Appendix A Mutual Information Maximization for Mitigating Inference Collapse

During the training of VAEs, inference collapse occurs when the model converges to a local optimum where the approximate posterior $q_\phi(\mathbf{z} \mid \mathbf{x})$ collapses to the prior $p(\mathbf{z})$, indicating the vanishment of the encoder network due to the decoder's negligence of the encoder signals. Quantifying, diagnosing, and devising a mitigation technique for the inference collapse phenomenon have been studied extensively in the past (Chen et al., 2016; Zhao et al., 2017; Cremer et al., 2018; Razavi et al., 2018; He et al., 2019). However, current approaches for mitigating inference collapse are limited to significant modifications to the existing VAE framework (He et al., 2019; Kim et al., 2018) or limited to specific architectural designs (Razavi et al., 2018). Current approaches do not work well on our model due to the complexity of our VAE structure. Instead, we employ a relatively simple technique that directly modifies the VAE objective. By doing so, we mitigate any significant changes to the main VAE framework while achieving satisfactory results on inference collapse mitigation. Though not covered in this paper, our method has applications in other VAE structures. In this appendix, we wish to delve more in-depth into the intuitions and detailed implementation of our approach.

Motivation. As first noted by Hoffman and Johnson (2016) (and subsequently utilized by (Zhao et al., 2017; Chen et al., 2018)), the KL-divergence term of the ELBO objective can be decomposed into two terms: (1) the KL-divergence between the aggregate posterior and the prior and (2) the mutual information between the latent variables and the data:

$$\mathbb{E}_{p_d}[D_{\mathrm{KL}}(q_\phi(\mathbf{z} \mid \mathbf{x}) \| p(\mathbf{z}))] = D_{\mathrm{KL}}(q_\phi(\mathbf{z}) \| p(\mathbf{z})) + I_{q_\phi}(\mathbf{x}; \mathbf{z}) \qquad (3)$$

where p_d is the empirical distribution of data and the aggregate posterior $q_\phi(\mathbf{z})$ is obtained by marginalizing the approximate posterior using the empirical distribution:

$$q_\phi(\mathbf{z}) = \mathbb{E}_{\mathbf{x} \sim p_d}[q_\phi(\mathbf{z} \mid \mathbf{x})]. \qquad (4)$$

Using the definition of inference collapse, we can deduce that the KL-divergence term $D_{\mathrm{KL}}(q_\phi(\mathbf{z} \mid \mathbf{x}) \| p(\mathbf{z}))$ is zero during inference collapse. This fact implies that both decomposed terms in Equation 3 must be zero since both terms are non-negative.

Our preliminary studies show an interesting pattern in the KL-divergence term and its decomposed terms during basic training (training without inference-collapse treatments) (Figure 2). We observe that the KL-divergence of the aggregate posterior term vanishes earlier than the mutual information does. We also observe that the mutual information term, which represents the encoder effectiveness, vanishes eventually. This collapse happens after the KL-divergence cannot be minimized without sacrificing the encoder's expressiveness. Note that optimization of the ELBO objective minimizes the ELBO's KL-divergence term and its underlying terms, one of which is directly related to the encoder health. Although the reconstruction term in the ELBO encourages maximization of the mutual information, the autoregressive property of the decoder and the complexity of the reconstruction loss "dilutes" the goal of maximizing mutual information. Hence, to minimize inference collapse, we propose a modified VAE objective that explicitly maximizes the mutual information between the latents and the data by "canceling" out the mutual information term in the KL-divergence[5]:

$$\begin{aligned}\mathcal{L}_{\mathrm{VHDA}} = &\mathbb{E}_{p_d}[\mathbb{E}_{q_\phi}[\log p_\theta(\mathbf{c} \mid \mathbf{z})]] \\ &- \mathbb{E}_{p_d}[D_{\mathrm{KL}}(q_\phi(\mathbf{z} \mid \mathbf{c}) \| p(\mathbf{z}))] \\ &+ I_{q_\phi}(\mathbf{c}; \mathbf{z}). \end{aligned} \qquad (5)$$

Note that some notations (expectation over the empirical distribution) have been omitted in the main paper for clarity.

Relation to Prior Work. Our approach is related to previous work on manipulating the VAE objective for customizing the VAE behavior (Zhao et al., 2017; Chen et al., 2018). It can also be thought of as a special case of Wasserstein Autoencoders (Tolstikhin et al., 2018) Although not all related works were original proposed to directly combat inference collapse, our approach can be considered a special case of InfoVAE (Zhao et al., 2017) and β-TCVAE (Chen et al., 2018). Specifically, Zhao et al. (2017) proposed a modified VAE objective as

---

[5] On a side note, we did not observe any "lag" in the inference network, as described by He et al. (2019). This observation is evident from the sustained mutual information level throughout the training session (Figure 2). Hence we did not employ the recently proposed method.

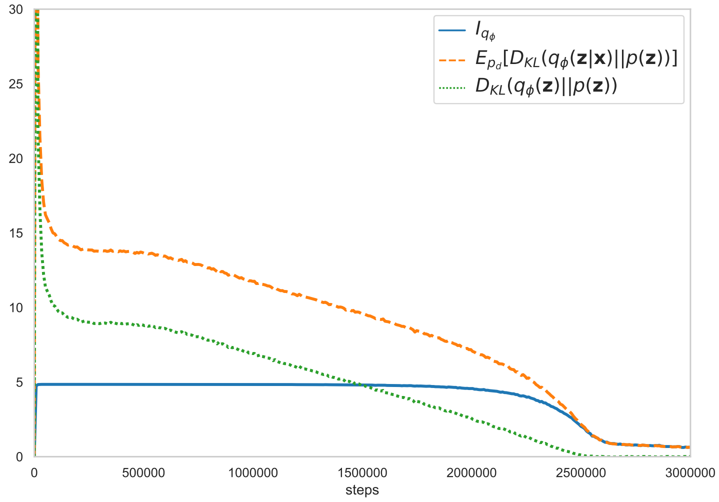

Figure 2: Failed training behavior.

follows:

$$\begin{aligned}\mathcal{L}_{\text{InfoVAE}} =& \mathbb{E}_{p_d}[\mathbb{E}_{q_\phi}[\log p_\theta(\mathbf{x} \mid \mathbf{z})]] \\ & - (1-\alpha)\mathbb{E}_{p_d}[D_{\text{KL}}(q_\phi(\mathbf{z} \mid \mathbf{x})\|p(\mathbf{z}))] \\ & - (\alpha + \lambda - 1)D_{\text{KL}}(q_\phi(\mathbf{z})\|p(\mathbf{z})).\end{aligned} \tag{6}$$

Rearranging the equation, we can express the same objective related to the mutual information:

$$\begin{aligned}\mathcal{L}_{\text{InfoVAE}} =& \mathbb{E}_{p_d}[\mathbb{E}_{q_\phi}[\log p_\theta(\mathbf{x} \mid \mathbf{z})]] \\ & - \lambda D_{\text{KL}}(q_\phi(\mathbf{z})\|p(\mathbf{z})) \\ & - (1-\alpha)I_{q_\phi}(\mathbf{x};\mathbf{z}).\end{aligned} \tag{7}$$

Hence, our method is a special case of InfoVAE where $\alpha = 1$ and $\lambda = 1$. Meanwhile, Chen et al. (2018) proposed an extended modification to β-VAE (Higgins et al., 2017) to further decompose the KL-divergence of the aggregate posterior in terms of latent correlation:

$$\begin{aligned}\mathcal{L}_{\text{InfoVAE}} =& \mathbb{E}_{p_d}[\mathbb{E}_{q_\phi}[\log p_\theta(\mathbf{x} \mid \mathbf{z})]] \\ & - \alpha I_{q_\phi}(\mathbf{x};\mathbf{z}) \\ & - \beta D_{\text{KL}}(q_\phi(\mathbf{z})\| \textstyle\sum_i q_\phi(z_i)) \\ & - \gamma \displaystyle\sum_i D_{\text{KL}}(q_\phi(z_i)\|p(z_i)).\end{aligned} \tag{8}$$

In the equation above, our approach corresponds the case where $\alpha = 0$ and $\beta = \gamma = 1$.

Mutual Information Estimation. We can estimate the mutual information between the latents and the data under the empirical distribution of $\mathbf{x}$ using Monte Carlo sampling. However, this estimation method is known to be biased (Belghazi et al., 2018). Despite recent advances in MI estimation techniques, we find that our unparameterized method is sufficient for achieving inference collapse mitigation and probing.:

The equation for estimating the mutual information is shown in Equation 9. where $\mathbf{x}$ is sampled from the empirical distribution of the dataset and N, M and L are hyperparameters. In practice, the estimation is performed over the data samples in a mini-batch for computational efficiency. Given a mini-batch of size N, we further approximate the estimation by sampling the latent variables $\mathbf{z}$ once for each data point ($M = 1$) (Equation 10).

We visualize the variance in our mutual information estimation method in Figure 3.

Appendix B Architectural Diagram

We include a more detailed architectural diagram (Figure 4) depicting the latent variables and the model inference, which we could not illustrate in Figure 1 due to space constraints. Note that the orange crosses denote decoder dropouts. The figure also illustrates the hierarchically-scaled dropout scheme, motivated by the need to minimize information loss while discouraging the decoders from relying on training signals, leading to exposure bias.

$$\begin{aligned} I_{q_\phi}(\mathbf{x},\mathbf{z}) =& \mathbb{E}_{p_d}\left[D_{\mathrm{KL}}(q_\phi(\mathbf{z}\mid\mathbf{x})\,\|\,q_\phi(\mathbf{z}))\right] \\ \approx & \frac{1}{NM}\sum_i^N\sum_j^M \left(\log q_\phi(\mathbf{z}_j\mid\mathbf{x}_i) - \log\sum_k^L q_\phi(\mathbf{z}_j\mid\mathbf{x}_k)+\log L\right) \end{aligned} \tag{9}$$

$$I_{q_\phi}(\mathbf{x},\mathbf{z}) \approx \frac{1}{N}\sum_i^N \left[\log q_\phi(\mathbf{z}\mid\mathbf{x}_i) - \log\sum_j^N q_\phi(\mathbf{z}\mid\mathbf{x}_j)+\log N\right]_{\mathbf{z}\sim q_\phi(\mathbf{z}\mid\mathbf{x}_i)} \tag{10}$$

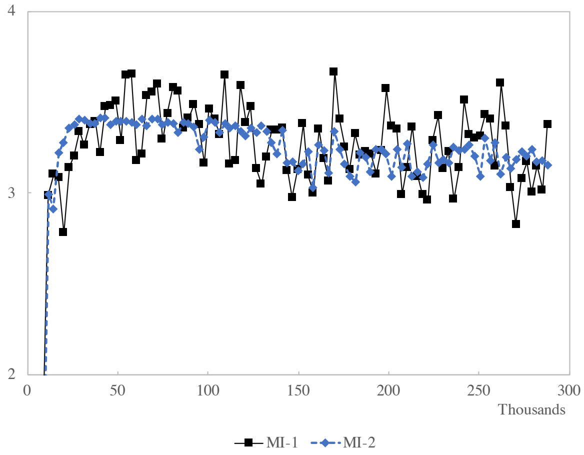

Figure 3: Estimation of the mutual information over the course of training. MI-2 corresponds to our approach. MI-1 is derived from the Monte Carlo estimation of $D_{\mathrm{KL}}(q_\phi(\mathbf{z})\|p(\mathbf{z}))$ (not described). Our approach results in less variance in the MI estimation.

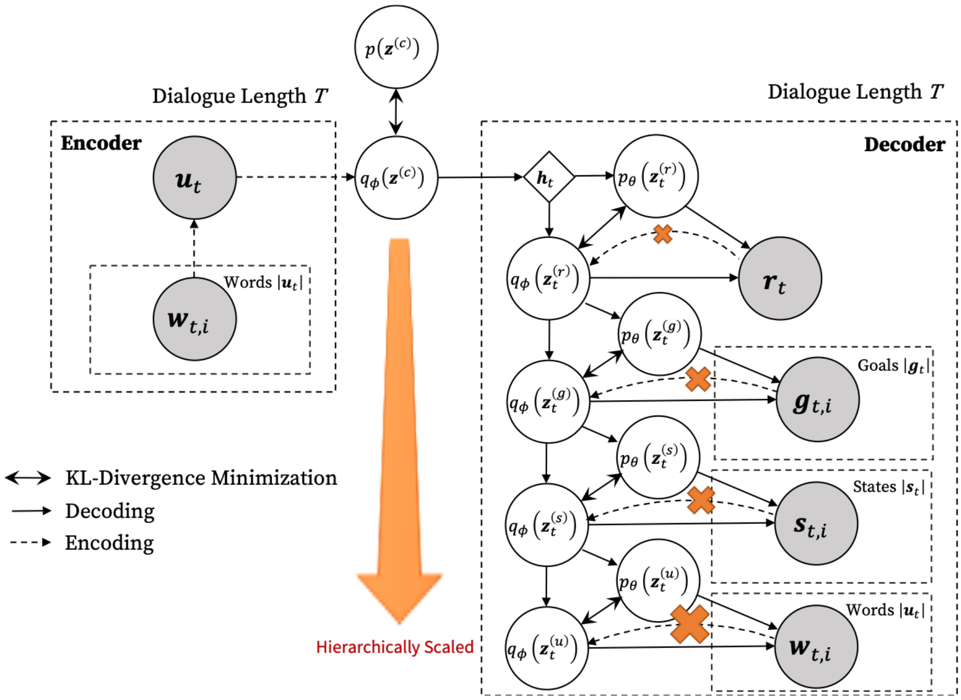

Figure 4: The architectural diagram.

Appendix C Full Results of Data Augmentation

The full data augmentation results are shown below, including the statistics. Note that generative data augmentation also has the effect of reducing the variance of the downstream models.

Appendix D Exhibits of Synthetic Samples

This section describes the method we use to sample synthetic data points from our model's posterior and presents some synthetic samples generated from our model using the described technique.

We use *ancestral sampling* (He et al., 2019), or the *posterior sampling* technique (Yoo et al., 2019), to sample data points from the empirical distribution of the latent space. Specifically, we choose an anchor data point from the dialog dataset: $\mathbf{c} \sim p_d(\mathbf{c})$, where p_d is the empirical distribution of goal-oriented dialogs. Then, we sample a set of latent variables $\mathbf{z}^{(c)}$ from the encoded distribution of $\mathbf{c}$: $\mathbf{z}^{(c)} \sim q_\phi(\mathbf{z}^{(c)} \mid \mathbf{c})$. Next, we decode a sample $\mathbf{c}'$ that maximizes the log-likelihood for each sampled conversational latents:

$$\mathbf{c}' = \arg\max_{\mathbf{c}} p_\theta(\mathbf{c} \mid \mathbf{z}^{(c)}).$$

We use these samples to augment the original dataset. Also, we fix the ratio of the synthetic dataset to the original dataset to 1. In our experiments, we observe that all of the synthetic samples generated via ancestral sampling are mostly coherent and, most importantly, novel, i.e., each synthetic data point is somehow different from the original anchor point (e.g., variations in utterances, dialog-level semantics, or sometimes annotation errors).

In the following tables, we showcase few dialog samples from our augmentation datasets. The tables present the generated samples along with their reference dialog samples.

Appendix E $\mathbf{z}^{(c)}$ Interpolation Results (Including Both Anchors)

Visualizing samples from a linear interpolation of two points in the latent space (Bowman et al., 2016) is a popular way to showcase the generative capability of VAEs. Given two dialog samples $\mathbf{c}_1$ and $\mathbf{c}_2$, we map the data points onto the conversational latent space to obtain $\mathbf{z}_1^{(c)}$ and $\mathbf{z}_2^{(c)}$. Multiple equidistant samples $\mathbf{z}'_1, ..., \mathbf{z}'_N$ are selected from the linear interpolation between the two points: $\mathbf{z}'_n = \mathbf{z}_1^{(c)} + n(\mathbf{z}_2^{(c)} - \mathbf{z}_1^{(c)})/N$. Likelihood-maximizing samples $\mathbf{x}'_1, \ldots, \mathbf{x}'_N$ are chosen from the model posteriors given the intermediate latent samples.

Abstract

Knowledge selection plays an important role in knowledge-grounded dialogue, which is a challenging task to generate more informative responses by leveraging external knowledge. Recently, latent variable models have been proposed to deal with the diversity of knowledge selection by using both prior and posterior distributions over knowledge and achieve promising performance. However, these models suffer from a huge gap between prior and posterior knowledge selection. Firstly, the prior selection module may not learn to select knowledge properly because of lacking the necessary posterior information. Secondly, latent variable models suffer from the exposure bias that dialogue generation is based on the knowledge selected from the posterior distribution at training but from the prior distribution at inference. Here, we deal with these issues on two aspects: (1) We enhance the prior selection module with the necessary posterior information obtained from the specially designed Posterior Information Prediction Module (PIPM); (2) We propose a Knowledge Distillation Based Training Strategy (KDBTS) to train the decoder with the knowledge selected from the prior distribution, removing the exposure bias of knowledge selection. Experimental results on two knowledge-grounded dialogue datasets show that both PIPM and KDBTS achieve performance improvement over the state-of-the-art latent variable model and their combination shows further improvement.

Context	I just got a husky puppy.	
Knowledge Pool	#	**Knowledge Sentence**
	0	Husky is a general name for a sled type of dog used in northern regions, differentiated from other **sled-dog** types by **their fast pulling style**.
	1	Huskies are also today kept as pets, and groups work to find new pet homes for retired racing and adventure trekking dogs.
	2	Huskies are used in sled dog racing.
	3	The use of "husk" is recorded from 1852 for dogs kept by Inuit people
	...	...
	L	Child of the Wolves is a children's **novel**, published in 1996, **about a Siberian husky puppy that joins a wolf pack**.
Response a	It sounds cute! Huskies are known amongst **sled-dogs for their fast pulling style**.	
Response b	It sounds cute! I have read a **novel about a husky puppy joining a wolf pack**. Is your husky puppy wolf-like in appearance?	

Table 1: An example shows the diversity of knowledge selection in knowledge-grounded dialogue. Here, we show two different responses with two possible selection decisions. For the same context, there may be diverse knowledge sentences to generate different responses which help their selection decisions in turn. The *prior knowledge selection* only depends on context while the *posterior knowledge selection* means selection with context and response (Lian et al., 2019).

1 Introduction

Knowledge-grounded dialogue (Ghazvininejad et al., 2018) which leverages external knowledge to generate more informative responses, has become a popular research topic in recent years. Many researchers have studied how to effectively leverage the given knowledge to enhance dialogue understanding and/or improve dialogue generation (Zhao et al., 2019b; Sun et al., 2020; Madotto et al., 2018; Chen et al., 2019; Yavuz et al., 2019; Tang and Hu, 2019; Li et al., 2019; Zheng and Zhou, 2019; Niu et al., 2019; Meng et al., 2019; Ren et al., 2019; Ye et al., 2020). However, they usually use the pre-identified knowledge (Zhang et al., 2018; Moghe et al., 2018; Qin et al., 2019) which is not available in some real-world scenarios. And others leverage the retrieval system to get the knowledge which may contain noisy and irrelevant data (Chaudhuri et al., 2018; Parthasarathi and Pineau, 2018; Zhou et al., 2018; Gopalakrishnan et al., 2019). Recently, Dinan et al. (2019) propose to decompose this task into two subproblems: knowledge selection and response generation. This pipeline framework has been widely used for the open domain setting (Chen et al., 2017; Min et al., 2018; Nie et al., 2019) and shows promising performance with explicit use of knowledge in knowledge-grounded dialogue (Dinan et al., 2019).

Knowledge selection plays an important role in open-domain knowledge-grounded dialogue (Di-

nan et al., 2019) since the inappropriate knowledge selection may prevent the model from leveraging the knowledge accurately (Lian et al., 2019), or even lead to an inappropriate response. The example in Table 1 shows two phenomena: (1) There may exist one-to-many relations between the dialogue context and the knowledge, resulting in the diversity of knowledge selection (Kim et al., 2020); (2) The posterior knowledge selection with context and response is much easier than the prior knowledge selection only depending on context. It is rather intuitive that we can dramatically reduce the scope of knowledge selection when we know the knowledge contained in the response, while such posterior information is not available at inference. Recently, latent variable models (Lian et al., 2019; Kim et al., 2020), using the posterior distribution to guide the prior distribution, have been proposed to deal with the diversity of knowledge selection. They can jointly model knowledge selection with response generation and achieve promising performance. Despite their success, latent variable models suffer from a huge gap between prior and posterior knowledge selection as discussed below.

We analyze the gap in latent variable models on two aspects: (1) Compared with the posterior selection module, the prior selection module has no access to the necessary posterior information. As a result, it is hard for the prior distribution to approximate the posterior distribution correctly at training, so that the prior selection module may not select knowledge properly at inference. (2) Response generation of latent variable models is based on the knowledge selected from the posterior distribution at training but from the prior distribution at inference. This discrepancy, also named exposure bias, leads to a gap between training and inference (Ranzato et al., 2015; Zhang et al., 2019; Zhao et al., 2019a), and therefore the decoder may have to generate a response with inappropriate knowledge selected from an unfamiliar prior distribution.

In this paper, we propose to bridge the gap between prior and posterior knowledge selection for knowledge-grounded dialogue generation. Firstly, we enhance the prior selection module with the necessary posterior information which is obtained by the specially designed Posterior Information Prediction Module (PIPM). Secondly, inspired by knowledge distillation (Hinton et al., 2015), we design a Knowledge Distillation Based Training Strategy (KDBTS) to train the decoder with the knowledge selected by the prior module, removing the exposure bias of knowledge selection. Experimental results show that both PIPM and KDBTS bring performance improvement on two knowledge-grounded dialogue datasets, i.e., Wizard of Wikipedia (Dinan et al., 2019) and Holl-E (Moghe et al., 2018). And the combination of PIPM and KDBTS obtains the new state-of-the-art performance with further improvement.

Our contributions are summarized as follows:[1]

- We clearly point out the gap between prior and posterior knowledge selection of latent variable models and propose to enhance the prior selection module with the necessary posterior information. Moreover, we explore several variants of posterior information.

- We focus on the exposure bias of knowledge selection for knowledge-grounded dialogue, and design a knowledge distillation based training strategy to deal with it.

- Experimental results show that both PIPM and KDBTS bring performance improvement, and their combination achieves the state-of-the-art performance with further improvement.

2 Background

2.1 Task Formulation

For a dialogue with T turns, each turn is a pair of message x_t and response y_t. Besides, each turn is associated with a knowledge pool $\mathcal{K}_t = \{k_t^l\} = \{k_t^1, \cdots, k_t^L\}$ consisting of L sentences. The context ctx_t consists of the dialogue history $hist_t = [x_1, y_1, \cdots, x_{t-1}, y_{t-1}]$ and the message x_t.

Given the context ctx_t, we firstly select a knowledge sentence $k_t^{\text{sel}} \in \mathcal{K}_t$ from the knowledge pool, then leverage the selected knowledge to generate an informative response y_t. The selection history at the t-th turn is $kh_t = [k_1^{\text{sel}}, \cdots, k_{t-1}^{\text{sel}}]$.

2.2 Latent Knowledge Selection For Response Generation

To obtain the likelihood of response y_t, latent variable models treat knowledge k as the latent variable and marginalize over all possible knowledges $\mathcal{K}_t$:

$$p\left(y_t|ctx_t\right) = \mathbb{E}_{k\sim\pi_\theta(\mathcal{K}_t)} p_\theta\left(y_t|ctx_t, k\right), \qquad (1)$$

---

[1] The code is available at `https://github.com/youngornever/bridge_latent_knowledge_selection_gap_for_conversation`.

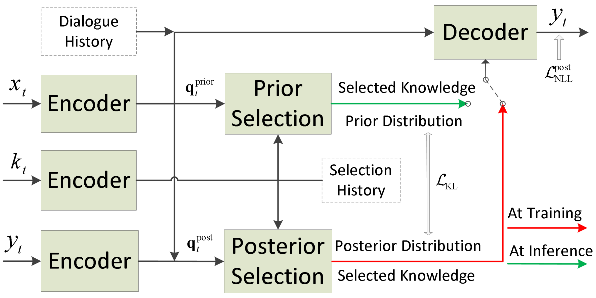

Figure 1: Latent knowledge selection for response generation. We train the decoder with the selected knowledge from posterior distribution with the red line, while we have to infer with the knowledge selected by the prior selection module without access to the response.

where $p_\theta\left(y_t|ctx_t, k\right)$ is the decoder network, and $\pi_\theta\left(\mathcal{K}_t\right)$, short for $\pi_\theta\left(\mathcal{K}_t|ctx_t, kh_t\right)$, is the prior distribution over the knowledge pool $\mathcal{K}_t$ based on the context ctx_t and selection history kh_t. The evidence lower bound (ELBO) is written as:

$$\begin{aligned} \mathcal{L}_{\text{ELBO}} &= -\mathcal{L}_{\text{NLL}}^{\text{post}} - \mathcal{L}_{\text{KL}} \leq \log p\left(y_t|ctx_t\right) \\ \mathcal{L}_{\text{NLL}}^{\text{post}} &= -\mathbb{E}_{k\sim q_\phi(\mathcal{K}_t)}\left[\log p_\theta\left(y_t|ctx_t, k\right)\right], \\ \mathcal{L}_{\text{KL}} &= D_{\text{KL}}\left(q_\phi\left(\mathcal{K}_t\right)\|\pi_\theta\left(\mathcal{K}_t\right)\right) \end{aligned} \quad (2)$$

where $q_\phi\left(\mathcal{K}_t\right)$, short for $q_\phi\left(\mathcal{K}_t|ctx_t, y_t, kh_t\right)$, is an inference network to approximate the true posterior distribution $p\left(\mathcal{K}_t|ctx_t, y_t, kh_t\right)$.

The Gap between Prior and Posterior Knowledge Selection. Firstly, compared with the posterior selection module, the prior selection module has no access to the posterior information as shown in Figure 1. As a result, it is hard for the prior distribution to approximate the posterior distribution correctly by minimizing the KL divergence in Equation 2 at training. Hence, the prior selection module may not select knowledge properly at inference. Secondly, comparing the two expectation terms in Equation 1 and 2, we see that the selected knowledge for response generation at training and inference is drawn from different distributions, i.e., the posterior distribution $k \sim q_\phi\left(\mathcal{K}_t\right)$ at training and the prior distribution $k \sim \pi_\theta\left(\mathcal{K}_t\right)$ at inference. Figure 1 clearly shows this discrepancy which will cause the decoder to have to generate with knowledge selected from the unfamiliar prior distribution. These issues lead to the gap between prior and posterior knowledge selection, which we try to deal with in this paper.

2.3 Sequential Knowledge Transformer

Recently, Kim et al. (2020) propose Sequential Knowledge Transformer (SKT), the state-of-the-art latent variable model for knowledge selection. Here, we briefly describe SKT, based on which we validate the effectiveness of our approach.

Sentence Encoding. For any sentence $sent_t$ with N_w words at t-th turn, SKT uses a shared BERT (Devlin et al., 2019) to obtain the context aware word representations $\mathbf{H}_t^{sent}$ with d dims and then converts them into the sentence representation $\mathbf{h}_t^{sent}$ by mean pooling (Cer et al., 2018):

$$\begin{aligned} \mathbf{H}_t^{sent} &= \text{BERT}\left(sent_t\right) \in \mathbb{R}^{N_w\times d} \\ \mathbf{h}_t^{sent} &= \text{Mean}\left(\mathbf{H}_t^{sent}\right) \in \mathbb{R}^{d} \end{aligned} . \quad (3)$$

As a result, we obtain $\mathbf{H}_t^x$ and $\mathbf{h}_t^x$ for the message x_t, $\mathbf{H}_t^y$ and $\mathbf{h}_t^y$ for the response[2] y_t, and $\mathbf{H}_t^{k_t^l}$ and $\mathbf{h}_t^{k_t^l}$ for any knowledge sentence $k_t^l \in \mathcal{K}_t$.

Knowledge Selection. To utilize the dialogue history and selection history, two GRUs (Cho et al., 2014) are used to summarize them as corresponding states $\mathbf{s}_t^{hist}$ and $\mathbf{s}_t^{kh}$ with zero initialization:

$$\begin{aligned} \mathbf{s}_t^{hist} &= \text{GRU}_{\text{dial}}\left(\left[\mathbf{h}_t^x; \mathbf{h}_t^y\right], \mathbf{s}_{t-1}^{hist}\right) \in \mathbb{R}^d \\ \mathbf{s}_t^{kh} &= \text{GRU}_{\text{sel}}\left(\mathbf{h}_t^{k_t^{\text{sel}}}, \mathbf{s}_{t-1}^{kh}\right) \in \mathbb{R}^d \end{aligned} , \quad (4)$$

where $\mathbf{h}_t^x$, $\mathbf{h}_t^y$ and $\mathbf{h}_t^{k_t^{\text{sel}}}$ are sentence vectors of message x_t, response y_t and the selected knowledge k_t^{sel} and $[\cdot;\cdot]$ denotes concatenation. Then, the prior query $\mathbf{q}_t^{\text{prior}}$ and posterior query $\mathbf{q}_t^{\text{post}}$ are obtained:

$$\begin{aligned} \mathbf{q}_t^{\text{prior}} &= \left[\mathbf{s}_{t-1}^{kh}; \mathbf{s}_{t-1}^{hist}; \mathbf{h}_t^x\right] \\ \mathbf{q}_t^{\text{post}} &= \left[\mathbf{s}_{t-1}^{kh}; \mathbf{s}_t^{hist}\right] \end{aligned} . \quad (5)$$

Note that $\mathbf{s}_{t-1}^{kh}$ summarizes the selection history $kh_t = \left[k_1^{\text{sel}}, \cdots, k_{t-1}^{\text{sel}}\right]$, and $\mathbf{s}_t^{hist}$ contains current response information, i.e., $\mathbf{h}_t^y$, not available at inference. The distribution $\mathbf{a}_t^{\text{P}}\left(\mathcal{K}_t\right)$ over knowledge pool $\mathcal{K}_t$ is obtained by the dot-product attention:

$$\begin{aligned} \mathbf{a}_t^{\text{P}}\left(\mathcal{K}_t\right) &= \text{softmax}\left(\mathbf{v}_t^{\text{P}}\left[\mathbf{h}_t^{k_t^1}, \cdots, \mathbf{h}_t^{k_t^L}\right]\right) \\ \mathbf{v}_t^{\text{P}} &= \mathbf{W}^{\text{P}}\mathbf{q}_t^{\text{P}} \in \mathbb{R}^d \end{aligned} , \quad (6)$$

where "P" denotes either prior or posterior, $\mathbf{W}_{\text{P}}$ is the projection matrix and $\mathbf{a}_t^{\text{P}}\left(\mathcal{K}_t\right) \in \mathbb{R}^L$.

---

[2] Response is only used for the posterior selection module at the training stage.

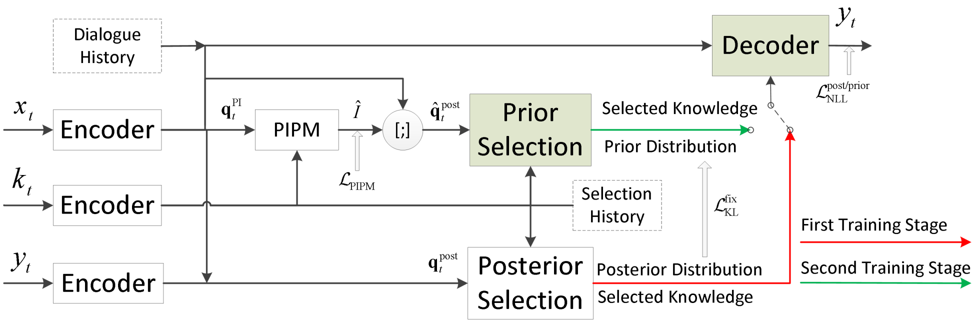

Figure 2: Our Framework. Firstly, we enhance the prior selection module with the necessary posterior information $\hat{I}$ obtained from the Posterior Information Prediction Module (PIPM). Secondly, we design a two-stage Knowledge Distillation Based Training Strategy (KDBTS). At the first stage, KDBTS trains the posterior selection module (the teacher) with the red line. At the second stage, response generation is based on the knowledge selected by the prior module, which is guided by the well-trained teacher, and we only update the green blocks at this stage.

Finally, the knowledge k_t^{sel} is selected by sampling from the posterior distribution $q_\phi\left(\mathcal{K}_t\right) = \mathbf{a}_t^{\mathrm{post}}\left(\mathcal{K}_t\right)$ at training while selected with the highest probability over the prior distribution $\pi_\theta\left(\mathcal{K}_t\right) = \mathbf{a}_t^{\mathrm{prior}}\left(\mathcal{K}_t\right)$ at inference.

Generation with Knowledge. SKT takes the concatenation of message x_t and selected knowledge sentence k_t^{sel} as input and generates responses by the Transformer decoder (Vaswani et al., 2017) with copy mechanism (Gu et al., 2016). Though there are various models studying how to improve the generation quality based on the given knowledge, here, we simply follow the decoder of SKT and mainly focus on the knowledge selection issue.

3 Approach

In this section, we show how to bridge the gap between prior and posterior knowledge selection in knowledge-grounded dialogue. Firstly, we design the Posterior Information Prediction Module (PIPM) to enhance the prior selection module with the necessary posterior information. Secondly, we design a Knowledge Distillation Based Training Strategy (KDBTS) to train the decoder with the knowledge selected from the prior distribution, removing the exposure bias of knowledge selection.

3.1 Posterior Information Prediction Module

As shown in Figure 2, we design a Posterior Information Prediction Module (PIPM) to predict the necessary posterior information. The main motivation is that we want to enhance the prior selection module with the necessary posterior information, so that it could approximate the posterior distribution better at training and leverage the posterior information for knowledge selection at inference. Following the typical setting in latent variable models (Lian et al., 2019; Kim et al., 2020), we use the response in bag-of-words (BOW) format (Zhao et al., 2017) as the posterior information. Here we take the dialogue context and the knowledge pool as input to generate the posterior information.

We firstly summarize the context as the query of this module $\mathbf{q}_t^{\mathrm{PI}} = \left[\mathbf{s}_{t-1}^{hist}; \mathbf{h}_t^{x}\right]$ and use it to get the attention distribution $\mathbf{a}_t^{\mathrm{PI}}\left(\mathcal{K}_t\right)$ over the knowledge pool $\mathcal{K}_t$ by Equation 6. Then, we summarize the knowledge representation in the knowledge pool with the weights in $\mathbf{a}_t^{\mathrm{PI}}\left(\mathcal{K}_t\right)$ considered:

$$\mathbf{h}_t^{\mathrm{PI}} = \left[\mathbf{h}_t^{k_t^1}, \cdots, \mathbf{h}_t^{k_t^L}\right] \cdot \mathbf{a}_t^{\mathrm{PI}}\left(\mathcal{K}_t\right) \in \mathbb{R}^d. \tag{7}$$

Secondly, we take the summarization of the dialogue context and the knowledge pool as input and use a position wise feed-forward network (FFN) (Vaswani et al., 2017) to generate the posterior information $\hat{I}_t$ in BOW format as:

$$\hat{I}_t = \mathrm{softmax}\left(\mathrm{FFN}\left(\left[\mathbf{q}_t^{\mathrm{PI}}; \mathbf{h}_t^{\mathrm{PI}}\right]\right)\right) \in \mathbb{R}^{|V|}. \tag{8}$$

Finally, we use the generated posterior information $\hat{I}_t$ to obtain the updated prior query $\hat{\mathbf{q}}_t^{\mathrm{post}}$ as:

$$\hat{\mathbf{q}}_t^{\mathrm{post}} = \left[\mathbf{q}_t^{\mathrm{prior}}; \hat{I}_t \cdot \mathbf{E}\right], \tag{9}$$

where $\mathbf{E} \in \mathbb{R}^{|V| \times d}$ is the embedding matrix and $|V|$ is the vocabulary size. Compared with $\mathbf{q}_t^{\mathrm{prior}}$ in Equation 5, $\hat{\mathbf{q}}_t^{\mathrm{post}}$ additionally contains the predicted posterior information, and we replace $\mathbf{q}_t^{\mathrm{prior}}$ with $\hat{\mathbf{q}}_t^{\mathrm{post}}$ for knowledge selection in Equation 6. We supervise this module by an addition loss $\mathcal{L}_{\mathrm{PIPM}}$ with the grounded posterior information I, i.e., the bag of tokens in the golden response:

$$\mathcal{L}_{\text{PIPM}} = -1/|I| \sum\nolimits_{w \in I} \log \left(\hat{I}_t^w \right). \tag{10}$$

Note that we remove the context information from I because this information is already contained in the prior query $\mathbf{q}_t^{\text{prior}}$.

3.2 Knowledge Distillation Based Training Strategy

Current latent variable models (Lian et al., 2019; Kim et al., 2020) suffer from the exposure bias of knowledge selection as shown in Figure 1. Therefore, the decoder may have to generate a response with inappropriate knowledge selected from an unfamiliar prior distribution. Inspired by knowledge distillation (Hinton et al., 2015), we design the Knowledge Distillation Based Training Strategy (KDBTS) to deal with this exposure bias. KDBTS is a two-stage training strategy that we firstly train the posterior selection module as the teacher and then leverage the well-trained posterior module to train the prior selection module as the student.

First Training Stage. We train a teacher at this stage, which is used to guide the student at the next stage. We can obtain a teacher as the by-product, i.e., the posterior selection module, from the training process of latent variable models in Figure 1. However, we find the posterior selection module is affected by the prior distribution when minimizing the KL term in Equation 2, and experiments in Section 5.2 show that it is usually not good enough. As a result, we introduce a "fix" operation to make sure that the posterior selection module can not be affected by the prior distribution, and replace the KL term $\mathcal{L}_{\text{KL}}$ with the fixed KL term $\mathcal{L}_{\text{KL}}^{\text{fix}}$:

$$\mathcal{L}_{\text{KL}}^{\text{fix}} = D_{\text{KL}} \left(\text{fix} \left(q_\phi \left(\mathcal{K}_t \right) \right) \parallel \pi_\theta \left(\mathcal{K}_t \right) \right). \tag{11}$$

The total loss for training the teacher is as follows:

$$\mathcal{L}_1 = \mathcal{L}_{\text{NLL}}^{\text{post}} + \mathcal{L}_{\text{KL}}^{\text{fix}} - \log q_\phi \left(k_t^a \right) + \lambda \mathcal{L}_{\text{PIPM}}, \tag{12}$$

where $\mathcal{L}_{\text{NLL}}^{\text{post}}$ is defined in Equation 2, $k_t^a \in \mathcal{K}_t$ is the golden selected knowledge for knowledge loss $-\log q_\phi \left(k_t^a \right)$ which is proposed by (Kim et al., 2020) and λ is a hyperparameter.

Second Training Stage. Once we obtain the teacher, we could leverage the posterior distribution from the well-trained teacher to deal with the diversity of knowledge selection. At this training stage, we feed the knowledge selected by the prior module into the decoder as shown in Figure 2, which is the same as the inference process. In this way, KDBTS removes the exposure bias of knowledge selection. Here, we only update the prior selection module and the decoder (the green blocks in Figure 2) because the encoder is shared by the student and the teacher. The total loss for training the student at this stage is:

$$\mathcal{L}_2 = \mathcal{L}_{\text{NLL}}^{\text{prior}} + \mathcal{L}_{\text{KL}}^{\text{fix}} - \log \pi_\theta \left(k_t^a \right), \tag{13}$$

where $\mathcal{L}_{\text{NLL}}^{\text{prior}} = -\mathbb{E}_{k \sim \pi_\theta(\mathcal{K}_t)} \left[\log p_\theta \left(y_t | ctx_t, k \right) \right]$ and $-\log \pi_\theta \left(k_t^a \right)$ is the knowledge loss.

Compared with $\mathcal{L}_{\text{NLL}}^{\text{post}}$ defined in Equation 2, $\mathcal{L}_{\text{NLL}}^{\text{prior}}$ optimizes the decoder with knowledge selected from the prior distribution. Figure 2 clearly shows that KDBTS removes the exposure bias of knowledge selection by feeding the knowledge selected from prior distribution into the decoder.

4 Experiments

4.1 Dataset

We adopt two multi-turn knowledge-grounded dialogue datasets for experiments.

Wizard of Wikipedia (Dinan et al., 2019) contains $18,430$ training dialogues, $1,948$ validation dialogues and $1,933$ test dialogues on 1365 topics. And test set is split into two subsets according to topics, which are Test Seen with 965 dialogues and Test Unseen with 968 dialogues whose topics are never seen in training and validation set. There are about 61 sentences on average in the knowledge pool per turn, which are retrieved from Wikipedia based on the context.

Holl-E (Moghe et al., 2018) contains $7,228$ training dialogues, 930 validation dialogues and 913 test dialogues. There are two versions of the test set: one with a single golden reference, the other with multiple golden references. Each dialogue is assigned with a document of about 60 sentences on average as the knowledge pool. Here, we use the modified version (Kim et al., 2020) which fits for knowledge selection.

4.2 Baseline Models

We compare our approach with a set of competitive baselines:

TMN is short for E2E Transformer MemNet (Dinan et al., 2019). TMN uses a Transformer memory network for knowledge selection and a Transformer decoder with copy mechanism for utterance prediction. Knowledge selection is trained based on the knowledge label without posterior distribution.

TMN_{BERT}, is short for TMN+BERT, implemented by (Kim et al., 2020). TMN_{BERT} replaces the Transformer memory network with a pre-trained BERT.

PostKS (Lian et al., 2019) only uses the posterior knowledge distribution as a pseudo-label for knowledge selection. PostKS uses GRU-based encoder and decoder without copy mechanism and does not use the knowledge label at the training stage.

$\text{TMN}_{\text{BERT+PostKS+CP}}$ is short for TMN+BERT+PostKS+Copy, implemented by (Kim et al., 2020). Compared with TMN_{BERT}, it additionally uses the the posterior distribution in PostKS.

SKT (Kim et al., 2020) is the current state-of-the-art latent variable model. Compared with TMN_{BERT}+$\text{PostKS}_{\text{cp}}$, SKT leverages the posterior distribution by sequential latent modeling.

4.3 Implementation Details

We validate the effectiveness of our approach based on current state-of-the-art model SKT (Kim et al., 2020), using the same datasets and data-processing codes[3]. A shared encoder initialized with $\text{BERT}_{\text{BASE}}$ (Devlin et al., 2019) is used to encode dialogue and knowledge sentences. Then, a 5-layer Transformer decoder with copy mechanism is used to generate the response. We use a FFN with 512 hidden dims to generate the posterior information in BOW formats. The hidden size d is 768 and the vocabulary size $|V|$ is $30,522$. Each batch consists of dialogues rather than individual turns, and the batch size is 1. The hyperparameter λ in Equation 13 is set to 0.5 for all experiments without searching. The "fix" operation in Equation 11 is implemented by gradient stoping.

Models are trained end-to-end using the Adam optimizer (Kingma and Ba, 2014) with gradient clipping at 0.4 and the learning rate is 0.00002. And we apply label smoothing (Pereyra et al., 2017) and set 0.1 for knowledge selection and 0.05 for response generation. We approximate the expectation in Equation 1 and 2 by drawing one sample with Gumbel-Softmax function (Jang et al., 2016) with temperature $\tau = 0.1$. We train our teacher with 5 epochs, then select the teacher to teach the student according to the prior knowledge selection accuracy rather than posterior selection accuracy, because the shared encoder and decoder may be optimized overly for the posterior selection module, which is not a good initialization for the student. We train other models 20 epoches and select them according to the R-1 score as the final goal is to generate high-quality responses.

