she will be blocked from the task and his/her annotation will be discarded.

3.3.2 Post-processing

We performed post-processing procedures to filter out some trivial mistakes in the crowdsourced annotation. For event annotation, we excluded negative events in this project since negative events do not have temporal locations. However, even though we made this clear in our instructions to the workers, some crowd workers still annotated negative events as events. We take advantage of the Stanford CoreNLP dependency parser (Chen and Manning, 2014) to filter out some of these unwanted events.

---

[2] This list is publicly available along with the annotated data set.

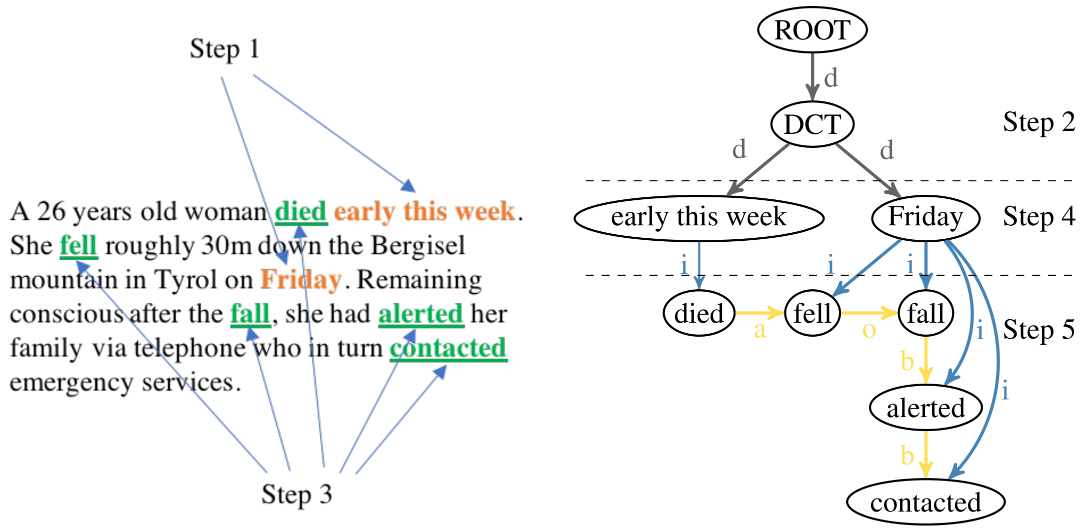

Figure 3: Constructing a TDG in 5 steps.

3.4 Step 4: Identifying Reference Timex for Events

In this step, the crowdworkers are asked to select a reference timex for a given event from a list of candidate time expressions. In theory, all the time expressions in a text can be considered as candidate reference times. However, in practice, we observe that in the vast majority of cases the reference timex of an event is in the same paragraph as the event itself. We also observe that in news reports, key events and time expressions are usually described in the first paragraph. To reduce the number of candidate time expressions and simplify this task, for each event, we present crowd workers with time expressions in the same paragraph as well as time expressions in the first paragraph as its candidate reference timexes.

To participate in this task, crowd workers need to achieve 70% accuracy on the qualifying test. Four questions with gold answers are added to each HIT.

3.4.1 Answer Aggregation

Additionally, after computing each worker's average accuracy on all the tasks they submitted, we found that some workers were able to maintain a higher average accuracy that was between 0.7 to 0.8. This discovery inspires us to come up with a tiered-approach with weighted answer aggregation. Specifically, we compute the average accuracy of each worker and create a "best workers" group which consists of the crowd workers whose average accuracy is above 0.7. Then, for each question, if the three crowd workers give the same answer, that answer becomes the gold answer. Otherwise, if one crowd worker is in the "best workers" group, his/her answer becomes the gold answer; else, the majority answer is the gold answer.

3.5 Step 5: Identifying Reference Event for Events

In addition to reference timexes, some events also have a reference event, which gives it the most specific temporal location. In a crowdsourcing setting, given an event, the crowd worker is provided with a list of candidate events that are potential reference times for the event. This is a challenging problem as the list of candidates can be very long in a typical text, and there are now no obvious heuristics that can be used to shrink down the list. We rely on linguistic insights from research on *temporal anaphora* to identify where potential reference events are (Hinrichs, 1986; Webber, 1988), and split this task into subtasks that reflect different scenarios of how an event is related to its reference time.

We split this task into two subtasks: a within-sentence reference event identification task and a cross-sentence reference event identification task. In the first subtask, given a non-sentence-initial event, crowdworkers are asked to identify its reference event in the same sentence. In the second subtask, given a sentence-initial event, crowdworkers are asked to identify its reference event from previous sentences.