4.4 Evaluation

Automatic Evaluation. Following (Dinan et al., 2019; Kim et al., 2020), we use accuracy (Acc) to evaluate the knowledge selection and use perplexity (PPL), unigram F1 (R-1) and bigram F1 (R-2) to evaluate the quality of response generation automatically. Following (Kim et al., 2020), we remove all the punctuation and (a, an, the) before computing the R-1 and R-2 scores. Note that lower perplexity and higher R-1 and R-2 indicate better generation quality.

Human Evaluation. We firstly select 100 samples from each test set on the Wizard of Wikipedia dataset for human evaluation. Then, we ask three annotators to judge whether the response makes sense (Sensibleness) or is specific (Specificity) with the dialogue context. Finally, we obtain Sensibleness and Specificity Average (SSA) scores, which could penalize boring and vague responses and is suitable for the goal of knowledge-grounded dialogue (Adiwardana et al., 2020). Moreover, compared with Engagingness and Knowledgeability used in (Dinan et al., 2019; Kim et al., 2020), SSA, evaluated in 0/1 format, is more objective and easier to conduct (Adiwardana et al., 2020).

5 Results and Analysis

5.1 Main Results

Quantitative Results. We report automatic results on the Wizard of Wikipedia dataset in Table 2 and we have the following observations: (1) From row 4 and 5 we can see that the PIPM indeed provides some necessary posterior information which is helpful for knowledge selection. (2) Comparing row 4 and 6, we see that the KDBTS brings about significant improvement on generation quality by removing the exposure bias of knowledge selection. (3) The combination of PIPM and KDBTS achieves further improvement on most metrics, except the knowledge selection accuracy. We think the reason is that there may exist several similar knowledge sentences leading to the same response. As a result, SKT+PIPM+KDBTS may select a reasonable

$I = y^x_{\text{BOW}}$	y_{BOW} - x_{BOW}
$I = yk^x_{\text{BOW}}$	y_{BOW} + k^a_{BOW} - x_{BOW}
$I = y_{\text{Seq}}$	the response

Table 5: Several variants of posterior information.

knowledge but not the golden one to generate informative and fluent responses, because models are selected according to the generation quality rather than the selection accuracy (Kim et al., 2020).

Results in Table 3 lead to consistent observations on the Holl-E dataset that both PIPM and KDBTS bring performance improvement over the state-of-the-art latent variable model SKT, and their combination achieves further improvement, resulting in the new state-of-the-art performance.

Qualitative Results. We report human evaluation results of the generated responses in Table 4. We see that our approach brings about consistent improvement over the state-of-the-art model SKT. Our approach can leverage the selected knowledge appropriately to generate more sensible and specific responses, which are fluent and informative.

5.2 Analysis

PIPM. We explore several variants of posterior information in Tabel 5 to better study this module. Besides the default y^x_{BOW}, we also explore two variants in BOW format: (1) y_{BOW} does not remove the context information; (2) yk^x_{BOW} additionally considers another source of posterior information, i.e., the golden selected knowledge k^a_t. And we consider the sequence information in y_{Seq}, as the BOW format discards the word order. Note that we use the FFN in Equation 8 to obtain the posterior information in BOW formats, and we take $\mathbf{H}^x_t + \mathbf{h}^{\text{PI}}_t$ as input and use a 3-layer Transformer decoder to generate y_{Seq}. Moreover, we also perform an ablation study to investigate the effectiveness

Table 6: Quantitative results for model analysis on the Wizard of Wikipedia dataset. The default setting of PIPM is y^x_{BOW}. Models with † are teachers which are not comparable as they use the posterior knowledge selection at inference, and their results can be regarded as the upper bound. KLfix means that we replace $\mathcal{L}_{\text{KL}}$ with $\mathcal{L}^{\text{fix}}_{\text{KL}}$.

of generated posterior information for prior knowledge selection. We remove the predicted posterior information $\hat{I}$ in Equation 9, but still use $\mathcal{L}_{\text{PIPM}}$ in Equation 10 for comparison.

These results are reported in the upper part (row $1\sim5$) of Table 6 and the observations are stated as follows: (1) Compared with SKT in row 0, the variants of posterior information in row $1\sim4$ bring improvement on selection accuracy, though some generation metrics are slightly lower because of the exposure bias of knowledge selection. (2) From row 1 and 2, we see that the sequence information in y_{Seq} contributes to the knowledge selection. However, it is inefficient to generate y_{Seq} word by word, and y_{Seq} is not better than y^x_{BOW} in row 4. And there is no significant difference between y^x_{BOW} and yk^x_{BOW} which combines another source of posterior information. (3) We report the ablation result in row 5 to investigate the effectiveness of generated posterior information for knowledge selection. We see that this information improves the selection accuracy (compared with row 4).

KDBTS. We investigate the training strategy in the lower part (row $6\sim9$) of Table 6 and the observations are stated as follows: (1) Comparing row 6 and 7, we see that SKT (KLfix)† is a good teacher with a much higher selection accuracy because $\mathcal{L}^{\text{fix}}_{\text{KL}}$ in Equation 11 guarantees the posterior selection module not affected by the prior distribution. When using $\mathcal{L}_{\text{KL}}$ in Equation 2, SKT† achieves the lower accuracy (32.8 vs 52.0) and the lower KL divergence (0.31 vs 1.41), which indicates that the posterior module is affected by the prior distribution. (2) Despite doing well in knowledge selection, SKT (KLfix) in row 8 performs worse in generation than SKT. Because SKT (KLfix) has a larger KL divergence (1.41 vs 0.31) than SKT[4], it has to generate the response with the knowledge selected from a much more unfamiliar prior distribution. (3) As our KDBTS in row 9 does not suffer from the exposure bias of knowledge selection, the generation quality is improved significantly. We are amazed at finding that the selection accuracy is also improved and we argue that the KDBTS drives the prior distribution to approximate the posterior distribution at most by minimizing the KL term with the posterior distribution fixed.

5.3 Case Study

Table 7 shows two example response on the Wizard of Wikipedia dataset. We see that the posterior information $\hat{I}$, e.g., "rock band" and "formed", provided by the PIPM, is helpful for knowledge selection, although there is some noise information, e.g., "american". And quantitative results in Section 5.1 show that this module is effective although not perfect. We see that the responses generated by SKT have repeated words in case 1 and do not reply directly in case 2. Our method can leverage the selected knowledge sufficiently to generate a fluent and informative response because our KDBTS removes the exposure bias of knowledge selection by training the decoder with knowledge selected in the same way as the inference process.

---

[4] Note that SKT and SKT† are the same network tested with prior and posterior knowledge selection, respectively. Hence, the KL divergence is same.

6 Related Work

We mainly focus on knowledge selection in open domain knowledge-grounded dialogue, and there are several work studying this issue (Dinan et al., 2019; Lian et al., 2019; Kim et al., 2020). Here, we point out the gap between prior and posterior knowledge selection and try to deal with this gap.

The PIPM has some relations with several work. Deliberation Decoder (Xia et al., 2017; Wang et al., 2019; Li et al., 2019) leverages two decoders for two-pass generation. We also use two decoders in PIPM (y_{Seq}), but the first decoder is used to generate posterior information for the knowledge selection rather than the second-pass generation. BOW loss, proposed by (Zhao et al., 2017), is adopted to supervise the posterior module (Lian et al., 2019). Here, we have three different aspects: (1) We use the BOW loss for the prior module rather than the posterior module; (2) We use posterior information in BOW format to enhance the prior selection module; (3) We explore several BOW variants.

Our KDBTS is inspired by knowledge distillation (Hinton et al., 2015). Instead of using more complex structure as the teacher for model compression, we treat the posterior selection module with additional input information (e,g., the response) as the teacher, and deal with the exposure bias of knowledge selection. Lite ELBO (Zhao et al., 2019a) is proposed to remove the exposure bias at latent space for a different task. However, Lite ELBO naturally does not leverage the posterior distribution as it sets the posterior module the same as the prior module. Our KDBTS is a two-stage training strategy that uses the posterior distribution as the teacher to guide the prior selection module and uses the knowledge selected from the prior distribution to train the decoder.

7 Conclusion

In this paper, we firstly analyze the gap between prior and posterior knowledge selection for open-domain knowledge-grounded dialogue. Then, we deal with it on two aspects: (1) We enhance the prior selection module with the posterior information obtained by the PIPM and we explore several variants of posterior information. (2) We design the KDBTS to train the decoder with knowledge selected from the prior distribution, removing the exposure bias of knowledge selection. Experiments show that both PIPM and KDBTS improve the state-of-the-art latent variable model and their combination achieves further improvement. In the future, we would explore three aspects: (1) more efficient posterior information representation and corresponding prediction module, (2) the interpretability of knowledge selection and (3) knowledge selection without knowledge label.

Abstract

Open-domain dialogue generation suffers from the data insufficiency problem due to the vast size of potential responses. In this paper, we propose to explore potential responses by counterfactual reasoning. Given an observed response, the counterfactual reasoning model automatically infers the outcome of an alternative policy that could have been taken. The resulting counterfactual response synthesized in hindsight is of higher quality than the response synthesized from scratch. Training on the counterfactual responses under the adversarial learning framework helps to explore the high-reward area of the potential response space. An empirical study on the DailyDialog dataset shows that our approach significantly outperforms the HRED model as well as the conventional adversarial learning approaches.

1 Introduction

Open-domain dialogue generation (Shang et al., 2015a; Vinyals and Le, 2015; Sordoni et al., 2015a) intends to produce coherent responses given dialogue history. Nevertheless, it suffers from data insufficiency problem as there may exist many potential responses for a given dialogue history (Li et al., 2016). An ideal way of exploring the potential responses is to train the model by chatting with real users, which is usually time-consuming and labor-intensive in practice. Although replacing a real user with a user simulator could address the issue, the simulator only roughly approximates real user statistics, and its development process is costly (Su et al., 2016).

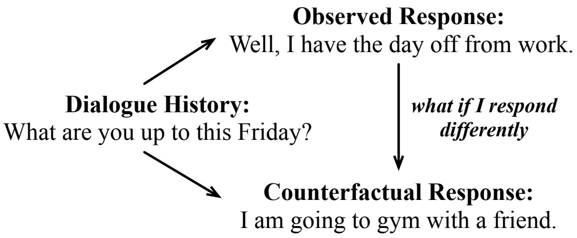

Figure 1: An example of a counterfactual response, which is a potential response inferred in hindsight from given observed response.

In contrast, humans could independently reason potential responses based on past experiences from the true environment. Having observed a response, one might naturally ask himself or herself: "*What would happen if I respond differently, while everything else in the environment remains the same.*" Answering the question will result in a potential response (as an example in Figure 1), and it is beneficial for improving future decision making (Roese, 1997). The potential response inferred in hindsight is called a *counterfactual* response, where the concept "counterfactual" describes the posterior process of reasoning the outcome of alternative actions (i.e., a different responding policy) that could have been taken while keeping everything else unchanged (Buesing et al., 2019).

Motivated by this, we propose a counterfactual off-policy training (COPT) approach to explore potential responses. Building upon the adversarial learning framework, COPT casts a dialogue generator as a structural causal model (SCM), which describes a generation process with two ingredients: *scenarios* and *causal mechanisms* (Wright, 1920; Buesing et al., 2019). The scenario is a random noise variable that captures all unobserved yet relevant aspects of the environment, i.e., user profiles. The causal mechanism is a deterministic function that takes a scenario and dialogue history as input and outputs a response. In this way, reasoning a counterfactual response in an observed response's environment can be achieved by feeding the scenario of the observed response into the

November 16–20, 2020.

causal mechanism. After generating the counterfactual response, the generator will receive a reward from a discriminator and optimize itself accordingly.

Intuitively, a counterfactual response is synthesized by grounding the model in the scenario where an observed response occurs, rather than the scenario sampled from scratch as standard adversarial learning-based approaches. This improves the quality of the synthesized responses and subsequently benefits the model that learns from the synthesis. To verify the effectiveness of our approach, we conduct experiments on the public available DailyDialog dataset (Li et al., 2017b). Experimental results show that our approach significantly outperforms previous adversarial learning-based approaches in both automatic and human evaluations. The contributions of this paper are summarized as follows:

- We connect the concept of counterfactual reasoning with the dialogue generation by casting the dialogue generation model as a structural causal model.
- Our counterfactual response is of higher quality than the response synthesized from scratch in standard adversarial learning-based dialogue generation model.
- Our approach is model-agnostic and can be applied to any adversarial learning-based dialogue generation model.

2 Related Work

Dialogue Generation Data-driven dialogue systems can be roughly divided into two categories: retrieval-based (Leuski et al., 2006; Ji et al., 2014; Yan et al., 2016) and generation-based (Shang et al., 2015b; Sordoni et al., 2015b; Vinyals and Le, 2015). Responses of retrieval-based methods come from a fixed candidate response set and thus are incapable of being customized. The generation-based methods can create new responses, but the vanilla sequence to sequence model tends to produce generic responses (Li et al., 2016).

One way to address the generic response problem is by introducing external knowledge, such as keywords (Mou et al., 2016; Zhu et al., 2019b), topics (Xing et al., 2017), persona information (Zhang et al., 2019; Song et al., 2019), and retrieved candidate responses (Song et al., 2018; Wu et al., 2019; Zhu et al., 2019a). Another way is to optimize the architecture of networks. There are two architectures widely employed in this research line: the variational auto-encoder (Bowman et al., 2016; Zhao et al., 2017) and the generative adversarial network (Goodfellow et al., 2014; Li et al., 2017a; Zhang et al., 2018; Xu et al., 2018; Tuan and Lee, 2019). Our approach falls into the latter category. The differences between our approach and other adversarial learning-based approaches are as follows. First, we cast the dialogue generation model as an SCM to explore potential responses in the environment where observed responses occur. Second, we learn on counterfactual responses that inferred from the SCM. Third, a pre-trained behavior policy is involved during the generation process, making our approach an off-policy algorithm and benefits the exploration of potential responses.

Counterfactual Reasoning The counterfactual reasoning is a concept derived from psychology. It describes the human capacity to learn from experience by reasoning the outcome of an alternative action that could have been taken (Pearl and Mackenzie, 2018). Combined with the SCM, counterfactual reasoning improves the performance of policy evaluation in reinforcement learning (Buesing et al., 2019; Oberst and Sontag, 2019). In the area of NLP, counterfactual reasoning in previous work is mainly used for data augmentation (Qin et al., 2019; Fu et al., 2020; Kaushik et al., 2020), which rewrites the original data given a counterfactual label or condition. In this paper, we connect the concept of counterfactual reasoning with the dialogue generation and are the first to cast a generation model as an SCM under the adversarial learning framework.

3 Method

We cast a dialogue generation model as an SCM to explore potential responses by counterfactual reasoning during the training process. We will first review the concept of the SCM (Sec. 3.2), and then introduce our COPT approach (Sec. 3.3).

3.1 Notation

We use capital letters for random variables (e.g., V), lowercase letters for instances of random variables (e.g., v), and bold letters for vectors (e.g., $\boldsymbol{V} = \{V_1, ..., V_N\}$). During the training process, we denote the response generated by COPT as *counterfactual response*. In contrast, the response of standard adversarial learning-based dialogue

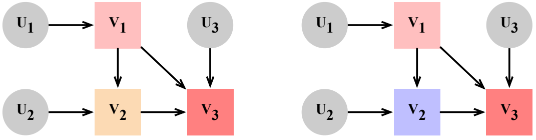

Figure 2: An example of an SCM and an intervention. **Left:** An SCM with random variables $\boldsymbol{V}$, scenarios $\boldsymbol{U}$, and causal mechanisms $\boldsymbol{F}$ represented by colored squares. **Right:** A new SCM after taking an intervention on the left SCM. The original causal mechanism $f_2(\boldsymbol{V}_1, \boldsymbol{U}_2)$ (denoted by the orange square) is replaced by $f_2^T(\boldsymbol{V}_1, \boldsymbol{U}_2)$ (denoted by the purple square).

generation (i.e., REGS Li et al., 2017a) is denoted as *standard response*.

3.2 Background: Structural Causal Model

A structural causal model over random variables $\boldsymbol{V} = \{\boldsymbol{V}_1, ..., \boldsymbol{V}_N\}$ consists of independent noise random variables $\boldsymbol{U} = \{\boldsymbol{U}_1, ..., \boldsymbol{U}_N\}$ with distribution $P_{\boldsymbol{U}}$ and deterministic functions $\boldsymbol{F} = \{f_1, ..., f_N\}$ such that $\boldsymbol{V}_i = f_i(\boldsymbol{PA}_i, \boldsymbol{U}_i)$, where $\boldsymbol{PA}_i \subset \boldsymbol{V}$ are the parents of $\boldsymbol{V}_i$ in a given DAG (Buesing et al., 2019). $\boldsymbol{U}$ is called *scenarios*, and $\boldsymbol{F}$ is called *causal mechanisms*. Figure 2 (Left) shows an example of an SCM. Each random variable $\boldsymbol{V}_i$ is determined by its parents in $\boldsymbol{V}$, $\boldsymbol{U}_i$, and f_i, e.g., $\boldsymbol{V}_2 = f_2(\boldsymbol{V}_1, \boldsymbol{U}_2)$.

During the training process, we cast a dialogue generation model as an SCM over two random variables: dialogue history $\boldsymbol{X}$ and response $\boldsymbol{Y}$. This is achieved by converting the conditional distribution $P(\boldsymbol{Y}|\boldsymbol{X})$ into a deterministic function $\boldsymbol{Y} = f_\pi(\boldsymbol{X}, \boldsymbol{U})$ (for more details see Sec. 3.3). The scenario $\boldsymbol{U}$ is a random noise variable that captures all unobserved yet relevant properties, like user profiles. The causal mechanism is denoted as f_π to highlight the role of the policy (parameters) π of the model. The dialogue generation SCM makes it possible to sample counterfactual responses in the scenario where observed responses occur. This improves the quality of synthesized responses and subsequently helps the model to explore the high-reward area of the potential response space in the training process.

Intervention in SCM Given an SCM, an intervention T is defined as the replacement of some causal mechanisms. Figure 2 shows an example of intervention. The original causal mechanism $f_2(\boldsymbol{V}_1, \boldsymbol{U}_2)$ in the left SCM is replaced with $f_2^T(\boldsymbol{V}_1, \boldsymbol{U}_2)$, resulting in a new SCM in the right. Accordingly, intervention in our dialogue generation SCM denotes the update of the policy. For instance, the update from the behavior policy μ that generates observed responses to the target policy π that we aim to learn is the intervention of replacing $f_\mu(\boldsymbol{X}, \boldsymbol{U})$ with $f_\pi(\boldsymbol{X}, \boldsymbol{U})$.

Counterfactual Reasoning in SCM Given an SCM and observed a variable $\boldsymbol{V}_i = \boldsymbol{v}_i$, counterfactual reasoning answers the question: *"What the variable $\boldsymbol{V}_i$ would have been if I take an intervention T while remaining everything else unchanged"*. In this way, generating a counterfactual response can be seen as querying: *"Having observed a response $\boldsymbol{Y} = \boldsymbol{y}$, what the response $\boldsymbol{Y}$ would have been if I take an intervention by following the target policy π, rather than the behavior policy μ that generates the observed responses"*.

Typically, counterfactual reasoning answers the question by the following steps (as Figure 3):

- Observed $\boldsymbol{Y} = \boldsymbol{y}$ when $\boldsymbol{X} = \boldsymbol{x}$, infer the scenario $\boldsymbol{u}$ in hindsight from $\boldsymbol{Y} = f_\mu(\boldsymbol{X}, \boldsymbol{U})$.
- Take an intervention by replacing the causal mechanism $f_\mu(\boldsymbol{X}, \boldsymbol{U})$ with $f_\pi(\boldsymbol{X}, \boldsymbol{U})$.
- Reason a counterfactual response $\hat{\boldsymbol{y}} = f_\pi(\boldsymbol{x}, \boldsymbol{u})$ by the resulting new SCM.

In the following sections, we denote an observed response from the training set as $\boldsymbol{Y}$ and a model-generated response as $\hat{\boldsymbol{Y}}$.

3.3 Counterfactual Off-Policy Training

Our COPT approach is model-agnostic and can be applied to any adversarial learning-based dialogue generation model. Without loss of generality, we take the combination of COPT and the reward for every generation step (REGS) model (Li et al., 2017a) as an example in this section. It consists of two main components: a generator G and a discriminator D.

Generator The generator G is a sequence to sequence (Seq2Seq) model (Sutskever et al., 2014) equipped with the attention mechanism (Bahdanau et al., 2015; Luong et al., 2015). During the encoding process, G reads the dialogue history into hidden states using an encoder LSTM (Hochreiter and Schmidhuber, 1997):

$$\boldsymbol{H}_i = \text{LSTM}(X_i, \boldsymbol{H}_{i-1}), \tag{1}$$

where X_i is the i-th word of the dialogue history, and $\boldsymbol{H}_i$ denotes the corresponding hidden state.

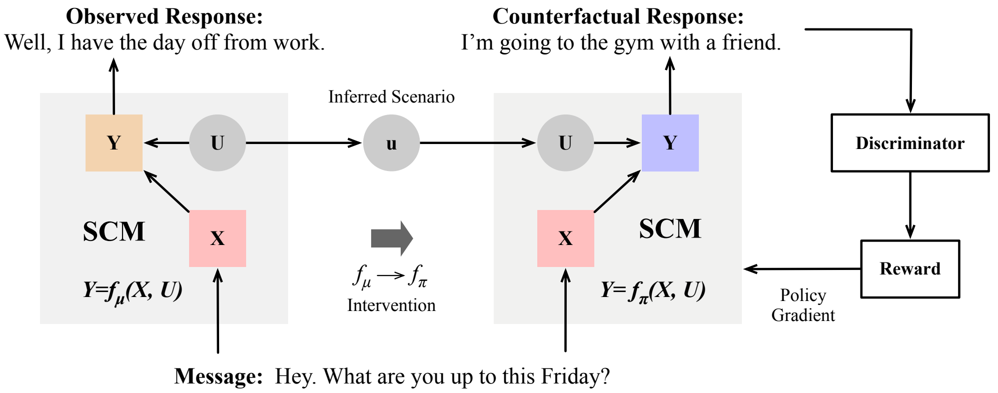

Figure 3: The architecture of our COPT approach. π is the target policy that we aim to learn. μ is the behavior policy that generates observed responses. First, we infer the scenario $\boldsymbol{u}$ where the observed response occurs. Then we update the policy from μ to π, which can be seen as an intervention on the left SCM and results in the right SCM. Then, the counterfactual response is reasoned in the inferred scenario $\boldsymbol{u}$ by the causal mechanism $\boldsymbol{Y} = f_\pi(\boldsymbol{X}, \boldsymbol{U})$.

At the j-th decoding time step, the hidden states are summarized into a context vector $\boldsymbol{C}_j$ by the attention mechanism. Subsequently, G predicts the distribution of the next word over the vocabulary by a decoder LSTM:

$$\boldsymbol{S}_j = \mathrm{LSTM}([\,\boldsymbol{e}(\hat{Y}_{j-1}), \boldsymbol{C}_j\,], \boldsymbol{S}_{j-1}), \qquad (2)$$

$$\boldsymbol{P}_j^{\pi}(\hat{Y}_j | \boldsymbol{X}, \hat{\boldsymbol{Y}}_{1:j-1}) = \mathrm{softmax}(\boldsymbol{S}_j \cdot \boldsymbol{O}), \qquad (3)$$

where the bracket $[\cdot,\cdot]$ denotes concatenation, and $\boldsymbol{e}(\cdot)$ denotes the embedding of a word. $\boldsymbol{S}_j$ is the j-th hidden state of the decoder LSTM. $\hat{Y}_{j-1}$ is the word generated in the previous time step. $\boldsymbol{O}$ is the output matrix. We use the superscript in $\boldsymbol{P}_j^{\pi}$ to highlight the role of the policy (parameters of G).

Adversarial learning-based dialogue generation model is optimized according to the reward of responses sampled from $\boldsymbol{P}_j^{\pi}(\hat{Y}_j | \boldsymbol{X}, \hat{\boldsymbol{Y}}_{1:j-1}) \in \mathbb{R}^{|V|}$ (abbreviated as $\boldsymbol{P}_j^{\pi}$ in the following), where $|V|$ is the vocabulary size. Using the Gumbel-Max Trick (Luce, 2012), the sampling process can be achieved by:

$$\hat{Y}_j = \arg\max\nolimits_{\hat{Y}_j} (\log \boldsymbol{P}_j^{\pi} + \boldsymbol{U}_j), \qquad (4)$$

where the element of $\boldsymbol{U}_j$ follows the standard Gumbel distribution. In this way, the generator turns into a Gumbel-Max SCM (Oberst and Sontag, 2019), whose scenarios and causal mechanisms are represented by $\boldsymbol{U}_j$ and Equation 4, respectively.

From the perspective of the SCM, each response is generated in a scenario. For instance, a standard response is produced in a scenario sampled from scratch. In contrast, the scenario for a counterfactual response is inferred from an observed response $\boldsymbol{y} = \{y_j | \, y_j = \arg\max_{y_j} (\log \boldsymbol{p}_j^{*} + \boldsymbol{u}_j)\}$, where $*$ is the user's policy that generates the observed response in the true environment. However, the user's policy is not available in practice, which hinders the posterior inference of the scenario. To this end, we introduce a behavior policy μ instead and learn it by minimizing the MLE loss on observed responses. In this way, an observed response can be seen as generating in a scenario $\boldsymbol{u}_j$ while following the policy μ: $y_j = \arg\max_{y_j} (\log \boldsymbol{p}_j^{\mu} + \boldsymbol{u}_j)$.

According to Oberst and Sontag (2019), there are two ways to infer the scenario $\boldsymbol{u}_j$ in hindsight from $y_j = \arg\max_{y_j} (\log \boldsymbol{p}_j^{\mu} + \boldsymbol{u}_j)$ given y_j and μ. One way is the rejection sampling, which samples $\boldsymbol{u}_j$ from the standard Gumbel distribution and rejects those where $y_j \neq \arg\max_{y_j} (\log \boldsymbol{p}_j^{\mu} + \boldsymbol{u}_j)$. The other way of the posterior inference makes use of the properties of the shifted Gumbel $\boldsymbol{g} = \log \boldsymbol{p}_j^{\mu} + \boldsymbol{u}_j$: the maximum of $\boldsymbol{g}$ follows the standard Gumbel distribution and is independent with the argmax of $\boldsymbol{g}$ (Maddison et al., 2014). Therefore, $\boldsymbol{g}$ can be obtained by first sampling a maximum and then sampling the remaining elements truncated at the maximum. And $\boldsymbol{u}_j$ is subsequently computed by subtracting $\log \boldsymbol{p}_j^{\mu}$ from $\boldsymbol{g}$. We employ the second method to infer the scenario in COPT because it is more time-efficient than rejection sampling[1].

Given the scenario inferred from the observed response, COPT reasons the counterfactual response by feeding the dialogue history and the scenario into the SCM (Equation 4). Then the discriminator evaluates the counterfactual response and returns

---

[1] In our experiments, using the second sampling method takes 0.79 seconds training on a batch when the batch size is 64. In contrast, the rejection sampling takes roughly 1.45 hours, making it hard to be used in practice.

a reward to the generator. Note that the counterfactual response and the SCM are utilized for the training process. During the inference process, responses are generated in the same way as the standard adversarial learning-based dialogue generation (beam search or sampling from $\boldsymbol{P}_j^{\pi}$, we use the former in our approach) because the observed response is not available.

Discriminator The discriminator D provides a reward for each generation step. It takes as input the dialogue history $\boldsymbol{X}$, the word $\tilde{Y}_j$ produced in the current generation step, and the prefix $\tilde{\boldsymbol{Y}}_{1:j-1}$ in previous steps, where $\tilde{\boldsymbol{Y}} \in \{\boldsymbol{Y}, \hat{\boldsymbol{Y}}\}$ can be either an observed response or a model-generated response. The output reward $D(\tilde{Y}_j|\boldsymbol{X}, \tilde{\boldsymbol{Y}}_{1:j-1})$ is the probability that $\tilde{Y}_j$ is human-generated. Concretely, D first reads $\boldsymbol{X}$ and $\tilde{\boldsymbol{Y}}_{1:j}$ with an encoder-decoder model. Then, it computes the reward by a Multi-Layer Perceptron (MLP), which takes as input the last hidden state of the decoder.

Adversarial Learning We train G and D under the adversarial learning framework, where G tries to fool D by generating human-like responses while D aims to distinguish between model-generated and human-generated (the observed) responses. Since a response is a sequence of discrete tokens, we pass by the gradient of D to G using the policy gradient algorithm. In this way, G converts into an agent whose partially generated response and parameters define a state and a policy, respectively. At each generation step, the agent takes an action by producing a word and observes a reward from D to update its policy.

Note that there are two policies in COPT: the target policy that we aim to learn and the behavior policy used for the reasoning of scenarios. The behavior policy is pre-trained and then froze during adversarial learning because it aims to maximize the likelihood of a fixed set of observed responses. Introducing the behavior policy makes COPT an off-policy approach because the counterfactual response, from which the target policy learns, is not entirely based on the target policy itself.

The goal of the generator is to minimize the negative expected reward: $J_G(\boldsymbol{\theta}) = -\mathbb{E}_{\hat{\boldsymbol{Y}}_{1:j} \sim G} D(\hat{Y}_j|\boldsymbol{X}, \hat{\boldsymbol{Y}}_{1:j-1})$, where $\boldsymbol{\theta}$ is the parameters of π. The gradient of $\boldsymbol{\theta}$ can be derived by the likelihood ratio trick (Williams, 1992):

$$\begin{aligned}\triangledown J_G(\boldsymbol{\theta}) = &- \mathbb{E}_{\hat{\boldsymbol{Y}}_{1:j} \sim G} D(\hat{Y}_j|\boldsymbol{X}, \hat{\boldsymbol{Y}}_{1:j-1}) \\ &\cdot \triangledown \log G_{\pi}(\hat{Y}_j|\boldsymbol{X}, \hat{\boldsymbol{Y}}_{1:j-1}),\end{aligned} \tag{5}$$

where $G_{\pi}(\hat{Y}_j|\boldsymbol{X}, \hat{\boldsymbol{Y}}_{1:j-1})$ is the probability of generating $\hat{Y}_j$ with the policy π given $\boldsymbol{X}$ and $\hat{\boldsymbol{Y}}_{1:j-1}$.

Algorithm 1 Counterfactual Off-Policy Training

```
Pre-train $\pi$ and $\mu$ with MLE loss;
Pre-train $D$ on positive instances sampled from observed responses, and negative instances generated by pre-trained $\pi$;
for epoch in number of epochs do
    for $g$ in g-steps do
        Infer $\boldsymbol{u}$ from an observed response;
        Generate a counterfactual response in $\boldsymbol{u}$;
        Optimize $\boldsymbol{\theta}$ according to Equation 5;
    end for
    for $d$ in d-steps do
        Sample positive instances from observed responses;
        Sample negative instances from responses generated by $\pi$;
        Update $\boldsymbol{\phi}$ according to Equation 6;
    end for
end for
```

The discriminator distinguishes between observed responses and model-generated responses. This is achieved by minimizing the following loss:

$$\begin{aligned}J_D(\boldsymbol{\phi}) = &- \mathbb{E}_{\boldsymbol{Y}_{1:j} \sim \boldsymbol{S}} \log D(Y_j|\boldsymbol{X}, \boldsymbol{Y}_{1:j-1}) \\ &- \mathbb{E}_{\hat{\boldsymbol{Y}}_{1:j} \sim G} \log(1 - D(\hat{Y}_j|\boldsymbol{X}, \hat{\boldsymbol{Y}}_{1:j-1})),\end{aligned} \tag{6}$$

where $\boldsymbol{\phi}$ is the parameters of D. As a positive instance, $\boldsymbol{Y}_{1:j}$ is a prefix randomly sampled from observed response set $\boldsymbol{S}$. A negative instance $\hat{\boldsymbol{Y}}_{1:j}$ for training D is a prefix of a standard response, rather than a counterfactual response. This is because the latter is of higher quality than the former (as shown in Sec. 4.7).

Pre-training Initialized with different parameters, π and μ are pre-trained on the training set with MLE loss. The pre-training of D depends on the specific model that COPT applied to. For example, REGS pre-trains D on the prefix of a response. In contrast, the discriminator of StepGAN (Tuan and Lee, 2019) is randomly initialized during the adversarial learning process. The overall algorithm of COPT is summarized as Algorithm 1.

Training Dialogues	11,118
Validation Dialogues	1,000
Test Dialogues	1,000
Average Tokens Per Dialogue	114.7
Average Tokens Per Utterance	14.6

Table 1: Statistics of the DailyDialog dataset.

4 Experiments

4.1 Data

The experiments are conducted on the DailyDialog dataset (Li et al., 2017b).[2] It is a multi-turn dialogue dataset and covers various topics of daily life. The dataset has already been divided into training, validation, and test sets, as shown in Table 1. Given a dialogue that consists of K utterances, we divide it into K-1 instances. Each instance has at most three continuous utterances. The last utterance is the response, and the previous utterances are concatenated as the dialogue history.

4.2 Baselines

We compare COPT with the following dialogue generation models:

- HRED (Serban et al., 2016): The hierarchical recurrent encoder-decoder. An implementation by Park et al. (2018) is available[3].
- REGS (Li et al., 2017a): Reward for every generation step. Its discriminator is trained on partially generated responses to provide a reward for each generation step.
- DPGAN (Xu et al., 2018): The diversity-promoting GAN introduces a language model based discriminator to encourage the generation of informative responses.[4]
- StepGAN (Tuan and Lee, 2019): The stepwise GAN trains the discriminator by maximizing the average of state-action values of observed responses. During the adversarial learning process, the discriminator assigns scores for every generation step in the same way as REGS.

Distinct from previous approaches, COPT casts a dialogue generation model as an SCM and trains it on counterfactual responses. It is model-agnostic and can be applied to any adversarial learning-based dialogue generation model, such as REGS, DPGAN, and StepGAN.

Model	Time (s/epoch)
HRED	84
DPGAN	608
REGS	912
REGS+COPT	1,215
StepGAN	951
StepGAN+COPT	1,244

Table 2: The average training time (in seconds per epoch) on a single GPU.

4.3 Training Details

We implement REGS, StepGAN, and their variants with COPT using OpenNMT (Klein et al., 2017), an open-source framework for building sequence to sequence models. We manually tune the parameters according to the perplexity on the validation set. The vocabulary consists of the most frequent 10,000 words. Including more words (up to 17,438, the total number of DailyDialog vocabulary) observes no improvement but takes more time for training. We use 300 dimensional GloVe (Pennington et al., 2014) vectors to initialize word embeddings. Both the encoder and the decoder are a two-layer LSTM in G and a single layer LSTM in D. The number of hidden units is 500.

During the adversarial learning process, we use the ADAM algorithm to alternately optimize G and D for one batch and five batches. The batch size is 64. We have tested the learning rate from 1e-6 to 1e-3. REGS+COPT and StepGAN+COPT achieve the best performance on 1e-5. The number of parameters for all the baselines is in a range of 21M to 26M. Equipping an adversarial learning baseline with COPT will introduce extra parameters with the same amount of the generator's parameters. Contributed by the behavior policy, the parameters are learned by pre-training, and COPT will not increase the number of trainable parameters in adversarial learning. Table 2 shows the average training time. COPT may increase the training time due to the posterior inference of scenarios. But it facilitates the exploration of the high-reward area of the potential response space and subsequently improves the quality of responses.

4.4 Evaluation Metrics

Automatic Evaluation We evaluate the diversity and the relevance of generated responses using *distinct* (Li et al., 2016) and *BLEU* (Papineni et al., 2002), respectively. The distinct-k is the number of distinct k-grams normalized by the number of words of responses. Since BLEU might correlate weakly with human judgments of quality in the single-reference setting (Liu et al., 2016), we use the multi-reference DailyDialog test set (Gupta et al., 2019), where each instance is augmented with four human-written diverse responses.[5]

Human Evaluation The human evaluation is conducted on 200 instances randomly sampled from the test set. We create a project on Amazon Mechanical Turk (Buhrmester et al., 2016) (AMT) and employ five AMT workers to give a preference between two responses generated by our approach and a baseline.[6] To maintain the quality of the evaluation, the task is visible to workers whose approve rate is greater than 95%, and the number of approved is greater than 500.

4.5 Results

Table 3 shows the results of automatic evaluation. Both REGS and StepGAN outperform HRED in distinct-1 and distinct-2, indicating that adversarial learning is beneficial for improving the diversity of responses. There is no increase in DPGAN compared with HRED in our experiments. We believe this is because the scale of the DailyDialog dataset is not large enough for sufficiently training the language model based discriminator. For the same reason, COPT is not added to DPGAN. After introducing COPT, both distinct-1 and distinct-2 in REGS and StepGAN further increase, and the improvement is significant (t-test, p <0.01). This suggests that COPT is model-agnostic to adversarial learning-based approaches and helps to promote the diversity. In terms of BLEU in Table 3, both REGS and StepGAN achieve higher BLEU scores with COPT, and the improvements of BLEU-1 and BLEU-2 are significant (p <0.05). This demonstrates the effectiveness of COPT in improving the relevance of responses. The less significant result of BLEU-3 and BLEU-4 is mainly due to the sparsity of tri-grams and four-grams, which are harder to be covered by references than uni-grams and bi-grams.

The human evaluation results are shown in Table 5. Our approach is clearly preferred as it

Figure 4: Reward distribution and the average reward of the counterfactual response (w/ COPT) and the standard response (w/o COPT). The y-axis in (a) and (b) is the percentage, and the x-axis corresponds to three reward intervals in different epochs, including: **L**ow reward interval [0.00, 0.33], **M**iddle reward interval (0.33, 0.66], and **H**igh reward interval (0.66, 1.00]. The y-axis in (c) and (d) is the reward, and the x-axis corresponds to epochs.

	Win	Tie	Lose
REGS+COPT vs. HRED	63.15	13.20	23.65
REGS+COPT vs. REGS	32.28	43.81	23.92
StepGAN+COPT vs. HRED	65.95	15.38	18.67
StepGAN+COPT vs. StepGAN	45.69	20.91	33.40

Table 5: Wins, losses, and ties (in %) of our approach against baselines based on the human evaluation.

has more winning instances than losing instances (p <0.01). The results indicate that COPT helps improve the quality of responses. Following Zhou et al. (2018) and Ke et al. (2018), we measure the agreement of annotators using inter-rater consistency. The percentage of instances that at least three annotators have the same preference (3/5 agreement) is 84.18%. The percentage for 4/5 agreement is 46.89%.

4.6 Case Study

Table 4 shows an example of responses generated by baselines and our approach. The response of DPGAN sometimes is not fluent and can be very long. We believe this is also because the scale of the DailyDialog dataset is not enough for the language model discriminator. The response of HRED is not as informative as that of our approach. Its first part is generic, and what the pronoun "that" refers to is not clear. The response of StepGAN is not informative enough as well. In contrast, the response of REGS is quite informative, but its content is not entirely relevant to the dialogue history. After introducing COPT, the responses of REGS+COPT and StepGAN+COPT propose offering a discount to address Person B's concern of the price, which is both informative and relevant.

4.7 Analysis

To further analyze COPT's effectiveness in exploring the high-reward area of the potential response space during the training process, we compare the reward of a counterfactual response and a standard response on the same 10,000 randomly sampled training instances. However, the comparison between the two types of responses could be biased if their rewards are computed by different discriminators. Besides, the quality of responses is determined not only by the way they generated (with or without COPT) but also by the generator. To focus on the analysis of COPT and eliminate the bias between generators and discriminators, we generate and evaluate the two types of responses using an identical generator and its corresponding discriminator. Here, we use REGS+COPT and StepGAN+COPT as testbeds because they could generate both the two types of responses.

Figure 4 shows the distribution of rewards and the average reward. The percentage of counterfactual responses in the high reward interval (0.66, 1.00] is higher than that of standard responses. Meanwhile, counterfactual responses generated with COPT achieve a higher average than standard responses. The results demonstrate the effectiveness of the counterfactual response in exploring the high-reward area of the potential response space during the training process. Note that the distribution and the average between different epochs are not comparable due to the update of the discriminator as the training processes.

5 Conclusion

We propose a model-agnostic approach, COPT, that can be applied to any adversarial learning-based dialogue generation models. In contrast to existing approaches, it learns on counterfactual responses inferred from the structural causal model, taking advantage of observed responses. This helps the model to explore the high-reward area of the potential response space. Experiments show that the COPT significantly improves the quality of the generated responses, which demonstrates the effectiveness of this approach.

Abstract

Recent advances in open-domain dialogue systems rely on the success of neural models that are trained on large-scale data. However, collecting large-scale dialogue data is usually time-consuming and labor-intensive. To address this data dilemma, we propose a novel data augmentation method for training open-domain dialogue models by utilizing unpaired data. Specifically, a data-level distillation process is first proposed to construct augmented dialogues where both post and response are retrieved from the unpaired data. A ranking module is employed to filter out low-quality dialogues. Further, a model-level distillation process is employed to distill a teacher model trained on high-quality paired data to augmented dialogue pairs, thereby preventing dialogue models from being affected by the noise in the augmented data. Automatic and manual evaluation indicates that our method can produce high-quality dialogue pairs with diverse contents, and the proposed data-level and model-level dialogue distillation can improve the performance of competitive baselines.

1 Introduction

Open-domain dialogue systems have attracted much research attention (Shum et al., 2018; Huang et al., 2020), thanks to the success of neural generation models trained with large-scale data. Existing research has been endeavored to address various aspects in dialogue systems, such as modeling persona (Qian et al., 2018; Zheng et al., 2019; Zhang et al., 2018), expressing emotion (Zhou et al., 2018a), or generating knowledge-grounded dialogues (Ghazvininejad et al., 2018; Zhou et al., 2018b, 2020).

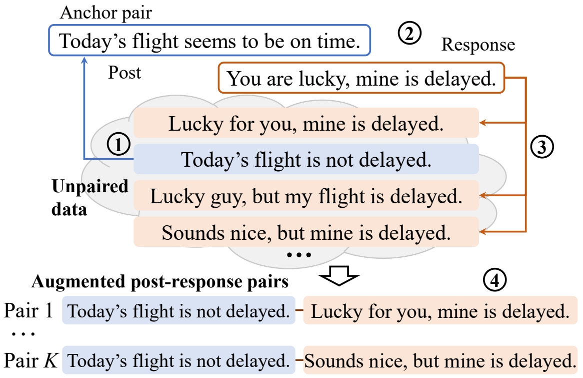

Figure 1: Process of constructing augmented post-response pairs. The sentence in blue rectangle is used to match the anchor pair and the corresponding response is then used to retrieve similar sentences in unpaired data. Each augmented pair contains two sentences both from unpaired data.

In general, training neural open-domain dialogue models requires a large amount of high-quality *paired data*, e.g., post-response pairs, which are usually labor-intensive and time consuming to collect. A feasible solution to this data dilemma is to use data augmentation techniques, which are popular in various research areas such as computer vision (Cubuk et al., 2019) or machine translation (Sennrich et al., 2016). Nevertheless, this technique is rarely investigated in the study of open-domain dialogues, and few existing approaches are specifically designed for either the generation-based dialogue models (Li et al., 2019) or the retrieval-based dialogue models (Du and Black, 2018). Moreover, existing data augmentation approaches only take a set of paired data as input without considering to utilize unpaired data.