Within-sentence annotation When the reference time of an event is from the same sentence, we can take advantage of syntactic patterns to identify candidate reference events. For example, for events in complement clauses their reference events are typically the matrix events. The event in the subject of a sentence depends on the main verb for temporal interpretation (3a). In (3b), the event in a purpose clause depends on the main verb. When there is a temporal conjunction (3c), it provides clue for the temporal dependency between the event in the temporal modifier and the event in the main clause. Based on this discovery, we extract event pairs in the following structures with Stanford dependency parser (Chen and Manning, 2014): complement clauses, relative clauses, temporal conjunctions, arguments and predicates, and purpose expressions.

(3) a. The **landslide hit** the village.
b. I **got** up at 6am to **take** the train.
c. Right **before** I **got** to the station, the train **left**.

Cross-sentence annotation In wikinews articles, each paragraph is usually a self-contained discourse segment. We assume that the first event of a discourse segment starts a new temporal chain and does not have a reference event. In addition, to make the annotation problem practical, we limit the maximum number of reference event candidates to be 4 when proposing reference event candidates from previous sentences for crowd-workers to choose from.

In Step 5, 11K events are given to crowd workers for reference event resolution. Crowd workers need to achieve 0.6 accuracy on the qualification test. We use the same answer aggregation approach as Step 4.

4 Corpus Statistics

The news articles that we use for our annotation are sampled from English Wikinews[3] and extracted with the publicly available WikiExtractor.py script to remove hypertext markups.[4]

Table 2 presents a comparison of this corpus and some other temporally annotated corpora. TDT-Crd (Zhang and Xue, 2019) is a crowdsourced TDT corpus annotated on top of TimeBank (Pustejovsky et al., 2003b), while TB-Dense (Cassidy et al., 2014) is annotated on a subset of TimeBank. MATRES (Ning et al., 2018) was first annotated on TB-Dense, then extended[5] to the TempEval-3 (UzZaman et al., 2012) data set. TDT-Crd includes events that are matrix verbs. MATRES annotates verb events on the main axis and orthogonal axes (see Ning et al., 2018 for their axis types), and does not annotate the relations between events and time expressions. Compared to the four TimeBank-based corpora, our corpus is much larger on every count, with 500 news articles, 14,974 events, 2,485 time expressions, and 28,350 temporal relations.

	Docs	Timex	Events	Rels
TimeBank	183	1,414	7,935	6,418
TB-Dense	36	289	1,729	12,715
MATRES	275	-	1,790	13,577
TDT-Crd	183	1,414	2,691	4,105
This work	500	2,485	14,974	28,350

Table 2: Events, time expressions and temporal relations in various corpora.

A more detailed analysis of temporal relations in our corpus shows that for reference timex identification, 19% of the events have a reference timex that is in the same sentence, while 17% of the events have a reference timex that is in different sentences. Around 64% of the events have DCT as the reference timex. This indicates that in the majority of cases, the reference timex of an event cannot be found in the same sentence, and our TDG annotation is able to capture these relations as a document-level annotation framework. Our analysis also shows that for reference event identification, 27% of the events do not have an reference event, and these are usually the first event of a paragraph. Table 3 shows the distribution of temporal relations in reference event identification.

No RE	Before	After	Overlap
27%	24%	25%	24%

Table 3: Distribution of temporal relations between events and events. RE refers to reference event.

5 Annotation Evaluation

We evaluate the annotation quality of our data set with two evaluation metrics. The first metric measures the agreement between crowd workers and experts, and the second metric, Worker Agreement With Aggregate (WAWA) (Ning et al., 2018), measures the agreement among the crowd-workers. Both metrics have their advantages and disadvantages but in conjunction, they provide a fuller picture of the annotation consistency of our data set.

---

[3] `https://en.wikinews.org/`

[4] `https://github.com/attardi/wikiextractor`

[5] `https://cogcomp.seas.upenn.edu/page/publication_view/834`

To measure the agreement between the expert and crowd-workers, ten percent of the articles are double annotated by experts and crowd workers. As shown in Table 4, high agreements are achieved in the first two steps. The post-processing effort in Step 3 brings the agreement from 0.79 to 0.83. Table 5 presents the agreement scores of the reference time identification for events. In Step 4 and 5, annotations are conducted both on crowdsourced events and time expressions and gold events and time expressions. Agreement scores are calculated for both labeled (L) and unlabeled (U) annotation. Unlabeled agreement evaluates reference time identification, while labeled agreement evaluates both reference time identification and relation annotation between a given event and its reference time. We achieve a labeled (unlabeled) F1-score of 0.77 (0.85) on gold events and time expressions in the reference timex identification, and a labeled (unlabeled) F1-score of 0.75 (0.83) on gold events in the reference event identification. There is an error propagation effect when crowdsourced events and time expressions are used, and the agreement scores are lower.

We also evaluate our annotation with the WAWA metric, which measures the average agreement between crowd workers' annotation and the aggregate answer. The WAWA score measures the agreement among crowd workers, and as such it is sensitive to the number of crowd workers and whether there are outliers. Nevertheless, it is a useful metric, assuming that when an annotation task is well-defined, there should be less variation among the annotators. When computing WAWA, we used the majority aggregation instead of the weighted majority aggregation, and we only computed the labeled agreement. The WAWA scores for the subtasks are also reported in Tables 4 and 5.

Task	Agreement	WAWA
S1: Timex ID	0.96	0.97
S2: Timex RT	0.89	0.95
S3: Event ID	0.79	0.84

Table 4: Agreement F1 and WAWA for time expression identification (ID), time expression reference time (RT) identification and event identification.

Relation only annotation evaluation is also performed for Step 4 and Step 5 on gold events and time expressions. Specifically, we compute the portion of correct relation when the reference time is correctly annotated. As we can see in Table 6, our relation-only annotation agreements between crowd workers and experts for S4 and S5 are 0.91 and 0.85. This shows that finding the appropriate reference timex and reference event is the more challenging aspect of the annotation. The relation-only agreement is in the ballpark of annotation frameworks such as Ning et al. (2018) that do not require the identification of reference events or timexes, although a strict comparison is impossible given different data sets are used.

Task	Node	L	U	WAWA
S4: RT ID	Gold	0.77	0.85	0.81
	Crowd	0.61	0.67	0.78
S5: RE ID	Gold	0.75	0.83	0.75
	Crowd	0.52	0.59	0.70

Table 5: Agreement F1 for reference timex (RT) and reference event (RE) identification for events. The third column evaluates the labeled (L) annotation, the fourth column evaluates the unlabeled (U) annotation.

	S4	S5
Agreement	0.91	0.85

Table 6: Relation only annotation agreement.

5.1 Error Analysis for Reference Event Identification

The most challenging aspect of this project is identifying the reference event for a given event and determining their temporal relations. To gain a better understanding of the quality of the crowdsourced data set, we did a manual error analysis of this pass. We randomly sampled 100 instances where the crowdsourced reference events are different from that identified by the expert. We then decide if the crowdsourced annotation is simply wrong or is different from the expert annotation but is still reasonable. For example, in (4), the reference event identified by crowdworkers for event *discovered* is *pursued*. However, the *pursued* event happened before the *incident* event, and the *incident* event happened before the *discovered* event, so we get the most specific temporal location for event *discovered* when *incident* is used as the reference event. The crowdsourced annotation in this case is simply wrong. Example (5) is an edge case where it is reasonable to say the *fight* event happened before event *lose*, but it's also reasonable to say that the *lose* event is a part of the *fight* process, so the *fight* event overlaps the *lose* event.

(4) The **incident** took place after three youngsters on bicycles **pursued** two youths who sought cover inside the store. Investigators have **discovered** that Kamaleswaran's mother was also inside the store during the shooting.

(5) Terror organisations and their pawns are targeting our innocent citizens in the most immoral and heartless way as they **lose** the **fight** against our security forces.

In the 100 instances, 36 of them are wrong, while the other 64 are different from that of the expert but reasonable. As we can see in Table 7, in the 36 wrong annotations, 21 (58%) of them are caused by the crowd worker identifying the incorrect referent event while the other 15 (42%) of them are annotated with incorrect temporal relations. This shows that identifying the correct reference time is more challenging than determining the temporal relation.

Structure	Relation	Total
21 (58%)	15 (42%)	36

Table 7: Distribution of the cause of the wrong annotations in the 100 sampled instances.

6 Experiments

We test our data with an attention-based neural ranking temporal dependency parser[6] that Zhang and Xue (2018a) developed for TDT, which parses the temporal dependency tree by ranking the candidate parents for each node. To apply the tree parser to the graph data, we first add a meta node as reference event for events that only have a reference timex. Then, we rank all the time expressions for events and pick the one with the highest score as its reference timex, and rank all the events and select its reference event. To help the model learn the relations between DCT and events, a POS tag feature is added which only distinguishes present tense verb events with other events. This feature is represented as a one hot vector. We use the same hyperparameter values as Zhang and Xue (2018a). In the 500 documents, 400 are used as training data, 50 as validation data, and 50 as test data. The test data is annotated by experts, and the validation data is generated from crowdsourced annotation as follows: if there is no agreement for one question, i.e. three crowd workers chose three different answers, then experts annotate that question.