As a matter of fact, high-quality *unpaired data*, i.e., non-conversational texts, are generally easier to collect compared to high-quality dialogue pairs. Specifically, these unpaired data provide us a rich

bank of alternative expressions for different contents. It is thus feasible to augment the training dialogue pairs utilizing sentences extracted from the unpaired data. As shown in Figure 1, we can extract various sentences from the unpaired data that are similar to a given post-response pair (i.e., anchor pair). Augmented pairs that carry richer expressions can be then constructed by combining these extracted sentences. To the best of our knowledge, there are no previous studies for open-domain dialogues that try to construct augmented dialogue pairs by utilizing retrieved unpaired data.

In this paper, we propose a novel data augmentation method "**Dialogue Distillation**" to improve the performance of open-domain dialogue models by utilizing unpaired data. Our method involves two phases of distillation. The first phase is at the data level as it constructs (i.e., distills) post-response pairs by matching sentences retrieved from a set of unpaired data. Specifically, given a set of training pairs $\{\langle x_i, y_i \rangle\}$, a randomly selected sentence s is firstly used as a query to retrieve the most similar x_i, and then the corresponding y_i are used as queries to retrieve similar s_i from the unpaired data. Augmented pairs $\langle s, s_i \rangle$ are then constructed and filtered using a ranking module. Note that different from previous approaches, *the post and response sentences that constitute an augmented pair are both from the unpaired data*, which are human written and thereby fluent and content-rich. The second phase is at the model-level as it distills a teacher model using the augmented data. Specifically, we borrow the idea of knowledge distillation (Hinton et al., 2015) to first train a teacher model on a set of high-quality dialogue pairs, and then distill the dialogue model by mimicking the distribution produced by the teacher model on the augmented data to prevent the final dialogue models from being affected by the noise in the augmented data.

Automatic and manual evaluation results indicate that our data-level distillation process can produce high-quality post-response pairs that are content-rich, and our model-level distillation process can better utilize these augmented data to improve the performance of both retrieval-based and generation-based open-domain dialogue models.

Our contributions are summarized as follows:

1) We propose a data-level and model-level distillation method for open-domain dialogue models. The data-level distillation constructs new post-response pairs where both post and response are retrieved from unpaired data, and the model-level distillation distills a teacher model trained on high quality paired data to augmented pairs. To the best of our knowledge, this is the first attempt to augment open-domain dialogue pairs by utilizing the retrieved unpaired data.

2) Automatic and manual evaluation shows that the augmented pairs produced by our method are content-rich, and these augmented data can be used to improve the performance of both generation-based and retrieval-based dialogue models.

2 Related Work

There are two major categories of open-domain dialogue models: 1) retrieval-based models, which retrieve the best matching response from the pre-collected dialogues (Lu and Li, 2013); and 2) generation-based models, which decode responses from a learned distribution (Sutskever et al., 2014; Vinyals and Le, 2015). Recent advances in these two categories all focus on DNN-based data-driven methods (Huang et al., 2020).

Data augmentation is an effective approach to boost the performance of neural models. It has been explored in various NLP tasks, such as text classification (Wei and Zou, 2019; Zheng et al., 2020a), machine reading comprehension (Yu et al., 2018) and machine translation (Sennrich et al., 2016). Although proved to be effective, this technique is rarely investigated in open-domain dialogue models. Few existing approaches are restricted to only take the dialogue pairs as their inputs (Li et al., 2019; Zhao et al., 2017; Cai et al., 2020), whereas unpaired texts, i.e., sentences without replies, are not utilized.

Note that the pre-training based methods (Devlin et al., 2019; Radford et al., 2019; Golovanov et al., 2019; Zheng et al., 2020b) share a similar motivation with our study, i.e., to boost the performance of neural NLP models utilizing unlabeled (i.e., unpaired) texts. Nevertheless, the data augmentation method proposed in our study can be regarded as a supplement to these pre-training approaches. Experiments demonstrate that our method can be used to improve the performance of dialogue models even if these models are initialized with strong pre-trained models.

Our study is also related to the knowledge distillation method (Hinton et al., 2015), which also employs a teacher model and tries to minimize

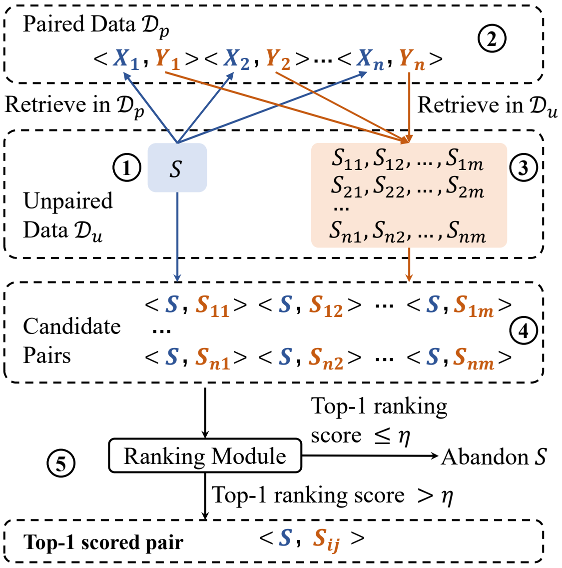

Figure 2: Framework of data-level distillation. (1) The sentence S is randomly selected in the unpaired data $\mathcal{D}_u$. (2) A set of posts $X_1, \ldots, X_n$ that are similar to S are retrieved from the paired data $\mathcal{D}_p$. (3) Each corresponding response Y_i is then used to retrieve m sentences $S_{i1}, \ldots, S_{im}$ that are similar to Y_i from $\mathcal{D}_u$. (4) Then $n \times m$ candidate pairs can be formed by grouping S with each sentence: $\langle S, S_{ij} \rangle$, $(i = 1, \ldots, n,$ $j = 1, \ldots, m)$. (5) A ranking module is used to rank these candidate pairs.

the KL divergence between the teacher distribution and the model distribution. The most related work in this branch compared to ours was done by Kim and Rush (2016). However, their methods do not utilize unpaired data, and the augmented data are decoded from a probability model using beam search. Whereas our method tries to utilize the unpaired data, and the augmented data are generated by aligning human produced sentences.

There are also works that try to utilize retrieved non-conversational texts to improve the diversity of the dialogue model (Wu et al., 2019; Cai et al., 2019; Zhu et al., 2019; Su et al., 2020). However, most of these studies focus on extracting templates from these non-conversational texts rather than generating augmented pairs, and they typically use specifically designed model structures. Nevertheless, the data augmentation method proposed in our study can be used in combination with any dialogue models to improve the performance.

3 Data-level Distillation

The data-level distillation in our method aims at constructing a set of new post-response pairs $\mathcal{D}_a$ by matching non-parallel sentences retrieved from unpaired data $\mathcal{D}_u$. Specifically, $\mathcal{D}_p$ consists of N post-response pairs: $\mathcal{D}_p = \{\langle X_i, Y_i \rangle\}_{i=1}^{N}$, in which X_i and Y_i is the post and response, respectively, and $\mathcal{D}_u$ consists of M non-parallel sentences: $\mathcal{D}_u = \{S_i\}_{i=1}^{M}$. Note that M is usually much larger than N because non-parallel sentences are generally easier to collect.

Further, the output of our data-level distillation process is a set of augmented post-response pairs: $\mathcal{D}_a = \{\langle X_i', Y_i' \rangle\}_{i=1}^{K}$, in which both the post and response come from the unpaired dataset $\mathcal{D}_u$, i.e., $X_i' \in \mathcal{D}_u$ and $Y_i' \in \mathcal{D}_u$ for $i = 1, \ldots, K$.

The data-level distillation involves two major processes: 1) constructing candidate pairs and 2) filtering low-quality candidates. The whole framework is shown in Figure 2 and detailed below.

3.1 Constructing Candidate Pairs

We first construct candidate dialogue pairs with the help of some post-response pairs $\langle X_i, Y_i \rangle$ selected from $\mathcal{D}_p$. The basic intuition is that sentences that are similar to post X_i can usually be responded with sentences that are similar to the corresponding response Y_i. Candidate dialogue pairs can be then constructed by anchoring sentences in $\mathcal{D}_u$ using $\langle X_i, Y_i \rangle$.

The construction of candidate pairs starts by randomly selecting a sentence S from the unpaired dataset $\mathcal{D}_u$. We then treat S as a candidate post, and it is used to retrieve n posts X_i $(1 \leq i \leq n)$ that are similar to S from the paired data $\mathcal{D}_p$. In this study, the sentence retrieval process is implemented based on the Okapi BM25 algorithm, which scores the similarity of input sentences using bag-of-words features. Then the corresponding n post-response pairs $\langle X_i, Y_i \rangle$ $(1 \leq i \leq n)$ are extracted from $\mathcal{D}_p$. For each response Y_i, we further retrieve m sentences S_{ij} $(1 \leq j \leq m)$ that are similar to Y_i from the unpaired dataset $\mathcal{D}_u$. These sentences S_{ij} can then serve as candidate responses to the original sentence S, and therefore $n \times m$ candidate pairs $\langle S, S_{ij} \rangle$, $(1 \leq i \leq n,\ 1 \leq j \leq m)$ are generated. Moreover, for each candidate pair $\langle S, S_{ij} \rangle$, we name the post-response pair $\langle X_i, Y_i \rangle$ in $\mathcal{D}_p$ that are used to produce $\langle S, S_{ij} \rangle$ as its *"anchor pair"* since it anchors the sentences S and S_{ij} from $\mathcal{D}_u$.

Note that we have explored other variants of the above process, such as treating the initial sentence S as a candidate response rather than a candidate post or utilizing more advanced text retrieval methods to extract similar sentences. However, we notice little difference in neither the quality of the final augmented pairs nor the performance improvement brought to the dialogue models.

3.2 Filtering Candidate Pairs

In order to enhance the quality of the augmented data, we propose to filter out low-quality pairs using a ranking module, which calculates a score for each candidate pair obtained above. Specifically, high-quality pairs that are fluent and coherent are expected to receive high scores. In this study, we implement the score function as a text matching model, which is built by fine-tuning a pre-trained BERT model on the paired dataset $\mathcal{D}_p$. Negative samples are constructed by replacing the original responses using randomly sampled sentences from $\mathcal{D}_p$. The ranking score for each input pair is calculated as the matching score produced by the matching model.

In this study, we follow a quite rigorous policy to select the final augmented pairs in $\mathcal{D}_a$. For each sample sentence S from $\mathcal{D}_u$, we only extract the top-1 scored pair $\langle S, S_{ij} \rangle$ among all its $n \times m$ candidate pairs, and $\langle S, S_{ij} \rangle$ is added to $\mathcal{D}_a$ only when its matching score exceeds a certain threshold $\eta (0.9 \leq \eta)$. We repeat the above procedures with newly sampled sentences from $\mathcal{D}_u$ until a desired number of augmented pairs in $\mathcal{D}_a$ are obtained. The whole data-level distillation process in our method is summarized in Algorithm 1.

Note that the matching model used in the ranking process can also be directly used to align sentences from the unpaired dataset $\mathcal{D}_u$. Specifically, for a sampled sentence S from $\mathcal{D}_u$, we can treat all other sentences in $\mathcal{D}_u$ as its candidate response and select an augmented pair by ranking all these candidates. Although theoretically possible, this approach is practically infeasible considering the large amount of sentences in $\mathcal{D}_u$ and the tremendous computational load to rank these candidates. Note that previous works on effective ranking (such as Henderson et al. (2017, 2020)) can not be directly adapted to this study because our ranking model does not use dot-product scoring function.

4 Model-level Distillation

A straightforward way to improve a dialogue model with the augmented dialogue data is to directly merge the original paired data $\mathcal{D}_p$ with $\mathcal{D}_a$. However, this naive approach may lead to sub-optimal performance since the augmented pairs in $\mathcal{D}_a$ might not be as high-quality as these human-crafted pairs in $\mathcal{D}_p$. In this study, we apply the model-level distillation in the training process to prevent the dialogue models from being affected by the noise in $\mathcal{D}_a$. This approach can be used in both retrieval-based and generation-based dialogue models.

Algorithm 1 Data-level distillation process

```
Input: A set of unpaired data $\mathcal{D}_u=\{S_i\}_{i=1}^M$, a set of paired
       data $\mathcal{D}_p=\{\langle X_i, Y_i \rangle\}_{i=1}^N$, a threshold $\eta$.
Output: Augmented dialogue pairs $\mathcal{D}_a=\{\langle X_i', Y_i' \rangle\}_{i=1}^K$.
$\mathcal{D}_a \leftarrow$ Empty set
while $|\mathcal{D}_a| < K$ do
    $\widetilde{\mathcal{D}}_a \leftarrow$ Empty set
    Sample a sentence $S \sim \mathcal{D}_u$.
    Retrieve $n$ posts $\{X_i\}_{i=1}^n$ that are similar to $S$ in $\mathcal{D}_p$.
    Get the responses $\{Y_i\}_{i=1}^n$ for $\{X_i\}_{i=1}^n$ from $\mathcal{D}_p$.
    for each $Y_i$ do
        Retrieve $m$ sentences $\{S_{ij}\}_{j=1}^m$ that are similar to
        $Y_i$ in $\mathcal{D}_u$.
        $\widetilde{\mathcal{D}}_a \leftarrow \widetilde{\mathcal{D}}_a \bigcup \{\langle S, S_{ij} \rangle\}_{j=1}^m$
    end for
    Calculate the ranking score for each pair in $\widetilde{\mathcal{D}}_a$.
    Extract the top-1 scored pair $\langle S, S_{ij} \rangle$ from $\widetilde{\mathcal{D}}_a$.
    if The ranking score of $\langle S, S_{ij} \rangle$ exceeds $\eta$ then
        $\mathcal{D}_a \leftarrow \mathcal{D}_a \bigcup \{\langle S, S_{ij} \rangle\}$
    end if
end while
```

4.1 Retrieval-based Dialogue Model

A retrieval-based dialogue model produces responses by retrieving a best matching sentence from the pre-collected dialogue dataset. Its key component is a matching function $\mathcal{P}_\theta(l|X, Y)$ that predicts whether a response Y matches a given post X. Specifically, $l \in \{0, 1\}$ is a matching label, where $l = 1$ means Y is a proper response for X and $l = 0$ otherwise. The model parameters θ can be learned by optimizing a negative log likelihood (NLL) loss defined as

$$\begin{aligned} \mathcal{L}_{m-nll}(\theta) = & -(1-l)\log\mathcal{P}_\theta(0|X, Y) \\ & - l\log\mathcal{P}_\theta(1|X, Y) \end{aligned} \tag{1}$$

In this study, we formalize the matching function using the BERT model (Devlin et al., 2019; Whang et al., 2020). A teacher model $\mathcal{P}_{\theta_t}(l|X, Y)$ is first obtained by optimizing the NLL loss $\mathcal{L}_{m-nll}(\theta_t)$ on the paired dataset $\mathcal{D}_p$. After the training is completed, the teacher model is fixed and used to compute a knowledge distillation (KD) loss (Kim and Rush, 2016) as

$$\mathcal{L}_{m-kd}(\theta) = -\sum_{i=0}^{1} \mathcal{P}_{\theta_t}(i|X, Y) \cdot \log\mathcal{P}_\theta(i|X, Y). \tag{2}$$

The final matching model is trained on the following loss:

$$\mathcal{L}_M(\theta) = \mathcal{L}_{m-nll}(\theta) + \alpha_m \mathcal{L}_{m-kd}(\theta), \quad (3)$$

where the loss $\mathcal{L}_M(\theta)$ is evaluated using $\mathcal{D}_p \bigcup \mathcal{D}_a$ and α_m is used to balance these two losses.

4.2 Generation-based Dialogue Model

A generation-based dialogue model tries to capture the distribution of the response sentences Y given the post sentence X, i.e., $\mathcal{P}_\phi(Y|X)$, which can be formalized as

$$\mathcal{P}_\phi(Y|X) = \prod_{i=1}^{|Y|} P_\phi(y_i|y_{<i}, X), \quad (4)$$

where $|Y|$ is the length of Y, $y_{<i} = y_1 \cdots y_{i-1}$ is the token sequence before y_i. The model parameters ϕ can be learned by optimizing the NLL loss:

$$\mathcal{L}_{g-nll}(\phi) = -\sum_{i=1}^{|Y|} \log P_\phi(y_i|y_{<i}, X). \quad (5)$$

In this study, we parameterize the dialogue generation model using the Transformer-based encoder-decoder framework (Vaswani et al., 2017; Golovanov et al., 2019; Zheng et al., 2020b). Similar to the retrieval-based approach, a teacher model is first obtained by optimizing the NLL loss $\mathcal{L}_{g-nll}$ on the paired dataset $\mathcal{D}_p$ and the trained teacher model is used to compute a KD loss as

$$\begin{aligned}\mathcal{L}_{g-kd}(\phi) = -\sum_{i=1}^{|Y|}\sum_{j=1}^{|\mathcal{V}|} & P_{\phi_t}(y_i = j|y_{<i}, X) \\ & \times \log P_\phi(y_i = j|y_{<i}, X),\end{aligned} \quad (6)$$

where $|\mathcal{V}|$ denotes the size of the vocabulary and ϕ_t is the parameter of the teacher model, which is fixed.

The final loss for the generation model is:

$$\mathcal{L}_G(\phi) = \mathcal{L}_{g-nll}(\phi) + \alpha_g \mathcal{L}_{g-kd}(\phi), \quad (7)$$

where the loss $\mathcal{L}_G(\theta)$ is evaluated using $\mathcal{D}_p \bigcup \mathcal{D}_a$ and α_g is used to balance these two losses.

5 Experiment

5.1 Dataset

The evaluation of our method is performed on a corpus collected from Weibo[1]. Specifically, the paired data $\mathcal{D}_p$ contains 300K post-response pairs, which are made up of Weibo posts and their following replies. All these pairs are manually filtered with annotators by removing ungrammatical sentences and incoherent dialogues. The unpaired data $\mathcal{D}_u$ contains about 2 million posts on Weibo that do not have replies. Non-fluent sentences in $\mathcal{D}_u$ are filtered out using a set of heuristic rules. Further, two additional sets of paired data are also prepared to validate and test the dialogue models, with 10K and 5K pairs respectively. These dialogue pairs are collected and manually filtered using the same criterion as $\mathcal{D}_p$.

5.2 Implementation Details

Data-level Distillation: We implement the retrieval module in Section 3.1 using the Lucene library [2], and set the value of both n and m to 5. The matching model used in Section 3.2 is fine-tuned with $\mathcal{D}_p$ for three epochs based on the pretrained BERT-base model (Devlin et al., 2019). The hyper-parameter setting of the matching model follows the work of Devlin et al. (2019).

Model-level Distillation: For the *retrieval-based dialogue model*, the matching model used in Section 3.2 is directly used as the teacher model to calculate the KD loss (Eq. 2). The final retrieval-based dialogue model is initialized with the pre-trained BERT-base weights and fine-tuned using the loss in Eq. 3 for 2 epochs on $\mathcal{D}_p \bigcup \mathcal{D}_a$. The value of α_m in Eq. 3 is set to 1.

For the *generation-based dialogue model*, the encoder and decoder share the same set of parameters, which is initialized using a pretrained GPT model (Wang et al., 2020). The teacher model uses the same architecture and it is fine-tuned using the paired dataset $\mathcal{D}_p$ for 15 epochs on the NLL loss (Eq. 5). The final generative dialogue model is first initialized using the pre-trained GPT weights and fine-tuned using the loss in Eq. 7 for 50 epochs on $\mathcal{D}_p$ and $\mathcal{D}_a$. The value of α_g in Eq. 7 is set to 1. Moreover, the GPT model used in the initialization phase is trained on a corpus collected from various Chinese novels. This corpus contains about 0.5 billion tokens and a character-level vocabulary of size 13,084.

See Appendix A for more details of the model setting and reproduction guidance. The data and code for all experiments can be downloaded from

the link[3].

5.3 Evaluating Augmented Dialogue Pairs

5.3.1 Baselines

We first evaluate the quality of the augmented pairs generated by our Data-Level (**DL**) distillation process. Three different matching thresholds η in Algorithm 1 are tested, i.e., η = 0.90, 0.95, 0.99. Several strong baselines are also compared:

CVAE: A CVAE-based model as proposed by Li et al. (2019) is trained on the paired data $\mathcal{D}_p$. Augmented pairs are generated by sampling different latent codes.

BT: Augmented pairs are generated by Back Translating (i.e., translate Chinese to English and then translate back to Chinese) the post sentences of the dialogue pairs in $\mathcal{D}_p$. The translation is done via the Google Translate API.

SP: A variant of our method is implemented by first Sampling a post-response Pair $\langle X, Y\rangle$ from $\mathcal{D}_p$, and then retrieving a best-matching post and response from the unpaired data $\mathcal{D}_u$ using X and Y as the query, respectively. An augmented pair is constructed by pairing the retrieved post and response sentence without the ranking process.

Note that there are two major differences between the baseline SP and our data-level distillation process: 1) the baseline SP starts with a dialogue pair $\langle X, Y\rangle$ sampled from $\mathcal{D}_p$ rather than a candidate post sampled from $\mathcal{D}_u$; 2) The ranking process is not used in the baseline SP to further filter the candidate pairs.

5.3.2 Metrics

The automatic evaluation of augmented dialogue pairs uses the following metrics: 1) ***Distinct*** (Li et al., 2016) is used to measure the proportion of unique n-grams in the augmented dialogue pairs (n=1,2,3,4); 2) ***Novelty*** (Wang and Wan, 2018) is used to measure the proportion of new n-grams in the augmented dialogue pairs (n=1,2,3,4), i.e., n-grams that are covered by the augmented dialogue pairs but are not shown in the paired dataset $\mathcal{D}_p$. A higher novelty score means the augmented dialogue pairs contain more "novel" contents.

Manual evaluation is also used to evaluate the quality of augmented dialogue pairs. Three annotators are employed to rate these pairs from two aspects: 1) *Fluency* (**Flu.**): whether the augmented pairs are fluent; 2) *Coherency* (**Coh.**): whether the response is coherent with the post so that they make a plausible dialogue pair. The rating scale for each measure is of (0, 1, 2), in which 0 means worst and 2 best.

5.3.3 Results

Each data augmentation method introduced above are used to generate 300K augmented dialogue pairs, and on which automatic evaluation is performed. Further, manual evaluation is carried out on 200 dialogue pairs that are randomly sampled from these augmented data, and the inter-rater agreement between annotators is measured using the Fleiss's kappa κ (Randolph, 2005). The κ value for *Fluency* and *Coherency* is 0.69 (substantial agreement), and 0.42 (moderate agreement), respectively. Note that this evaluation is purely regarding the augmented dialogue data, without considering any dialogue model training.

The evaluation results in Table 1 demonstrate that the augmented dialogue data produced by our method outperform all the baselines in almost all the metrics. We can further observe that: **1**) Our method obtains similar scores on all the metrics compared to these human-produced and filtered dialogue pairs in $\mathcal{D}_p$. This indicates that the augmented dialogue pairs generated by our method are of high quality. We present some examples of the augmented pairs together with their associated anchor pairs in Table 2. **2**) The matching threshold η can be used to trade off between the coherency and diversity of the augmented dialogue pairs. Specifically, a higher η value improves Fluency and Coherency scores but hurts Distinct and Novelty scores of the augmented pairs.

5.4 Evaluating Dialogue Models

5.4.1 Baselines

We evaluate the benefit of the augmented dialogue data in both retrieval-based and generation-based dialogue models. Specifically, 300K augmented dialogue pairs are generated using these three baselines introduced in Section 5.3.1, and the model-level distillation process as introduced in Section 4 is used to train the dialogue models. We denote these three dialogue model baselines as **CVAE+ML**, **BT+ML**, and **SP+ML**, respectively. Note that the notation "ML" means that the Model-Level distillation is used. Moreover, besides comparing to different data augmented methods as introduced in Section 5.3.1, several other competitive

The best results are in **bold**, and the second best results are underlined (except "human"). Significant tests between the best model and others were performed using t-test. † and ‡ indicates p-value < 0.01 and 0.001, respectively.

	Augmented pairs	Associated anchor pairs from $\mathcal{D}_p$
Post	I'm almost moved to cry (我已经快感动地哭了)	I am so moved today! (今天感动得快哭了！)
Resp	What happened there? (发生什么事情呢？)	What happen (发生什么事)
Post	I like it, men should be like this (这话我喜欢。男人就该这样)	I like this types of man (喜欢这样的男人)
Resp	I like it too, just as you do (我也喜欢。跟你一样)	Your taste is just like mine (怎么跟我喜欢的一样)
Post	I liked to play it when I was young (小时候很喜欢玩)	My favorite toy in kindergarten (幼儿园最喜欢玩的)
Resp	I have also played, it's so cute (表示有幸玩过，很萌哒)	I have also played, lol (我也玩过哒)

Table 2: Example pairs produced by the proposed data augmentation method. The associated anchor pairs are also shown. More examples are shown in Appendix B

dialogue model baselines are also tested:

Teacher: Training the dialogue models on the paired data $\mathcal{D}_p$ with the NLL loss. Note that this setting produces the teacher models used in Section 4.

AP: Training dialogue models only on the Augmented Pairs $\mathcal{D}_a$ with the NLL loss.

UP+PreT: First fine-tuning the pre-trained GPT (with the NLL loss in Eq. 5) or BERT-base model (with the MLM loss (Devlin et al., 2019)) on the UnPaired Data $\mathcal{D}_u$, and then using these fine-tuned weights to initialize the dialogue models, which are further fine-tuned on $\mathcal{D}_p$ with the NLL loss.

NP+ML: Sampling 300K pairs from a set of Weibo dialogues that are not manually filtered and use these "Noisy Pairs" as the augmented pairs. The model-level distillation process introduced in Section 4 is used to train this baseline.

We denote our method as **DL+ML** since it trains the dialogue model using both the data-level and model-level distillation. The threshold η in Algorithm 1 is set to 0.95 for a better trade-off between the coherency and diversity of the augmented data. Further, we also test another method to work with data-level distillation (i.e., utilizing $\mathcal{D}_a \bigcup \mathcal{D}_p$): **DL+PreT**, i.e., first pre-train the dialogue model on $\mathcal{D}_a$ and then fine-tune on $\mathcal{D}_p$ with the NLL loss.

Further, we also performed several ablation tests on our method to validate the effect of each component: 1) training dialogue models on $\mathcal{D}_p \bigcup \mathcal{D}_a$ using only the NLL loss, i.e., without the model-level distillation (**w/o ML**); 2) training dialogue models only on the paired data $\mathcal{D}_p$ using $\mathcal{L}_M(\theta)$ or $\mathcal{L}_G(\phi)$, i.e., the data-level distillation are not used (**w/o DL**); 3) training dialogue models on the augmented data $\mathcal{D}_a$ using $\mathcal{L}_M(\theta)$ or $\mathcal{L}_G(\phi)$, i.e., the paired data $\mathcal{D}_p$ are not used (**w/o PD**); 4) generating $\mathcal{D}_a$ without the ranking module (**w/o Ranking**), i.e., the candidate pairs are used as the augmented data without filtering.

Note that all the baselines and ablation models are initialized with pre-trained GPT or BERT-base weights.

5.4.2 Metrics

The retrieval-based dialogue models are evaluated using the following metrics: 1) *Mean Average Precision* (**MAP**): the average rank of the reference responses; 2) $\boldsymbol{R_{10}@k}$: the recall of the reference response being in the top-k ranked candidates (k=1,2,5) when given 10 candidates in total.

The generation-based dialogue models are evaluated both automatically and manually. Specifically, the following automatic metrics are used: 1) *Perplexity* (**PPL**) which measures how the model fits the test data; 2) ***BLEU*** which evaluates the overlap of n-grams (n=1,2) between the generated and reference responses; 3) *Distinct* (**Dist.**) measures the proportion of unique n-grams in the generated responses (n=1,2). Manual evaluation is also performed for the generated dialogue responses following the same protocol as introduced in Section 5.3.2.

Model	MAP	R_{10}@1	R_{10}@2	R_{10}@5
Teacher	80.2	69.7	82.1	95.1
AP	76.5	65.1	78.0	92.1
UP+PreT	80.6	70.3	82.6	**95.3**
NP+ML	80.8	70.5	82.9	95.2
CVAE+ML	80.3	69.8	82.5	94.9

w/o Ranking	80.5	70.1	82.5	95.2

Table 3: Automatic evaluation for retrieval-based dialogue models with different training and data augmentation methods.

5.4.3 Results

Automatic evaluation for each dialogue model is performed on 5K test data (see Table 3 and Table 4 for the results), and manual evaluation is performed using 200 pairs that are randomly sampled from these test data (see Table 5 for the results). The κ value for the *Fluency* and *Coherency* annotation is 0.9 (substantial agreement) and 0.56 (moderate agreement), respectively.

Our method outperforms all the baselines in almost all the metrics for both retrieval-based and generation-based dialogue models. We can further observe that: **1**) The dialogue models that utilize unpaired data $\mathcal{D}_u$ (e.g. DL+ML, DL+PreT, UP+PreT) generally outperform the models that are only trained on $\mathcal{D}_p$ (e.g., Teacher, CVAE+ML). This demonstrates that utilizing unpaired data is more effective at improving the performance of dialogue models; **2**) Training the dialogue models on the merged data $\mathcal{D}_p \bigcup \mathcal{D}_a$ without utilizing the model-level distillation (i.e., w/o ML) brings little or no performance improvements compared to directly training on $\mathcal{D}_p$ (i.e., Teacher). This verifies the effectiveness of the model-level distillation process proposed in our method; **3**) When the model-level distillation is employed, the augmented data produced by our data-level distillation process (i.e., DL+ML) can better improve the performance of dialogue models compared to the augmented data produced by other data augmentation methods (e.g. CVAE+ML, NP+ML, SP+ML, BT+ML). This verifies the effectiveness of the data-level distillation process proposed in our study.

Table 4: Automatic evaluation results for generation-based dialogue models with different training and data augmentation methods. Significance tests between the best model and others were performed using t-test with booststrap resampling (Koehn, 2004). † and ‡ indicates p-value $<$ 0.005 and 0.001, respectively.

6 Conclusion

This paper presents a novel dialogue distillation method that consists of two processes, i.e., 1) a data augmentation process to construct new post-response pairs from unpaired data and 2) a model distillation process that distills a teacher model trained on the original data to the augmented data. Automatic and manual evaluation shows that our method can produce high-quality post-response pairs that are both coherent and content-rich, which can be further used to improve the performance of competitive baselines. Our method may inspire other research in low-resource NLP tasks.

A Implementation Details of Dialogue Models

Retrieval-based dialogue model: For the retrieval-based dialogue models, we implement the matching models by fine-tuning the BERT-base model (Devlin et al., 2019), which contains 12 Transformer layers with 768-dimensional hidden states. The feed-forward layer's inner states are 3,072 dimensions, and the multi-head attention layer involves 12 attention heads. The vocabulary size is 21,128, and the max sequence length is set to 512. We use the Adam optimizer ($\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 10^{-8}$) with a learning rate of 2e-5, the batch size is set to 32 and the warm-up step is set to 2000. Moreover, We fine-tune both the teacher and student models for three epochs.

Generation-based dialogue model: For the generation-based dialogue models, we share the weights of the encoder and decoder in each dialogue model and initialize these weights using a pre-trained GPT model (Radford et al., 2018). Specifically, the GPT model we used is pre-trained on a dataset collected from a set of Chinese novels that cover various genres (including Comedy, Romance, Mystery). The final pre-training corpus contains about 0.5 billion tokens. Moreover, we use the character-level vocabulary of size 13,084, and the context length is set to 512. Our model contains a total number of 191.01M parameters, and the pre-training process lasts for a week on 8 GTX1080Ti GPUs.

When fine-tuning our dialogue models, the teacher model is trained for 15 epochs (about 12 hours), and the student model is trained for 50 epoch (about 40 hours) on 4 GTX1080Ti GPUs. Moreover, the batch size is set to 128, and the maximum learning rate is 6.25e-5. The training starts with a warm-up step of 1,000, and the learning rate is annealed proportionally to the inverse square root of the step number. The Adam optimizer is used with the parameter $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$. In the inference phase, we use the beam search with size 5. The length penalty is set to 1.6, and the maximum decoded sequence length is set to 50.

Note that because the pre-training approach is utilized in our model and baselines, we inherit most of the hyper-parameter settings from the previous studies of the pre-training model Radford et al. (2018); Devlin et al. (2019), and skip the hyper-parameter tuning process. Moreover, for fair comparisons, we use a fixed set of the hyper-parameters in all our experiments (including all the ablation models and the Transformer-based baselines).

B More Augmented Dialogues Pairs

We provide more examples of the augmented pairs together with their associated anchor pairs in Table 6.

Abstract

We introduce a framework of Monte Carlo Tree Search with Double-q Dueling network (MCTS-DDU) for task-completion dialogue policy learning. Different from the previous deep model-based reinforcement learning methods, which uses background planning and may suffer from low-quality simulated experiences, MCTS-DDU performs decision-time planning based on dialogue state search trees built by Monte Carlo simulations and is robust to the simulation errors. Such idea arises naturally in human behaviors, e.g. predicting others' responses and then deciding our own actions. In the simulated movie-ticket booking task, our method outperforms the background planning approaches significantly. We demonstrate the effectiveness of MCTS and the dueling network in detailed ablation studies, and also compare the performance upper bounds of these two planning methods.

1 Introduction

Designing a task-completion dialogue system has become an important task due to its huge commercial values. The dialogue agent aims to help users to complete a single or multi-domain task, e.g. booking a flight and making a hotel reservation. The core of such a system is the dialogue policy module, which enables the agent to respond properly and provide users with the desired information. Early work has shown that dialogue policy learning can be designed as a Markov Decision Process (MDP) (Singh et al., 2002; He et al., 2018; Zhao et al., 2019; Takanobu et al., 2019). Reinforcement learning (RL) is a common framework to solve MDP but it requires huge amounts of interactions with real users, which is generally infeasible in the real world. One way to work around this problem is by designing a user simulator using the real human conversation data (Schatzmann et al., 2007; Li et al., 2016).

Recently, following these ideas, many researchers have applied deep model-based RL methods to task-completion dialogue policy learning (Peng et al., 2018; Su et al., 2018; Wu et al., 2018). In a model-based method, the agent not only updates its action value or policy function through real experiences but also learns how the environment produces the next states and rewards. The learned environment is called a *model*, which can be further used to generate simulated experiences. Using both real and simulated experiences is referred to as *background planning* and can substantially improve the learning efficiency (Sutton and Barto, 2018). Peng et al. (2018) extend Dyna-Q (Sutton, 1990; Sutton et al., 2012) to Deep Dyna-Q (DDQ) for dialogue policy learning and achieve appealing results. However, since model learning cannot be perfect, some simulated experiences with large errors may hinder policy learning (Su et al., 2018). Su et al. (2018) propose to train a discriminator to filter low-quality simulated experiences. Wu et al. (2018) design a switcher-based mechanism to automatically balance the use of real and simulated experiences. Nevertheless, the overall improvement is still limited.

In this paper, we first upgrade the common baseline model of the task-completion dialogue policy learning problem, Deep Q-network (DQN) (Mnih et al., 2015) by adopting its two variants: Deep Double Q-networks (DDQN) (Van Hasselt et al., 2016) and Dueling network (Wang et al., 2015). The purpose is to fully exploit the advanced value-based methods that are orthogonal to planning. We show that the new baseline can achieve comparable performance with DDQ. To further boost the performance, we propose to use Monte Carlo Tree Search (MCTS) (Chaslot et al., 2008) as *decision-*

time planning (Sutton and Barto, 2018). The differences between background and decision-time planning are illustrated in Figure 1 and 2. Decision-time planning doesn't use the model to generate simulated experiences. In the testing stage or a real decision time, rather than directly picking actions based on action values, a rollout algorithm like MCTS uses the model to build a search tree by running simulations. Performing policy evaluation on the search tree generally yields more accurate estimations of action values assuming that the model is correct.

Due to this property, MCTS has achieved huge success in the game of Go (Silver et al., 2016, 2017). However, its applications in the non-gaming settings, such as dialogue systems, are still rare and little studied. One difficulty is that the model now has to learn the more complex dynamics of state transitions than the deterministic game rules. Consequently, MCTS may grow a erroneous search tree and the resulting estimated action values may be wrong.

To alleviate simulation errors, we design a new MCTS method incorporating the DDQN object and the dueling architecture. The main idea is to focus on the more promising parts of the state-action space and reduce the rollout depths. The dueling network can be used as heuristic or scoring functions in this case. Given dialogue states, it outputs two streams of data: action advantages and state values. Action advantages can be viewed as the prior knowledge to differentiate actions. State values can be used as the approximated rollout results. We denote an agent under this design as MCTS-DDU. Experiments show that MCTS-DDU agent outperforms previous methods by a wide margin in both task success rate and learning efficiency.

Briefly, the main contributions of our work are in the following aspects:

- For the direct reinforcement learning of dialogue policy, we show that an agent trained by the extensions of DQN can perform comparatively with the latest deep model-based methods, which can serve as an advanced baseline for future works.

- For the planning part, we propose to incorporate MCTS with DDQN and Dueling network which exceeds previous approaches significantly. To our best knowledge, we are the first to apply decision-time planning and adapt MCTS for this task.

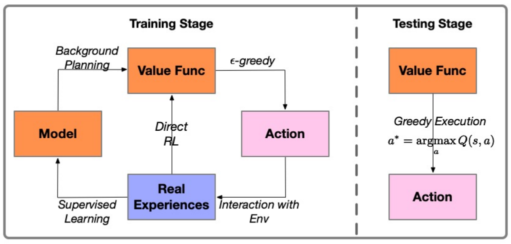

Figure 1: Training and testing stages of value-based background planning.

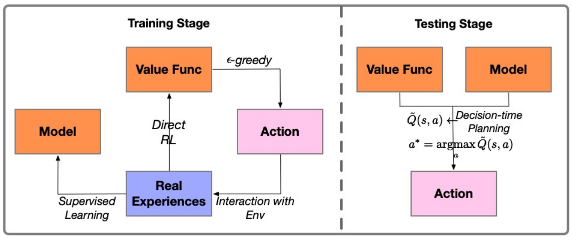

Figure 2: Training and testing stages of decision-time planning.

2 Background

2.1 Reinforcement Learning for Task-Completion Dialogue

Reinforcement learning is a framework to solve sequential decision problems. The problem can be formalized as a Markov Decision Process $\langle \mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma \rangle$, where $\mathcal{S}$ is a finite state space, $\mathcal{A}$ is a finite action space, $\mathcal{P}$ is a state transition function, $\mathcal{R}$ is a reward function, and γ is a discount factor. A value-based agent aims to learn an action value function as its implicit policy, so that its expected long-term rewards are maximized. Next, we show how to formalize a task-completion dialogue session as a MDP.

State s_t is defined as the dialogue history of previous t turns, containing user intents, associated slots, and agent responses.

Action a_t is defined as dialog act, $(intent, slot)$, representing the agent's intent on a specific slot. Take movie-ticket booking as an example, *(request, #tickets)* means that the agent asks the user how many tickets are needed.

Transition $\mathcal{P}$ represents the dialogue state updates according to stochastic responses from the user to the agent. In the case of a user simulator, the handcrafted rules define the state transitions implicitly.

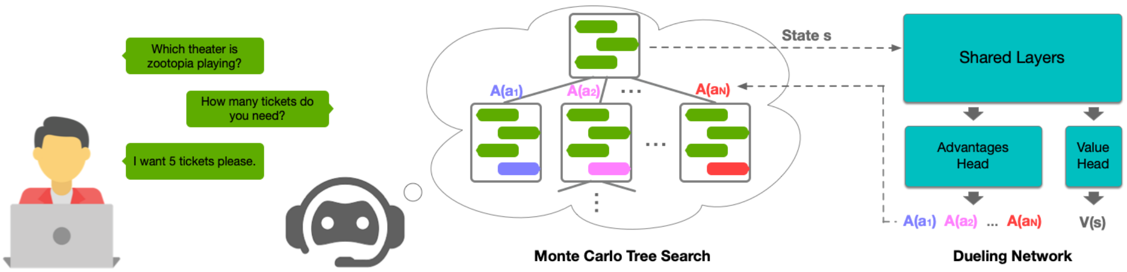

Figure 3: MCTS with dueling network as decision-time planning.

Reward $\mathcal{R}$ is the immediate feedback signal after the agent takes an action to the user, which generally depends on the dialogue status, such as in-process, success, or failure.

2.2 Deep Q-networks and Variants

Deep Q-networks (DQN) DQN combines q-learning (Watkins and Dayan, 1992) with a deep network, noted as $Q(s,a;\theta)$, to approximate state-action values. Generally speaking, training a deep neural network as a value function approximator trends to be notoriously unstable and has no convergence guarantee. To mitigate this problem, Mnih et al. (2015) utilize the *experience replay* technique (Lin, 1991) to reduce data correlation and improve data efficiency. Another critical trick is to maintain a separate *target network* $Q(s,a;\theta^-)$, whose outputs serve as target values, and the parameters θ^- get soft-updated towards θ periodically. To update $Q(s,a;\theta)$, the loss function is defined as:

$$L(\theta)=\mathbb{E}_{e\sim\mathcal{D}}[(y-Q(s_t,a_t;\theta))^2] \qquad (1)$$
$$y=r_{t+1}+\gamma\max_a Q(s_{t+1},a;\theta^-)$$

where $\mathcal{D}$ is the replay buffer holding experiences $e=(s_t,a_t,r_{t+1},s_{t+1})$ and γ is the discount factor.

Double Deep Q-networks (DDQN) Q-learning and the plain DQN have the maximization bias problem (Sutton and Barto, 2018). Since the action selection and evaluation are coupled via the maximization operator, $Q(s,a;\theta)$ trends to produce overoptimistic estimations (Hasselt, 2010). Extending the idea of double q-learning (Hasselt, 2010) to the deep reinforcement learning settings, DDQN proposes an alternate loss to use:

$$L(\theta)=\mathbb{E}_{e\sim\mathcal{D}}[(y-Q(s_t,a_t;\theta))^2] \qquad (2)$$
$$\hat{a}_{t+1}=\operatorname*{argmax}_a Q(s_{t+1},a;\theta)$$
$$y=r_{t+1}+\gamma Q(s_{t+1},\hat{a}_{t+1};\theta^-)$$

Dueling networks Dueling network is proposed as a novel architecture design for DQN. The network architecture is shown in Figure 3. Given a state, the shared layers generate a compact hidden representation. Then, instead of estimating action values directly, the computation is separated into two streams: state value and action advantages, according to $Q(s,a)=V(s)+A(s,a)$ (Baird III, 1993). This decomposition brings several benefits, such as the improved training efficiency and the separate access to state values and action advantages.

2.3 Planning

Besides directly improving the action value function, real experiences can also be used to learn a model $\mathcal{M}=(\mathcal{P},\mathcal{R})$, where $\mathcal{P}$ and $\mathcal{R}$ are defined in Section 2.1. Planning refers to utilizing $\mathcal{M}$ to further improve the policy (Sutton and Barto, 2018). Background planning uses $\mathcal{M}$ to generate simulated experiences. By doing this, more data is available for learning. Dyna-Q, DDQ (Peng et al., 2018), D3Q (Su et al., 2018), and Switch-DDQ (Wu et al., 2018) all fall into this category. In contrast, decision-time planning focuses on how to pick an action for a specific state. Namely, it tries to solve a sub-MDP starting from the "current" state. Monte Carlo Tree Search (MCTS) is a kind of decision-time planning algorithm. It uses the model to grow search trees and continually simulate more promising trajectories. Appropriate methods, like Monte Carlo and temporal-difference learning, can be then applied on the search tree to select the best action.