We also develop a heuristic baseline system as follows. First, each time expression is attached to DCT. For each event, if there is a time expression in the same sentence, we attach the event to that time expression, and designate the relation as "Include". Otherwise that event is attached to DCT, and the relation is "Before". For the reference events, we attach each event to the immediately previous event in the text, and designate the relation as "Overlap", which is the most common relation between events in experts' annotation. As shown in Table 8, the neural ranking system achieves 0.66 labeled F1-score on the test data, compared with a baseline of 0.51. Table 8 also includes a breakdown of accuracy for different subtasks. The neural ranking model outperforms the baseline by a large margin for all subtasks. Overall, these results show that temporal dependency parsing is a very challenging task, and by making this data set available, it will aid in the development of more sophisticated machine learning models to advance the state of the art in this area.

		Unlabeled F		Labeled F	
		dev	test	dev	test
Baseline	te,te	0.80	0.82	0.80	0.82
	e,te	0.54	0.70	0.46	0.58
	e,e	0.64	0.61	0.26	0.34
	full	0.62	0.68	0.41	0.51
Neural	te,te	0.88	0.93	0.88	0.93
	e,te	0.62	0.77	0.53	0.66

7 Related Work

7.1 Temporal Dependency Structure

Kolomiyets et al. (2012) are the first work that use the term temporal dependencies, and they extract timelines from narrative stories as temporal dependency trees. However, in their work, only events are included as nodes in the dependency tree, and the parent of each node is not explicitly defined as the reference event of the child event. Zhang and Xue (2018b) first defined a temporal dependency tree structure that have both events and time expressions as nodes in the tree, and attempted

---

[6] `https://github.com/yuchenz/tdp_ranking`

to explicitly define the parent of each event or time expression as the reference event or time expression of the child node. This temporal dependency tree has been applied to both Chinese (Zhang and Xue, 2018b) and English (Zhang and Xue, 2019) data, and to both news reports and narrative stories, indicating this framework can be applied across languages and genres. The present work extends temporal dependency trees to the temporal dependency graphs, and crowd-sourced temporal dependency graphs on English news articles.

7.2 Crowdsourcing Temporal Relations

Early studies on crowdsourcing temporal relations usually focus on some subtask of this problem. Snow et al. (2008) crowdsources the relations of a subset of verb event pairs from TimeBank (Pustejovsky et al., 2003b) whose relations are either "strictly before" or "strictly after". Ng and Kan (2012) only focuses on the relation between events and time expressions from news data. Caselli et al. (2016) conducts crowdsourcing experiments on both temporal relation annotation and event / time expression extraction. In the time expression extraction experiments, they ask crowd workers to select time expressions directly from the raw text. In contrast, we give crowd workers time expression candidates and ask them binary questions. Our approach prevents crowd workers from selecting wrong textual spans. Ning et al. (2018) comes up with a multi-axis approach for event temporal relation annotation (see Ning et al., 2018 Section 2 and Appendix A for more details about their multi-axis model). The multi-axis approach is a way of factoring out modalities in event annotation, and combined with the decision to only consider the start point of events, they are able to achieve high accuracy in annotating temporal relations assuming gold events are provided. Our annotation is more challenging in that crowdworkers also need to identify time expressions and events, in addition to annotating temporal relations.

Zhang and Xue (2019) crowdsourced a temporal dependency tree (TDT) corpus, and is the work that is the most related to ours. The differences between their work and this work are as follows. First, our work extends the temporal dependency tree to temporal dependency graph, where events always have a reference timex and optionally also have a reference event. In TDT, events only have one reference time, either a reference timex or a reference event, but not both. The second difference is that the TDT corpus is constructed on top of TimeBank (Pustejovsky et al., 2003b), without having to annotate events and time expressions. In contrast, we construct the TDG corpus from scratch in that we first extract events and time expressions, then annotate the relations between them as part of the graph structure.

8 Conclusion

In this paper, we proposed a temporal annotation scheme called temporal dependency graphs which extend previous research on temporal dependency trees. The temporal dependency graphs, like temporal dependency trees, draw inspiration from previous research on narrative times and temporal anaphora, allow a good trade-off between completeness and practicality in temporal annotation. We proposed a crowdsourcing strategy and demonstrated its feasibility with a comparative analysis of the quality of the annotation. We also demonstrated the utility of the data set by training a neural ranking model on this data set, and the data set is publicly available.

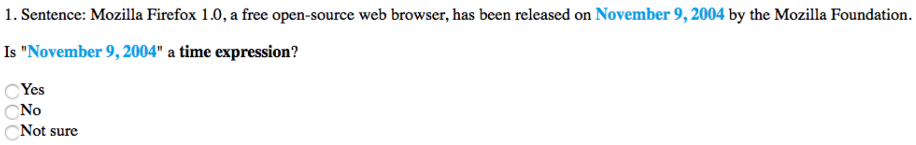
A Appendix

In this section, we give examples of the annotation interface of each step. In step 4 and 5, the number of options we gave to crowd workers is varied. The template we have here for step 5 has the maximum number of options. The options are also ranked by likelihood: the first event is usually the most likely choice.

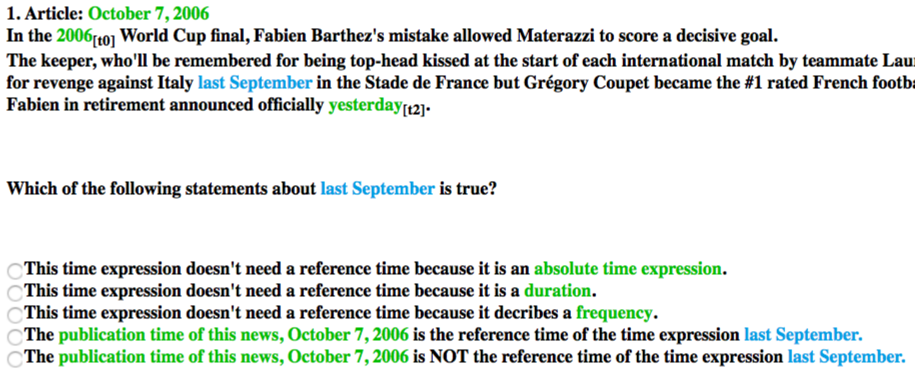


1. Sentence: Mozilla Firefox 1.0, a free open-source web browser, has been released on November 9, 2004 by the Mozilla Foundation.

Is "November 9, 2004" **a time expression**?

○ Yes
○ No
○ Not sure

Figure 4: Annotation interface for time expression identification.



1. Article: October 7, 2006
In the 2006$_{[t0]}$ World Cup final, Fabien Barthez's mistake allowed Materazzi to score a decisive goal.
The keeper, who'll be remembered for being top-head kissed at the start of each international match by teammate Laurent Blanc, was desperately hoping for revenge against Italy last September in the Stade de France but Grégory Coupet became the #1 rated French football goalkeeper therefore pushing Fabien in retirement announced officially yesterday$_{[t2]}$.

Which of the following statements about last September is true?

○ **This time expression doesn't need a reference time because it is an absolute time expression.**
○ **This time expression doesn't need a reference time because it is a duration.**
○ **This time expression doesn't need a reference time because it decribes a frequency.**
○ **The publication time of this news, October 7, 2006 is the reference time of the time expression last September.**
○ **The publication time of this news, October 7, 2006 is NOT the reference time of the time expression last September.**

0. **August 26, 2007**
Investigators have discovered a hole in the fuel tank of the China Airlines jet that caught fire and exploded on August 20$_{[t0]}$ on the island of Okinawa, Japan.
Investigators from Japan, Taiwan and the United States have all been examining the wreckage of China Airlines Flight 120 since the accident. Now$_{[t1]}$, Japanese investigators say that they have found that a structural bolt had pierced the fuel tank of the Boeing 737-800 series aircraft.
"We spotted a hole in a fuel tank," said a brief statement by the transport ministry's investigative division."We suspect that oil leaked from this hole and spilled from the right wing to the outside."
It is understood that, prior to the discovery of the hole, the investigation had been focusing on the tubing connecting the fuel tank to the engine, rather than the tank itself.
Taiwan-based China Airlines's only comment was to repeat earlier comments that the plane had been inspected last month, at which point the airline had been unable to find any problem with it. However, prior to this news, the chief executive flew to Okinawa to console worried tourists, while chairman Philip Wei offered to resign "...in a bid to shoulder his responsibility,", according to an airline official. The airline is also offering compensation to passengers on the flight.
Boeing refused to comment on the incident, citing the fact that the investigation remains open. However, the "Jiji Press" has reported that Boeing had warned airlines in 2006 about the possibility of bolts piercing the fuel tanks, after a number of incidents in which tank piercing was found to have occurred.

The event found happens (ed)

○ Now$_{[t1]}$

○ on August 20$_{[t0]}$

○ before August 26, 2007, which is when the news was published

○ around August 26, 2007, which is when the news was published

○ after August 26, 2007, which is when the news was published

7. May 14, 2008

According to police sources, a series of seven coordinated bombs detonated in Jaipur, the capital of the state Rajasthan, in India on Tuesday, May 13. At least eighty people were killed and over two hundred injured in the attacks.