3 Methodology

For a dialogue process involving complex state dynamics, applying planning directly is problematic, since the model learning cannot be perfect. This may result in low-quality simulated experiences for Dyna-Q and an erroneous search tree for MCTS. In the former case, it is inevitable that parameter updates would be made in some wrong directions for the action value network. While for MCTS, it is possible to reduce the incorrect portions by trimming the depths based on value function that summarize the subtrees, and preferring the actions with higher advantages for branch exploration. Since a value-based agent picks actions based on the action advantages, the state transitions induced by the higher advantages are more likely to be generalized well. Thus, branch exploration with the higher action advantages contains fewer errors by focusing more on the neighborhood of those well learned state space.

Our framework for task-completion dialogue policy learning is presented in Figure 3 and Algorithm 1. In the training stage, the action value network or Q-network $Q = (A, V)$ is optimized via direct reinforcement learning and the model $\mathcal{M} = (\mathcal{P}, \mathcal{R})$ is optimized via model learning respectively. In the testing stage, the agent take actions in a more thoughtful way by performing MCTS with the action advantage head A and the state value head V.

Direct reinforcement learning In this stage, the agent interacts with an user, receives real experiences of the next states and rewards, and optimizes $Q(s, a; \theta, \phi)$ based on the DDQN objective (Eq.2). The reward function works as follows: in each step, the agent receives a penalty of -1. By the end of a dialogue session with the maximal dialogue turns L, the agent receives a reward of 2*L if the task is completed successfully or a reward of -L if the task fails. Note that, no planning is executed during this stage, actions are chosen using the ϵ-greedy strategy. Concretely, $a^* = \mathrm{argmax}_a\, Q(s, a)$ with probability $1 - \epsilon$ and $a^* = uniform(\mathcal{A})$ with probability ϵ.

Model learning The model $\mathcal{M}(s, a; \alpha, \beta) = (\mathcal{P}(s, a; \alpha), \mathcal{R}(s, a; \beta))$ is trained via supervised learning based on pairs $\{(s_t, a_t, s_{t+1})\}$, $\{(s_t, a_t, r_{t+1})\}$ sampled from the replay buffer. We design $\mathcal{M}$ to be a *sample model*, whose $\mathcal{P}(s, a; \alpha)$ produces a sample of s_{t+1} not a distribution over all the next states. By such design, the modelings of user behaviors and state updating are combined in an end-to-end manner. For the transition loss, we use the l_2-norm of the representational differences between s_t and s_{t+1}. For the reward loss, we use the regular regression loss, Mean-Square-Error(MSE).

$$L_{\mathcal{P}}(\alpha) = \mathbb{E}_{e\sim\mathcal{D}}[\|\mathcal{P}(s_t, a_t; \alpha) - s_{t+1}\|_2^2] \quad (3)$$

$$L_{\mathcal{R}}(\beta) = \mathbb{E}_{e\sim\mathcal{D}}[(\mathcal{R}(s_t, a_t; \beta) - r_{t+1})^2] \quad (4)$$

Monte Carlo Tree Search with Dueling network In MCTS, each node represents a state and each edge represents an action causing the state transition. Each edge also stores the statistics of a cumulative action value $Q_c(s, a)$ and a visit count $N(s, a)$. There are four steps in one MCTS simulation process, including *selection*, *expansion*, *simulation* and *backpropagation* (Chaslot et al., 2008). To be more specific, we use the *Upper Confidence Bounds for Tree(UCT)* (Kocsis and Szepesvári, 2006; Kocsis et al., 2006) among the MCTS family.

As mentioned, using an approximated complex environment to simulate with large branch factors and depths may lead to both high bias and high variances problems. To address these issues, the dueling network can assist the plain MCTS by providing 1) normalized action advantages as breadth-wise priorities for exploration and 2) state value estimation as depth-wise early stop, both of which essentially prune the enormous state-action space. Formally, we incorporate UCT with dueling architecture and propose a new upper confidence bound called UCT$_D$:

$$\mathrm{UCT}_D(s, a) = \frac{Q_c(s, a)}{N(s, a)} + c \cdot A(s, a) \cdot \sqrt{\frac{2 \ln N(s)}{N(s, a)}}$$

where $N(s) = \sum_a N(s, a)$ is the sum of visit counts of all available actions. The first term helps to track the action with the highest empirical action value. The second term encourages the search process to explore the actions with higher normalized advantages or lower visit counts. The constant c is the hyperparameter balancing exploitation and exploration. Silver et al. (2016) use a policy network to produce a prior probability and formulate the second term as $\frac{P(s,a)}{1+N(s,a)}$. The key difference from our method is that: policy network is trained by a policy gradient method (Sutton et al., 2000), which trends to concentrate on the right action given a state but neglects the differences among the rest actions. Next, we will describe the simulation process in detail.

Selection Given a state as the root, the action with the highest UCT_D score is chosen on each tree level. This selection process runs recursively until a not fully expanded node, whose children nodes haven't been expanded all.

Expansion Once such node is reached and the action is again picked by UCT_D, the model $\mathcal{M}$ would produce a leaf node s_L that represents the next state. The reward is stored for that edge and would be used in the backpropagation step.

Simulation In this step, unlike the conventional rollout strategies , we simply use the value head $V(s;\theta)$ of $Q(s,a;\theta,\phi)$ to estimate the state value of s_L as $v(s_L)$. This approach has proved to be effective due to using a deep network as the value function and also efficient since no single rollout is played (Silver et al., 2017).

Backpropagation When the simulation step is finished, $v(s_L)$ is backpropagated upwards through all the ancestor edges and updates the corresponding statistics $Q_c(s,a)$ and $N(s,a)$. The update rules are as follows:

$$N(s,a) \leftarrow N(s,a) + 1 \quad (5)$$

$$\Delta Q_c(s,a) \leftarrow r(s,a) + \gamma \Delta Q_c(s',a') \quad (6)$$

where (s',a') is the child edge of (s,a). The update value for the last edge (s_{L-1},a_{L-1}) is defined as: $\Delta Q_c(s_{L-1},a_{L-1}) \leftarrow r(s_{L-1},a_{L-1}) + \gamma V(s_L)$.

4 Experiments

In this section, we first introduce the experimental setup and baseline models. We also propose a new model-free baseline based on the recent extensions of DQN. The effectiveness of MCTS, advantage function, and DDQN objective are demonstrated via thorough ablation studies. We also explore the tradeoff between exploitation and exploration in MCTS. Lastly, we compare the performance upper bounds of background and decision-time planning with a perfect model.

4.1 Setup and Baselines

We consider the movie-ticket booking task that has been studied in Peng et al. (2018), Su et al. (2018) and Wu et al. (2018). Li et al. (2016) convert 280 real dialogues from Amazon Mechanical Turk to a user goal set $\mathcal{G}$ and a dialogue schema containing 11 *intents* and 16 *slots*, which defines the feasible actions for both users and the agent. Evaluation

Algorithm 1 MCTS with Double-q and Dueling Network for Task-Completion Dialogue Policy Learning

```
Initialize q-network $Q = (V(s;\theta), A(s,a;\phi))$
Initialize target network: $\theta^- = \theta, \phi^- = \phi$
Initialize model $\mathcal{M} = (\mathcal{P}(s,a;\alpha), \mathcal{R}(s,a;\beta))$
Initialize user goals set $\mathcal{G}$
while True do
    Sample a user goal from $\mathcal{G}$          ▷ Training
    Initialize $s_1$ from user first utterance
    for $t = 1, T$ do
        $a_t \leftarrow \epsilon\text{-}greedy(Q(s_t,\cdot;\theta,\phi))$
        Execute $a_t$ and observe $s_{t+1}, r_{t+1}$
        Store experience $(s_t, a_t, s_{t+1}, r_{t+1})$
    end for
    Optimize $Q(s,a;\theta,\phi)$ based on Eq.(2)
    Optimize $\mathcal{M}(s,a;\alpha,\beta)$ based on Eq.(3-4)
    Update $\theta^- = \tau * \theta^- + (1-\tau) * \theta$,
    $\phi^- = \tau * \phi^- + (1-\tau) * \phi$

    Sample a user goal from $\mathcal{G}$          ▷ Testing
    Initialize $s_1$ as the root
    for t $= 1, T$ do
        for Simulation $= 1, M$ do          ▷ MCTS
            $s \leftarrow s_t$
            while $s$ is fully expanded do
                $a' \leftarrow \text{argmax}_a \text{UCT}_D(s,a)$
                $s \leftarrow \mathcal{P}(s,a';\alpha)$
            end while
            $a' \leftarrow \text{argmax}_a \text{UCT}_D(s,a)$
            Expand leaf state $s_L \leftarrow \mathcal{P}(s,a';\alpha)$
            Estimate $v(s_L) \leftarrow V(s_L;\theta)$
            while the root $s_t$ is not reached do
                Update statistics $Q_c(s,a)$ and
                $N(s,a)$ based on Eq.(5-6)
            end while
        end for
        $a_t \leftarrow \text{argmax}_a \frac{Q_c(s_t,a)}{N(s_t,a)}$
        Execute $a_t$ and observe $s_{t+1}, r_{t+1}$
    end for
end while
```

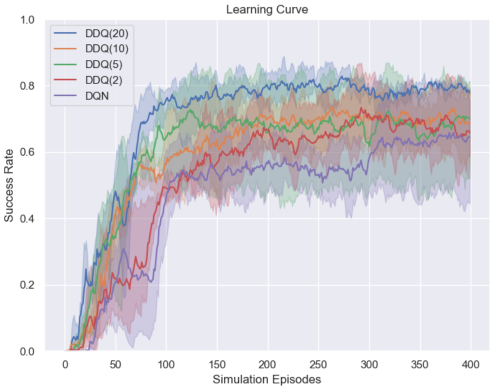

Figure 4: The learning curves of DDQ(K).

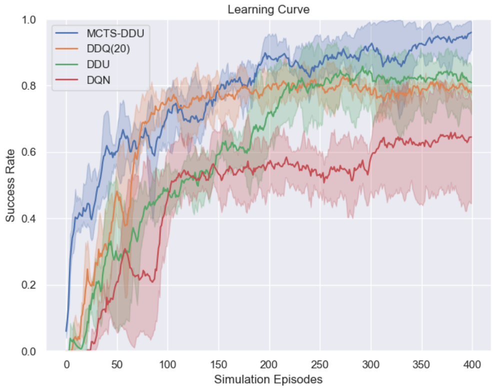

Figure 5: The learning curves of MCTS-DDU, DDU, DDQ(20) and DQN.

metric is the task success rate. The task is considered as completed successfully only when the agent manages to provide all of the users' desired information, propose appropriate suggestions, and finally inform the booking.

In the training stage, we use the user simulator implemented by Li et al. (2016) as the environment. For a dialogue session, the simulator first samples a goal from the goal set $\mathcal{G}$ and generate the first utterance. Once the conversation begins, the user simulator would make responses based on the predefined rules and agent's replies. Rewards are provided to the agent based on the dialogue status (as described in the part of Direct reinforcement learning).

We also use the strategy called *Replay Buffer Spiking* proposed in Lipton et al. (2018), to prefill the experience replay buffer by allowing a rule-based agent to interact with the user simulator. The successful experiences executed by the rule-based agent could considerably speed up the following training stage. Otherwise, it may take thousands of episodes for the agent to get the first positive reward due to the large state-action space.

We compare our method MCTS-DDU with recently proposed methods shown as follows. Moreover, we propose a stronger baseline called DDU.

- **DQN**: Agent is trained by DQN (Eq.1) using real experiences only.
- **Deep Dyna-Q (DDQ(K))**: Agent is trained by DQN (Eq.1) with background planning. The ratio between simulated experiences and real experiences is $K - 1$ (Peng et al., 2018).
- **Switch-based Active Deep Dyna-Q (Switch-DDQ)**: Agent is trained by DQN (Eq.1) with background planning. The switcher automatically controls the ratio between simulated experiences and real experiences (Wu et al., 2018).
- **DDU**: Agent uses dueling architecture as Q-network and is trained by DDQN (Eq.2) using real experiences only.
- **MCTS-DDU** Agent is trained in the same way as **DDU**. While in the decision time, actions are picked based on MCTS with Q-network.

For all agents, the main components of Q-networks and models are implemented as two-layer neural networks with the hidden size being 80 and ReLU activation.

4.2 Evaluation with User Simulator

In this part, agents are evaluated by interacting with the same user simulator used in the training stage. However, a reserved part of the goal set is used for testing here. We evaluate the performances of each agent on the test goal set by the end of every training episode. The evaluation process runs 50 trials and averages the success rates. The evaluation results of all agents are summarized in Table 1. To align with the settings of Wu et al. (2018), we sample the success rates at episode 100, 200 and 300. MCTS-DDU has the highest performance at all times. Note that, MCTS-DDU continues to learn even after episode300. Detailed numerical comparisons are presented in the following parts.

DDQ(K) is an important group of baselines as the first proposed deep planning method in dialogue tasks, but its performances are reported with

Agent	Episodes100			Episodes200			Episodes300		
	Success	Return	Turns	Success	Return	Turns	Success	Return	Turns
DQN[2]	.2867	-17.35	25.51	.6733	32.48	18.64	.7667	46.87	12.27

Switch-DDQ[2]	.5200	15.48	15.84	.8533	56.63	13.53	.7800	48.49	12.21
DDU	.4675	14.15	24.01	.7611	33.89	17.41	.8562	43.07	15.69
MCTS-DDU	**.7312**	46.63	19.77	**.9090**	57.26	12.79	**.9314**	55.87	12.13

Table 1: The performance summary of MCTS-DDU and baselines in terms of success rate and discounted cumulative return. (K) stands for K planning steps. MCTS-DDU uses $c = 4$ in UCT$_D$ and runs 50 simulations per dialogue turn. The results are sampled at Episode 100, 200, and 300 and are averaged over three random seeds. All model parameters are initialized randomly without extra human conversational data pre-training. Superscripts indicate the data sources, [1] for (Peng et al., 2018), [2] for (Wu et al., 2018), and [3] for our own implementations based on open-sourced codes.

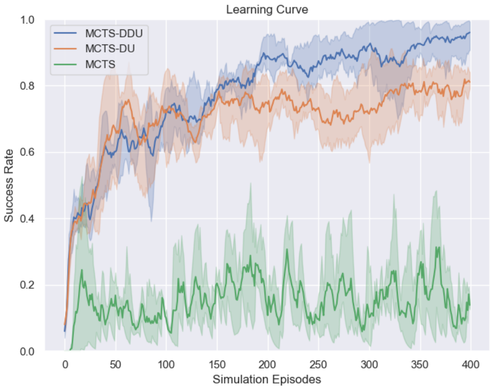

Figure 6: Ablation of advantages function.

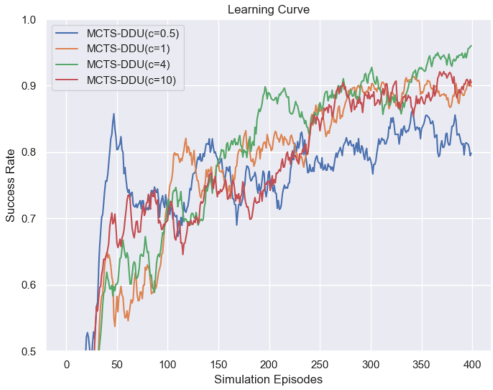

Figure 7: Effects of the balancing coefficient c.

large differences in Peng et al. (2018) and Wu et al. (2018). We reproduce it on our own and present the results in Table 1 and Figure 4. We then study the effectness of planning step K and select the best K that results in the highest average success rate in long term as the representative of the group DDQ(K) for the latter studies. The learning curves of $K = (2, 5, 10, 20)$ are shown in Figure 4. We have the similar results to Peng et al. (2018) that larger values of K make the learning process faster and success rate higher.

Then we compare DQN, DDQ(20), and MCTS-DDU. The result is shown in Figure 5. Methods incorporated with planning outperform than DQN both in training efficiency and success rate significantly, which proves the effectiveness of planning. MCTS-DDU achieves the highest task performance and data efficiency. Technically, MCTS-DDU exceeds DDQ(20) by absolute 12.65% and relative 14.79%. And it exceeds DQN by absolute 28.77% and relative 41.44%.

We define the number of episodes taken for achieving 60% success rate as a metric for comparing training efficiency. With this setting, MCTS-DDU is relatively 45.31% faster than DDQ(20) and 78.26% faster than DQN. Moreover, MCTS-DDU can reach over 50% success rate within 10 episodes.

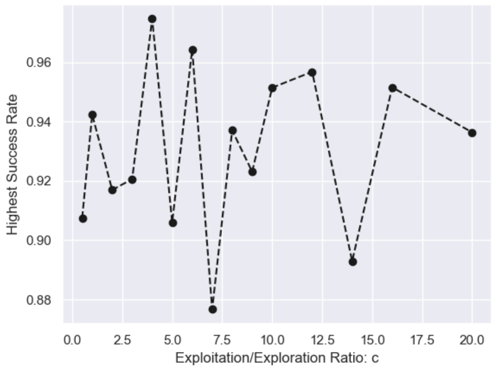

Figure 8: The highest success rates under different c.

4.3 Ablation studies

Effectiveness of MCTS We compare the performances between MCTS-DDU and DDU that exploits Q-network directly. The result is shown in the Table 1 and Figure 5. Based on the metric defined above, MCTS-DDU exceeds DDU by absolute 8.9% and relative 9.8% with 73.3% faster efficiency.

One interesting observation is that DDU could achieve slightly higher performance than DDQ(20) in spite of the lower training efficiency. It shows that the direct reinforcement learning part has not been investigated enough in the dialogue policy learning scenario. Solely using the advanced value-based learning methods can actually bring considerable improvement. Thus, we consider DDU to be a stronger baseline model than DQN for future study, based on which more complex mechanisms like planning can be added on.

Effectiveness of advantages and double-q Next, we investigate the effectiveness of the advantages function $A(s, a; \phi)$ and DDQN objective incorporated in UCT$_D$. The result is shown in the Figure 6. Without advantages as prior knowledge for exploration, the performance of plain MCTS is much worse than that of MCTS-DDU. The success rate fluctuates drastically due to the fact that more simulations are needed to make the action value estimations converged. We observe a slow and unstable learning process, implying merely using $V(s; \theta)$ is insufficient. Therefore, the conclusion can be reached that the advantages function $A(s, a; \phi)$ indeed improves the efficiency of simulations and is also critical for the high performance guarantee. We also perform the experiment in which the DDQN objective(Eq. 2) is replaced with the original DQN objective(Eq. 1). Even though the learning processes are quite commensurate in the early stage, MCTS-DU runs into a performance bottleneck after 200 episodes.

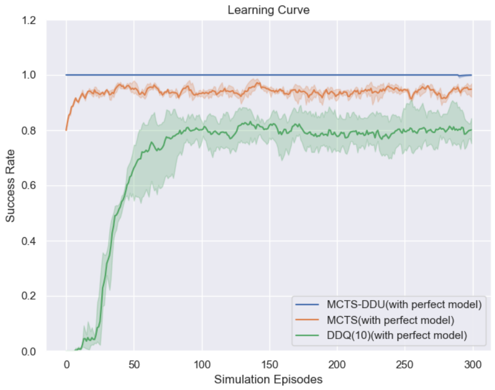

Figure 9: Performance comparison between background /decision-time planning with a perfect model.

Exploitation v.s. Exploration We also explore how the coefficient c, balancing exploitation and exploration in UCT$_D$, effects task performances. We set the testing range to be roughly from 2^{-1} to 2^4 and the results are shown in Figure 7 and 8. As c increases from 0.5 to 4, the final success rate gets improved, emphasizing the importance of exploration. However, the performance starts to degenerate when c continues to increase. But it is still higher than those of the cases where c is small. Empirically, we believe a well-guided exploration, such as guided by an advantage function, is more influential in this task. In short, this experiment result is a clear illustration of the tradeoff between exploitation and exploration when using MCTS.

From a practical perspective, the coefficient c needs to be searched carefully for the optimal value. We present the highest success rates under different settings of c within 400 episodes in Figure 8.

Performance upper bound comparisons Lastly, we compare the performances of DDQ(10) and MCTS-DDU under perfect modeling learning. By ”perfect”, we mean there is no error in learned transition and reward functions. Our goal is to investigate the performance upper bounds of background and decision-time planning. The result in Figure 9 shows that DDQ(10) still stucks in a local optimal whereas MCTS-DDU can solve the task perfectly. We argue that the bottleneck of DDQ(10) comes from the use of a value function approximator. Contrastly, decision-time planning is able to build a true sub-MDP with a perfect model and solves it exactly. In addition, we test the plain MCTS in this setting. It almost perfectly solves the task but is less stable than MCTS-DDU, which again demonstrates the effectiveness of the advantage function.

5 Conclusions

Our work introduces a novel way to apply deep model-based RL to task-completion dialogue policy learning. We combine the advanced value-based methods with MCTS as decision-time planning. In the movie-ticket booking task, MCTS-DDU agent exceeds recent background planning approaches by a wide margin with extraordinary data efficiency.

In this paper, one main focus is to demonstrate the differences between background and decision-time planning. However, it is reasonable and straightforward to combine them together. This might be an interesting topic for future work.

A Appendices

A.1 User goal set

The user goal set consists of 280 goals from real human conversation in the movie domain. We split it into 70%, 15%, and 15% for training, validation(hyperparameter tuning), and testing respectively. A sample user goal is shown as follows, where $constraint\_slots$ are the determined parts of a user goal and $request\_slots$ are the slots that need to be recommended by the agent.

{
$constraint\_slots$:
moviename: star wars
#people: 2
state: illinois
city: du quoin
$request\_slots$:
date: ?
theater: ?
starttime: ?
}

The feasible action sets of the user simulator and the agent are defined by the schema of intent and slot.

Intent	request, inform, deny, greeting, confirm_answer, confirm_question, closing, not_sure, multiple_choice, thanks, welcome
Slot	city, closing, distance, date greeting, moviename, #people, price, starttime, state, taskcomplete, theater_chain, theater, zip ticket, video_format

Table 2: The schema of intent and slot.

A.2 Hyperparameters

The main hyperparameters used in our method are listed in Table 3.

Hyperparameter	Search range	Optimal value
Max dialogue turns (Horizon)	None	32
Replay buffer capacity	None	5000
Batch size	$\{16, 32, 64, 128\}$	16
Optimizer	$\{$SGD, RMSprop, Adam, AdamW$\}$	AdamW
Epochs	[1, 15] (Step=5)	10
Learning rate	[1e-5, 1e-3] (Step=5e-5)	5e-3
ϵ-greedy (ϵ)	[0.05, 0.3] (Step=0.05)	0.2
Discount (γ)	[0.4, 0.9] (Step=0.1)	0.5
Exploitation v.s. Exploration (c)	[1,20] (Step=1)	4

Table 3: Hyperparameters for MCTS-DDU. $\{\cdot\}$ indicates the exact value range. $[\cdot]$ indicates the lower and upper bound for searching. Hyperparameter tunings are based on task success rates and performed over three random seeds. We use one NVIDIA V100 GPU as computing infrastructure and average runtime is about 2 hours per trial.

Learning a Simple and Effective Model for Multi-turn Response Generation with Auxiliary Tasks

Abstract

We study multi-turn response generation for open-domain dialogues. The existing state-of-the-art addresses the problem with deep neural architectures. While these models improved response quality, their complexity also hinders the application of the models in real systems. In this work, we pursue a model that has a simple structure yet can effectively leverage conversation contexts for response generation. To this end, we propose four auxiliary tasks including word order recovery, utterance order recovery, masked word recovery, and masked utterance recovery, and optimize the objectives of these tasks together with maximizing the likelihood of generation. By this means, the auxiliary tasks that relate to context understanding can guide the learning of the generation model to achieve a better local optimum. Empirical studies with three benchmarks indicate that our model can significantly outperform state-of-the-art generation models in terms of response quality on both automatic evaluation and human judgment, and at the same time enjoys a much faster decoding process.

1 Introduction

As an important topic in conversational AI, open-domain human-machine conversation is gaining increasing attention from both academia and industry. A common approach to building such a system is to learn a response generation model within an encoder-decoder framework using neural sequence architectures (Sutskever et al., 2014; Vaswani et al., 2017). While the encoder-decoder framework has been successfully applied in various text generation tasks such as machine translation (Vaswani et al., 2017), summarization (Rush et al., 2015), paraphrase generation (Dong et al., 2017), etc., it has to deal with a unique challenge in the task of response generation: modeling conversation contexts. A conversation context often exhibits a hierarchical structure with dependency existing on both a word-level and an utterance-level. Moreover, as indicated in (Xing et al., 2018; Zhang et al., 2019), information in a context is rather redundant for responding: commonly only a few words and utterances are useful for response generation, and the positions of the relevant words and utterances vary from case to case. To model the hierarchy of conversation contexts, hierarchical recurrent encoder-decoder (HRED) (Serban et al., 2016) extends the vanilla sequence-to-sequence model by a word-level encoder and an utterance-level encoder. Later on, a hierarchical recurrent attention network (HRAN) (Xing et al., 2018) harnesses the decoder of the HRED model with word-level attention and utterance-level attention to dynamically highlight the effect of relevant words and utterances in response synthesis. Very recently, ReCoSa (Zhang et al., 2019) further exploits multi-layer multi-head self-attention[1] to model long-term dependency among utterances and responses. From HRED to HRAN, and then to ReCoSa, the performance of the models in terms of response quality becomes better and better (Zhang et al., 2019), but the models also grow to be more and more complicated. For example, the number of parameters in ReCoSa is more than twice as that in HRED. Thus, when we enjoy the improved performance from the increased complexity, the complexity may also impede the application of the models in some scenarios (e.g., in a mobile scenario).

In this work, we study multi-turn response generation and target on a model that has a simple structure yet can make use of conversation contexts

---

[1] The fact that both the encoder and the decoder of ReCoSa contain multiple layers is not highlighted in the paper, but is revealed by the source code released by the authors at `https://github.com/zhanghainan/ReCoSa`.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3472–3483,
November 16–20, 2020.

as well as the existing deep models. The key idea is to transfer the burden of context understanding from modeling to learning by designing several auxiliary tasks, and leverage the auxiliary tasks as regularization in model estimation. Specifically, the model we use for response generation concatenates utterances in a conversation context as a long sequence, and only exploits one-layer self-attention in encoding and one-layer context attention in decoding. In such a frugal setting, the representation capability of the model shrinks a lot compared with deep transformers. As a remedy, we augment the maximum likelihood estimation (MLE) in learning with objectives from four auxiliary tasks including word order recovery, utterance order recovery, masked word recovery, and masked utterance recovery. In the first two tasks, we predict the correct order of words and utterances from a random shuffle of words in an utterance and a random shuffle of utterances in a context respectively. The goal of the two tasks is to enhance understanding of the sequential dependency among words and utterances within a context. The other two tasks are inspired by the recent breakthrough from BERT (Devlin et al., 2019), in which we randomly mask a word in an utterance and an utterance in a context respectively, and predict the masked word and the masked utterance using the remaining words and utterances. The two tasks may encourage the learning process to pay more attention to semantics of words and utterances in their contexts, and help the learning process find better representations of words and utterances for the generation model. The auxiliary tasks and the MLE task share the encoder of the generation model. Through learning with multiple tasks, optimization for response generation and optimization for context understanding are performed in a joint form. The context understanding related tasks can guide the MLE to achieve a better local optimum, and thus realize superior performance in response generation with a simple neural structure.

We test the proposed approach with three benchmarks including the Ubuntu Dialogue Corpus (Lowe et al., 2015), DailyDialog (Li et al., 2017), and PERSONA-CHAT (Zhang et al., 2018). Evaluation results on all three datasets indicate that our model can significantly outperform state-of-the-art generation models in terms of both automatic evaluation and human judgment. Moreover, with a parameter set even smaller than HRED, our model is 2x faster than ReCoSa in response decoding.

Our contributions in the paper are three-fold: (1) proposal of balancing model complexity and model capability in multi-turn response generation; (2) proposal of four auxiliary learning tasks that transfer context understanding from modeling to learning; and (3) empirical verification of the effectiveness and the efficiency of the proposed model on three benchmarks.

2 Related Work

End-to-end open-domain dialogue generation is built upon the encoder-decoder architecture (Shang et al., 2015; Vinyals and Le, 2015), and the vanilla sequence-to-sequence structure has been widely extended to address challenges such as generic responses (Li et al., 2015; Xing et al., 2017), context modeling (Serban et al., 2016, 2017; Xing et al., 2018; Zhang et al., 2019), and grounding by persona/emotion/knowledge (Li et al., 2016; Zhang et al., 2018; Zhou et al., 2018; Dinan et al., 2018). In this work, we study how to leverage conversation context for multi-turn response generation, which represents a fundamental problem in dialogue generation. Different from the existing work that enhances the representation capability of models through neural architecture engineering, we turn to an orthogonal direction that we keep the generation model simple, and optimize the simple structure by learning with auxiliary tasks that encode context understanding. As a result, our model can provide high-quality responses at a low cost. Before us, there have been a few studies on learning a primary task with auxiliary ones (Rei and Yannakoudakis, 2017; Yu and Jiang, 2016; Ding et al., 2017; Trinh et al., 2018; Mehri et al., 2019; Wu et al., 2019). The work is unique in that through extensive empirical studies, we verified that a simple structure learned with auxiliary tasks can work as well as deep architectures in dialogue generation.

3 Approach

We first formalize the problem in question, and then detail the model and the learning tasks.

3.1 Problem Formalization

Suppose that we have a dataset $\mathcal{D} = \{(\mathcal{U}_i, R_i)\}_{i=1}^{N}$, where $\mathcal{U}_i = (U_{i,1}, \dots, U_{i,n})$ denotes a context with $U_{i,j}$ the j-th utterance, and R_i is a response regarding to $\mathcal{U}_i$. The goal is to estimate a generation probability distribution $P(R|\mathcal{U})$ from $\mathcal{D}$, and thus, given a new context $\mathcal{U}$, one can generate a response for $\mathcal{U}$ following $P(R|\mathcal{U})$. A common practice is to learn $P(R|\mathcal{U})$ by maximizing the log-likelihood of $\mathcal{D}$ (i.e. MLE) which can be formulated as

$$\sum_{i=1}^{N} \log P(R_i|\mathcal{U}_i). \tag{1}$$

When $P(R|\mathcal{U})$ is in a simple structure, only learning with MLE could be insufficient to obtain a model that can well capture the syntax and the semantics of contexts. An evidence is that simple architectures like HRED is much worse than complicated architectures like ReCoSa in terms of response quality, as reported by the existing work (Zhang et al., 2019). Since a simple structure is still favored, we consider aiding the objective given by Equation (1) with extra ones that can reinforce context understanding in the learning process.

3.2 Generation Model

Figure 1 illustrates the architecture of the generation model. In a nutshell, the model is in a transformer-based structure (Vaswani et al., 2017) with one attentive layer (in the transformer layer) in the encoder and one attentive layer in the decoder. The auxiliary tasks, which will be presented later, share the encoder with the generation model. We prefer a transformer-based structure instead of a recurrent structure, because the former is easier to parallelize than the latter, and thus can further enhance efficiency of the model in an online system.

Encoder: we unfold all words in $(\mathcal{U}, R)$ into $\mathcal{W} = (w_1, \ldots, w_m, w_{m+1}, \ldots, w_{m+t})$, where m is the number of words in context $\mathcal{U}$, and t is the number of words in response R. $\forall i \in \{1, \ldots, m+t\}$, w_i is represented by a summation of word embedding, position embedding, and segment embedding:

$$B(w_i) = WE(w_i) + PE(w_i) + SE(w_i), \tag{2}$$

where $WE(w_i)$ represents the word embedding of w_i initialized using GloVe (Pennington et al., 2014), $PE(w_i)$ is the position embedding of w_i which is defined by $Pe(w_i)$, where $e(w_i)$ is a one-hot vector with the only non-zero entry indicating the position of w_i in $\mathcal{W}$, and $P \in \mathbb{R}^{d \times M_p}$ is a randomly initialized matrix with M_p an upper bound of the number of words in a dialogue. $SE(w_i)$ is the segment embedding of w_i defined similarly with the one-hot vector indicating the position of the utterance that contains w_i. The embedding matrix is then fed to a transformer layer, which can be formulated as

$$\begin{aligned} I &= [B(w_1), B(w_2), \ldots, B(w_{m+t})], \\ E &= \text{FNN}(\text{MultiHead}(I, I, I)), \end{aligned} \tag{3}$$

where $\text{FNN}(\cdot)$ is a feed-forward neural network and $\text{MultiHead}(Q, K, V)$ is a multi-head attention function with Q a query, K a key, and V a value. To control the receptive field of self-attention in different tasks, we add a mask matrix $M \in \mathbb{R}^{(m+t)\times(m+t)}$ (Dong et al., 2019) in attention computation, and let M determine whether a pair of words can attend to each other according to the learning tasks. Thus, $\text{MultiHead}(Q, K, V)$ is defined by

$$\begin{aligned} &\text{MultiHead}(Q, K, V) = \oplus_{i=1}^{K} \text{Head}_i(Q, K, V), \\ &\text{Head}_i(Q, K, V) = \text{Attention}(W_i Q, W_i K, W_i V), \\ &\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^\top}{\sqrt{d_k}} + M)V, \end{aligned} \tag{4}$$

where $\oplus$ refers to a concatenation operation, and M is given by

$$M_{ij} = \begin{cases} 0, & \text{allow to attend,} \\ -\infty, & \text{prevent from attending.} \end{cases} \tag{5}$$

Decoder: suppose that $(w_{m+1}, \ldots, w_{m+l-1})$ are words generated until step $l-1$, then the next word w_{m+l} is predicted according to:

$$P(w_{m+l}|w_1, \ldots, w_{m+l-1}) = \text{softmax}(W_s O(w_{m+l-1})), \tag{6}$$

where $O(w_{m+l-1})$ is defined by $\text{FNN}(\text{MultiHead}(E(w_{m+l-1}), E, E)$ with $E = [E(w_1), \ldots, E(w_{m+l-1})]$ the output of the encoder, and W_s is a trainable parameter.

3.3 Auxiliary Tasks

Heading for learning the simple structure that can effectively make use of contexts for response generation, we design two kinds of auxiliary tasks including order recovery and masked content recovery. The order recovery tasks aim to enhance the capability of the self-attention module on capturing the sequential relationship among words and utterances, while the masked content recovery tasks can optimize the self-attention module to enhance semantic connection among words and utterances.

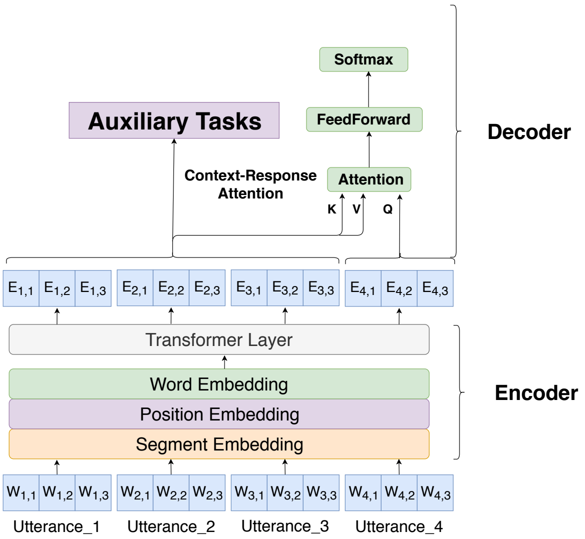

Figure 1: Architecture of the generation model.

Order recovery: a recent study (Sankar et al., 2019) indicates that transformer-based models are insensitive to ordering of words and utterances, which means that the information they learn could be just bag-of-words representations. Thus, we consider recovering the correct order from random shuffling on both a word level and an utterance level to force self-attention to be aware of relative positions of words and utterances in the context.

Word order recovery: Figure 2 (a) illustrates the task. Given a randomly sampled utterance $U = (w_1, \dots, w_k)$ from a context $\mathcal{U}$, we randomly shuffle the words in U and obtain a disordered utterance $\bar{U} = (\bar{w}_1, \dots, \bar{w}_k)$. Then, we replace U in $\mathcal{U}$ with $\bar{U}$ and form a corrupt context $\bar{\mathcal{U}}$. The goal of the task is to predict U from $\bar{U}$. The loss of the task can be formulated as

$$\begin{aligned}\mathcal{L}_{\text{wor}} &= -\frac{1}{k}\sum_{i=1}^{k}\log(p(w_i|\bar{U})),\\ p(w_i|\bar{U}) &= \text{softmax}(W_s E(\bar{w}_i)),\end{aligned} \tag{7}$$

where $E(\bar{w}_i)$ is obtained from $E(\bar{\mathcal{U}})$ which is the representation of $\bar{\mathcal{U}}$ given by the encoder of the generation model, W_s is shared with Equation (6).

For this task, the mask matrix M in Equation (4) is defined by:

$$M_{ij} = \begin{cases} 0, & w_i \text{ and } w_j \text{ are in the same utterance,} \\ -\infty, & w_i \text{ and } w_j \text{ are in different utterances.} \end{cases} \tag{8}$$

Utterance order recovery: Figure 2 (d) illustrates the task. Given context $\mathcal{U} = (U_1, \dots, U_n)$, we randomly shuffle the utterances and obtain a disordered context $\bar{\mathcal{U}} = (U_{o_1}, \dots, U_{o_n})$. The goal is to predict the correct positions for utterances in $\bar{\mathcal{U}}$. The prediction model falls in a read-process-write framework (Vinyals et al., 2015). In the reading module, the model first represents $\bar{\mathcal{U}}$ as $\bar{E} = (\bar{E}(w_{1,1}), \dots, \bar{E}(w_{n,m}))$ via the encoder of the generation model, where $w_{i,j}$ is the j-th word in utterance U_{o_i} (words within an utterance are ordered), and then obtains the representation of utterance U_{o_i} through

$$S_i = \sum_{j=1}^{k_i} \bar{E}(w_{i,j}), \tag{9}$$

where k_i is the number of words in U_{o_i}. $\mathcal{S} = \{S_i\}_{i=1}^{n}$ forms a sentence memory that is accessible by the processing module. The processing module exploits multi-head self-attention and GRU to guarantee the property that vectors retrieved from memory $\mathcal{S}$ will not change if the memory is randomly shuffled. Formally, the processing module is defined by

$$\begin{aligned}\{A_i\}_{i=1}^{n} &= \text{MultiHead}(\mathcal{S}, \mathcal{S}, \mathcal{S}),\\ h_t &= \text{GRU}(h_{t-1}, A_t),\end{aligned} \tag{10}$$

where the last hidden state h_n is permutation invariant regarding to input. The writing module is another GRU that decodes $\{o_1, \dots, o_n\}$ one by one. At step i, the hidden state $\bar{h}_i$ is defined by

$$\bar{h}_i = \text{GRU}(\bar{h}_{i-1}, [c_i \oplus x_i]), \tag{11}$$

where $\bar{h}_{i-1}$ is the hidden state at step $i-1$ with $\bar{h}_0 = h_n$, x_i is the embedding of o_{i-1} (i.e., the embedding of the ground-truth position of $U_{o_{i-1}}$ in $\mathcal{U}$), and c_i is a context vector which is defined via attention over $\{h_t\}_{t=1}^{n}$:

$$\begin{aligned} c_i &= \sum_{t=1}^{n} a_{i,t} h_t, \\ \{a_{i,t}\}_{t=1}^{n} &= \text{softmax}(\{e_{i,t}\}_{t=1}^{n}), \\ e_{i,t} &= V^{\top}\tanh(W_1 \bar{h}_{i-1} + W_2 h_t + b_1), \end{aligned} \tag{12}$$

where V_1, W_1, W_2, and b_1 are parameters. The prediction model is finally formulated as

$$\begin{aligned} P(o_i|\{o_1, \dots o_{i-1}\}, \bar{\mathcal{U}}) &= \text{softmax}(u_i), \\ u_i &= \text{FNN}(\bar{h}_i \oplus x_i \oplus c_i). \end{aligned} \tag{13}$$

The loss function of the task is defined by

$$\mathcal{L}_{\text{uor}} = -\frac{1}{n}\sum_{i=1}^{n}\log(p(o_i|\{o_1, \dots, o_{i-1}\}, \bar{\mathcal{U}})). \tag{14}$$

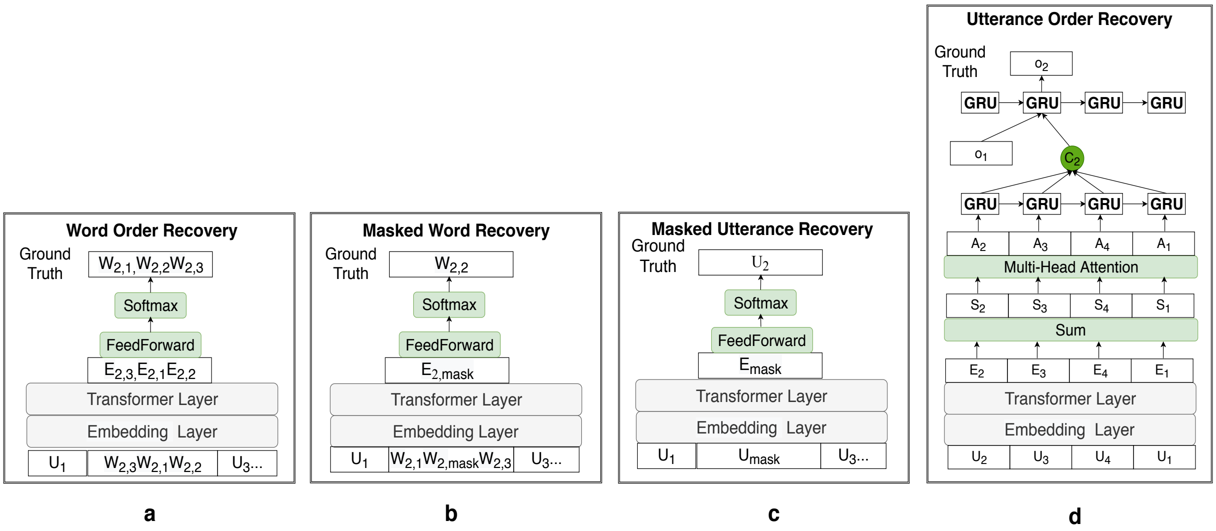

Figure 2: Auxiliary tasks.

For this task and the following ones, M in Equation (4) is defined as a zero matrix meaning that every pair of words can attend to each other in the context.

Masked content recovery: a major challenge in context understanding is the information omission problem (e.g., coreferences) that widely exists in utterances (Su et al., 2019). The challenge requires a model to connect semantically related words and utterances. Thus, we design masked content recovery tasks on both a word level and an utterance level to enhance the self-attention module in terms of awareness of the semantic connections.

- **Word level**: for each utterance in a context, we randomly replace 15% words with a special token [MASK].
- **Utterance level**: we randomly pick an utterance from a context, and replace all words in the utterance with a special token [MASK].

Figure 2 (b) and Figure 2 (c) illustrate the task of masked word recovery (mwr) and the task of masked utterance recovery (mur) respectively. Since the only difference of the two tasks is the input, we present them in a uniform way. Given a context $\mathcal{U} = (w_1, \ldots, w_m)$, suppose that the masked context is $\bar{\mathcal{U}} = (w_1^*, \ldots, w_m^*)$, where $w_i^* = \text{[MASK]}$ if w_i is masked, otherwise $w_i^* = w_i$, then, the loss of the tasks can be formulated as

$$\begin{aligned} \mathcal{L}_x &= -\frac{1}{k}\sum_{i=1}^{m} \mathbb{I}[w_i^*\text{=[MASK]}] \log(p(w_i|\bar{\mathcal{U}})), \\ k &= \sum_{i=1}^{m} \mathbb{I}[w_i^*\text{=[MASK]}], \\ p(w_i|\bar{\mathcal{U}}) &= \text{softmax}(W_s E(w_i^*)), \end{aligned} \tag{15}$$

where $E(w_i^*)$ is the representation of w_i^* obtained by passing $\bar{\mathcal{U}}$ through the encoder of the generation model, $x \in \{\text{mwr}, \text{mur}\}$ indexes the two tasks, $\mathbb{I}[\cdot]$ is an indicator function, and W_s is shared with Equation (6).

3.4 Learning Objective

The full loss function is finally defined by:

$$\begin{aligned} \mathcal{L}_{\text{full}} &= \text{MLE} + \alpha\mathcal{L}_{\text{aux}}, \\ \mathcal{L}_{\text{aux}} &= \mathcal{L}_{\text{wor}} + \mathcal{L}_{\text{uor}} + \mathcal{L}_{\text{mwr}} + \mathcal{L}_{\text{mur}}, \end{aligned} \tag{16}$$

where α is a hyper-parameter as a trade-off between MLE and the objectives of the auxiliary tasks. The learning algorithm is summarized in Algorithm 1, where Θ refers to a set of parameters including both the parameters of the generation model and the parameters of the auxiliary objectives.

4 Experiments

We conduct experiments on DailyDialog (Li et al., 2017), PERSONA-CHAT (Zhang et al., 2018), and the Ubuntu Dialogue Corpus (UDC) (Lowe et al., 2015), and compare our model with state-of-the-art baselines in terms of response quality, parameter size, and decoding speed.

```
Algorithm 1: Optimization Algorithm
Input: Training data $\mathcal{D}$, GlobalMaxStep $T_1$,
       AuxTrainEpoch $T_2$, InitialRate $\alpha$,
       BatchNumPerEpoch $N$
Init: $\Theta$
$t = 0$
$\alpha = 1.0$
$d = \alpha/(T_2 * N)$
while $t < T_1$ do
    Randomly sample a mini-batch $k$ from $\mathcal{D}$.
    if $\alpha > 0$ then
        Compute $\mathcal{L}_{\text{aux}}$.
    Compute MLE.
    Update the parameters of the model with respect to $\mathcal{L}_{\text{full}}$ using Adagrad.
    $\alpha = max(0, \alpha - d)$
    $t = t + 1$
Output: $\Theta$
```

4.1 Datasets

Both DailyDialog and PERSONA-CHAT are open domain datasets. Dialogues in DailyDialog cover a wide range of topics in daily scenarios and resemble human communications in their daily life; while PERSONA-CHAT contains multi-turn chitchat conversations between turkers according to their assigned profiles. Since the focus of the work is how to leverage conversation history for response generation, we just append the profiles (the original ones) to the corresponding dialogues as an extension of contexts. To control the length of the dialogues and increase the number of instances, we slide a window on the training/validation/test dialogues in both datasets, and split a dialogue longer than 11 utterances to multiple instances (i.e., the window size is 11). Moreover, we also truncate long utterances with the first 25 words kept. Vocabularies are formed with all words appearing in the entire data and are shared by contexts and responses. The vocabulary size of DailyDialog is $25,000$ and the vocabulary size of PERSONA-CHAT is $18,750$. The UDC data are collected from Ubuntu chat logs with two-person multi-turn conversations about Ubuntu-related problems. Here we use the same data as in (Zhang et al., 2019). Table 1 reports some statistics of the three datasets.

	DailyDialog	PERSONA-CHAT	Ubuntu
# dialogues for training	44,050	95,682	3980,000
# dialogues for validation	4,176	11,602	10,000
# dialogues for test	3,864	11,152	10,000
avg. # utter. per dialogue	7.0	9.4	4.3
avg. utter. length	13.6	14.5	16.6

Table 1: Statistics of the datasets.

4.2 Baselines

We select several multi-turn response generation models as baselines: (1) **HRED**[2]: hierarchical encoder-decoder proposed in (Serban et al., 2016); (2) **VHRED**[3]: an extension of HRED that factorizes response generation with latent variables (Serban et al., 2017); (3) **HRAN**[4]: hierarchical encoder-decoder equipped with a hierarchical attention mechanism (Xing et al., 2018); (4) **ReCoSa**[5]: a hierarchical transformer-based model that exhibits state-of-the-art performance on benchmarks (Zhang et al., 2019); and (5) **SSN**: a very recent study on enhancing dialogue generation learning with self-supervision signals extracted from utterance order (Wu et al., 2019).

4.3 Implementation Details

We train the baselines and our model on RTX 2080, and initialize word embedding with GloVe vectors (Pennington et al., 2014). In our model, the dimension of all vectors is set as 512. The number of heads in multi-head attention is set as 8. We adopt the Adagrad algorithm (Duchi et al., 2011) in optimization with a learning rate 0.05 and a batch size 80/60/32 in DailyDialog/PERSONA-CHAT/Ubuntu. All models are tuned on the validation sets according to perplexity. We stop training if the perplexity does not drop in three consecutive epochs. The GlobalMaxStep T_1 is set as 50k. The AuxTrainEpoch T_2 is set as 30. The BatchNumPerEpoch N is $551/1595/124,375$ for DailyDialog/PERSONA-CHAT/Ubuntu.

4.4 Evaluation Metrics

We evaluate the performance of the models in terms of response quality with both automatic metrics and human judgment. In automatic evaluation, besides BLEU-4 (Papineni et al., 2002) and perplexity (Sutskever et al., 2014), we follow (Serban et al.,

Table 2: Evaluation results on automatic metrics. Numbers in bold indicate the best performing model on the corresponding metrics.

2017) and employ Embedding Average (Average), Embedding Extrema (Extrema), and Embedding Greedy (Greedy) as metrics. We also follow (Li et al., 2015) and measure the informativeness of responses with distinct-1 and distinct-2 that are calculated as the ratios of distinct unigrams and bigrams. In human evaluation, we randomly sample 500 dialogues from each of the three test sets, and recruit 3 native speakers as human annotators. For each context in the 500 dialogues, each annotator compares a response from our model and a response from a baseline model. The two responses are top one results from greedy search, and are randomly shuffled to hide their sources. The annotators judge which response is better based on informativeness, consistency, and fluency of the responses. If an annotator cannot tell which response is better, he/she is required to label a "tie". Each annotator individually judges 500 pairs for all combinations of our model and baseline models. In total, each one labels $2,500$ pairs for one dataset. Fleiss' kappa (Fleiss and Cohen, 1973) is employed to measure agreement among the annotators.

In addition to response quality, we also compare our model with baselines on decoding speed. We calculate the average prediction time per word in response generation using all dialogues in the test sets. The efficiency comparison is conducted on a GPU environment with a single RTX 2080.

4.5 Evaluation Results

Table 5 reports evaluation results on automatic metrics. Our model outperforms all baseline methods on most of the metrics on all the three datasets. The last two columns of the tables compare different models in terms of parameter size and decoding speed. Note that in training, the auxiliary tasks contain parameters outside the generation model. Therefore, in the column of parameter size, we report two numbers for our model with the one before "/" parameter size in training and the one after "/" parameter size of the generation model. It is remarkable that the parameter size of our model, even in training, is smaller than HRED. In spite of this, the model still outperforms ReCoSa with only $19.5\%/18.2\%/14.0\%$ parameters on the DailyDialog/PERSONA-CHAT/Ubuntu data. This is because (1) the auxiliary tasks can effectively aid the learning of the generation model in our method; and (2) ReCoSa, although in a deep structure, is still inadequate in terms of context modeling due to the RNN-based encoder and the only utterance-level attention. Besides the superior performance on response quality, our model also enjoys a fast decoding process, thanks to the small model size. In terms of decoding speed, our model is comparable with HRED, and 2x faster than ReCoSa. The generation model of SNN is just a simple RNN sequence-to-sequence with one layer encoder and one layer decoder. Therefore, our model is comparable with SSN in terms of complexity and speed. However, SSN is worse than our model on response quality due to (1) the RNN-based seq2seq model in SSN is worse than a transformer-based structure on the benchmarks used in this work, which has been indicated by Sankar et al. (2019); (2) SSN only considers utterance order, while we also leverage word order, word content, and utterance content in

learning. In fact, we find that the proposed auxiliary tasks can improve a 2-layer (one for encoder and one for decoder) RNN-based seq2seq model as well, as reported in Supplementary Material. On most metrics, RNN with full auxiliary tasks is better than SSN but worse than the proposed model.

Table 4 summarizes human evaluation results. We can see that our model outperforms all baseline models, and most of the kappa values exceed 0.6 indicating substantial agreement among the annotators. Based on the annotation results, we find that our model tends to generate diverse and context consistent responses, indicating the effect of the auxiliary tasks.

4.6 Discussions

To further understand the merit of the auxiliary tasks, we make some analysis regarding to the following questions: **Q1** how do the simple architecture learned with the auxiliary tasks compare with a deep architecture; **Q2** if learning with the auxiliary tasks can also improve deep architectures; and **Q3** how different auxiliary tasks affect the performance of the model.

Answer to Q1: we aim to move one step further to understand how the auxiliary tasks enhance the capability of the simple generation model on context understanding. While this is not trivial for neural models, we assume that one can let a transformer-based model capture more semantics in contexts by stacking more layers in the encoder, and examine to what extent the simple model learned with the auxiliary tasks is equivalent to a deep architecture. Figure 3 compares our model with deep architectures in terms of perplexity on the three datasets, in which we get the deep architectures by stacking transformer layers in the encoder of our model. The dotted lines represent our model learned with the auxiliary tasks, and the solid lines represent the deep architectures learned with MLE. Approximately, our model is equivalent to a deep model with a 4-layer encoder on the DailyDialog data, a 6-layer encoder on the PERSONA-CHAT data, and a 7-layer encoder on the Ubuntu data.

Answer to Q2: since the auxiliary tasks are useful for the simple model, it is also interesting to check if they work as well for deep architectures. Figure 3 shows the results, in which the dash-dotted lines represent the deep architectures learned with the full auxiliary tasks. First of all, we can conclude

Table 4: Human evaluation results. The ratios are calculated by combining annotations from three judges together.

that the auxiliary tasks are also useful for deep architectures, since there is clear PPL drop for the same models learned with and without (i.e., the solid lines) the auxiliary tasks. Secondly, the auxiliary tasks are more useful for simple structures, since the gap between the same models learned with and without the tasks becomes smaller and smaller when the number of encoding layers increases. The results indicate that after stacking enough layers, the effect of the auxiliary tasks is overwhelmed by the model itself. Therefore, the merit of the auxiliary tasks is to allow us to learn a generation model that enjoys both efficacy and efficiency, which is exactly the goal of the work. Improvement with respect to the number of layers of the encoder on UDC is more steady than that on DailyDialog and PERSON-CHAT. This is because the training set of UDC is much larger than those of the other two datasets.

Answer to Q3: we keep the architecture of the generation model and remove the objectives of the auxiliary tasks one at a time from the full learning objective given by Equation (16). Table 3 reports the ablation results. First of all, all auxiliary tasks are useful as removing any of them will cause a performance drop. When all auxiliary tasks are removed, the approach degenerates to learning a 2-layer transformer architecture through MLE. Without any optimization on context understanding, the simple structure is worse than ReCoSa. Secondly, on DailyDialog and UDC, order recovery tasks are more crucial than content recovery tasks due to the order insensitive nature of self-attention. Finally, on PERSONA-CHAT, word-level recovery tasks matter more than utterance-level recovery tasks. This might stem from the fact that in PERSONA-CHAT, dialogues highly depend on the profiles used as contexts. In many cases, utterances are just formed by copying a proportion of words from the profiles. Thus, recognizing the semantic connections and the relationship among words in contexts is more critical for the data.

5 Conclusions

We propose a simple generation model with order recovery and masked content recovery as auxiliary tasks. Evaluation results on three benchmarks indicate that our model can significantly outperform state-of-the-art deep generation models in terms of both response quality and decoding speed.

A RNN with Auxiliary Tasks

As a follow-up investigation, we are curious about if the auxiliary tasks can enhance the performance of other simple architectures in the task of multi-turn response generation. Table 5 reports the results on the three benchmarks, where the simple architecture is an RNN-base seq2seq model with one layer encoder and one layer decoder. The architecture of the model is the same as the one in SSN, that is the encoder is defined with a bi-directional GRU, the decoder is defined with a unidirectional GRU, and the decoder is equipped with an attention mechanism on the input context. From the results, we can see that the auxiliary tasks are also useful for the RNN architecture, although it is still worse than the proposed transformer-based architecture under the same learning protocol. On most metrics, the RNN model is better than SSN, since it leverages signals from full auxiliary tasks.

Abstract

Retrieving the proper knowledge relevant to conversational context is an important challenge in dialogue systems, to engage users with more informative response. Several recent works propose to formulate this knowledge selection problem as a path traversal over an external knowledge graph (KG), but show only a limited utilization of KG structure, leaving rooms of improvement in performance. To this effect, we present *AttnIO*, a new dialog-conditioned path traversal model that makes a full use of rich structural information in KG based on two directions of attention flows. Through the attention flows, *AttnIO* is not only capable of exploring a broad range of multi-hop knowledge paths, but also learns to flexibly adjust the varying range of plausible nodes and edges to attend depending on the dialog context. Empirical evaluations present a marked performance improvement of *AttnIO* compared to all baselines in OpenDialKG dataset. Also, we find that our model can be trained to generate an adequate knowledge path even when the paths are not available and only the destination nodes are given as label, making it more applicable to real-world dialogue systems.

1 Introduction

One of the milestone challenges in conversational AI is to engage users with a more informative and knowledgeable response, rather than merely outputting generic sentences. For instance, given a user's utterance saying "I'm a big fan of Steven Spielberg", it would be more engaging to respond "My favorite movie is his science fiction film A.I.", rather than "I like him too.". An external source of knowledge such as knowledge graph (KG) can play a crucial role here, as it could help the conversational agent with informative paths, such as "Steven Spielberg, directed, A.I., has genre, Science Fiction".

The above mentioned motivation gave rise to a conspicuous need for path retrieval model on KG, which can learn to traverse a path consisting of proper entities and relations to mention in the next response, given the dialog context. Previous approaches to this knowledge selection problem rely on either an RL-based agent (Liu et al., 2019) or a recurrent decoder (Moon et al., 2019), which greedily selects the most proper entity to traverse regarding its previous decision. Despite their novelty, we find several rooms of improvement from the previous works, to move toward a more fine-grained modeling of knowledge path retrieval for dialogue systems.

First, a model could make use of the rich relational information residing at the neighborhood of each node on KG. Typically, the number of entities in KG is large, while the numbers of each entity's usage in actual dialogues are small. Thus leveraging the neighborhood information of each entity in knowledge graph could be crucial, to overcome the sparsity of entity usage and learn proper representation of entities and relations.

Also, we find that the range of knowledge paths plausible for a response to a given dialog may vary, depending on the dialog context and user intent. In response to a closed question such as "Who directed the movie A.I.?", there could be only one or two knowledge paths valid as answer. On the contrary, in response to an open question such as "Do you know Steven Spielberg?", there could be a variety of knowledge paths natural enough to carry on the conversation. Therefore, a model should be able to choose the range of entities to attend, depending on the characteristics of a given dialog.

Lastly, one should note that it is practically hard

November 16–20, 2020.

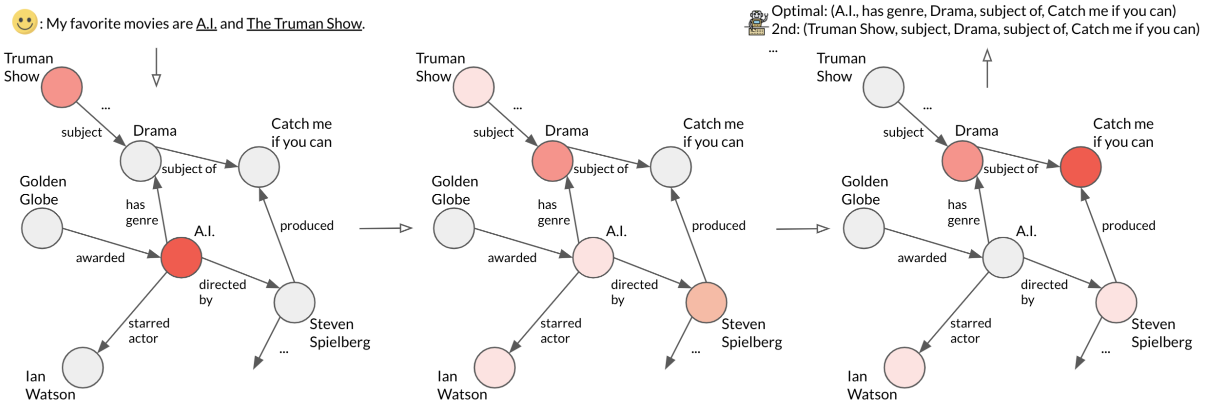

Figure 1: **Path decoding process** of AttnIO. By propagating attention values at each step rather than selecting one node to traverse, AttnIO can choose between focusing on small number of entities or attending to multiple relevant neighbors, depending on the dialog context.

to gather a large-scale dialog-KG path parallel corpus, fully annotated with all entities and relations comprising each path. Retrieving the initial, and final entities of the KG path is relatively easier, as it only requires post-processing the {query, response} pairs in dialog. Therefore, it would be more desirable if a model could be trained to traverse a proper knowledge path, only with the destination nodes provided as label.

To this end, we propose *AttnIO* (**Attention In**-flow and **Out**-flow), a novel KG path traversal model that overcomes all challenges stated above. Aside to the conventional textual encoder which encodes dialog history and user utterance, *AttnIO* models the KG traversal mechanism into two subprocesses: *incoming attention flow*, and *outgoing attention flow*. Inspired by Attention Flow (Xu et al., 2018), the two attention flows explore KG by propagating the attention value at each node to its reachable neighbor nodes, as shown in Figure 1. The attention propagation mechanism enables our model to start exploring KG from multiple entities (*A.I.*, and *The Truman Show*), then find out an intermediate node *Drama* relevant to both movies, and end the multi-hop reasoning by arriving at *Catch me if you can*. Such a complex interaction between entities cannot be modeled by a greedy decoder, limited to consider only an optimal node at each decoding step. In addition, our model provides better interpretation of its path reasoning process, by visualizing the attention distribution of nodes and edges at each step. Lastly, we consider our model in a more challenging, but more realistic setting of path retrieval task, where no ground-truth path is available for supervision, but only the final destination nodes are given. Even in this setting, we find that *AttnIO* can be trained to infer a proper knowledge path for the input dialog.

In summary, our contributions are as follows: (1) We suggest a novel path traversal model *AttnIO*, achieving state-of-the-art performance in dialog-conditioned knowledge path retrieval task on the OpenDialKG dataset. (2) We demonstrate that *AttnIO* can be trained even in a challenging setting where only the destination nodes are given, and show through both qualitative and quantitative analysis that the quality of paths generated from this setting does not fall behind that of the all-path supervision setting. (3) Through visualizing the attention distribution at each decoding step, we show that our model possesses better interpretability over the path reasoning process.

2 Related Works

Recently, lots of research effort have been devoted to grounding dialogue systems on structured-knowledge embedded in knowledge graphs. These works can be broadly classified into two categories, depending on the range of exploration over candidate knowledge. The first line of works, namely *breadth-centric approaches*, tend to focus on augmenting dialog context with entity representations, by aggregating their *shallow* (i.e., 1-hop or 2-hop) neighborhood information from an external knowledge graph (Young et al., 2018; Liu et al., 2018; Parthasarathi and Pineau, 2018; Chen et al., 2019). Zhou et al. (2018) suggest to encode an auxiliary knowledge vector by attentively reading all 1-hop relations of each initial entity that appears in user's utterance. Zhang et al. (2019) extends the previous work's knowledge encoding scheme to 2-hop relations, encoding all initial entities and their 1-hop neighbors with two independent attention mechanisms. While these works are successful in contextualizing each entity with various relations in KG, they lack in retrieving small set of focused knowledge paths relevant to the dialog, or generalizing to multi-hop relations. We extend these approaches by suggesting a new framework that can be generalized to an arbitrary length of traversal, and dynamically updating entity features at each decoding step to facilitate multi-hop relational inference.

On the other hand, the second line of works resort to *depth-centric search* over candidate knowledge paths. Rather than augmenting entity representation with shallow but wide range of knowledge, they concentrate on traversing only a specific range of entities and relations directly usable for response generation. Liu et al. (2019) formulate the knowledge selection problem as Partially Observed Markov Decision Process, employing a policy network to traverse KG. Meanwhile, Moon et al. (2019) suggest a recurrent path decoder that relies on a hidden state vector to choose the next entity among reachable nodes. Although these models are competent at inferring multi-hop relations, their discrete selection mechanism neglects rich relational information of nodes and edges they did not explicitly choose to traverse. To complement the weakness, AttnIO does not select an optimal node in advance; rather, it first propagates attention to all reachable entities, and then decode an optimal path from the output attention distribution.

Our work is also closely motivated from recent techniques suggested in the domain of knowledge graph completion tasks. To compensate for weak representation power of translative embedding (Bordes et al., 2013; Trouillon et al., 2016) and convolution-based embedding (Dettmers et al., 2018; Nguyen et al., 2018), several models have adopted graph neural networks (GNN), encoding structural information into entity embedding (Shang et al., 2019; Nathani et al., 2019). Other works perform traversal-based inference in node-prediction tasks based on reinforcement learning (Das et al., 2018; Lin et al., 2018), or attention propagation (Xu et al., 2018). We extend these previous works by adopting graph neural network and attention propagation for the dialog-conditioned path generation problem.

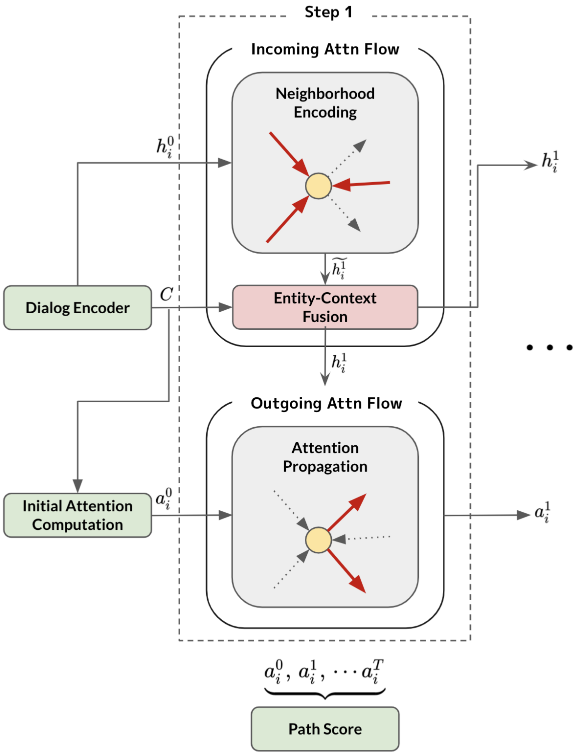

Figure 2: **AttnIO Model Overview**

3 Proposed method

3.1 Overview

We denote the external knowledge graph as $G_{KG} = V_{KG} \times R_{KG}$, with nodes as entities and edges as relations between a pair of entities. We denote $G_{v,n} \subseteq G_{KG}$ as a subgraph containing all nodes and edges reachable in less then or equal to n-hops, starting from vertex v. Also, we define $\overrightarrow{N}_i$ as a set of incoming neighbor nodes of v_i, i.e. nodes possessing edges toward v_i, and $\overleftarrow{N}_i$ as a set of outgoing neighbor nodes of v_i.

Figure 2 illustrates the overview of AttnIO's path generation process. Given the input multi-turn dialog sequence $\{s_1, \cdots, s_n\}$ and the set of entities $V_{init} = \{e_1, \cdots, e_m\}$ appearing in the user's last utterance s_n, AttnIO starts from encoding the input dialog into a fixed-size context vector. It also constructs the dialog-relevant subgraph $G_{input} = \bigcup_i G_{e_i,T}$, where T is a hyperparameter indicating the maximal length of path to traverse.

At each decoding step $t = 1, \cdots, T$, the *incoming attention flow* iteratively updates the KG entity features by attentively aggregating rich relational features from their incoming neighbor nodes. Then, the *outgoing attention flow* propagates the attention value of each node to its outgoing neighbor nodes, yielding the node attention distribution a_i^t and edge attention distribution a_{ij}^t as step t's output. We show that each candidate entity path $P_v = \{P_v^{(0)}, \cdots, P_v^{(T)}\}$ and the relation path $P_r = \{P_r^{(1)}, \cdots, P_r^{(T)}\}$ can easily be ranked from these output attention distributions, in Section 3.4.1.

3.2 Dialog Encoder

AttnIO encodes the input multi-turn dialog into a fixed-size contextual representation. Specifically, we employ state-of-the-art textual representation from ALBERT (Lan et al., 2019), to effectively capture the context and intent of the user's utterance. We concatenate maximum of 3 last utterances in the dialog, and put it as input to the pretrained ALBERT. We use the final layer's hidden representation of [CLS] token, as it is typically considered to be an approximation of the sequence context. We denote this context vector as $\mathbf{C}$, in the following section.

Note that our architecture does not require a specific type of textual encoder, and ALBERT can be replaced with any sequence encoder such as bidirectional RNN. For a fair comparison with previous work, we conduct an ablation study on ALBERT by replacing it with bidirectional GRU (Section 4.1).

3.3 Incoming Attention Flow

In order to find better entity representation, the Incoming Attention Flow iteratively updates each entity feature $\mathbf{h}_j$ for all $v_j \in G_{input}$, by aggregating v_j's neighbor information. Recently suggested message-passing mechanism of *graph attention networks* (GAT) from Veličković et al. (2018) is suitable for this, as it learns to encode each node by selectively attending over its neighbors. Since GAT does not take account of edge features and hence may lose useful relational information integral in KG, we extend the attention-based message passing scheme of GAT into relational graphs. At each decoding step t, the Incoming Attention Flow computes message from entity v_i to v_j as follows:

$$\mathbf{m}_{ij} = \mathbf{W}_m \left[\mathbf{h}_i + \mathbf{r}_{ij}\right] \tag{1}$$

where $\mathbf{h}_i$ denotes the feature of v_i at step t, and $\mathbf{r}_{ij}$ denotes the relation feature assigned to the edge between v_i and v_j. Then, the new node feature $\widetilde{\mathbf{h}}'_j$ for the next time step $t+1$ is computed as an attention-based weighted sum of messages from all incoming neighbor nodes of v_j:

$$\widetilde{\mathbf{h}}'_j = \sum_{i \in \overrightarrow{N_j}} a_{ij} \mathbf{m}_{ij} \tag{2}$$

The attention a_{ij} is computed by applying softmax over v_j's all incoming neighbor nodes:

$$\begin{aligned} a_{ij} &= \underset{i \in \overrightarrow{N_j}}{\texttt{softmax}}(\alpha_{ij}), \\ \alpha_{ij} &= \sigma\left((\mathbf{W}_Q \mathbf{h}_j)^T (\mathbf{W}_k(\mathbf{h}_i + \mathbf{r}_{ij}))\right) \end{aligned} \tag{3}$$

where σ denotes LeakyReLU non-linearity.

In addition, we extend our attentive aggregation scheme to multi-headed attention, which helps to jointly attend to information from different representation subspaces of incoming messages (Vaswani et al., 2017). Thus our message aggregation mechanism in Eq.2 is transformed into:

$$\widetilde{\mathbf{h}}'_j = \Big\Vert_{k=1}^{K} \sum_{i \in \overrightarrow{N_j}} a_{ij}^k \mathbf{m}_{ij}^k \tag{4}$$

where K denotes the number of attention heads. The attention heads perform independent self-attention over neighborhood features, then are concatenated to form the new node feature $\widetilde{\mathbf{h}}'_j$.

Another crucial step in Incoming Attention Flow is to fuse entity features with dialog context, such that even if a same set of initial entities are given, the decoder could traverse possibly different paths according to the dialog context. We achieve this fusion by concatenating the dialog context vector with entity feature computed from Eq.4 and then linear-transforming back to the entity embedding dimension:

$$\mathbf{h}'_j = \mathbf{W}_h \left[\widetilde{\mathbf{h}}'_j \,\Vert\, \mathbf{C}\right] \tag{5}$$

3.4 Outgoing Attention Flow

At the core of AttnIO lies the Outgoing Attention Flow, which defines path traversal on KG as an attention propagation mechanism. In the beginning of the decoding step, it starts from computing the initial attention value a_i^0 of nodes in V_{init}, i.e. the set of entities appearing in the user's last utterance.

$$a_i^0 = \underset{i \in V_{init}}{\texttt{softmax}}\left((\mathbf{W}_{init}\mathbf{C})^T \mathbf{h}_i\right) \tag{6}$$

The relevance of each candidate node is scored as the dot-product with the dialog context vector. In case of entities not in V_{init}, we initialize the node attention value to zero.

Hereafter, the decoder iterates for step 1 to T, where T denotes the maximal possible path length. We add self-loops to each node in G_{input}, in order to indicate that a traversal ended before step T. Given the context-fused entity feature $\mathbf{h}_i^t$ for all $v_i \in G_{input}$ at each step t, Outgoing Attention Flow essentially computes how much attention value to propagate from v_i to its outgoing neighbor v_j, as follows:

$$\begin{aligned} &\widetilde{a}_{ij}^{t+1} = \mathcal{T}_{ij}^{t+1} a_i^t, \; a_j^{t+1} = \sum_{i \in \overrightarrow{N_j}} \widetilde{a}_{ij}^{t+1} \\ &s.t. \; \sum_i a_i^{t+1} = 1, \; \sum_{ij} \widetilde{a}_{ij}^{t+1} = 1 \end{aligned} \tag{7}$$

A key here is the transition probability $\mathcal{T}_{ij}$, which can be derived from a function of two relevant node features, $\mathbf{h}_i$ and $\mathbf{h}_j$. In this work, we formulate the process as averaging the multi-headed attentions computed over all outgoing neighbor nodes:

$$\begin{aligned} &\mathcal{T}_{ij} = \frac{1}{K} \sum_{k=1}^{K} \underset{j \in \overleftarrow{N_i}}{\mathtt{softmax}}(\tau_{ij}^k), \\ &\tau_{ij}^k = \sigma\left((\mathbf{W}_Q \mathbf{h}_i^k)^T (\mathbf{W}_k (\mathbf{h}_j^k + \mathbf{r}_{ij}^k)) \right) \end{aligned} \tag{8}$$

3.4.1 Scoring candidate paths

Given the output of Outgoing Attention Flow at each decoding step i.e. the node attention distribution $a_i^0, \cdots a_i^T$ and the edge attention distribution $\widetilde{a}_{ij}^1, \cdots \widetilde{a}_{ij}^T$, we can score each candidate entity paths with the product of respective node attention value at each step:

$$\mathtt{score}(P_v) = \prod_{t=0}^{T} a_{P_v^{(t)}}^t \tag{9}$$

Likewise, the score of the relation path P_r associated with P_v can be retrieved by the product of respective edge attention value at each step:

$$\mathtt{score}(P_r) = \prod_{t=1}^{T} \widetilde{a}_{P_r^{(t)}}^t \tag{10}$$

3.4.2 Training Objective

We train the whole model in an end-to-end manner by directly supervising on the attention distribution at each step. In a default setting where the whole ground-truth paths are available, we use a negative log-likelihood loss on each step's attention distribution (left), and in the target-supervision setting where only the final entity labels are given, we supervise with the same loss only at the final step's attention distribution (right):

$$\mathcal{L} = \sum_t -log\, a_{label}^t, \text{ or } -log\, a_{label}^T \tag{11}$$

3.4.3 Dialog-KG Alignment by Initialization

AttnIO's training phase tends to be unstable in the beginning, as the model has to deal with two completely different modalities: KG entities, and the dialog. In order to align the two different features, we find that initializing each entity feature as the representation from pretrained ALBERT helps. Just as the dialogue context representation, we put each entity phrase as input with [CLS] token. We then take the hidden representation of [CLS] token from the last layer of ALBERT, and linear-transform it to create initial entity feature $\mathbf{h}_i^0$. Note that we do not fine-tune ALBERT, but back-propagate to $\mathbf{h}_i^0$ during training. This additional process not only narrows down the gap between feature space of entities and dialog contexts, but also helps better understand each entity in several cases, as some entities span a lengthy phrase of natural language tokens (e.g. *Grammy Award for Best Pop Collaboration with Vocals*).

4 Experiments and Results

Dataset We evaluate our proposed method on OpenDialKG (Moon et al., 2019), a dialog - KG parallel corpus designed for knowledge path retrieval task. The dataset consists of 91k multi-turn conversations in form of either task-oriented (recommendation) dialog, or chit-chat on a given topic. Each pair of utterances in the conversations is annotated with a KG path, where its initial entity is mentioned in the former turn, and its destination entity is mentioned in the latter turn. As the train/valid/test partitions of OpenDialKG are not publicly available, we create our own split by randomly partitioning into train (70%), valid (15%), and test set (15%).

Baselines We take 4 models suggested by Moon et al. (2019) as baselines. These models include DialKG Walker, a state-of-the-art model designed to traverse a dialogue conditioned knowledge path. Other 3 models are Seq2Seq (Sutskever et al., 2014), Extended Encoder-Decoder (Parthasarathi and Pineau, 2018), Tri-LSTM (Young et al., 2018) all modified to fit the entity path retrieval task.

	Recall@k									
Model	*path@1*	*path@3*	*path@5*	*path@10*	*path@25*	*tgt@1*	*tgt@3*	*tgt@5*	*tgt@10*	*tgt@25*
Seq2Seq	3.1	18.3	29.7	44.1	60.2	-	-	-	-	-
Tri-LSTM	3.2	14.2	22.6	36.3	56.2	-	-	-	-	-
EXT-ED	1.9	5.8	9.0	13.3	19.0	-	-	-	-	-
DialKG Walker	13.2	26.1	35.3	47.9	62.2	-	-	-	-	-
Seq2Path	14.92	24.95	31.1	38.68	48.15	15.65	27.04	33.86	42.52	53.28
AttnFlow	17.37	24.84	30.68	39.48	51.4	18.97	36.23	45.48	58.84	71.35
AttnIO (GRU)	22.36	36.72	42.98	51.22	61.91	23.45	42.31	51.71	64.33	77,64
AttnIO (no context)	7.27	25.12	31.03	40.39	54.72	14.33	33.3	43.26	58.32	76.49
AttnIO (no alignment)	21.84	35.19	41.19	48.85	59.08	22.99	41.3	50.63	64.01	78.02
AttnIO-AS	**23.72**	**37.53**	**43.57**	**52.17**	**62.86**	**24.98**	**43.78**	**53.49**	**65.48**	**78.79**
AttnIO-TS	12.09	23.65	30.5	39.48	51.68	22.82	40.01	49.86	61.04	74.49

Table 1: **Performance** of AttnIO in OpenDialKG, in comparison with baselines and ablation models. Results of the above 4 baselines (from Seq2Seq to DialKG Walker) are directly taken from Moon et al. (2019), as their code or implementation details are not available. Our model trained with all path supervision (AttnIO-AS) significantly outperforms all baselines.

Also, we implement another baseline model named Seq2Path, by modifying attention based Seq2Seq model to decode entity paths. On the contrary with Seq2Seq baseline in Moon et al. (2019) which added zero-shot learning layer on KG embedding as decoder, Seq2Path explicitly traverses along the graph structure by masking unreachable nodes at each decoding step. Lastly, in order to find the importance of neighbor node encoding over each entity, we suggest AttnFlow, where Incoming Attention Flow is excluded (hence node features are not updated at each step) and the Outgoing Attention Flow directly generates knowledge path from dialog context and initial entity features.

Implementation Details Our model depends heavily on message passing scheme of graph neural networks, which may lead to excessive memory usage when G_{input} is large. To further scale AttnIO to larger graphs, we reduce the size of the input graph through edge-sampling on G_{input} during training. Detailed explanation on this edge-sampling is presented in Appendix A.

As all ground-truth paths in OpenDialKG are either 1-hop or 2-hop, we set the maximal path length T = 2. We search for the best set of hyperparameters using grid-based search, choosing value with the best path accuracy with all other hyperparameters fixed. We implemented our model using PyTorch (Paszke et al., 2019) and DGL (Wang et al., 2019). Additional implementation details including hyperparameter search bounds and the best configuartion are provided in Appendix E.

4.1 Results

Table 1 presents the overall evaluation results of AttnIO, and its comparison to baseline models. In addition to the recall@k of ground-truth paths (*path@k*), we report recall@k on the target nodes (*tgt@k*), as the destination node can be considered as the most important component in knowledge path to generate response.

As can be seen in the table, our model outperforms all baselines in both *path@k* and *tgt@k*, when supervised with all entities in each path as label (AttnIO-AS). Especially, AttnIO-AS shows significantly better performance in metrics with small k. We also report our model in a more challenging setting of target supervision, assuming that only the destination node of each path is available (AttnIO-TS). In this case, our model shows a comparable target prediction performance (*tgt@k*) to AttnIO-AS, while its *path@k* is relatively poor in small ks.

Recurrent decoder based models, such as DialKG Walker and Seq2Path, relies only on a single state vector to model the transition between each decoding step. Therefore, once the model chooses to traverse a sub-optimal entity, it is hard to get back onto the right track without help of an aggressive beam search. In our method, on the contrary, the state of the decoder is essentially distributed into all the walkable entities' feature vectors; therefore, the transition is modeled alongside all the entities with nonzero attention value at each step, making the model more robust to 'misleading' hops. Also, note that AttnFlow shows consistent performance drop of about 30% then AttnIO-AS in all metrics, indicating the importance of neighborhood encod-

Dialog	A: *Fiona Stafford wrote Emma. It's a romance novel. Are you into that genre?* B: *Any other books that might fall under comedy? I'm in the mood for something light.* A: *[RESPONSE]*
AttnIO-AS	*Comedy ⇒ subject of ⇒ The War of the Worlds ⇒ written by ⇒ Arthur. C. Clarke*
AttnIO-TS	*Comedy ⇒ subject of ⇒ The War of the Worlds ⇒ subject ⇒ Comedy*
AttnFlow	*Comedy ⇒ parent genre ⇒ Slapstick*
GT	*Comedy ⇒ subject of ⇒ One Crazy Summer*

Table 2: **Sample paths** generated from each model, along with the ground-truth path. More examples are provided in Appendix D.

Model	Relation Path Accuracy
AttnIO-AS	0.403
AttnIO-TS	0.365

Table 3: **Relation Path Accuracy** at all path supervision (AttnIO-AS), and target supervision setting (AttnIO-TS).

ing step for knowledge path retrieval.

Ablation Study We conduct ablation study with three different configurations. First, we put GRU (Cho et al., 2014) as dialog encoder in replace of ALBERT, for a fairer comparison with baseline models. As shown in Table 1, we find that although the performance of AttnIO with GRU slightly degrades from that with ALBERT, it still outperforms all existing models. Next, in order to find out the value of dialog context in the traversal, we train our model with only the initial entities given as input (with uniform attention prior assigned to each initial entity), but not the dialog context. Recall@1 significantly drops in this case, while metrics with large k relatively stays moderately. This implies that although information on initial nodes appearing in last utterance might be sufficient to prune improbable paths, the dialog context is essential in finding an optimal path among probable ones. We also find in the third ablation model where no dialog-KG alignment is applied (Section 3.4.3), that ALBERT initialization of node embedding helps, leading to performance gain of about 2% in *path@1*.

4.2 Analysis

Relation Accuracy The poor entity path accuracy of AttnIO-TS may seem natural, as the initial node and intermediate node (in case of multi-hop) are not given as label in target supervision setting. However, one should note that there can be a variety of entity paths that match human sense in naturalness and coherence for a specific dialog. For an example shown in Table 2, any film of comedy genre shall replace *One Crazy Summer* in GT-path, without loss of naturalness. The generated path from AttnIO-AS could even be an answer, giving more information on the chosen film. The inherent one-to-many relationship between dialog context and probable knowledge, makes it hard to correctly assess the performance of knowledge retrieval models. Relation path accuracy could be one way to relieve this problem, as relations represent important attributes shared by similar entities.

The relation path accuracy of AttnIO in both supervision setting is as shown in Table 3. The relation path accuracy under both setting is clearly higher than the entity path accuracy, implying the generalization capability of our model based on reasoning over relations, rather than depending on specific entities. Notably, AttnIO-TS shows only about 10% relative difference from AttnIO-AS, unlike in entity *path@1* in Table 1. This indicates that our model can learn to competently perform relational reasoning, even in this in-the-wild setting of target supervision.

	vs. GT		
Model	Win	Tie	Lose
AttnIO-AS	11.2%	55.2%	33.6%
AttnIO-TS	17.6%	55%	27.4%

Table 4: **Pairwise human evaluation** results between model-generated paths, and ground-truth paths.

Human Evaluation In order to further examine the quality of paths from the two supervision setting, we conduct a human evaluation. We randomly sample 100 dialogues from test set, then generate knowledge paths for half of the dialogues from AttnIO-AS, and half of the dialogues from AttnIO-TS. We then perform a pairwise comparison between the path generated from AttnIO, and the ground-truth path actually used in the dataset. For each dialogue, we ask 5 crowd-source workers to evaluate which knowledge path is more suitable for response generation among the two.

We report the win/tie/lose statistics of the model generated paths against ground-truth paths in Table 4. In both all-path supervision and target supervision setting, more than half of the paths from our model tied with the actual paths. The result attests to the quality of the generated paths, even including those marked as wrong in quantitative measures.

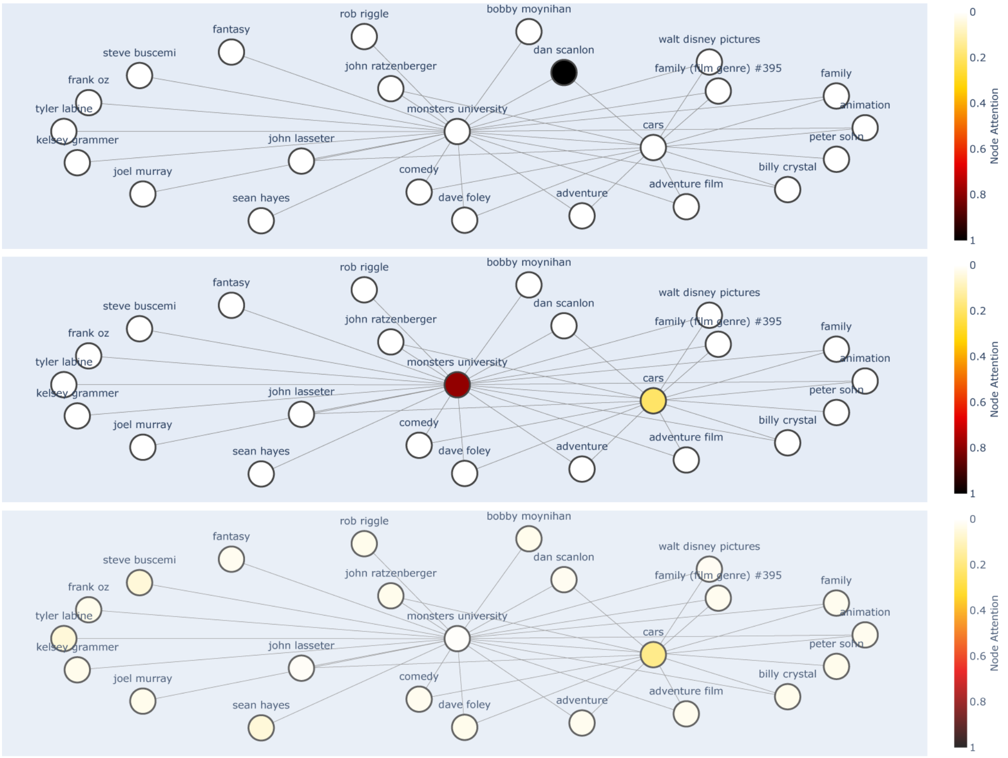

Figure 3: **Node attention visualization** from the case study. Each figure represents the node attention at the initial state (Top), after the first decoding step (Center), and after the second decoding step (Bottom). We omit the edge attention to avoid visual cluttering. Best viewed in color.