The bombs went off over a period of twenty minutes and tore through the city's crowded bazaars, beginning at 7:20 p.m. IST (UTC+5:30). An eighth bomb, which did not go off, was recovered. Ten of the dead were children.

In the wake of the bombing, a daytime curfew has been in place. "The curfew is a precaution to ensure peace," said Vasundhara Raje, the Chief Minister of Rajasthan.

On Wednesday, two arrests were **announced**$_{[e10]}$. "We have **arrested**$_{[e11]}$ two people and have **detained**$_{[e12]}$ several more for questioning," **said**$_{[e13]}$ Vasundhara Raje. "This seems to have been done by some international group," she **added**, in a comment that was intrepreted by "The Daily Telegraph" to suggest Pakistan-based Islamic militants.

Which of the following best describes added

○ Undecidable.

○ added happens (ed) before said$_{[e13]}$

○ added happens (ed) after said$_{[e13]}$

○ added happens (ed) at the same time with said$_{[e13]}$

○ added happens (ed) before detained$_{[e12]}$

○ added happens (ed) after detained$_{[e12]}$

○ added happens (ed) at the same time with detained$_{[e12]}$

○ added happens (ed) before arrested$_{[e11]}$

○ added happens (ed) after arrested$_{[e11]}$

○ added happens (ed) at the same time with arrested$_{[e11]}$

○ added happens (ed) before announced$_{[e10]}$

○ added happens (ed) after announced$_{[e10]}$

○ added happens (ed) at the same time with announced$_{[e10]}$

Abstract

Detecting cybersecurity events is necessary to keep us informed about the fast growing number of such events reported in text. In this work, we focus on the task of event detection (ED) to identify event trigger words for the cybersecurity domain. In particular, to facilitate the future research, we introduce a new dataset for this problem, characterizing the manual annotation for 30 important cybersecurity event types and a large dataset size to develop deep learning models. Comparing to the prior datasets for this task, our dataset involves more event types and supports the modeling of document-level information to improve the performance. We perform extensive evaluation with the current state-of-the-art methods for ED on the proposed dataset. Our experiments reveal the challenges of cybersecurity ED and present many research opportunities in this area for the future work.

1 Introduction

With the proliferation of cyber technologies (i.e., social networks, Internet of Things) in our daily life, the frequency of cyberattacks and cybercrimes is also rapidly increasing, potentially imposing serious threats to our cyber activities. Cybersecurity has thus become an important field for which a large amount of text data would be produced to report and discuss various aspects of cyber vulnerabilities. The expected sheer amount of this type of data calls for automatic techniques to analyze the cybersecurity text and extract useful knowledge. Among others, these techniques can help to detect the trends of the cyberattacks for better policy making or populate cybersecurity knowledge bases for automatic reasoning systems.

In this work, we examine Information Extraction technologies (IE) in Natural Language Processing (NLP) as a promising candidate for the knowledge extraction task from cybersecurity text. In particular, we focus on Event Detection (ED), an important task in IE that seeks to identify trigger words of specified types of events in text (Ahn, 2006; Ji and Grishman, 2008). ED is an actively studied task in IE where deep learning models have been the dominant approach to deliver the state-of-the-art performance (Nguyen and Grishman, 2015; Chen et al., 2015). For instance, consider the sentence:

Remote attackers to completely **takeover** *player accounts just by tricking users into clicking an unsuspectable link.*

An ED system for cybersecurity texts should be able to identify "*takeover*" as an event trigger word of the event type *ATTACK.User Compromise* in this case.

In order to enable the application of the ED methods in the cybersecurity domain, a crucial requirement has to do with the benchmark datasets to facilitate the development and evaluation of ED models. Unfortunately, most of the current benchmark datasets for ED (i.e., the ACE and TAC KBP datasets (Walker et al., 2006; Mitamura et al., 2015)) cannot serve this purpose as they have mainly concerned the common events in a person's life of the general domain (e.g., being born, getting married, or being arrested). In addition, the events in the general domain might involve substantial differences with those in the cybersecurity domain (i.e., the divergences in lexical forms, sentence structures and domain expertise), necessitating the development of cybersecurity-focused datasets to aid the research on ED and reveal the nature for the events in this domain. To this end, (Satyapanich et al., 2020) recently presents the first dataset for cybersecurity ED (called CASIE) that annotates event instances with rich annotation. However, this dataset involves at least three limitations that hinder future research in this area.