AttnIO-TS especially performs much more comparably to AttnIO-AS than in Table 1, indicating that the destination nodes can function as an adequate guidance to our model, in replace of the whole path label.

Case Study We resort to a case study, for a clear presentation of AttnIO's path reasoning process. Figure 3 presents the visualization of output attention distribution from our model, when the dialog context is given as follows:

> A: *Can you recommend some films by <u>Dan Scanlon</u>?*
> B: *[RESPONSE]*

Note that there are hundreds of neighbor nodes connected to each entity in the external KG, but for the sake of clarity, we pruned most of them in the visualization leaving only entities relevant to the dialog. Intuitively, there could be diverse knowledge paths as response to the user's question. Before the initial step, AttnIO starts from assigning an attention value of 1.0 to the only entity mentioned in the utterance, *Dan Scanlon*. In the first propagation step, our model finds from the dialog context, that the most relevant relation in this case is *wrote*, propagating most attention in *Dan Scanlon* to two movie entities, *Monster's University* and *Cars*. In the second step, AttnIO understands that most of the entities directly connected to these two movies, can be a good option for the destination node. As a consequence, AttnIO chooses to propagate a fair amount of attention value evenly to all reachable entities, resulting in the distribution visualized at the third figure. Finally, an optimal path can be retrieved as *Dan Scanlon* $\Rightarrow$ *wrote* $\Rightarrow$ *Monster's University* $\Rightarrow$ *starred actor* $\Rightarrow$ *Steve Buscemi*.

Through the case study, we find that AttnIO directly reflects human intuition regarding an open question. It learns to perform relation-centric reasoning, and assign even amount of attention to equally likely reachable entities. In contrast, given a closed question such as "Who direced movie *Cars*?", AttnIO focuses on a small set of relevant entities and relations. A detailed analysis on the contrasting example is provided in Appendix C.

5 Conclusion

In this work, we suggest AttnIO, a novel path traversal model that reasons over KG based on two directions of attention flows. The empirical evaluations on OpenDialKG dataset show the strength of AttnIO in knowledge retrieval compared to baselines. AttnIO can also be trained to generate proper paths even in a more affordable setting of target supervision. Lastly, we show through case study that our model enjoys from transparent interpretation of path reasoning process, and is capable of intuitively modeling knowledge exploration depending on the dialog characteristics.

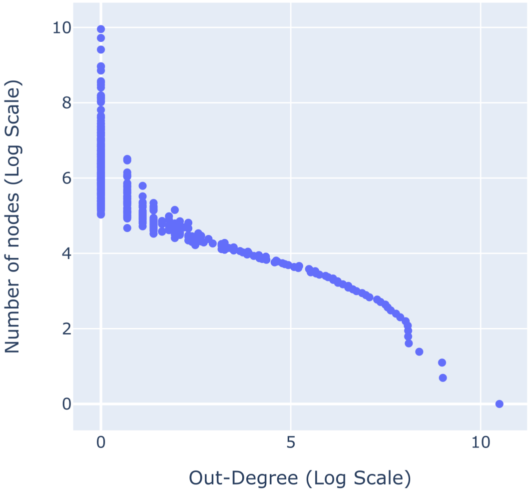

Figure 4: **Out-degree distribution** of all nodes in G_{KG}. Both axis are in log scale.

A Subgraph Sampling

We explain in more detail the subgraph sampling method adopted by AttnIO, as mentioned in Section 4.

As shown in Figure 4, the out-degree distribution of G_{KG} follows an extreme power-law distribution, which is typical in relational graphs. Among 100K nodes in G_{KG}, about 31K nodes possess only one incoming neighbor node, making the graph extremely sparse. Meanwhile, a node with the highest in-degree has more than 21K incoming neighbor nodes, connecting the node to about 20% of all entities in the whole graph.

We find that the small number of *hub nodes* with high in/out degrees are the major factor that increases the size of input graph G_{input}. Therefore, we choose to limit the maximal number of neighbors to sample from each entity, while constructing G_{input} in the training time. We denote this limit as N_{max}.

The effect of subgraph sampling with different N_{max} is shown in Figure 5. Setting N_{max} to 100, subgraph sampling effectively reduces down the number of edges in the input graph to only 5.67% of the original G_{input} on average, while losing only about 1.0 absolute performance in *path@1*. In all our experiments, we set $N_{max} = 1000$, leaving only 32.4% of the edges originally in G_{input}, while not compromising for the retrieval accuracy.

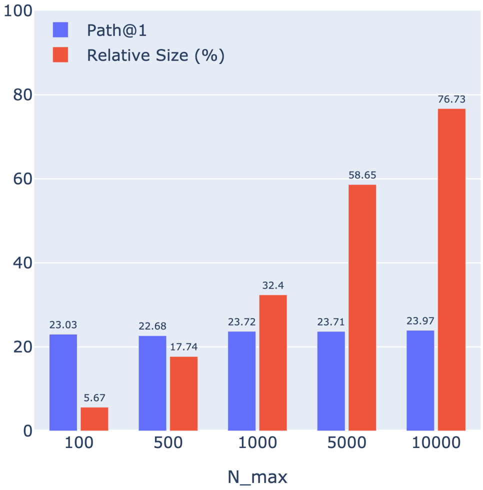

Figure 5: **Effect of subgraph sampling**. Blue bar denotes *path@1* for each N_{max}, while red bar denotes the average relative size of the sampled subgraph compared to the original G_{input}.

B Dataset Statistics

Dialog		KG	
# of dialogues:	15,673	$\|V\|$:	100,813
# of turns:	91,209	$\|E\|$:	1,190,658

Table 5: **Dataset Statistics** of OpenDialKG.

The statistics of OpenDialKG dataset is as shown in Table 5. There are 1358 distinct types of relations comprising 1M+ edges.

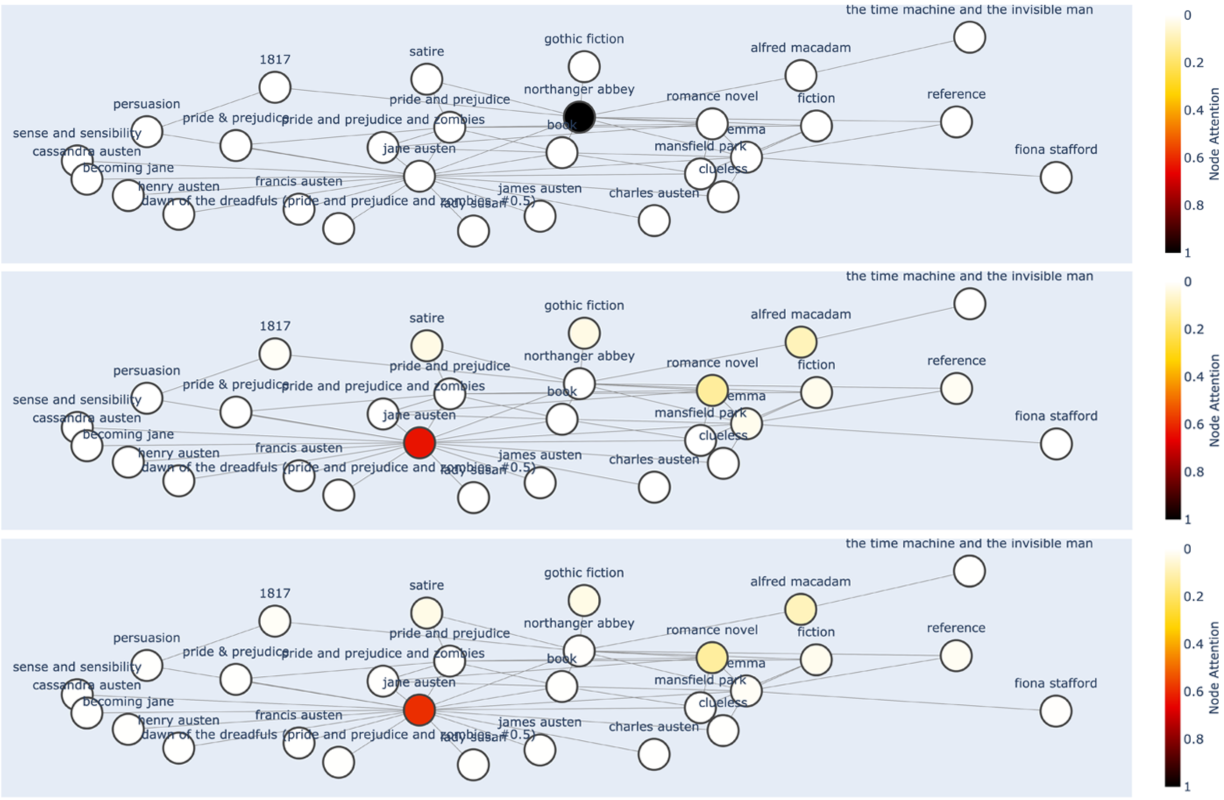

Figure 6: **Node attention visualization** for the additional case study. Each figure represents the node attention at the initial state (Top), after the first decoding step (Center), and after the second decoding step (Bottom). The center and bottom figure might look similar, due to the slight difference of node attention distribution between the two steps. The attention is focused on small number of entities, on the contrary with the even distribution at the former case study.

C Additional Case Study

We provide an additional visualization of node attention distribution for a given dialogue in Figure 6. This time, the model is given a dialogue context as following:

> A: *Someone suggested the Northanger Abbey book to me. Do you know who the author is?*
> B: *[RESPONSE]*

The dialogue is of a similar topic with the case study provided in Section 4.2, but the query in this case is a closed question that specifically asks for the author of a book.

AttnIO first starts from the only initial entity *Northanger Abbey*, and finds from the context that the most relevant relation here is *written by*. Therefore in the first decoding step, AttnIO propagates more than half of the attention value (0.63) from *Northanger Abbey* to its writer, *Jane Austen*. In the second propagation step, AttnIO chooses not to propagate much attention to any of *Jane Austen*'s neighbor nodes, preserving most of the attention value (0.59) by traversing a self-loop. (We omitted self-loops in the visualization for clarity.)

Note that there are a variety of neighbor nodes walkable from *Jane Austen*, just as in the former case study. However, AttnIO understands the intent of user's utterance requiring for a specific answer, concentrating most of the attention to the nodes and edges directly related to the dialogue context.

D Generation Examples

In Table 6, we present more path generation examples along with ground-truth paths for the given dialogues. Note that we only sampled cases where the paths generated from our model are different from the ground-truth paths. Dialogs are partially shown to meet the spatial constraints.

Dialog	A: *I'm not sure who else was in it, but Ralph Fiennes also starred in Wrath of the Titans.* B: *Wrath of the Titans, I didn't know Ralph Fiennes was in that movie. Tell me more about that movie and the stars in it.* A: *[RESPONSE]*
MODEL-AS	*Wrath of the Titans ⇒ starred ⇒ Liam Neeson*
MODEL-TS	*Wrath of the Titans ⇒ starred ⇒ Liam Neeson*
AttnFlow	*Ralph Fiennes ⇒ starred ⇒ The hurt Locker*
GT	*Ralph Fiennes ⇒ starred ⇒ Wrath of the Titans ⇒ written by ⇒ Greg Berlanti*

Dialog	A: *I think Tiger Woods is a good golf player, but is he retired right now?* B: *No he is actually still playing. Is he half asian?* A: *[RESPONSE]*
MODEL-AS	*Asian ⇒ ethnicity of ⇒ Tiger Woods*
MODEL-TS	*Asian ⇒ ethnicity of ⇒ Tiger Woods*
AttnFlow	*Asian ⇒ language ⇒ Vietnamese Language*

Abstract

The challenge of both achieving task completion by querying the knowledge base and generating human-like responses for task-oriented dialogue systems is attracting increasing research attention. In this paper, we propose a "Two-Teacher One-Student" learning framework (TTOS) for task-oriented dialogue, with the goal of retrieving accurate KB entities and generating human-like responses simultaneously. TTOS amalgamates knowledge from two teacher networks that together provide comprehensive guidance to build a high-quality task-oriented dialogue system (student network). Each teacher network is trained via reinforcement learning with a goal-specific reward, which can be viewed as an expert towards the goal and transfers the professional characteristic to the student network. Instead of adopting the classic student-teacher learning of forcing the output of a student network to exactly mimic the soft targets produced by the teacher networks, we introduce two discriminators as in generative adversarial network (GAN) to transfer knowledge from two teachers to the student. The usage of discriminators relaxes the rigid coupling between the student and teachers. Extensive experiments on two benchmark datasets (i.e., CamRest and In-Car Assistant) demonstrate that TTOS significantly outperforms baseline methods. For reproducibility, we release the code and data at `https://github.com/siat-nlp/TTOS`.

1 Introduction

Task-oriented dialogue systems (TDSs), which help users to complete specific tasks with natural language, have attracted increasing attention recently due to the broad applications such as event scheduling and flight booking. Conventional TDSs have a complex pipeline (Williams and Young, 2007), which consists of modularly connected components for natural language understanding (NLU), dialogue state tracking (DST), and dialogue policy (DP). A limitation of such pipelined design is that errors made in upper stream modules may propagate to downstream components, making it hard to identify and track the source of errors. In addition, these methods usually require a large number of handcrafted features and labels, which may restrict the expressive power and learnability of the models.

To ameliorate the limitations with the conventional pipeline TDSs, great efforts have been made in designing deep neural network-based end-to-end solutions (Bordes et al., 2017; Eric et al., 2017; Madotto et al., 2018). Recent advances are overwhelmingly contributed by sequence-to-sequence (seq2seq) models (Bordes et al., 2017; Eric and Manning, 2017; Eric et al., 2017), which have taken the state-of-the-art of TDSs to a new level. These methods map dialogue context to output responses directly without explicitly providing handcrafted features and NLU/DST/DP labels, thus reduce human effort and are easily adapted to new domains.

Despite the effectiveness of previous studies, there are several technical challenges in building a TDS that is capable of retrieving accurate entries from the knowledge base (KB) and generating human-like responses. (1) Previous work (Carbonell, 1983) shows that users of TDSs tend to use succinct language which often omits entities or concepts made in previous utterances. However, seq2seq models often ignore how the conversation evolves as information progresses (Raghu et al., 2019) and thus result in generating incoherent and ungrammatical responses that are dominated by words appearing with high frequency in

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3498–3507,
November 16–20, 2020.

the training data. (2) Seq2seq models suffer from effectively reasoning over and incorporating KB information (Madotto et al., 2018). It is difficult to encode and decode the knowledge from a large and dynamic KB, making the response generation unstable. In addition, typically, a shared memory is used for both dialogue context and KB triples, making the TDSs struggle to reason over the two forms of data. Although some previous methods (Reddy et al., 2019) leverage separate memories for modeling dialogue context and KB facts, they either focus on capturing the dialogue patterns or retrieving accurate KB entities, but not both. One possible solution to the aforementioned problems is to explicitly encourage the seq2seq model to learn dialogue patterns and model the exterior KB knowledge retrieval with separate guidance for each.

In this study, we propose a "Two-Teacher One-Student" learning framework (TTOS) for building a high-quality TDS (student), where a student network is encouraged to integrate the knowledge from two expert teacher networks. Concretely, a KB-oriented teacher network (T_{KB}) is trained via reinforcement learning with entity score as the reward, which specializes in retrieving accurate KB entities; a dialogue pattern-oriented teacher network (T_{DP}) is trained via reinforcement learning with BLEU as the reward, which is expected to learn the language patterns of the dialogue (Eric and Manning, 2017), and thus specializes in generating coherent and grammatical responses. Afterwards, we optimize the student with distilled expert knowledge from two teacher networks. Our motivation is that the two teachers can provide different supervisory information that can be fully utilized through collaborative training. Instead of adopting the classic student-teacher learning strategy of forcing the output of a student network to exactly mimic the soft targets produced by the teacher networks, we employ the generative adversarial network (GAN) to transfer knowledge from two teachers to the student. To be more specific, the generator is the student network to produce dialogue responses, and the two discriminators distinguish the learned output representations from the student and teacher networks. By employing the output of the two discriminators as feedback, the student network can achieve collective success in both retrieving accurate KB entities and generating natural responses.

This paper has three main contributions listed as follows.

- We introduce a "Two-Teacher One-Student" learning framework for TDSs, where the student network benefits from the two teacher networks' complementary targets and achieves collective success in both retrieving accurate KB entities and generating natural responses.
- The expert knowledge is transferred from two teacher networks to the student network through two discriminators in our GAN-based approach. The usage of discriminators relaxes the rigid coupling between the student and teachers.
- Experimental results on In-Car Assistant and CamRest datasets demonstrate that TTOS achieves impressive results compared to the baseline methods across multiple evaluation metrics.

2 Related Work

2.1 Task-oriented Dialogue Systems

Task-oriented dialogue systems (TDSs), different from open-domain dialogue systems, are required to help users complete specific tasks with natural language. Conventional TDSs usually require a large number of handcrafted features, which may restrict the expressive power and learnability of the models (Williams and Young, 2007; Young et al., 2013). Inspired by the success of the sequence-to-sequence (seq2seq) models in text generation, there are several studies that build TDSs with the seq2seq model in an end-to-end trainable way. These methods have shown promising results recently since they have a great ability to learn the latent representations of dialogue context and are easily adapted to a new domain (Lei et al., 2018; Eric et al., 2017; Madotto et al., 2018).

However, as revealed by previous studies (Eric et al., 2017; Madotto et al., 2018), the performance of the seq2seq model deteriorates quickly with the increase of the length of the generated sequence. Therefore, how to improve the stability of the neural network models has gained increasing attention. (Eric et al., 2017) proposed a copy augmented seq2seq model by copying relevant information directly from the KB information. Mem2Seq (Madotto et al., 2018) and GLMP (Wu et al., 2019) further augmented memory-based methods by incorporating copy mechanism (Gulcehre et al., 2016) to enable copying words from past dialog utterances or from KB when generating responses. Recently, separating memories for modeling dialog context and KB results are explored to improve the performance of TDSs (Raghu et al., 2019; Reddy et al., 2019; Chen et al., 2019). BossNet (Raghu et al., 2019) implicitly disentangled the language model from knowledge incorporation and thus enhanced the ability to copy unknown KB entries. Multi-level memory model (Reddy et al., 2019) represented the KB results using a multi-level memory instead of the form of triples. WMM2Seq (Chen et al., 2019) further employed a working memory to interact with two separated memories. Nevertheless, existing methods either achieve a good language model for the response generation or effective progress towards the KB modeling, but not both.

2.2 Student-teacher Learning Paradigm

In parallel, student-teacher learning has received intensive attention because of its excellent performance on various tasks. A typical application is to transfer knowledge from a large, powerful teacher network to a compact yet accurate student network, so as to boost the training process and the resulting performance (Watanabe et al., 2017; Bucilu and Niculescu-Mizil, 2006; Wang et al., 2018). For example, in (Bucilu and Niculescu-Mizil, 2006), a student network was encouraged to mimic the output of a teacher network via mean squared error. (You et al., 2017) proposed a dark knowledge distillation method, in which the student network accommodated the true labels and captured the structures among the labels. Instead of considering one single teacher network, several studies trained a student network by incorporating multiple teacher networks in the output layer or the hidden layers (Park and Kwak, 2019; You et al., 2017).

3 Our Methodology

Given the dialogue context $x = \{x_1, x_2, \dots, x_M\}$ with M words and the system response $y = \{y_1, y_2, \dots, y_T\}$ with T words, the dialogue system aims to optimize the generation probability of y conditioned on x, i.e., $p(y|x)$.

As illustrated in Figure 1, TTOS consists of three networks: a KB-oriented teacher network (T_{KB}) that is specialized for retrieving entities from KB, a dialogue pattern-oriented teacher network (T_{DP}) that is specialized for learning the dialogue patterns, and a student network (S) that tries to extract accurate KB entities and generate human-like responses. The three networks share the same network structure but different training strategies.

The learning procedure of TTOS contains two stages of training. In the first stage, the three networks are pre-trained independently with different training strategies. In particular, the student network is trained with supervised learning, while the two teacher networks T_{KB} and T_{DP} are trained via the reinforcement learning (RL) with goal-specific rewards (i.e., entity score and BLEU respectively), which can be viewed as experts towards the goals. Then, we employ GAN to learn the student network, where the generator is the student network to produce dialogue responses, and two discriminators distinguish the learned output responses from student and teacher networks. Next, we will introduce the three networks and the GAN-based student-teacher learning paradigm in detail.

3.1 Student Network

The student network a task-oriented dialogue system, which is responsible for both inquiring KB and generating human-like responses. In this study, the sequence-to-sequence (seq2seq) model (Luong et al., 2015) is used as the backbone to implement the student network. The seq2seq model additionally consists of a dialogue memory module and a KB memory module to store the information from the dialogue context and the retrieved KB entities, respectively.

Encoder Each input token in the dialogue context is converted to a fixed-length vector via an embedding layer. The input embedding sequence then goes into a layer of the bidirectional gated recurrent unit (BiGRU) (Chung et al., 2014) to learn the contextualized representation of the dialogue context, which is then passed into the dialogue memory.

Dialogue Memory and KB memory Different from Mem2Seq (Madotto et al., 2018), our dialogue memory is implemented with a dynamic key-value memory network (Zhang et al., 2017), which maintains a timely updated key memory to keep track of attention history and a fixed value-memory to store the dialogue context features throughout the whole generation process. In this way, the task-oriented dialogue system can keep track of the attention history along with the update-chain of

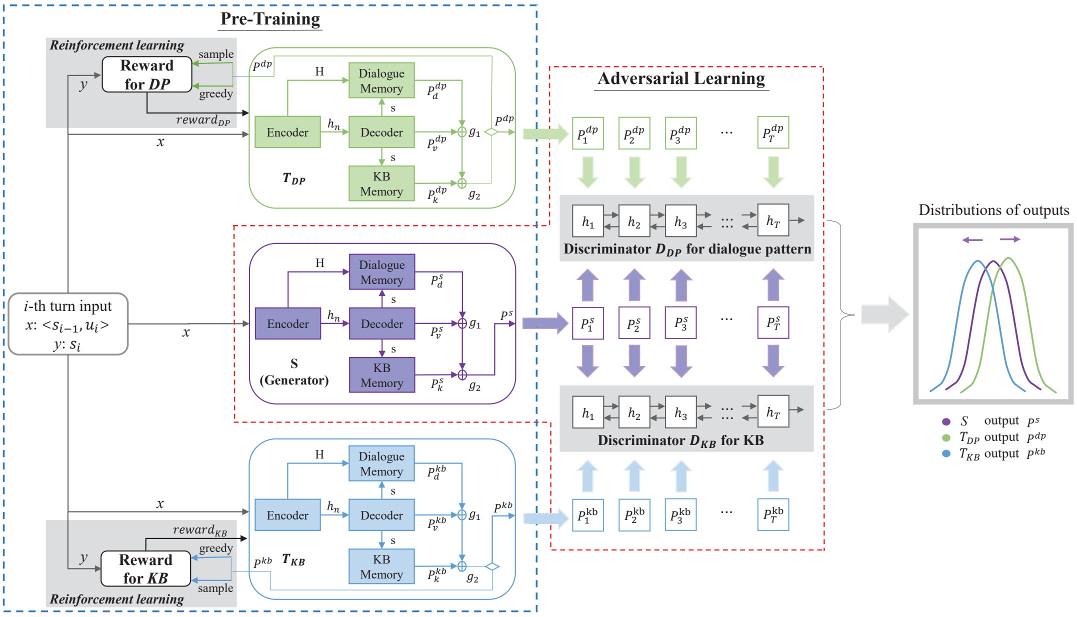

Figure 1: The overview of TTOS, which consists of two teacher networks (T_{KB} and T_{DP}) and a student network (S).

the decoder state, and therefore generate coherent and natural responses. In addition, we employ a separate KB memory, which is implemented with end-to-end memory networks (Sukhbaatar et al., 2015), to store the KB tuples.

Decoder The seq2seq model generates the response word by word. At decoding step t, the target word is either generated from the vocabulary or copied from the dialogue memory or KB memory. Formally, we use $P^s_{t,v}$, $P^s_{t,d}$, $P^s_{t,k}$ to denote the probabilities of generating the t-th target word from vocabulary, copying it from dialogue memory and KB memory, respectively. A soft gate g_1 controls whether a word is generated from vocabulary or copied from memories, and another gate g_2 determines which of the two memories is used to copy values. The final output distribution P_t for the t-th target word is calculated as:

$$P^s_t = g_1 P^s_{t,v} + (1 - g_1)\left[g_2 P^s_{t,d} + (1 - g_2) P^s_{t,k}\right] \tag{1}$$

The student network is optimized with supervised learning. We compute the loss function L_S of the student network as the cross-entropy between the output distribution P^s_t and the ground-truth target word y_t:

$$L_S = -\sum_{t=1}^{T} y_t \log(P^s_t) \tag{2}$$

where T is the length of the output response.

3.2 Two Teacher Networks

The two teacher networks share the same seq2seq network structure with the student network. Different from the student network that is trained with supervised learning, the two teacher networks T_{DP} and T_{KB} are trained via the reinforcement learning with goal-specific rewards (i.e., entity score and BLEU respectively), which can be viewed as experts towards different goals.

Dialogue Pattern-oriented Teacher Network The teacher network T_{DP} is specialized for learning the dialogue patterns so as to generate natural responses. To this end, we adopt the reinforcement learning technique, i.e., self-critical sequence training (SCST) algorithm (Rennie et al., 2017), to train the teacher network T_{DP} by using the BLEU as the reward function. As discussed in (Eric and Manning, 2017), BLEU can be used to gauge the model's ability to accurately generate the dialogue patterns seen in the training data. In particular, we generate two separate output sequences at each training iteration: (1) the output y^s that is obtained by sampling from the output distribution P^{dp}_t, and (2) the baseline output $\hat{y}$ that is obtained by maximizing the output distribution with a greedy search.

Following (Rennie et al., 2017), the loss function of the SCST algorithm for T_{DP} can be derived as:

$$L_{DP} = -(\text{BLEU}(y^s) - \text{BLEU}(\hat{y})) \sum_{t=1}^{T} \log(P_t^{dp}) \tag{3}$$

KB-oriented Teacher Network The teacher network T_{KB} is specialized for retrieving accurate KB entities from KB to accomplish the task. We employ SCST to optimize the network T_{KB} by using entity F1 score (Ent.F1) as the reward function. The entity F1 metric evaluates the model's ability to generate relevant entities from the underlying KB. Similar to the network T_{DP}, the loss function of the SCST algorithm for T_{KB} can be derived as:

$$L_{KB} = -(\text{Ent.F1}(y^s) - \text{Ent.F1}(\hat{y})) \sum_{t=1}^{T} \log(P_t^{kb}) \tag{4}$$

where P_t^{kb} is the output distribution of the teacher network T_{KB}.

3.3 Improving Student Network with GAN

After pre-training the three networks, we further train the student network to amalgamate expert knowledge from the two teacher networks. Different from previous student-teacher learning methods (Hinton et al., 2015; Kim and Rush, 2016) which force the output of the student network to exactly mimic the soft targets produced by the teacher networks, we introduce two discriminators as GAN to transfer knowledge from the two teacher networks to the student network. The two discriminators are trained to distinguish the learned output representations from student and teacher networks, while the student network (generator) is adversarially trained to produce dialogue responses to fool the discriminators. To be more specific, a discriminator D_{DP}, a binary classifier implemented with a BiGRU, is proposed to distinguish the output distributions generated by the student S and the teacher T_{DP}. Similarly, another binary classifier discriminator D_{KB} is employed to distinguish whether the output distribution is from the student S or the teacher T_{KB}.

By alternatively updating the student and the two discriminators in an adversarial process, the expert knowledge transferred from discriminators can eventually guide the student to produce responses similar to the responses generated by the two teachers. The details of the adversarial training are summarized in Algorithm 1.

3.3.1 Discriminator Update

The two discriminators and the student (generator) are alternatively updated in the GAN-based approach. We first introduce the update process of the discriminators. The discriminators are two binary classifiers that are trained to distinguish the output responses generated by the student and teachers. For each discriminator, we encode the output distribution P^o with a BiGRU as it shows great effectiveness in text classification. The last hidden state ($\mathbf{h}_T$) is then passed to an output layer (sigmoid) whose output is the probability of being "true". Formally, given the output distribution P_t^o at t-th time step, the binary classifier (discriminator) D is defined as:

$$\mathbf{h}_t = \text{BiGRU}(P_t^o, \mathbf{h}_{t-1}), \quad t \in [1, T] \tag{5}$$

$$D(P^o) = \text{sigmoid}(W\mathbf{h}_T) \tag{6}$$

where W is a learnable parameter, $\mathbf{h}_t$ is the hidden state at the t-th time step. In this way, we can obtain the dialogue pattern-oriented discriminator D_{DP} that predicts whether the input sequence is generated by the teacher T_{DP} and the KB-oriented discriminator D_{KB} that predicts whether the input sequence is generated by the teacher T_{KB}.

When training the discriminators, we fix the student (generator). The two discriminators (i.e., L_{DP} and L_{KB}) are trained to minimize the probability of assigning the incorrect labels to the output distributions of the student and teacher networks:

$$L_{DP} = -\log(1 - D_{DP}(P^s)) - \log(D_{DP}(P^{dp})) \tag{7}$$

$$L_{KB} = -\log(1 - D_{KB}(P^s)) - \log(D_{KB}(P^{kb})) \tag{8}$$

$$L_D = L_{DP} + L_{KB} \tag{9}$$

where are P^s, P^{dp}, P^{kb} are the output distributions produced by S, T_{DP}, T_{KB}, respectively. L_D is the final objective function for the discriminator update.

3.3.2 Student Update

In each iteration, we update the student network (generator) S after updating the two discriminator networks. When updating the student network S, we try to fool the two discriminators and minimize the adversarial loss L_G which is defined as:

$$L_G = -\log(D_{DP}(P^s)) - \log(D_{KB}(P^s)) \tag{10}$$

Algorithm 1 Adversarial training procedure.

Input: Three pre-trained networks S, T_{DP}, T_{KB}, and training dataset (X, Y).

Output: Student network S that integrates expert knowledge from two teachers.

```
1: Initialize the generator ($G = S$) and two discriminators ($D_{DP}$ and $D_{KB}$) in GAN;
2: repeat
3:     Sample an instance $(x, y)$ from the training data;
4:     Produce the output distributions $P^{dp}$ and $P^{kb}$ by two teachers $T_{DP}$ and $T_{KB}$;
5:     Produce output distribution $P^s$ by student $S$;
6:     Fix generator $G$ and update discriminators $D_{DP}$ and $D_{KB}$ by minimizing Eq. (9) via gradient descent.
7:     Fix the discriminators and update generator $G$ by minimizing Eq. (11) via gradient descent.
8: until convergence
```

The final loss function $\tilde{L}_S$ for the student network S is computed as:

$$\tilde{L}_S = L_S + \alpha L_G \tag{11}$$

where α is a scalar that determines the importance of the adversarial loss L_G of the student network.

4 Experimental Setup

Dataset We evaluate the proposed TTOS model on two widely used multi-turn task-oriented dialogue datasets: CamRest (Wen et al., 2016) and In-Car Assistant (Eric and Manning, 2017). The CamRest dataset is composed of 676 human-to-human multi-turn conversations in the restaurant reservation domain. The average number of turns per dialogue is about 5. Following in (Reddy et al., 2019), we divide the dataset into training/validation/testing sets with 406/135/135 dialogues respectively. The In-Car Assistant dataset contains 3031 multi-turn dialogues, which are divided into 2425/302/304 dialogues for training/validation/testing, respectively. In-Car Assistant includes three distinct domains: calendar scheduling, weather information retrieval, and point-of-interest navigation. There are 2.6 turns on average per dialogue. Compared to CamRest, the In-Car Assistant dataset is more diverse in the utterances, and the KB information is also more complicated.

Training Details The grid search algorithm (Bergstra et al., 2013) is applied on the validation set to automatically tune the hyper-parameters. We use the 300-dimensional word2vec vectors (Mikolov et al., 2013) to initialize the word embeddings. The size of the GRU hidden units is set to 256. The number of hops for the memory network is set to 3. The recurrent weight parameters are initialized as orthogonal matrices. We initialize the other weight parameters with the normal distribution $\mathcal{N}(0, 0.01)$ and set the bias terms to zero. To stabilize the process of training GAN, we use Adam optimizer (Kingma and Ba, 2014) with a relatively small initial learning rate of $1e^{-4}$ to train the model. The batch size is set to 8. The step ratio of G and D is set to 1:1 for reaching a training balance. We set the value of α to 1.0, because a too large α value will make student rely excessively on teachers' outputs without concrete guidance at each time step, while a loss with too low α value cannot guide the student to fool the two discriminators, which may make the adversarial training process unstable. In addition, we also apply dropout (dropout rate=0.2) on several layers of generator, but not for discriminators.

Table 2: Automatic evaluation results on In-Car Assistant dataset.

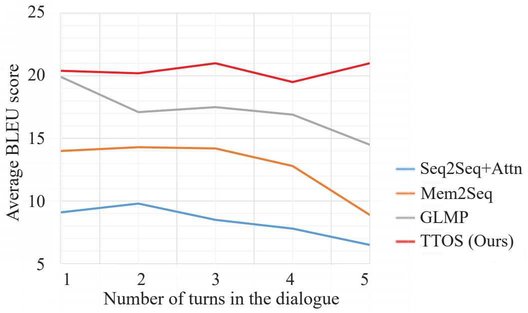

Figure 2: The performance of TTOS and baselines on CamRest dataset with the increase of dialogue turns.

local memory pointer network (GLMP) (Wu et al., 2019).

Automatic Evaluation Metrics Following previous works (Madotto et al., 2018; Wu et al., 2019), we evaluate TTOS and compared methods on two automatic evaluation metrics: BLEU (Papineni et al., 2002) and entity F1 (Madotto et al., 2018) scores. BLEU calculates n-gram overlaps between the generated response and the gold response, which could gauge the model's ability to accurately generate the dialogue patterns seen in our data. BLEU shows a comparatively strong correlation with the human assessment on task-oriented systems (Sharma et al., 2017). Entity F1 is computed by micro-averaging the precision and recall over KB entities in the entire set of system responses, which evaluates the ability of the TDSs to generate relevant entities to accomplish specific tasks by inquiring the provided KBs.

5 Experimental Results

Automatic Evaluation Results For each test instance, we use the response generated by the student network (learned by adversarial training) as the final output response. Table 1 shows the automatic evaluation results of TTOS and baseline methods. From the results, we can observe that TTOS achieves substantially and significantly better performance than the compared methods over the two evaluation metrics. Mem2Seq and BossNet consistently perform better than Seq2Seq(+Attn) and Ptr-Unk. This verifies the effectiveness of memory networks in incorporating KB information into the seq2seq model for generating better responses. GLMP has achieved a strong improvement over both BLEU and entity F1 scores over the previous models, which is mainly benefited from its global and local memory pointers to guide the KB attention and response generation. TTOS performs even better than GLMP on both metrics. Furthermore, Figure 2 shows the changes in average BLEU scores of TTOS and several baselines along with the increase of dialog turns on the CamRest dataset. The BLEU scores of the baseline models decrease sharply after four turns while TTOS achieves much more stable performance even in the last few turns. This verifies the effectiveness and stableness of TTOS in retrieving accurate KB entities and generating human-like responses. We observe similar trends on the In-Car Assistant dataset, as shown in Table 2. TTOS achieves competitive results on both BLEU and entity F1 compared to most of the baseline methods. In particular, TTOS achieves the best BLEU on the whole dataset and best entity F1 score in the domain of weather information retrieval.

Note that most methods (e.g., TTOS, GLMP, BossNet, Mem2Seq) except ECET achieve much worse entity F1 on Nav. sub-domain than on Sch./Wea. sub-domains. This may be because the KB of Nav. sub-domain is more complicated than the KBs of other two sub-domains. In particular, each entry in the KB of Nav. sub-domain has more complex attributes. On the other hand, the dialogues in Nav. sub-domain often involve multi-step reasoning, while single-step reasoning is usually involved in Sch./Wea. sub-domains. For example, for the request "give me directions to the nearest grocery_store", the dialogue system should first restrict the location type to be "grocery_store" and then find the nearest location based on distance attribute. In the future, we plan to design more advanced techniques to integrate the KB knowledge and further improve the multi-step reasoning ability of TTOS.

TTOS (Ours)	**4.19**	**4.28**	**4.22**	**4.18**

Table 4: Human evaluation results on CamRest and In-Car Assistant.

Model	In-Car		CamRest	
	BLEU	Ent. F1	BLEU	Ent.F1
w/o TDP	17.02	54.69	19.56	60.66
w/o TKB	17.11	52.96	19.98	59.88
w/o GAN	16.80	51.84	18.77	58.80
TTOS with KD	16.95	53.74	19.79	60.10
TTOS with GAN	**17.35**	**55.38**	**20.45**	**61.50**

Table 5: Ablation results of TTOS on two datasets.

Case Study To evaluate the proposed model qualitatively, we choose an exemplary dialogue from the CamRest test set and illustrate some generated responses by TTOS and the compared methods in Table 3. We observe that Mem2Seq fails to understand the dialogue context and thus generates irrelevant responses. GLMP generates more readable responses than Mem2Seq but fails to extract correct KB entities. In particular, the performance of GLMP deteriorates significantly with the increase of dialogue turns. Compared to GLMP, TTOS can retrieve more accurate KB entities and generate more natural responses, especially in the last few turns. This verifies that TTOS can identify key entities and keep track of dialog context from previous turns.

We also provide the generated responses by two teachers (T_DP and T_KB) and the pre-trained student ($S^{\#}$), to analyze where the empirical gains come from. From Table 3, we can observe that T_DP can captures the dialogue pattern while the response generated by $S^{\#}$ fails to extract "serving panasian food" that modifies the word "restaurants". On the other hand, the teacher T_KB works well for entity retrieval. For example, in the fourth turn, T_KB can trigger the accurate entity word "expensive", which is not recognized by $S^{\#}$.

Human Evaluation Results Similar to the previous work (Wu et al., 2019), we use human evaluation to evaluate the generated responses from two perspectives: informativeness (*Infor.*) and humanlikeness (*Humanlike.*). Specifically, we randomly select 100 dialogues from the CamRest and In-Car Assistant test sets, and invite three annotators to independently assign two scores (i.e., informativeness and human-likeness scores) from 1 to 5 for each generated response. A higher score means better performance. The agreement ratios computed with Fleiss' kappa (Fleiss, 1971) are 0.58 on CamRest and 0.51 on In-Car Assistant, showing moderate agreement. We report the average rating scores from all annotators as the final human evaluation results. As shown in Table 4, TTOS outperforms the compared methods on both informativeness and human-likeness by a noticeable margin, which is consistent with the automatic evaluation.

Ablation Study To investigate the effectiveness of each module in TTOS framework, we conduct ablation test in terms of removing the teacher T_DP (w/o TDP), removing the teacher T_KB (w/o TKB), removing the GAN-based student-teacher learning (w/o GAN). In addition, we also replace the GAN-based student-teacher learning with the standard knowledge distillation method (denoted as TTOS with KD). The experimental results are reported in 5. The performance of TTOS drops sharply when we discard the two teachers and the GAN-based student-teacher learning. This is within our expectation since TTOS achieves collective success from two teachers that are specialized for two different goals through two discriminators in GAN-based approach.

6 Conclusion

In this paper, we propose a novel "Two-Teacher One-Student" learning framework (TTOS) for task-oriented dialogue, which aims to improve the performance of the task-oriented dialogue system in retrieving accurate entries from KB and generating human-like responses simultaneously. With adversarial learning, we train the student network to amalgamate expert knowledge naturally from the two teacher networks for the above two goals. The experimental results on two benchmark datasets demonstrated that our model achieves impressive results compared to the state-of-the-art task-oriented dialogue systems.

Abstract

Meta-embedding learning, which combines complementary information in different word embeddings, have shown superior performances across different Natural Language Processing tasks. However, domain-specific knowledge is still ignored by existing meta-embedding methods, which results in unstable performances across specific domains. Moreover, the importance of general and domain word embeddings is related to downstream tasks, how to regularize meta-embedding to adapt downstream tasks is an unsolved problem. In this paper, we propose a method to incorporate both domain-specific and task-oriented information into meta-embeddings. We conducted extensive experiments on four text classification datasets and the results show the effectiveness of our proposed method.

1 Introduction

Building semantic representations (Zhao et al., 2017; Li et al., 2019; Neill and Bollegala, 2020) of words is a vital procedure in various Natural Language Processing (NLP) tasks. Over recent years, many pre-trained word embeddings have emerged, such as pre-trained Word2Vec (Mikolov et al., 2013) and pre-trained Glove (Pennington et al., 2014). Despite their usefulness, some previous works find that the performance of different pre-trained word embeddings has significant variation for different tasks (Chen et al., 2013; Hill et al., 2014). To obtain a stable and better performance, Yin and Schütze (2015) proposed the ***meta-embedding*** learning task that aims to obtain a robust and superior word embedding (*i.e.*, meta-embedding) by combining the different pre-trained word embeddings.

Most previous meta-embedding methods neglect the importance of domain-specific information and use the same embedding for each word in all domain-specific datasets (Bollegala and Bao, 2018; Coates and Bollegala, 2018; Bollegala et al., 2017). It is beneficial to incorporate domain-specific information into general word embeddings and provide different word representations for different domains, which has been shown to improve the performance in some other tasks (Bollegala et al., 2015; Xu et al., 2018).

This leads us to explore how to combine general and domain-specific information in meta-embedding learning. Intuitively, the importance of the general and domain embeddings depends on a specific domain. For example, in the computer domain, for the domain-specific words (*e.g.*, "mouse"), we should preserve their domain information but discard their general information. On the other hand, some general words (*e.g.*, "we", "people") may not be able to get a high-quality domain embedding due to the insufficient domain data, in this situation, their general word embeddings are preferable. However, most previous meta-embedding methods are unsupervised, it is hard to learn which embedding is preferable. We consider that it is necessary to use the supervision from a downstream task to address this limitation. Specifically, we focus on text classification (TC) and use the words' category distributions of a TC dataset to guide the meta-embedding learning process.

In this paper, we propose a supervised autoencoder method, named **Task-oriented Domain-specific AutoEncoded Meta-Embedding (TDAEME)**, to learn meta-embedding for text classification. TDAEME combines both general and domain word embeddings in a supervised manner, which is implemented by a supervised autoencoder. Specifically, TDAEME predicts the words' category distribution. This makes the downstream classifier easier to extract useful information from our task-oriented domain-specific

meta-embedding. We evaluate TDAEME on four text classification datasets, the results demonstrate the effectiveness of our method.

2 Related Work

Yin and Schütze (2015) first proposed a meta-embedding learning method (1TON) to combine the complementary information of multiple pre-trained word embeddings into one meta-embedding. Bollegala and Bao (2018) further improved 1TON by applying an autoencoder framework and three different objective functions to model multiple pre-trained word embeddings. The three new models are called DAEME, CAEME, and AAEME respectively. Bollegala et al. (2017) proposed an unsupervised locally linear method for learning meta-embeddings from a set of source embeddings. However, all the above methods only model the information in pre-trained word embeddings which were trained on unlabeled text but ignore the domain information. One similar work called dynamic meta-embedding which proposed by Kiela et al. (2018) aims to address the meta-embedding learning as a supervised learning paradigm. However, their method is built-in downstream models, which is quite different from our proposed method. Our method is model-independent, the obtained meta-embeddings can be used in any downstream models as features.

One contemporary work also uses the supervised autoencoder method for meta-embedding learning (O'Neill and Bollegala, 2020). However, their motivation and contribution are different from ours. O'Neill and Bollegala (2020) aim to enhance the meta-embedding with words' similarity information, so they use the similarity score between words as the supervision signal in meta-embedding learning, while we focus on a more specifically task (i.e., text classification), our model uses words' categories information as the supervision signal, which is specifically designed for the classification task. In text classification task, words within the same category should be close to each other in the representation space, using similarity information may make two words in different categories get closer (e.g., "learning" and "education" with high similarity but mainly appear in two different categories "AI" and "sociology" respectively).

3 Method

Suppose that we have a word embedding set $S = \{S_1, S_2, ..., S_n\}$ with a vocabulary V; a labeled text classification dataset X which contains a training set X_{train} and a test set X_{test}, we denote its vocabulary as V_X and its categories as C_X with $|C_X| = L$. We aim to learn the word task-oriented domain-specific meta-embedding $m(w)$ for each word $w \in V \cap V_X$. The architecture of TDAEME is visualized in Figure 1

3.1 Extraction Component

The extraction component is used to project different word embeddings into one coherent vector space. For each word w in the source embedding set vocabulary V, $S_i(w)$ denotes the i source embedding of word w, we first use n encoders to extract the semantic information of each source embedding into an d_M dimensional vector space, denote as $E_i(w)$:

$$E_i(w) = f_i(S_i(w)), \tag{1}$$

where f_i is the i encoder function for the i source embedding. Then we compute the task-oriented domain-specific meta-embedding $m(w)$ of word w:

$$m(w) = E_1(w) \oplus E_2(w) \oplus, ..., \oplus E_n(w), \quad (2)$$

where $\oplus$ is the concatenation operator.

3.2 Reconstruction Component

In this component, we take the $m(w)$ as input, then predict all n source embeddings $D_i(w)$:

$$D_i(w) = g_i(m(w)), \quad (3)$$

where g_i is the i decoder function to predict the i source embedding from the $m(w)$. The objective of this component can be represented as L_R:

$$L_R = \sum_{w \in V} \sum_{i=1}^{n} \lambda_i \|S_i(w) - D_i(w)\|_2^2, \quad (4)$$

where $S_i(w)$ and $D_i(w)$ is the i source and predict embedding of word w, λ_i is a hyperparameter to adapt the weight of different source embeddings.

3.3 Adaption Component

In this component, we make the $m(w)$ predict its category distribution of a downstream dataset. This makes words with the same category would get close in meta-embedding vector space. Formally, For each word w both in vocabulary V (the vocabulary of all source embeddings) and V_X (the vocabulary of the classification dataset X), its category distribution can be defined as $T_X(w)$:

$$T_X(w) = [T_X^{C_1}(w), T_X^{C_2}(w), ..., T_X^{C_L}(w)], \quad (5)$$

$$T_X^{C_j}(w) = \frac{t_X^{C_j}}{\sum_{k=1}^{L} t_X^{C_k}}, \quad (6)$$

where $T_X^{C_j}(w)$ is the document frequency of word w in jth category, $t_X^{C_j}$ is the number of documents that contain w in the class C_j.

An extra decoder is employed to predict the category distribution $P_X(w)$ of word w from the $m(w)$:

$$P_X(w) = [P_X^{C_1}(w), P_X^{C_2}(w), ..., P_X^{L}(w)]. \quad (7)$$

The objective of this component L_A can be represented as:

$$L_A = \sum_{w \in V \cap V_X} \sum_{j=1}^{L} \left\| T_X^{C_j}(w) - P_X^{C_j}(w) \right\|_2^2. \quad (8)$$

3.4 Joint Learning

The extraction component is shared between the reconstruction component and the adaption component, we propose to use the joint learning framework to jointly optimizing L_R and L_A. Then we obtained the final objective function L:

$$L = \alpha L_R + (1 - \alpha) L_A, \quad (9)$$

where α is a hyperparameter to adapt the reconstruction component and the adaption component.

4 Experiments

4.1 Source Word Embeddings

We use the Glove[1] and CBOW[2] as the two **general word embeddings** in our experiments. To obtain the **domain word embeddings**, we use the training set X_{train} of each downstream task to train the corresponding domain word embeddings for each dataset. In this paper, we use cbow model from the Word2Vec open source package2.

Datasets	Type	Train Size	Test Size	Class Num

Table 2: Experimental results. Bold scores are the best overall. w/o represents removing one component or one source embedding, while remaining other components. *, ** indicates p-value<0.05, <0,01, respectively.

(CONC) Yin and Schütze (2015) propose that the concatenation of the source embeddings is an effective method for creating meta-embeddings. (2) **Averaging (AVG)** Coates and Bollegala (2018) proposed averaging the source word embeddings for a word as a method for creating meta-embeddings without increasing the representation dimensionality. (3) **origin AEMEs** Bollegala and Bao (2018) proposed three autoencoder-based approaches DAEME, CAEME, and AAEME for learning meta-embeddings from multiple pre-trained source embeddings.We use the code[7] released by the authors in our experiments. (4) **LLE** Bollegala et al. (2017) proposed an unsupervised locally linear method for learning meta-embeddings from a set of source embeddings. We use the code[8] released by the authors in our experiments.

4.4 Experimental Settings

We use the average of word embeddings to represent the document. We trained a linear classifier using Liblinear (Fan et al., 2008) to test the classification performance of each embedding. Since the goal is to evaluate the embeddings, so we didn't tune the hyperparameters of the classifier on a validation set and just evaluate the test set performance with default hyperparameters. To train our proposed model TDAEME, we use a linear neural layer with the ReLU (Nair and Hinton, 2010) activation function as an encoder and a linear neural layer as a decoder. We employ Adam (Kingma and Ba, 2014) with mini-batches of size 128 and 0.001 learning rate as an optimizer. We also applied masking noises (Vincent et al., 2010) to randomly set 0.05% of the input elements to zero. α is set to 1e-4. We manually tuned the hyperparameters of TDAEME according to the training loss (*i.e.*, equation 4 8 9) of TDAEME. The computing infrastructure we used is a PC with GTX 980Ti.

4.5 Result

Overall Performance We use accuracy [9] as metric in our experiments. Table 2 shows the evaluation results. Compared with two general source embeddings, meta-embedding learning methods perform better in most cases, which demonstrates the effectiveness of meta-embedding methods. Moreover, fine-tuning meta-embedding learning methods (*i.e.*, AEMEs) have better performance than none-learning methods (*i.e.*, CONC and AVG). Compared with three origin AEME models and LLE, our proposed method TDAEME can make a further improvement in the text classification task, which demonstrates the effectiveness of the domain-specifc and task-orietend information.

Ablation The last 5 rows in Table 2 shows the ablation results. In most cases, combining one more high-quality general word embeddings will never harm the performance. While the results of the last two ablation methods indicate that both

the domain embeddings and the adaption component provide a significant boost compared to the raw AEMEs. Moreover, TDAEME achieves the best results among all ablation methods. This indicates the domain-specific and task-oriented information are beneficial to each other, our joint learning method can successfully model these two types of information.

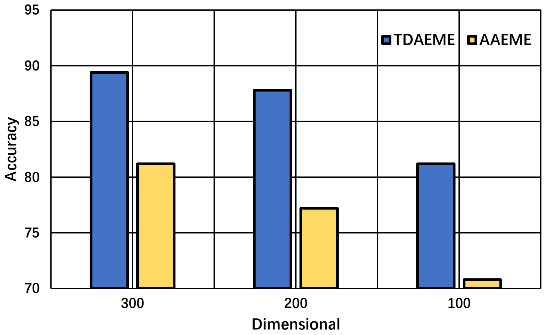

Figure 2: Experiment results of different meta-embedding dimensions on TREC dataset. The axes represent accuracy and dimension respectively.

Impact of Dimensional We also conducted an experiment on meta-embedding dimensionalities. We investigate the performance of AAEME and TDAEME on TREC dataset with 100, 200, and 300 meta-embedding dimensions respectively. The results are shown in Figure 2. We find that TDAEME outperforms AAEME in all cases and TDAEME is less sensitive to dimension reduction than AAEME.

Table 3: Experiments results of TDAEME and ELMo+SVM.

Compared with Contextualized Embeddings Contextualized Embeddings such as BERT, ELMo can outperform previous state-of-the-art models on multiple natural language understanding (NLU) benchmarks. We conduct an experiment to compared our TDAEME with ELMo (Peters et al., 2018). To make a fair comparsion, we use ELMo to get sentence embedding, and performance classification with the same SVM classifier. Table 3 shows the results. We observe that our TDAEME can achieve competitive performance against the contextualized embeddings.

5 Conclusion

In this paper, we propose a meta-embedding learning approach called Task-oriented Domain-specific Autoencoded Meta-Embedding (TDAEME), which leverages task-oriented supervision to improve the combination of general and domain embeddings. We conducted experiments on four text classification datasets and the results show the effectiveness of our proposed method.

Abstract

State-of-the-art methods for Word Sense Disambiguation (WSD) combine two different features: the power of pre-trained language models and a propagation method to extend the coverage of such models. This propagation is needed as current sense-annotated corpora lack coverage of many instances in the underlying sense inventory (usually WordNet). At the same time, unambiguous words make for a large portion of all words in WordNet, while being poorly covered in existing sense-annotated corpora. In this paper, we propose a simple method to provide annotations for most unambiguous words in a large corpus. We introduce the UWA (Unambiguous Word Annotations) dataset and show how a state-of-the-art propagation-based model can use it to extend the coverage and quality of its word sense embeddings by a significant margin, improving on its original results on WSD.

1 Introduction

There has been a lot of progress in word sense disambiguation (WSD) recently. This progress has been driven by two factors: (1) the introduction of large pre-trained Transformer-based language models and (2) propagation algorithms that extends the coverage of existing training sets. The gains due to pre-trained Neural Language Models (NLMs) such as BERT (Devlin et al., 2019) have been outstanding, helping reach levels close to human performance when training data is available. These models are generally based on a nearest neighbours strategy, where each sense is represented by a vector, exploiting the contextualized embeddings of these NLMs (Melamud et al., 2016; Peters et al., 2018; Loureiro and Jorge, 2019). However, training data for WSD is hard to obtain, and the most widely used training set nowadays, based on WordNet, dates back from the 90s (Miller et al., 1993, SemCor). This lack of curated data produces the so-called knowledge-acquisition bottleneck (Gale et al., 1992; Navigli, 2009).

However, there is a key source of information that has been neglected so far in existing sense-annotated corpora and propagation methods, which is the presence of unambiguous words from the underlying knowledge resource. Strikingly, WordNet, which is known to be a comprehensive resource, is mostly composed of unambiguous entries (30k lemmas are ambiguous, compared to 116k unambiguous). While the lack of unambiguous annotations does not have a direct effect in WSD, the fact that these unambiguous words are part of the same semantic network means they can have an effect on ambiguous words via standard propagation algorithms. These propagation algorithms start from a seed of senses occurring in the training data (and therefore their embeddings can be directly computed) and then propagate to the whole sense inventory via the semantic network (Vial et al., 2018; Loureiro and Jorge, 2019). Consequently, computing sense embeddings for unambiguous words can increase the number of seeds and improve the whole process. Covering these unambiguous words, however, is not an arduous task, as unlabelled corpora may suffice. We explore this hypothesis by labeling a large amount of unambiguous words in corpora extracted from the web, using WordNet as our reference sense inventory. While we can certainly find usages of a word not covered by WordNet, we found that our approach can obtain accurate occurrences with simple heuristics.

The contribution of this paper is twofold. First, we devise a simple methodology to construct UWA (Unambiguous Word Annotations), a large and, most importantly, diverse sense-annotated corpus that focuses on WordNet unambiguous words. Second, we show that by leveraging UWA, we can significantly improve a state-of-the-art WSD model.

2 Related Work

The knowledge-acquisition bottleneck has been frequently addressed by automatically constructing sense-annotated corpora. Recent works propose methods that exploit knowledge from Wikipedia, such as NASARI vectors (Camacho-Collados et al., 2016), for providing sense annotations for concepts and entities (Scarlini et al., 2019; Pasini and Navigli, 2019). In the case of Scarlini et al. (2019), and similarly to Raganato et al. (2016), their method requires hyperlinks and category information from Wikipedia, hence not extensible to other kinds of corpora.[1] Previous approaches relied on parallel corpora for two or more languages. The OMSTI corpus (Taghipour and Ng, 2015) was constructed by exploiting the alignments of an English-Chinese corpus. Similarly, Delli Bovi et al. (2017) presented EuroSense, a multilingual sense-annotated corpus using the Europarl parallel corpus for 21 languages as reference. In contrast to these approaches, we focus on unambiguous senses and, therefore, are not constrained to only nouns, knowledge from Wikipedia, or a specific type of corpus.

Earlier works exploiting unambiguous words (Leacock et al., 1998; Mihalcea, 2002; Agirre and Martinez, 2004) and especially the subsequent extension by Martinez et al. (2008) are the most directly related to our paper. Martinez et al. (2008) retrieved example sentences with monosemous nouns from web search snippets and used them towards improved performance on WSD by leveraging WordNet relations. However, the WSD methods analyzed were sensitive to frequency bias, leading their collection effort to collect a large number of examples for fewer senses (and only nouns). In contrast, our solution is designed for all monosemous words, retrieving examples from web texts instead of snippets, attaining performance gains with even a single example per word.

3 Methodology

In this section we first explain our method to construct a corpus with unambiguous word annotations (Section 3.1). Then, we explain current models based on language models for WSD (Section 3.2) and describe a propagation method to infer additional OOV sense representations (Section 3.3).

3.1 Unambiguous Word Annotations (UWA)

In order to properly test our hypothesis, we first require a sizable compilation of unambiguous words in context, particularly words that correspond to lemmas covered by WordNet. The extensiveness of WordNet means that most of its lemmas occur very rarely, and thus require processing large volumes of texts to achieve a high coverage. As such, in this work we develop the Unambiguous Word Annotations (UWA) corpus based on OpenWebText (Gokaslan and Cohen, 2019) and English Wikipedia (November 2019), processing over 53GB of texts from the web.

Each text is annotated for lemmas and part-of-speech using the Stanford CoreNLP toolkit (Manning et al., 2014). The annotations are filtered so that we only consider lemma/part-of-speech pairs that are present in WordNet, and correspond to a single sense (hence unambiguous), e.g., 'keypad/noun'. Naturally, some lemma/part-of-speech pairs may have additional meanings not covered in WordNet. For example, in "*Inception* was a box-office hit.", *Inception* makes reference to a movie and not to the unambiguous word *inception* from WordNet. To mitigate this issue, we applied Named Entity Recognition (NER) tagging, using spaCy (Honnibal and Montani, 2017), to discard lemmas that are recognized as entities but do not correspond to an entity in their WordNet sense. To this end, we leverage the entity annotations of WordNet synsets available in BabelNet (Navigli and Ponzetto, 2012). To keep the corpus at a reasonable size, we cut-off the maximum number of associated sentences (examples henceforth) per sense at 100.

Statistics. UWA covers a total of 98,494 senses, where 56.7% have 100 examples, and 81.2% have at least 10 examples. In Table 1 we show that UWA covers most senses for unambiguous words and, combined with SemCor, includes most senses in WordNet. This contrasts with other automatically-constructed datasets such as OMSTI (Taghipour and Ng, 2015) or T-o-M (Pasini and Navigli, 2019). These sense-annotated corpora, not aimed specifically at unambiguous words, have limited coverage in this respect, as they are mainly composed of annotations for senses already available in SemCor.

3.2 Neural Language Models for WSD

Recent NLMs, such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), have been used with a high degree of success on WSD. They have

Table 1: Number of instances, average number of examples per word sense, and coverage percentage (including SemCor) of various sense-annotated corpora.

been used differently depending on the nature of the disambiguation task: as feature providers for other neural architectures (Vial et al., 2019), simple classifiers after fine-tuning (Wang et al., 2019), or as generators of contextual embeddings to be matched through nearest neighbours (Melamud et al., 2016; Peters et al., 2018; Loureiro and Jorge, 2019; Reif et al., 2019, 1NN). Our experiments in this paper will focus on improving the latter type of approach. In particular, we will investigate the state-of-the-art LMMS model (Loureiro and Jorge, 2019). This model learns sense embeddings based on BERT states. These embeddings are then propagated through WordNet's ontology to infer additional senses, effectively providing a full coverage. While Loureiro and Jorge (2019) proposed variants of LMMS that combined propagation with gloss embeddings, or static embeddings, this paper is only concerned with the propagation method.

In our case, we essentially follow LMMS's layer pooling method to generate contextual embeddings for each sense occurrence in context (from a training set), and derive sense embeddings from the average of all corresponding contextual embeddings.

3.3 Network Propagation for Full-Coverage

The propagation method used in LMMS exploits the WordNet ontology to obtain a full coverage of sense embeddings from an initial set of embeddings based on a manually sense-annotated corpus like SemCor. This method explores different abstraction levels represented in WordNet: sets of synonyms (synsets), Is-A relations (hypernyms) and categorical groupings (lexnames[2]).

Initial sense embeddings are first used to compute synset embeddings as the average of all corresponding senses (analogously to how sense embeddings are computed from contextual embeddings). From that point, missing senses are represented by their corresponding synset embeddings. The remaining unrepresented senses are inferred from their hypernym and lexname embeddings, computed by averaging their neighbour synset embeddings. Note that this propagation process does not follow transitive relations in WordNet, i.e., a single synset's hypernym is considered, while the subsequent hypernyms along the root paths are ignored.

Since lexname embeddings can always be computed, this process can reach a full-coverage of WordNet starting with just the initial set of embeddings produced using SemCor. However, the set of SemCor embeddings only covers 16.1% of WordNet, so many of the inferred representations are redundant and therefore not entirely meaningful.

4 Evaluation

For our experiments we are interested in verifying the impact of using UWA to improve WSD performance. In particular, we test the unambiguous annotations of UWA as a complement of existing sense-annotated training data. To this end, as explained in Section 3, we make use of the state-of-the-art WSD model LMMS (Loureiro and Jorge, 2019). In addition to the original version using BERT, we also provide results with RoBERTa (Liu et al., 2019) for completeness. We use the 24-layer models for both BERT and RoBERTa.[3]

4.1 Word Sense Disambiguation (WSD)

Table 2 shows the WSD results on the standard evaluation framework of Raganato et al. (2017) for LMMS trained on the concatenation of SemCor and automatically-constructed corpora. In the table we include UWA with two different maximum number of examples per unambiguous word, i.e., 1 and 10. For comparison, we also include the results of EWISE (Kumar et al., 2019) and GlossBERT (Huang et al., 2019), which attempt to overcome the limited coverage of SemCor by exploiting textual definitions. As can be observed, the concatenation of our UWA corpus and SemCor provides the best overall results, regardless of the number of examples cut-off. Perhaps surprisingly, our corpus is the only one that provides improvements over the baseline (SemCor-only). These improvements are statistically significant on the full test set (i.e. ALL) for both BERT and RoBERTa with $p < 0.0005$, based on a t-test with respect to the

Results in datasets that were used as development are marked with *.

accuracy scores (equal to F1 in this setting). This can be explained by the fact that our corpus is the only one that significantly extends the coverage of SemCor, as explained in Section 3.1.

4.2 Uninformed Sense Matching (USM)

In standard WSD benchmarks, models are given the advantage of knowing the pre-defined set of possible senses before-hand. This is because gold PoS tags and lemmas are provided in these datasets. However, to better understand how robust a 1NN WSD model is, we can test it in an uninformed setting, i.e., where PoS tags and lemmas are not given and the model does not have access to the list of candidate senses. Instead, the model has to match senses from the whole sense inventory, unconstrained. Therefore, in this Uninformed Sense Matching (USM) setting we can use information retrieval ranking metrics with the model predictions (i.e. MRR or P@K) in addition to the standard F1. In line with the WSD results, Table 3 shows that UWA also substantially improves performance in the USM setting when comparing against currently available alternatives.

5 Analysis

In this section, we provide an analysis based on the number of examples (Section 5.1) and a visualization of the embedding space (Section 5.2).

Corpus	BERT			RoBERTa		
	F1	P@5	MRR	F1	P@5	MRR
OMSTI	50.2	66.0	57.5	44.1	59.9	51.7
T-o-M	45.8	62.1	53.3	42.1	60.7	50.2
UWA (10)	**54.9**	**74.1**	**63.5**	**62.1**	**80.2**	**70.1**

Table 3: Performance comparison in the uninformed setting. Each corpus is concatenated with SemCor.

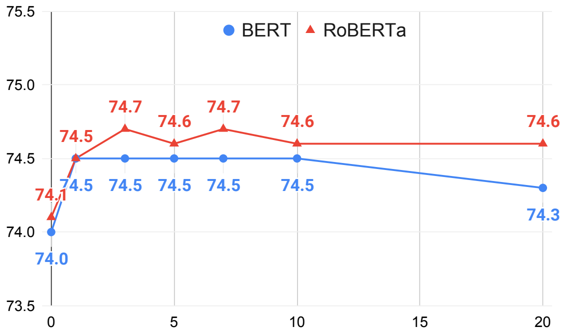

Figure 1: WSD performance (F1 on the ALL test set) with different numbers of UWA examples.

5.1 Number of Examples

When compiling examples for learning sense representations, a natural question that arises is: how many examples are required to learn effective representations? The answer to this question can not only guide collection efforts, but also help clarify the requirements for learning effective representations in the simplest setting. To that end, we analyse the impact of using different number of examples from UWA on LMMS's WSD and USM performance. In Figure 1, we show the WSD performance trend using different number of examples per sense. As can be seen, performance improves substantially with only one example, and then stops improving after just two examples.

Similarly to our findings for WSD, Table 4 shows that a low number of examples, such as 2, already achieves the best overall results in the USM setting for BERT. Likewise, RoBERTa does not benefit from more than 5 examples. More generally, in USM the differences with respect to SemCor are more marked in comparison to the regular WSD setting. This is expected as the propagation algorithm has a stronger effect in this setting where all sense embeddings are considered.

5.2 Visualization of the Embedding Space

The propagation method used in LMMS is designed to backoff to increasingly abstract repre-

	BERT			RoBERTa		
Corpus	**F1**	**P@5**	**MRR**	**F1**	**P@5**	**MRR**
SemCor	52.5	67.1	59.2	58.0	72.8	64.7
UWA (1)	55.1	74.1	63.5	61.3	79.8	69.5
UWA (2)	**55.5**	**74.6**	**64.0**	61.8	**80.3**	70.0
UWA (3)	55.4	74.5	63.9	61.9	**80.3**	70.0
UWA (5)	55.4	74.4	63.8	**62.1**	**80.3**	**70.1**
UWA (7)	55.2	74.1	63.7	61.9	**80.3**	70.0
UWA (10)	54.9	74.1	63.5	**62.1**	80.2	**70.1**
UWA (20)	54.9	73.7	63.3	**62.1**	79.9	70.0

Table 4: USM performance of the LMMS model using SemCor and UWA with different example thresholds. Models tested on the concatenation of all WSD datasets of Raganato et al. (2017). As before, UWA is concatenated with SC in this experiment.

sentation levels, from synsets, to hypernyms, to supersenses (see Section 3.3 of the main paper). This naturally leads to a clustering effect, where many senses are represented with very similar, or equal, embeddings. In fact, we find that only 22% of sense embeddings learned from SemCor, and propagated following LMMS, are actually unique (remaining are shared by two or more senses). The addition of UWA increases this percentage to 68%.

To better understand this clustering effect, we used T-SNE (Maaten and Hinton, 2008) to visualize the WordNet synset embedding space. In Figure 2 we show synset embeddings learned from the SemCor+UWA(10) dataset, and learned from SemCor alone, both based on RoBERTa. While the same number of synset embeddings are learned in both cases, SemCor+UWA embeddings are better distributed across the vector space. This, in turn, causes a substantial reduction of high-density clusters, which stand in opposition to a rich distributional representation of senses.[4]

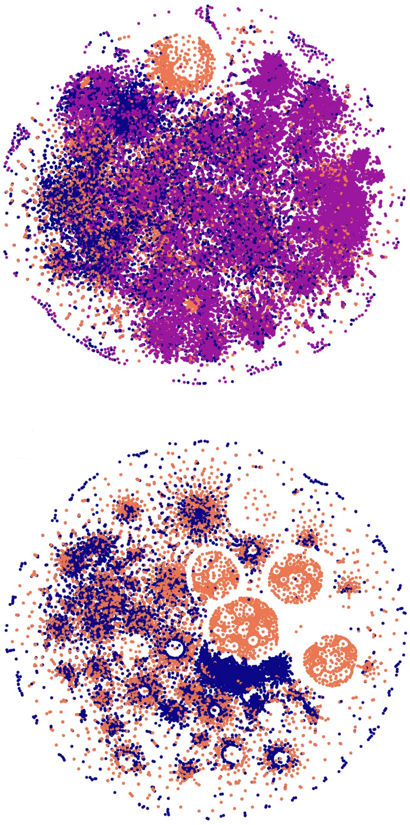

Figure 2: T-SNE comparison of synset embeddings for whole WordNet learned from SC+UWA10 (top), or just SC (bottom). Colors represent source of annotations for embeddings (● SC ● UWA ● Propagation).

6 Conclusion

Unambiguous words are a surprisingly large portion of existing knowledge resources like WordNet. At the same time, their coverage in existing sense-annotated corpora is very limited. In this paper, we proposed a simple method which exploits sense annotations of unambiguous words from unlabeled corpora, thereby effectively extending existing sense-annotated corpora with low-effort. By leveraging a state-of-the-art BERT-based WSD system that propagates sense embeddings across WordNet, we have shown that these unambiguous words provide an excellent bridge to reach a wider range of OOV senses. This translates, in turn, into improving results for WSD. For future work it would be interesting to test these sense embeddings in a wider range of applications outside WSD. Since the embedding space is clearly more diversified, as shown in Figure 2, this may lead to improvements in other downstream tasks.

Moreover, one of the most surprising findings from this paper is that a single occurrence of OOV unambiguous words is enough to improve the performance of WSD models. This is relevant because (1) it is not always easy to retrieve a large number of examples for unambiguous words, and (2) it facilitates a cheaper manual verification, if required.

Finally, we openly release UWA, a large corpus annotated with unambiguous words, together improved BERT and RoBERTa-based sense embeddings, model predictions and visualizations at `http://danlou.github.io/uwa`.

---

[4] We share interactive visualizations focusing on each of the 45 supersense groups (e.g. noun.communication) from WordNet at our UWA release website.

Abstract

We propose the novel *Within-Between* Relation model for recognizing lexical-semantic relations between words. Our model integrates relational and distributional signals, forming an effective sub-space representation for each relation. We show that the proposed model is competitive and outperforms other baselines, across various benchmarks.

1 Introduction and Related Work

Recognizing lexical-semantic relations between words is beneficial for a variety of NLP tasks such as machine translation (Thompson et al., 2019), relation extraction (Shen et al., 2018), natural language inference (Chen et al., 2018), and question answering (Yang et al., 2017).

The lexical relation classification task assigns a word-pair (pair of words) to its corresponding relation out of a finite set of relations. This set contains lexical relations, including the *random* relation (indicating that the words are unrelated). Two main lexical relation classification techniques are studied in the literature: Path-based methods (Hearst, 1992; Snow et al., 2005; Nakashole et al., 2012; Riedel et al., 2013) and distributional methods (Mikolov et al., 2013a; Pennington et al., 2014; Bojanowski et al., 2017; Glavaš and Vulić, 2018a), with some effort for integrating the two (Shwartz et al., 2016a).

In this work we follow the distributional approach, which was shown to improve upon path-based methods. This approach considers static word embeddings such as word2vec (Mikolov et al., 2013b), GloVe (Pennington et al., 2014),and FastText (Bojanowski et al., 2017), which produce out-of-context vector representation for each word. Note here that while *contextualized embeddings* (Devlin et al., 2019; Peters et al., 2018) have replaced the use of non-contextualized embeddings in many settings, static word embeddings remain the standard choice for lexical relation classification, since in this task the input word-pair is given out-of-context. Taking the word embeddings as input, a classifier is trained while considering each word's representation in the pair. The recent SphereRE method (Wang et al., 2019), a purely distributional method that learns hyperspherical relation representation, presented state-of-the-art lexical relation classification results.

While presenting state-of-the-art performance, prior distributional methods suffer from the "lexical memorization" problem Levy et al. (2015). This problem arises when a test word-pair includes a rather frequent word in the training set, which is labeled by a dominant category in training. In such cases, the supervised model often ignores the second word in the input pair and resorts to the dominant training label according to the frequent word. Notably, lexical memorization is common for *prototypical hypernyms* — "category" words that are frequently labeled as hypernyms. For example, the vast majority of training examples that include the word *fruit* are labeled as hypernymy (*fruit* is the hypernym of *apple*, *banana*, etc.). Therefore, at inference time, the classifier is likely to predict the hypernymy relation even for unrelated word-pairs that contain *fruit*, e.g., *(fruit,chair)*.

Another relevant line of research, which inspired our work, pertains to the integration of external lexical information to improve static word embeddings (Faruqui et al., 2015; Mrkšić et al., 2016; Glavaš and Vulić, 2018b; Arora et al., 2020; Barkan et al., 2020). Most of these methods aim to modify the distributional vector space, originally learned from corpus co-occurrence data, by using additional relational constraints. To that end, these techniques rely on lexical databases, e.g., Wordnet (Miller, 1995). Notably, Arora et al. (2020) present the LEXSUB model and suggest training static word

November 16–20, 2020.

embeddings by integrating lexical-relation and distributional data, through the combination of two corresponding loss terms. When modeling lexical relations data, each relation is projected to a separate subspace. Some of these ideas are adapted in certain parts of our work, while addressing the concrete goal of lexical relation classification rather than improving generic static word embeddings.

In this work, we present the novel *Within-Between* Relation (WBR) model, which is inspired both by previous relation classification models as well as by generic word embedding models that consider lexical relation constraints. This is performed through the combination of two objectives, both computed over the same projected sub-spaces, for each of the individual relations. Specifically, our *Between* objective aims to yield optimal classification of relation instances, while the *Within* objective aims to bring pairs of words sharing a relation close to each other in the corresponding relation sub-space. These objectives allow the incorporation of both relation and negative sampling signals, altogether addressing much better the lexical memorization problem.

2 The *Within-Between* Relation Model

In this section, we present the WBR model. Given a word-pair sharing a relation k, WBR is optimized to classify a word-pair to the correct relation (the *between* relation objective), and at the same time, separate it *within* the k relation space from other word-pairs that do not share the relation k. Let $\mathcal{I}$ and $\mathcal{K}$ be vocabularies of words and relations, respectively. $\mathcal{K}$ contains lexical relations such as *hypernym, antonym*, etc., including the *random* relation (words are unrelated) and the *co* (stands for co-occurrence) relation that is shared by words that co-occur in the corpus. We further denote $\mathcal{P} = \mathcal{I} \times \mathcal{I}$.

Let $\mathbf{u}_i, \mathbf{v}_i \in \mathbb{R}^d$ be random variables that form the context and target *base* representations for the word i. We further denote $\mathbf{U} = \{\mathbf{u}_i\}_{i \in \mathcal{I}}$ and $\mathbf{V} = \{\mathbf{v}_i\}_{i \in \mathcal{I}}$.

We assume normal priors $p(\mathbf{u}_i|\mathbf{a}_i, \tau) = \mathcal{N}(\mathbf{u}_i; \mathbf{a}_i, \tau^{-1}\mathbf{I})$ and $p(\mathbf{v}_i|\mathbf{b}_i, \tau) = \mathcal{N}(\mathbf{v}_i; \mathbf{b}_i, \tau^{-1}\mathbf{I})$, where $\mathbf{a}_i, \mathbf{b}_i \in \mathbb{R}^d$ are either zero or set to a pretrained embedding (that can be retrieved from any word embedding method such as FastText, word2vec, Glove, etc.), and τ is a precision hyperparameter. We further denote $\mathbf{A} = \{\mathbf{a}_i\}_{i \in \mathcal{I}}$ and $\mathbf{B} = \{\mathbf{b}_i\}_{i \in \mathcal{I}}$.

Let $I_k = \{(i,j)|i \xrightarrow{k} j\}$, where $i \xrightarrow{k} j$ means that words i and j share a directed relation k. In case of an undirected relation, it holds that $(i \xrightarrow{k} j) \leftrightarrow (j \xrightarrow{k} i)$. Note that in the specific case of the *random* relation, $I_{random} = \{(i,j)|(i,j) \notin \bigcup_{k \in \mathcal{K} \setminus \{random\}} I_k\}$. This assumption guarantees each word-pair $(i,j) \in \mathcal{P}$ is associated with a relation $k \in \mathcal{K}$.

Let $f^k : \mathcal{P} \to \mathbb{R}$ be a parametric function. Our goal is to learn parameters for f^k s.t. the score f_{ij}^k is high if and only if $(i,j) \in I_k$. In this work, we define $f_{ij}^k \triangleq \alpha \frac{\mathbf{p}_i^k \cdot \mathbf{q}_j^k}{||\mathbf{p}_i^k||_2 ||\mathbf{q}_j^k||_2}$, where $\mathbf{p}_i^k = \mathbf{\Psi}_k \mathbf{u}_i$, $\mathbf{q}_i^k = \mathbf{\Phi}_k \mathbf{v}_j$, and α is a hyperparameter. This forms a cosine similarity similarity metric with temperature, is motivated in Sec. 4. $\mathbf{\Psi}_k \in \mathbb{R}^{d_k \times d}$ and $\mathbf{\Phi}_k \in \mathbb{R}^{d_k \times d}$ are matrices whose entries have normal priors with zero mean and precision λ (hyperparameter). Therefore, f^k learns $\mathbf{\Psi}_k$ and $\mathbf{\Phi}_k$ that enable the projection to a new relation space k. In this space, word-pairs that share the relation k are separated from word-pairs that do not in terms of the angle between their repective vectors. Yet, in the general case, f^k can be a deep neural network. An exception is $k = co$, for which $\mathbf{\Psi}_k$ and $\mathbf{\Phi}_k$ are predetermined to $\mathbf{\Psi}_k = \mathbf{\Phi}_k = \mathbf{I}$ (not learned). We further denote $\mathbf{\Psi} = \{\mathbf{\Psi}_k\}_{k \in \mathcal{K}}$ and $\mathbf{\Phi} = \{\mathbf{\Phi}_k\}_{k \in \mathcal{K}}$. Finally, we denote the set of unobserved variables and the set of hyperparameters by $\mathbf{\Theta} = \{\mathbf{U}, \mathbf{V}, \mathbf{\Psi}, \mathbf{\Phi}\}$ and $\mathbf{H} = \{\mathbf{A}, \mathbf{B}, \tau, \lambda\}$, respectively.

2.1 The *Within*-Relation Likelihood

We define $\mathbf{Y}^k = \{y_{ij}^k|(i,j) \in \mathcal{P}\}$, where $y_{ij}^k : \mathcal{P} \to \{1, -1\}$ is an observed random variable, s.t. $y_{ij}^k = 1$ if $(i,j) \in I_k$, otherwise, $y_{ij}^k = -1$. We further denote $\mathbf{Y} = \{\mathbf{Y}_k\}_{k \in \mathcal{K}}$ and $\sigma(x) = (1 + e^{-x})^{-1}$. Then, the *within*-relation likelihood is given by:

$$\begin{aligned} p(\mathbf{Y}|\mathbf{\Theta}) &= \prod_{(i,j) \in \mathcal{P}} \prod_{k \in \mathcal{K}} p(y_{ij}^k|\mathbf{u}_i, \mathbf{v}_j, \mathbf{\Psi}_k, \mathbf{\Phi}_k) \\ &= \prod_{(i,j) \in \mathcal{P}} \prod_{k \in \mathcal{K}} \sigma(y_{ij}^k f_{ij}^k). \end{aligned}$$

2.2 The *Between*-Relation Likelihood

Denote $\mathcal{K}' = \mathcal{K} \setminus \{co\}$ and let $\mathbf{R} = \{r_{ij}|(i,j) \in \mathcal{P}\}$, where $r_{ij} : \mathcal{P} \to \mathcal{K}'$ is an observed categorical random variable s.t. $r_{ij} = k$ if $(i,j) \in I_k$. Then, the *between*-relation

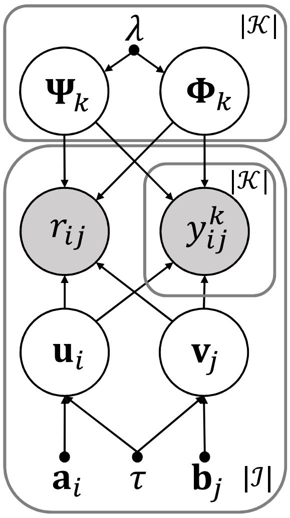

Figure 1: The WBR graphical model.

likelihood is given by:

$$\begin{aligned} p(\mathbf{R}|\boldsymbol{\Theta}) &= \prod_{(i,j)\in\mathcal{P}} p(r_{ij}|\mathbf{u}_i, \mathbf{v}_j, \boldsymbol{\Psi}, \boldsymbol{\Phi}) \\ &= \prod_{(i,j)\in\mathcal{P}} \frac{\exp f_{ij}^{r_{ij}}}{\sum_{k\in\mathcal{K}'} \exp f_{ij}^{k}} \end{aligned}$$

2.3 WBR Training and Inference

The *vanilla* WBR loss is derived by taking the negative log of the joint distribution as follows:

$$\begin{aligned} \mathcal{L}_{\text{vanilla}}(\boldsymbol{\Theta}) &= -\log p(\mathbf{Y}, \mathbf{R}, \boldsymbol{\Theta}|\mathbf{H}) \\ &= -\log\left[p(\mathbf{Y}|\boldsymbol{\Theta})p(\mathbf{R}|\boldsymbol{\Theta})p(\boldsymbol{\Theta}|\mathbf{H})\right] \\ &= -\sum_{(i,j)\in\mathcal{P}} \sum_{k\in\mathcal{K}} \log\sigma(y_{ij}^k f_{ij}^k) \\ &\quad - \sum_{(i,j)\in\mathcal{P}} f_{ij}^{r_{ij}} + \log\sum_{k\in\mathcal{K}'} \exp f_{ij}^k \\ &\quad + \frac{\tau}{2}\sum_{i\in\mathcal{I}} ||\mathbf{u}_i - \mathbf{a}_i||_2^2 + ||\mathbf{v}_i - \mathbf{b}_i||_2^2 \\ &\quad + \frac{\lambda}{2}\sum_{k\in\mathcal{K}'} ||\boldsymbol{\Psi}_k||_2^2 + ||\boldsymbol{\Phi}_k||_2^2 + \text{const.} \end{aligned} \tag{1}$$

A graphical model of WBR is presented in Fig. 1. The minimization of $\mathcal{L}_{\text{vanilla}}(\boldsymbol{\Theta})$ is equivalent to the Maximum A-*Posteriori* (MAP) estimation of $\boldsymbol{\Theta}$. However, the negative log likelihood terms in Eq. 1 contain a summation which is quadratic in the vocabulary size $\mathcal{I}$, implying a prohibitive computation. Therefore, we turn to a stochastic optimization: Let C be a text corpus (a sequence of words), and $Q_i^k = \{j|(i,j) \in I_k\}$. We define $s^k : \mathcal{I} \to \mathcal{I} \times \mathcal{I}$ as a sampler s.t. $s^k(i)$ retrieves a random word-pair $(i,j) \in Q_i^k$ if $Q_i^k \neq \emptyset$, otherwise, a random word-pair $(a,b) \in I_k$. The WBR stochastic optimization algorithm is described in Algorithm 1, together with the $\mathcal{L}_{\text{wbr}}$ loss function in Eq. 2.

Algorithm 1 WBR Stochastic Optimization

```
for $z \leftarrow 1$ to $T$ do
  for $i$ in $C$ do
    for $k$ in $\mathcal{K}$ do
      $\mathcal{P}_k \leftarrow \emptyset$
    end for
    Sample a positive word $j$ (within the window around $i$), and a negative word $n \in \mathcal{I}$
    $y_{i,j}^{co} \leftarrow 1, y_{i,n}^{co} \leftarrow -1,$
    $\mathcal{I}_u \leftarrow \mathcal{I}_u \cup \{i\}, \mathcal{I}_v \leftarrow \mathcal{I}_v \cup \{j, n\}$
    $\mathcal{P}_{co} \leftarrow \mathcal{P}_{co} \cup \{(i,j), (i,n)\}$
    for $k$ in $\mathcal{K}'$ do
      $(a, b) \leftarrow s^k(i)$
      Sample $n$ s.t. $(a, n) \notin I_k$
      $y_{a,b}^k \leftarrow 1, y_{a,n}^k \leftarrow -1$
      $\mathcal{I}_u \leftarrow \mathcal{I}_u \cup \{a\}, \mathcal{I}_v \leftarrow \mathcal{I}_v \cup \{b, n\}$
      $\mathcal{P}_k \leftarrow \mathcal{P}_k \cup \{(a,b), (a,n)\}$
      $r_{ab} \leftarrow k$
      if $k \neq random$ then
        $r_{an} \leftarrow random$
      end if
    end for
    $\boldsymbol{\Theta} \leftarrow$ OPT $(\boldsymbol{\Theta}, \mathcal{L}_{\text{wbr}})$ (See Eq. 2)
  end for
end for
```

$$\begin{aligned} \mathcal{L}_{\text{wbr}}(\boldsymbol{\Theta}) = &-\sum_{k\in\mathcal{K}} \sum_{(i,j)\in\mathcal{P}_k} \log\sigma(y_{ij}^k f_{ij}^k) \\ &- \sum_{k\in\mathcal{K}'} \sum_{(i,j)\in\mathcal{P}_k} f_{ij}^{r_{ij}} + \log\sum_{k\in\mathcal{K}'} \exp f_{ij}^k \\ &+ \frac{\tau}{2}\sum_{i\in\mathcal{I}_u} ||\mathbf{u}_i - \mathbf{a}_i||_2^2 \\ &+ \frac{\tau}{2}\sum_{i\in\mathcal{I}_v} ||\mathbf{v}_i - \mathbf{b}_i||_2^2 \\ &+ \frac{\lambda}{2}\sum_{k\in\mathcal{K}'} ||\boldsymbol{\Psi}_k||_2^2 + ||\boldsymbol{\Phi}_k||_2^2. \end{aligned} \tag{2}$$

Finally, in the inference phase, the probability of $i \xrightarrow{k} j$ is computed by $p(r_{ij} = k|\boldsymbol{\Theta}^*)$, where $\boldsymbol{\Theta}^*$ is the MAP estimate (produced by Algorithm 1).