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5381–5390,
November 16–20, 2020.

First, CASIE only contains a small number of event types (i.e., five types) that fail to cover a wide range of important cyber attack/vulnerability types in reality (Simmons et al., 2014). This would limit the application of the systems and restrict the comprehensiveness of the analysis about cybersecurity events developed from the dataset. Second, the event triggers in CASIE tend to be correctly detected and classified without considering the document-level information (i.e., simply relying on the local contexts in the sentences of the triggers is sufficient). This is not desirable as based on our analysis, the necessary contexts to recognize the event triggers in the cybersecurity domain might span the entire long documents and the limited requirement for document context in CASIE would not be able to reflect the data distribution of the cybersecurity events for ED well. For example, the word "*attack*" can appear somewhere in a document to refer to some event mentioned far away at the beginning of the document. As the local context of "*attack*" does not present any information about the specific type of this attack, the long document context (i.e., up to the beginning of the document) would be crucial to successfully determine the actual event type for "*attack*" in this case. Last but not least, CASIE has not been comprehensively evaluated with the state-of-the-art ED systems, making it challenging to accurately estimate the difficulty/complexity of the dataset.

Consequently, in this work, we introduce a novel dataset for cybersecurity ED (called CySecED) that is manually annotated for 30 event types to better characterize the important cyber attacks and vulnerabilities reported in texts. CySecED involves event triggers whose types can only be predicted if the long-range document context is effectively captured, thus offering a more challenging dataset for ED. Finally, we extensively evaluate the best-performing ED models on CySecED. Our experiments show that the performance of current models is far behind the human performance on this dataset and further research is needed to improve the models' performance. We will publicly release CySecED to promote the future research on ED and NLP for the cybersecurity domain.

2 Data Collection and Annotation

	CASIE	**CySecED**
# event types	5	30
# positive examples	8,470	8,014
# negative examples	240,682	282,220
# sentences per document (average)	16.69	24.94

Table 1: Statistics for CASIE and CySecED. Negative examples refer to non-trigger words while positive examples are the annotated trigger words for the 30 event types of interest.

We use the articles on the website "*The Hacker News*" (THN)[1] as the documents for cybersecurity event annotation in this work. THN (written in English) is a trusted and widely-acknowledged cybersecurity news platform that reports the latest cybersecurity news and in-depth coverage of current as well as future trends in cybersecurity.

In order to create an ED dataset for the cybersecurity domain, we consult the cyberattack taxonomy in (Simmons et al., 2014) to select a set of 30 cybersecurity event types that occur frequently and have high impact in THN. In particular, the 30 event types are grouped into four following categories to reflect four different stages of a cyber attack/vulnerability: **DISCOVER**: a vulnerability in a software or system is detected or mentioned by some entity (i.e., hackers, engineers) (e.g., kernel flows, buffer overflow, back door), **PATCH**: some entity (i.e., software companies) fixes or shows how to fix a known vulnerability, **ATTACK**: an attacker exploits some vulnerability to impact the systems using some means (e.g., user compromise, viruses, spyware, worms, denials of services), and **IMPACT**: the consequence of an attack for a system (e.g., disrupt, breach/disclosure of information). The full list of the event types along with their descriptions and examples for our dataset are shown in Appendix A.

The articles, once crawled from THN, would be processed to extract the title and text content (i.e., removing other elements such as html tags, images, etc.). We recruit two undergraduate students who specialize in security and networking to perform the data annotation for the processed articles. Each student is trained with the annotation guideline about the 30 event types and does a group of exercises to be able to better distinguish the event types. Among others, our guideline only annotates a single word for each event trigger (i.e., the most important word to clearly express the event), following the practice in prior ED work (Nguyen and Grishman, 2015). Overall, we annotate 292 documents and achieve a Cohen's Kappa score of

---

[1] `https://thehackernews.com/`

0.79 (i.e., very close to the near-perfect agreement range of $[0.81, 0.99]$). Finally, in order to improve the quality of the dataset, a cybersecurity expert is asked to resolve the cases where the two annotators disagree, leading to the final version of CySecED. Table 1 presents some statistics and comparisons between CASIE (Satyapanich et al., 2020) and the proposed dataset CySecED.

3 Annotation Challenges

We find that cybersecurity event annotation is a challenging task where the major challenges involve the disagreement between the annotators for the subtle cases and the high level of necessary domain expertise to annotate the triggers.

First, for the annotation disagreement, the highest disagreement concerns the decisions to annotate a word as a trigger or not. For instance, consider the following sentence:

"*The mobile* **apps** *in question disguised as photo editing and beauty* **apps** *purporting to use your mobile phone's camera to take better pictures or beautify the snaps you shoot, but were found including code that performs malicious activities on their users' smartphone.*"

In this sentence, both annotators believe the first word "*apps*" is referring to a malware and should be annotated as a trigger word of an event of type *ATTACK.Spyware*. However, for the second word "*apps*", one annotator treats it as a neutral apps and does not label it while the other annotator considers both words "*apps*" as coreferred and mark them as trigger words. The other disagreements have to do with the confusion between the types of cyberattacks where the differences are subtle (i.e., *ATTACK.Virus* vs. *ATTACK.Worm*, *ATTACK.Trojan* vs. *ATTACK.Spyware*, and *ATTACK.Root_Compromise* vs. *ATTACK.Arbitrary_Code_Execution*).

Second, for the domain expertise challenge, in many cases, the understanding about the cybersecurity attacks and crimes is necessary to analyze the context and assign the appropriate event types for the trigger words. For instance, consider the following sentence as an example:

"*Numerous* **cyberattacks** *on automobile companies have been reported yesterday where the hackers used compromised machines to* **hit** *the websites with floods of traffics measuring up to 140Gbps.*"

In this sentence, "*cyberattacks*" and "*hit*" are the trigger words of the events of type *ATTACK.Denial of Service*. As "Denial of Service" is not directly expressed in the sentence, the annotators would need to understand that "*floods of traffics*" is usually associated with Denial of Service attacks to be able to assign event types for these trigger words. In fact, this also presents an unique challenge for ED models in this domain where the recognition of such semantic association is important to successfully perform the task.

Word	Event Count	Event Rate
attack	1,564	42.5%
vulnerability	659	75.8%
malware	544	61.5%
exploit	338	69.2%
infect	296	70.2%

Table 2: Event rates of the words with the highest event counts.

4 Data Analysis

This section conducts some additional analysis to gain a better insight into the proposed dataset CySecED. First, Table 2 demonstrates the ambiguity in CySecED by showing five words with the highest occurrence as event triggers in the dataset (i.e., Event Count), along with the percentage of times they are labelled as event triggers in CySecED (i.e., Event Rate) (Sims et al., 2019). Among others, this table shows that even for popular event trigger words, there are still some chance that they are not labeled as trigger words in the dataset and the models need to appropriately capture the context to correctly make a prediction in these cases.

In addition, we find that sentences mentioning some events in CySecED often contain at least two event trigger words for the event types. In other words, cybersecurity events in CySecED tend to co-occur with each other in the sentences, suggesting potential inter-dependencies between events. These dependencies can be exploited to further improve the ED performance for cybersecurity domain in the future research (Li et al., 2013; Nguyen et al., 2016a; Nguyen and Nguyen, 2019). In particular, among the sentences in CySecED, 45.4% of the sentences do not contain any event triggers, 50.0% of the sentences host at least two event triggers, and only 4.6% of the sentences involve a single event trigger. Among the event types, the highest co-occurrence frequency involves the co-occurrence of two *ATTACK* event triggers in the same sentences (i.e., amounting to 22% of the total sentences in

CySecED).

5 Evaluation

Models: There are two classes of models for ED in the literature, i.e., the sentence-level models (i.e., the models that only exploit the local context information in the sentences of the triggers) and the document-level models (i.e., the models that further consider the document-level contextual information for ED). This section aims to reveal the complexity of CySecED by evaluating the performance of the state-of-the-art models for ED in these model classes. In particular, for the sentence-level class, we focus on the following ED models:

- **CNN** (Nguyen and Grishman, 2015): a Convolutional Neural Network model (CNN) for ED.
- **DMCNN** (Chen et al., 2015): a CNN model for ED with Dynamic Pooling.
- **GCN** (Nguyen and Grishman, 2018): a Graph Convolutional Neural Network model (GCN) based on dependency trees for ED.
- **MOGANED** (Yan et al., 2019): an ED model with Multi-Order Graph Convolution and Attention. This is currently the state-of-the-art ED model with uncontextualized word embeddings in the general domain (i.e., the ACE 2005 dataset).
- **CyberLSTM** (Satyapanich et al., 2020): a LSTM model developed for ED in the cybersecurity domain that exploits different features (e.g., the dependency trees) for the input representation.

Regarding the document-level models, we consider the following representative ED models:

- **HBTNGMA** (Chen et al., 2018): a Collective ED model with Hierarchical and Bias Tagging Networks and Gated Multi-level Attention Mechanisms to exploit the document-level information.
- **DEEB-RNN** (Zhao et al., 2018): a Document Embedding Enhanced Bidirectional RNN for ED.