3 Experimental Setup and Results

In this section, we present the datasets, hyperparameters, and experiments that we conducted to

Table 1: Precision, Recall and F1 results over lexical relation classification benchmarks. Best results are bolded.

evaluate our model and compare it with other methods.

3.1 Benchmarks and Co-Occurrence Data

In order to evaluate our model, we adopted the same experimental setup from Wang et al. (2019). The lexical relation classification datasets that were considered are K&H+N (Necşulescu et al., 2015), BLESS (Baroni and Lenci, 2011), ROOT09 (Santus et al.) and EVALution (Santus et al., 2015). Since the EVALution benchmark does not contain the *random* relation, we add it artificially for the negative sampling purpose. Due to space limitations, we do not provide the datasets' statistics. The reader may refer to (Wang et al., 2019) for the full details of the datasets.

For co-occurrence data, we extracted co-occurring word-pairs from the English Wikipedia corpus. We sampled co-occurrence data that correspond to the vocabulary of the relation classification dataset, by picking the sentences form the corpus that contain these words.

3.2 Evaluated Models

For baselines, we considered both traditional distributional models: Concat (Baroni et al., 2012) and Diff (Weeds et al., 2014), and path-based models NPB (Shwartz et al., 2016b), LexNET (Shwartz and Dagan, 2016) (which integrates both distributional model and pure path-based data), NPB+Aug and LexNET+Aug (the base models are trained on augmented dependency paths, used to improve coverege) (Washio and Kato, 2018), and the recent state-of-the-art model SphereRE (Wang et al., 2019). Note that SphereRE performs a pre-training phase for generating initial pseudo labels, and the (unlabeled) test data is used for both this phase and the training. Our method does not require the test data and does not perform and initial classification before training. We refer readers to the previous works for detailed descriptions of these baselines. Note that (Washio and Kato, 2018) reported only the F1 scores over the models that were trained using augmented dependency paths.

3.2.1 Ablation Study

In order to assess the contribution of each component in our model, we perform an ablation study. First, we denote WBR as the full model that is described in Section 2. In addition, we consider the following ablated versions of WBR:

BR: In this version, we omit the within loss and do not learn $\mathbf{U}$ and $\mathbf{V}$. Instead, we set $\mathbf{U} = \mathbf{A}$ and $\mathbf{U} = \mathbf{B}$ and keep them fixed for the entire opttimization procedure. This leads to the following loss:

$$\mathcal{L}_{\text{br}}(\mathbf{\Theta}) = -\sum_{k\in\mathcal{K}'}\sum_{(i,j)\in\mathcal{P}_k} f_{ij}^{r_{ij}} + \log\sum_{k\in\mathcal{K}'}\exp f_{ij}^{k} + \frac{\lambda}{2}\sum_{k\in\mathcal{K}'}||\mathbf{\Psi}_k||_2^2 + ||\mathbf{\Phi}_k||_2^2.$$

BR+co: In this version, we omit all the relations from the *within*-relation loss, except for the *co* (co-occurence) relation. In other words, we change the WBR loss to include the *between*-relation likelihood, co-occurrence likelihood and the priors as follows:

$$\begin{aligned}\mathcal{L}_{\text{br}+co}(\mathbf{\Theta}) = &-\sum_{(i,j)\in\mathcal{P}_{co}} \log\sigma(y_{ij}^{co} f_{ij}^{co})\\ &-\sum_{k\in\mathcal{K}'}\sum_{(i,j)\in\mathcal{P}_k} f_{ij}^{r_{ij}} + \log\sum_{k\in\mathcal{K}'}\exp f_{ij}^{k}\\ &+\frac{\tau}{2}\sum_{i\in\mathcal{I}_u}||\mathbf{u}_i - \mathbf{a}_i||_2^2\\ &+\frac{\tau}{2}\sum_{i\in\mathcal{I}_v}||\mathbf{v}_i - \mathbf{b}_i||_2^2\\ &+\frac{\lambda}{2}\sum_{k\in\mathcal{K}'}||\mathbf{\Psi}_k||_2^2 + ||\mathbf{\Phi}_k||_2^2.\end{aligned}$$

3.3 Hyperparameters Configuration

We set the projection dimension to $d_k = 15$, the precisions to $\lambda = \tau = 10^{-4}$, and the temperature to $\alpha = 5$. Either increasing d_k or changing the precisions or the temperature did not improve the performance of WBR over the validation sets. We used the Adam optimizer (Kingma and Ba, 2015) (as OPT from Algorithm 1) with a minibatch size of 32. Similar to Wang et al. (2019), we initialized the word-level representations to the pretrained 300 dimensional FastText word embeddings (Bojanowski et al., 2017). The SphereRE model uses constant FastText word embeddings and only learns relations' embeddings. However, we train both the relations' projections and continued the training of the word embeddings. For the rest of the baselines, the hyperparameters are adopted from the corresponding papers. For training stopping criteria, we used the validation set within each dataset (by computing the F1 score). For each test set, we report the averaged precision, recall, and F1 score for each lexical relation.

3.4 Results

The results of WBR and all of the baselines over the datasets are summarized in Table 1. Overall, our WBR model provides competitive performance results comparing to the tested baseline models. The recent SphereRE model outperforms the basic BR model on all the datasets. Adding the *within*-relation objective, but only with co-occurrence (BR+*co*) improved the performance. The results on the other benchmarks are close to SphereRE. Adding both the *random* relation and using the *within*-relation mechanism increased the performance gain over this dataset, which is extremely imbalanced compared to the rest of the datasets (Wang et al., 2019). The improvement on EVALution is reasonable since this dataset does not contain the *random* relation. This effect can be explained by addressing the lexical memorization problem. Finally, adding the relations data to the *within*-relation objective (the full WBR model) yielded additional performance gain, causing the model to outperform the SphereRE over three datasets slightly.

4 Mitigating the Lexical Memorization Problem

The lexical memorization problem is alleviated by the introduction of the *random* relation. This feature plays a key role both for the *between* and *within* loss terms: given a word-pair (a, b) and their corresponding, ground truth relation r, we randomly sample a word n and associate the word-pair (a, n) with the *random* relation, unless r happens to be equal to the *random* relation beforehand (see Algorithm 1). This unique mechanism is designed to balance each positive word-pair with a negative one, neutralizing the effect of multiple instances of the prototypical terms (e.g., *animal*, *fruit*, etc.) on the training objective, as a kind of regularization and data augmentation. For example, consider the positive data sample $(animal, b)$. It will be balanced with a negative sample $(animal, n)$. Therefore, during the training phase, the *between* classifier learns to consider the *random* label each time it is given the *hypernymy* label. Similarly, the corresponding *within* (*hypernymy*) classifier will encounter a negative sample for each positive sample. As a result, in the inference phase, the relation classifier does not always predict the *hypernym* relation for $(animal, x)$ - the classifier will consider the features of x as well, and thus mitigates the lexical memorization problem. Another way to ensure that each relation classifier exploits both words in the given pair is splitting them into two different linear projections' relation sets, $\mathbf{\Psi}$ for the first word, and $\mathbf{\Phi}$ for the second. Further, using the cosine similarity measure for computing f_{ij}^{k}, rather than a dot product, provides a normalization effect which neutralizes frequency biases, caused by typical larger norms for frequent words.

5 Conclusions

We presented WBR - a novel model for lexical relation classification. WBR facilitates the novel *between-within* relation loss, enabling the exploitation of distributional information. WBR is evaluated on four different datasets, where it is shown to outperform various baselines across all evaluation metrics.

With More Contexts Comes Better Performance: Contextualized Sense Embeddings for All-Round Word Sense Disambiguation

Bianca Scarlini, Tommaso Pasini and **Roberto Navigli**
Sapienza NLP Group
Department of Computer Science
Sapienza University of Rome
`{scarlini,pasini,navigli}@di.uniroma1.it`

Abstract

Contextualized word embeddings have been employed effectively across several tasks in Natural Language Processing, as they have proved to carry useful semantic information. However, it is still hard to link them to structured sources of knowledge. In this paper we present ARES (context-AwaRe Embeddings of Senses), a semi-supervised approach to producing sense embeddings for the lexical meanings within a lexical knowledge base that lie in a space that is comparable to that of contextualized word vectors. ARES representations enable a simple 1-Nearest-Neighbour algorithm to outperform state-of-the-art models, not only in the English Word Sense Disambiguation task, but also in the multilingual one, whilst training on sense-annotated data in English only. We further assess the quality of our embeddings in the Word-in-Context task, where, when used as an external source of knowledge, they consistently improve the performance of a neural model, leading it to compete with other more complex architectures. ARES embeddings for all WordNet concepts and the automatically-extracted contexts used for creating the sense representations are freely available at `http://sensembert.org/ares`.

1 Introduction

Contextualized word embeddings have proved to be highly beneficial to the majority of Natural Language Processing tasks (Wang et al., 2019). Indeed, language models like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019), etc., enable architectures built on top of them to attain performances that were previously out of reach (Wang et al., 2019). The main reason behind this great success is the fact that contextualized embeddings of words encode the semantics defined by their input context (Reif et al., 2019). Indeed, when tested in the Word-in-Context (WiC) task (Pilehvar and Camacho-Collados, 2019), i.e., a binary classification problem where a model has to classify whether a target word is used with the same meaning in two different sentences, contextualized word embeddings placed themselves as the best approaches across the board. Nevertheless, these latent representations do not provide any explicit information regarding the meaning expressed by the word in context, hence making it difficult to link texts to structured sources of knowledge such as lexical knowledge bases (LKB).

The task of associating a word in context with the most suitable meaning from a predefined sense inventory is better known as Word Sense Disambiguation (Navigli, 2009, WSD), and is usually tackled by two kinds of approach: knowledge-based and supervised ones. On the one hand, knowledge-based approaches (Scozzafava et al., 2020; Conia and Navigli, 2020) are able to scale across languages since they do not need sense-annotated corpora and rely only on the information within their underlying LKB. On the other hand, supervised models (Huang et al., 2019; Bevilacqua and Navigli, 2020) have proved to achieve state-of-the-art results on the English benchmarks by taking advantage of manually-annotated data for the task and machine learning algorithms. However, supervised approaches are mostly focused on English (Navigli, 2018; Pasini, 2020) and have only recently been applied to lower-resourced languages thanks to automatically-produced datasets (Scarlini et al., 2019; Barba et al., 2020; Pasini and Navigli, 2020). Another effective approach in this direction has been presented by Scarlini et al. (2020), who introduced SensEmBERT, a knowledge-based approach to building sense embeddings without relying on sense-annotated data. Since it is not tied to semantic annotations, SensEmBERT scales over different languages. However, it is limited to nominal concepts only and provides different

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3528–3539,
November 16–20, 2020.

representations for the same concepts across different languages, which hinders its applicability to cross-lingual tasks.

In this paper we present ARES (context-AwaRe Embeddings of Senses), a semi-supervised approach to producing sense embeddings for all the word senses in a language vocabulary. ARES makes up for the paucity of manually-annotated examples for a large portion of words' meanings by coupling the information within a knowledge base with the representational power of a pre-trained language model. This enables reliable representations to be built for those senses not appearing in manually-curated resources, while at the same time enriching the vectors for all the other concepts.

We tested our embeddings on the two tasks that measure a model's capabilities to encode word meanings, i.e., WSD and WiC. In both tasks, ARES representations prove to be of great benefit. In WSD, while employing a simple 1-Nearest-Neighbour (1-NN) algorithm, they attain state-of-the-art results on English, even beating dedicated architectures with long and expensive fine-tuning procedures. In WiC they lead a simple BERT-based model to perform in the same ballpark as other state-of-the-art alternatives which rely on more complex architectures. Furthermore, by taking advantage of pre-trained multilingual models we provide unified representations of meanings across languages, which, while using English data only, outperform their competitors and achieve the state of the art on all the languages available in the all-words multilingual WSD tasks, i.e., French, German, Italian and Spanish.

2 Related Work

Word Sense Disambiguation (WSD) is a core task in lexical semantics and has mainly been tackled by two kinds of approach: knowledge-based and supervised ones. Knowledge-based methods build upon lexical knowledge bases, such as WordNet (Miller et al., 1990) and BabelNet (Navigli and Ponzetto, 2012), and employ algorithms on graphs to address the word ambiguity in texts (Moro et al., 2014; Agirre et al., 2014; Tripodi and Navigli, 2019; Scozzafava et al., 2020). These approaches do not rely on semantically-tagged training data and are hence able to scale over all the languages supported by their underlying knowledge base. Nevertheless, they lag behind their supervised counterparts on English in terms of performance. Supervised approaches, by framing WSD as a classification task, have acquitted themselves as the state of the art in English (Hadiwinoto et al., 2019; Huang et al., 2019; Blevins and Zettlemoyer, 2020; Bevilacqua and Navigli, 2020; Bevilacqua et al., 2020), outperforming their knowledge-based competitors by several points.

Recently, Pilehvar and Camacho-Collados (2019) provided a new declination of WSD, formulating it as a binary classification problem where, given a target word and two contexts, a model has to predict whether the target word is used with the same meaning. This setting has the advantage of not drawing on sense inventories and provides an effective testbed for context-based word embeddings (Peters et al., 2019; Levine et al., 2020).

Contextualized sense representations have recently been employed to compute sense representations that can be applied directly to disambiguation. Some of the first approaches of this kind were proposed by Melamud et al. (2016) and Peters et al. (2018), who exploited the semantically-tagged sentences of SemCor (Miller et al., 1993) and neural language models to create embeddings for the senses in WordNet. Similarly, Loureiro and Jorge (2019, LMMS) computed sense embeddings using BERT (Devlin et al., 2019) and the relations in a lexical knowledge base in order to also provide vectors for those meanings that do not appear in SemCor. The most recent effort in this direction is SensEmBERT (Scarlini et al., 2020), which drops the need for sense-annotated corpora by exploiting the BabelNet mapping between WordNet senses and Wikipedia pages so as to collect contextual information for the senses in WordNet. Since it does not rely on manually-annotated data SensEmBERT can scale over different languages, being limited, however, to nominal senses only.

In this work we continue along this latter line of research and propose a novel method for producing sense embeddings which, by relying on English data only, also proves to be able to model meanings across languages. Rather than leveraging WordNet relations as LMMS does, ARES creates vector representations for all senses by automatically providing usage examples for the synsets within a knowledge base. In contrast to SensEmBERT, instead, ARES covers all the four WordNet POS tags, and, at the same time, disposes of the resources required by SensEmBERT, such as NASARI and the Wikipedia category graph.

3 Preliminaries

We now describe the resources that we use to build ARES embeddings.

WordNet (Miller et al., 1990) is the most used lexical knowledge base for English. It can be viewed as a graph where nodes are concepts, i.e., synsets, and edges are semantic relations between them. Each synset contains a set of synonyms, e.g., the synset defined as *A natural flow of ground water* comprises the lemmas *spring*, *fountain* and *natural spring*. We use the notation $\{l_1, \ldots, l_n\}$ (g) to refer to the concept with gloss g and expressed by the lemmas $l_1, \ldots, l_n$. We define a *sense* as a lemma-gloss pair, i.e., a meaning that is specific to a given lemma, e.g., *fountain*-(*A natural flow of ground water*) is a sense of {*spring, fountain, natural spring*} (*A natural flow of ground water*).

SyntagNet (Maru et al., 2019) is a repository containing approximately $88K$ lexical-semantic collocations, i.e., pairs of WordNet synsets that co-occur more frequently than would be expected.[1] For example, the concepts {*coach, bus, autobus*} (*A vehicle carrying many passengers*) and {*driver, motorist*} (*The operator of a motor vehicle*) appear in SyntagNet as they form a collocation.

UKB (Agirre et al., 2014) is a knowledge-based approach to WSD based on the Personalized PageRank algorithm (Haveliwala et al., 2002). We set WordNet as underlying knowledge base, disable the Most Frequent Sense backoff strategy and set the parameters according to Agirre et al. (2018).

SemCor (Miller et al., 1993) is the standard manually-curated corpus for WSD including more than $220K$ words tagged with $25K$ distinct WordNet meanings, hence providing annotated contexts for roughly 15% of the synsets in WordNet.

BERT (Devlin et al., 2019) is a deep neural architecture trained with the masked language model objective. Given a text, it provides contextual embeddings for the subtokens therein. We choose BERT because it has proven to capture the semantics of a word in context (Reif et al., 2019), while also being able to effectively generalize cross-lingually thanks to its multilingual representations (Pires et al., 2019).[2]

4 ARES

We now introduce ARES, a semi-supervised approach for creating sense embeddings that cover all the senses in a language vocabulary. Given as input a corpus C of raw sentences and a synset $s \in$ WordNet together with its lexicalizations L_s, ARES operates the following three steps:

1. **Context extraction,** which exploits the representation capabilities of BERT and the collocational information comprised in SyntagNet to extract a meaningful set of contexts where s is likely to appear (Section 4.1);

2. **Synset embedding,** which creates the embedding of the synset s by encoding the contextual information of the sentences gathered in the previous step (Section 4.2);

3. **Sense embedding,** which combines the sense-annotated contexts in SemCor, the definitional information of the glosses and our synset embeddings to create the final sense representation (Section 4.3).

4.1 Context Extraction

In this Section we describe our approach for automatically retrieving contexts for WordNet's synsets. First, as in Pasini et al. (2020), we utilize BERT and UKB to find contexts that are similar to each other and link them to a meaning in WordNet. Then, we enrich the set of contexts retrieved for a given synset s by exploiting the semantic collocations available in SyntagNet.

Similarity-Based Extraction Given a synset s and one of its lexicalizations l, we collect the occurrences of l in the input corpus C and compute their contextualized representations by means of BERT.[3] We then cluster the contextualized vectors of l's occurrences by using the k-*means* algorithm. We note that the sentences comprised within the same cluster define similar contexts for the target word, hence implying that l is very likely to be used with the same meaning across sentences. Therefore, we associate each cluster with one of l's meanings and a disambiguation score. To this end, we apply UKB (see Section 3) to the set of words that most characterize the given cluster, i.e., the top n most

---

[1] `http://syntagnet.org/`

[2] We note that a comparison with other pre-trained language models is outside the scope of this paper and a more extensive evaluation is left as future work.

[3] We discard all the sentences in which l is part of a larger span that is identified as a named entity.

Sentences for {*spring, fountain, natural spring*}
Springs that contain significant amounts of minerals are called 'mineral springs'.
The forcing of the **spring** to the surface can be the result of a confined aquifer.
Other **fountains** are the result of pressure from an underground source in the earth
Natural springs that contain significant amounts of minerals are called 'mineral springs'.
Other **natural springs** are the result of pressure from an underground source in the earth.

Table 1: Sentences retrieved for the synset {*spring, fountain, natural spring*} (upper part) and sentences where the target lemmas have been replaced with the missing ones (bottom part).

Sentences
He learned how to **play** the **guitar** at the age of eleven.
Michelle can **play** skillfully on **guitar** and piano.
The Ventures **played** Fender **guitars** for their live performances.

Table 2: Excerpt of sentences where the synsets {*play*} (*Play on an instrument*) and {*guitar*} (*A stringed instrument*) appear together.

frequent words[4] among its sentences.[5] Once each cluster has been disambiguated with one meaning of l, we retain only those clusters that are associated with s. Then, we associate each sentence with the disambiguation score provided by UKB for its cluster and sample t sentences according to their score, creating a set of contexts $\Phi_{l,s}$ for the lemma l in the synset s. We note that it might happen that none of the clusters of l is associated with s. This limits both the number and the diversity of contexts available for the target synset. To overcome this issue and increase coverage, we sample a set of ξ sentences from $\cup_{l' \in L_s} \Phi_{l',s}$ and replace the lexicalizations l' of s that appear therein with the lemma l. For example, let {*spring, fountain, natural spring*} (*A natural flow of ground water*) be the input synset, and the sentences in Table 1 (top) be the contexts retrieved thanks to the clustering and disambiguation steps, we replace some occurrences of *spring* and *fountain* with *natural spring*, as shown in the bottom part of the Table.

Collocation-Aware Extraction We now enrich the set $\Phi_{l,s}$ by leveraging the semantic collocations available in SyntagNet (see Section 3) for the synset s. To this end, we first retrieve from SyntagNet all the synsets s' that collocate with s, and then extract all the sentences in C where any of the lemmas l and l' of s and s', respectively, appear within a small window w. Finally, we disambiguate each occurrence of l with its synset s. For example, given the concepts {*play*} (*Play on an instrument*) and {*guitar*} (*A stringed instrument*) which are in collocation in SyntagNet, we search for all the occurrences of *play* and *guitar* in the sentences of the input corpus and retain only those where the two words appear within a window of size 3. In Table 2 we show an excerpt of the sentences extracted for the two aforementioned synsets. Each occurrence of *play* in those sentences is hence disambiguated with {*play*} (*Play on an instrument*).

At the end of this step, the synset s is associated with the set of sentences $\Phi_s = \cup_{l \in L_s} \Phi_{l,s}$ where any of the lemmas of s is disambiguated with s.

4.2 Synset Embedding

In this step we exploit the contexts retrieved for a target synset s in order to compute its latent representation.

First, we create the set $\hat{L}_s$ containing the lexicalizations of the synsets that are collocated with s in SyntagNet. For example, given the synset s = {*spring, fountain, natural spring*} (*A natural flow of ground water*), we consider the lexicalizations of its related concepts in SyntagNet, i.e., *flow* and *flowing* from the synset {*flow, flowing*} (*The motion characteristic of fluids*) and create $\hat{L}_s = \{flow, flowing\}$.

Then, we leverage the contexts in $\Phi_{l,s}$ and the lemmas in both L_s and $\hat{L}_s$ to compute the vector representation v_s for the synset s as follows:

$$v^s_{\text{C}} = \frac{\sum\limits_{l \in L_s} E(\Phi_{l,s}) + \sum\limits_{l' \in \hat{L}_s} E(\hat{\Phi}_{l',s})}{Z} \tag{1}$$

$$E(\Phi_{\lambda,s}) = \sum_{\sigma \in \Phi_{\lambda,s}} \textsc{Bert}(\lambda, \sigma) \tag{2}$$

where $\hat{\Phi}_{l',s}$ is a subset of $\Phi_{l,s}$ containing all the sentences where the lemma $l' \in \hat{L}_s$ appears in collocation with $l \in L_s$, Z is $\sum_{l \in L} |\Phi_{l,s}| + \sum_{l' \in \hat{L}} |\hat{\Phi}_{l',s}|$, and $\textsc{Bert}(\lambda, \sigma)$ is the contextualized embedding for the lemma λ in the context σ.

At the end of this step, the synset s is associated with a vector v^s_{C} created as shown above.

4.3 Sense Embedding

In this final step, we first create sense-level representations by leveraging the contexts in SemCor

---

[4] We discard from this calculation the non-content words and the stopwords.

[5] We use UKB as it can directly take as input the Bag-of-Words representations of the clusters.

	Synsets	Sentences	Annotations	Avg sentences per synset	Synsets with 1 example
Cluster	71,025	9,274,698	10,575,541	148	1096
SyntagNet	19,706	1,324,863	2,649,726	134	763
ALL	77,195	10,599,561	13,225,267	141	1318

Table 3: Statistics of the contexts extracted by the similarity-based (Cluster) and collocation-aware (SyntagNet) extraction step in Section 4.1.

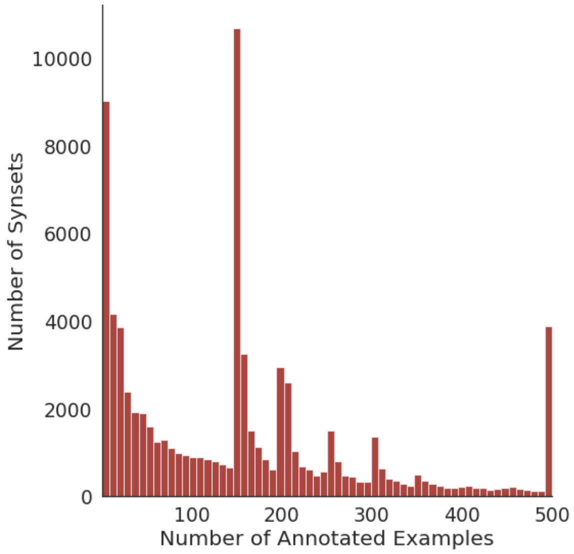

Figure 1: Histogram showing the number of synsets (y axis) by the number of annotated examples (x axis, bucket-based).

and the WordNet glosses, and then enrich them with our synset embeddings.

For each sense θ of s we create its embedding from its contextual occurrences within SemCor and its definition in WordNet. As for the SemCor part, we apply Peters et al. (2018)'s method to compute its representation v^{θ}_{SC}, i.e., we average the BERT embeddings of all the words in SemCor tagged with θ. As regards the sense gloss part, instead, we follow Loureiro and Jorge (2019) and prepend to the gloss of s both the lemma of θ and all the lexicalizations of s, and compute the sense gloss embedding v^{θ}_{G} by averaging the BERT representations of the words therein. For example, given the *spring* sense of the synset {*spring, fountain, natural spring*} (*A natural flow of ground water*), its sense gloss embedding is the average of the BERT representations of the following enriched gloss: *"spring - spring, fountain, natural spring - A natural flow of ground water"*.

We compute the representation ARES^{θ} for the sense θ of the synset s as follows:

$$\text{ARES}^{\theta} = v^{\theta}_{\text{SC}} \parallel v^{\theta}_{\text{G}} \odot v^{s}_{\text{C}}$$

where $\odot$ represents the mean between two vectors, and $\parallel$ their concatenation. If a sense does not occur in SemCor, we replace v^{θ}_{SC} with v^{θ}_{G} and apply the above formula. We recall from Section 3 that SemCor covers only 15% of WordNet's senses, nevertheless ARES is able to generalize over all the senses in WordNet thanks to the glosses and its automatically-retrieved contexts.

5 Statistics

In Table 3 we report the statistics of the sentences extracted as in Section 4.1. As one can see, our automatically-extracted annotations cover 65% of WordNet synsets (77,195 out of 117,659), providing at least one annotated example for 56,022 synsets that are not covered by SemCor. The total number of distinct tagged sentences is more than 10M for a total of 13M annotations. On average, most synsets have around 150 annotated examples, as shown in Figure 1.

6 WSD Experimental Setup

We now report the setup of the evaluation we conducted on the English and multilingual WSD tasks.

Evaluation Datasets We carried out the evaluation on the English all-words WSD framework by Raganato et al. (2017),[6] comprising five standard test sets, namely, Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Snyder and Palmer, 2004), SemEval-07 (Pradhan et al., 2007), SemEval-13 (Navigli et al., 2013), SemEval-15 (Moro and Navigli, 2015) along with ALL, i.e., the concatenation of all the test sets. As concerns the multilingual evaluation, we considered the latest versions of the two multilingual all-words WSD datasets of

---

[6] `http://nlp.uniroma1.it/wsdeval/`

SemEval-13 (Navigli et al., 2013) and SemEval-15 (Moro and Navigli, 2015), containing test sets for French, German, Italian and Spanish.[7] We report all results in terms of the F1 score, i.e., the harmonic mean of the precision and recall.[8]

ARES Configuration We used Wikipedia as input corpus since it is the largest general-domain resource currently available. Regarding the context extraction step (see Section 4.1), we set the number of clusters k for a lexeme l as the number of its senses in WordNet. We varied the number of words n to give as input to UKB between 5 and 25 with a 5 step and selected the value $n = 5$ by manually assessing the quality of a sample of the clusters' disambiguation output. As for the number of sentences t and ξ, we ranged them between 50 and 300 with a 50 step[9] and selected the values that maximized the performance in terms of F1 of ARES on SemEval-07,[10] i.e., $t = 150$ and $\xi = 50$. As regards the window size w, we followed Maru et al. (2019) and set $w = 3$.

Concerning BERT representations, we used the BERT large-cased model for English. To scale across languages, instead, we made use of BERT base-multilingual-cased (mBERT) so as to build unified representations that are shared across languages, i.e., ARES_{m}. For our multilingual representations, we focused on synset embeddings rather than sense ones. In fact, senses are language-specific as they are tied to one of the lemmas of the synset. Hence, we built ARES_{m} synset embeddings by averaging the representations of their English senses. We note that, while the pre-trained model differs between the two representations, the sentences used to create the embeddings are the same as the ones used for English. Following Loureiro and Jorge (2019), we took as BERT representation the sum of the last four hidden layers.

WSD Setup To test ARES on the WSD task, we employed the 1-NN algorithm. To this end, we computed the BERT representation of each word w in the test sentences and compared it with the embeddings corresponding to the senses of w in WordNet. Since ARES vectors are made of the concatenation of two BERT representations (Section 4.3), we repeated the embedding of w in order to match the shape of ARES vectors. Thus, we took as prediction the sense that maximizes the similarity with w's representation. For languages other than English, we considered as candidate synsets for a lemma those associated with it in BabelNet 4.0, i.e., a multilingual knowledge base providing lexicalizations of concepts in different languages.

Comparison systems We compared ARES with both knowledge-based and supervised approaches on English. As knowledge-based systems, we considered UKB with SyntagNet's relations (Scozzafava et al., 2020, $\text{UKB}_{\text{+Syn}}$), and SensEmBERT (Scarlini et al., 2020), along with its supervised version, i.e., $\text{SensEmBERT}_{\text{sup}}$. SensEmBERT and $\text{SensEmBERT}_{\text{sup}}$ cover only nominal senses, so we used the Most Frequent Sense (MFS) backoff strategy, i.e., predicting the most frequent sense of a lemma in WordNet, for tagging instances with other POS tags.

Among supervised systems, we tested against $\text{EWISE}_{\text{ConvE}}$ (Kumar et al., 2019), KnowBERT (Peters et al., 2019), the vocabulary compression model by Vial et al. (2019, BERT_{hyp}),[11] GlossBERT (Huang et al., 2019) and the approach proposed by Hadiwinoto et al. (2019, $\text{BERT}_{\text{GLU+LW}}$). Moreover, we compared against Loureiro and Jorge (2019, LMMS) and Peters et al. (2018)'s method using BERT (BERT k-NN). We also report the performance of these two latter approaches by using mBERT instead of BERT large, i.e., $\text{LMMS}_{\text{mBERT}}$ and mBERT k-NN. All supervised systems under comparison use SemCor only as training corpus.

We performed additional comparisons by using Peters et al. (2018)'s method with BERT on SemCor+OMSTI (Taghipour and Ng, 2015, $\text{SemCor+OMSTI}_{\text{BERT}}$), a semi-automatically generated extension of SemCor, and OneSeC (Scarlini et al., 2019, $\text{OneSeC}_{\text{BERT}}$), an automatically-tagged corpus.[12]

On the multilingual WSD tasks we compared against SensEmBERT and UKB augmented with SyntagNet's relations (Scozzafava et al., 2020, $\text{UKB}_{\text{+Syn}}$). We also trained a baseline on English data only, i.e., SemCor, and we tested it in all the

---

[7] `https://github.com/SapienzaNLP/mwsd-datasets`

[8] We used the scoring script in the Raganato et al. (2017)'s framework to compute all performances.

[9] All hyperparameters search spaces were manually chosen.

[10] We chose SemEval-07 as it is the standard development set used in the literature (Raganato et al., 2017).

[11] We excluded from the comparison both the ensemble and the model trained on SemCor and the WordNet disambiguated glosses reported by Vial et al. (2019) as it would not allow a fair comparison with the other systems under evaluation.

[12] OneSeC covers only nominal senses, so we resorted to the MFS strategy for instances with other POS tags.

other languages. To this end, we used mBERT with frozen weights followed by a linear layer with *swish* activation and an unbiased softmax classifier on top.[13] In addition, we report the performance of LMMS$_{\text{mBERT}}$ and mBERT k-NN on the multilingual datasets.

7 WSD Results

We now report the results of the evaluation we carried out on the English and multilingual WSD tasks, along with an ablation study of ARES components.

7.1 English all-words WSD

In Table 4 we report the results attained by the systems under comparison on the all-words English WSD datasets. Our direct competitors, i.e., SensEmBERT$_{\text{sup}}$ and LMMS, score, respectively, 5.1 and 2.5 F1 points lower than ARES. This comparison shows the effectiveness of different approaches in coping with the paucity of sense-annotated data for WSD. On the one hand, the SensEmBERT approach is effective in modeling nominal meanings, however, it cannot scale over other POS tags due to the limitations of its underlying resources. On the other hand, LMMS shows that the WordNet topology can be exploited to propagate the latent representations of frequent meanings towards those not appearing in sense-annotated corpora. Nevertheless, these less frequent senses do not have a specific characterization and thus their representations are less refined, as we also show in Section 7.2. Our approach overcomes both these limitations, being able to create better-characterizing representations across senses with different POS tags. This leads ARES to outperform the state of the art at the time of writing, i.e., GlossBERT, by almost 1 point on ALL by simply employing a 1-NN algorithm, and hence requiring no expensive fine-tuning procedure.

7.2 WSD on Infrequent Words and Senses

To test the ability of ARES and its competitors to scale over rare words and senses, we extracted two new test sets from ALL: i) ALL$_{\text{LFS}}$, which includes the 1139 instances in ALL associated with a sense not in SemCor; ii) ALL$_{\text{LFW}}$, which includes the 222 instances in ALL associated with a non-monosemous word not tagged in SemCor. As shown in Table 5, ARES proves to be the best system across the board, achieving the highest result on both datasets. This shows that the contexts extracted by ARES help balance the quality of meanings' representations across senses with different frequencies, without disadvantaging rare senses in favor of the more frequent ones. In contrast, both LMMS and GlossBERT are more

biased towards those representations in SemCor, hence losing ground on both datasets with a gap of 3.6 and 3.2 points, respectively, on ALL_{LFS} when compared to ARES. This latter, instead, by taking advantage of its automatically-retrieved contexts, scales better over rare words and senses, and outperforms its competitors on both datasets with the highest result of 81.1 on ALL_{LFW}.

7.3 Ablation Study

We now measure the impact that each part of our vectors has on the final results by means of an ablation study on the ALL dataset. The upper side of Table 6 compares the two kinds of contexts that we automatically retrieve (Section 4.1). As one can see, the $\text{Cluster}_{\text{cont}}$ alone, i.e., the sentences retrieved by means of the similarity-based step, already attains good results. When combined with the contexts extracted thanks to SyntagNet, i.e., Syn_{cont}, it gains 0.6 extra points. In the lower part of the Table, we show different combinations of the vectors built from SemCor, our contexts and the WordNet glosses. We indicate with A_{CS} and Gloss the vectors built from our extracted contexts (see Equation 4.2) and the sense gloss (see Section 4.3), respectively. SemCor alone attains 69.2 points, 1.3 points less than $\text{Cluster}_{\text{cont}}$. This is because SemCor does not provide examples for all WordNet meanings, therefore having a lower recall. When combining SemCor with WordNet's glosses (SemCor $\|$ Gloss) and A_{CS} (SemCor $\|$ A_{CS}), we have a 6.5 and 7.9 improvement, respectively. Finally, when combining the three components, we obtain our best score of 77.9 F1 points on ALL.

7.4 Multilingual all-words WSD

Finally, we investigate the ability of ARES_{m} to scale across languages by testing it on the multilingual WSD datasets of SemEval-13 and SemEval-15.[14] As shown in Table 7, ARES_{m} is the best system across the board, achieving state-of-the-art results on all languages of both datasets but the Italian nominal instances of SemEval-15. On average, ARES scores almost 2.0 F1 points higher compared to the second best performing system, i.e., mBERT. When compared to $\text{LMMS}_{\text{mBERT}}$, ARES achieves 7.0 F1 points higher on average. This may be due to the fact that our automatically-retrieved sentences provide a better contextualization of meanings than the propagation technique employed by LMMS, hence allowing our embeddings to scale effectively across languages. Finally, we surpass SensEmBERT and attain state-of-the-art performance on all languages of the multilingual all-words WSD tasks while at the same time keeping the quality on nouns high.

The evaluation carried out shows how beneficial our embeddings are to the English and the multilingual WSD tasks. ARES, in fact, proves to carry high-quality semantic information within its representations, which enables it to generalize over both words and languages, and achieve state-of-the-art results in all the tested settings.

8 WiC Experimental Setup

In this Section we further inspect the properties of our embeddings by measuring the improvements they bring to the Word-in-Context (WiC) task.[15]

Evaluation Dataset We tested on the Word-in-Context task (Pilehvar and Camacho-Collados, 2019, WiC),[16] i.e., a binary classification problem where, given a target word w and two contexts c_1 and c_2, the task is to determine if w occurs with the

---

[14] We also report the results on only the nominal instances of SemEval-15 to be comparable with SensEmBERT.

Table 8: Results in terms of accuracy on the WiC test set and number of trainable parameters of each model.

same meaning in c_1 and c_2. We report the results in terms of accuracy, i.e., the number of correct answers over the total number of predictions.

WiC Model We integrated our embeddings as features in the English BERT large-cased model, i.e., BERT$_{\text{ARES}}$, during finetuning. Following Wang et al. (2019) we concatenated the two input sentences c_1 and c_2 with the [SEP] token and fed them to BERT with a logistic regression classifier on top. The last layer took as input the [CLS] embedding and the two representations of the target word w in c_1 and c_2. As additional features, we considered the senses s_1 and s_2 of w in c_1 and c_2, respectively, that we predicted by means of ARES as in Section 6. Then, we applied a dense layer – which we trained during finetuning – to the ARES embeddings of s_1 and s_2 and reduced their dimensionality to 1024. Finally, we concatenated the input of the classifier with these two new representations.[17]

Comparison Systems We compared ARES against the best performing models on the WiC task. We considered three pre-trained language models fine-tuned on WiC, i.e., BERT$_{\text{LARGE}}$ (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and T5 (Raffel et al., 2019), and two language models which leverage external knowledge while pre-training, i.e., KnowBert (Peters et al., 2019) and SenseBERT$_{\text{LARGE}}$ (Levine et al., 2020).

9 WiC Results

In Table 8 we report the results of the systems under comparison on the WiC test set. BERT$_{\text{ARES}}$ attains 2.6 points more than its base model, i.e., BERT$_{\text{LARGE}}$, while exploiting ARES embeddings in a straightforward manner at finetuning. Moreover, BERT$_{\text{ARES}}$ performs better than or on a par with its closest competitors, i.e., KnowBert, SenseBERT$_{\text{LARGE}}$ and T5 (Large, and 3B), which, instead, rely on more complex architectures, specific pre-training phases and between 3000 M and 40 M more parameters. T5-11B is the only model achieving better results than BERT$_{\text{ARES}}$, mainly due to the large difference in terms of trainable weights (with T5-11B being 30 times bigger.)

10 Conclusion

In this paper we presented ARES, a semi-supervised approach for producing embeddings of senses in English and across different languages. ARES can couple the information within sense-annotated corpora with that automatically created by means of a cluster-based algorithm so as to produce high-quality latent representations for the concepts within a lexical knowledge base. Our experiments showed that despite relying on English data only ARES outperforms all its alternatives. It achieves state-of-the-art results on both English and multilingual WSD benchmarks, leveraging BERT large and mBERT, respectively, as underlying pre-trained language models. We further tested our embeddings in the WiC task where they lead a baseline neural model to outperform its closest competitors that rely on larger architectures or dedicated pre-training routines. Our embeddings computed with BERT large and mBERT and the automatically-extracted contexts are available at `http://sensembert.org/ares`.

As future work, we plan to exploit the information brought by our embeddings to other downstream tasks, such as multilingual Semantic Role Labeling (Di Fabio et al., 2019; Conia et al., 2020) and cross-lingual Semantic Parsing (Blloshmi et al., 2020).

A Supplementary Materials

A.1 Computing Infrastructures

All the experiments were performed using a x86-64 architecture with 64 GBs of RAM and a GeForce GTX 1080 Ti.

A.2 mBERT Baseline Training Details

The model was trained with Adam (Kingma and Ba, 2015) optimizer on SemCor for 50 epochs, and tuned on the SemEval-07 dataset. The learning rate was set to $2 \cdot 10^{-5}$ and gradient clipping to 1.0. The training was stopped earlier in the case that the loss ceased decreasing for 3 consequent epochs on the development set. We encoded each word by taking the sum of its hidden representations of the last four layers of the BERT base-multilingual-cased pre-trained model.

A.3 WiC Finetuning Details

We trained our BERT-based model with the `jiant`'s library.[18] As for the hyperparameters, we used the ones reported by Devlin et al. (2019), which are the standard configuration in the `jiant`'s framework. We finetuned the BERT large-cased pretrained model for 4 epochs with batch size equal to 4, learning rate $1 \cdot 10^{-4}$ and Adam as optimizer (Kingma and Ba, 2015). The dropout probability was set to 0.1 on every layer. The average runtime of the model was 30 minutes, including the validation on the development set at the end of each epoch. The accuracy we achieved on the development set was 73.7.

The accuracy on the test set was computed by uploading the predictions of our model on the SuperGLUE website (Wang et al., 2019).[19]

Convolution over Hierarchical Syntactic and Lexical Graphs for Aspect Level Sentiment Analysis

Mi Zhang, Tieyun Qian*
School of Computer Science, Wuhan University, China
{mizhanggd, qty}@whu.edu.cn

Abstract

The state-of-the-art methods in aspect-level sentiment classification have leveraged the graph based models to incorporate the syntactic structure of a sentence. While being effective, these methods *ignore the corpus level word co-occurrence information*, which reflect the collocations in linguistics like "nothing special". Moreover, they *do not distinguish the different types of syntactic dependency*, e.g., a nominal subject relation "food-was" is treated equally as an adjectival complement relation "was-okay" in "food was okay".

To tackle the above two limitations, we propose a novel architecture which convolutes over hierarchical syntactic and lexical graphs. Specifically, we *employ a global lexical graph* to encode the corpus level word co-occurrence information. Moreover, we *build a concept hierarchy* on both the syntactic and lexical graphs for differentiating various types of dependency relations or lexical word pairs. Finally, we *design a bi-level interactive graph convolution network* to fully exploit these two graphs. Extensive experiments on five benchmark datasets show that our method achieves the state-of-the-art performance.

1 Introduction

Aspect-level sentiment classification (ASC) (Hu and Liu, 2004) aims to determine the sentiment polarity (i.e., positive, negative, neutral) of the aspect(s) in a sentence. Take the review "*great food but the service was dreadful*" as an example. Given two aspect terms "food" and "service", the goal is to infer the sentiment polarities for the aspect terms: positive for food and negative for service. ASC can provide fine-grained analysis of the users' opinion towards the specific aspect and is fundamental to many natural language processing tasks. Consequently, it has aroused much research attention in recent years.

Early studies on ASC (Mohammad et al., 2013; Jiang et al., 2011) mostly use machine learning algorithms to build sentiment classifier. Later, various neural network models (Dong et al., 2014; Vo and Zhang, 2015; Chen et al., 2017) are proposed for this task, including long short-term memory (LSTM) based (Wang et al., 2016), convolutional neural networks (CNN) based (Huang and Carley, 2018; Li et al., 2018), and memory based (Tang et al., 2016b) or hybrid methods (Xue and Li, 2018). These models represent the sentence as a word sequence and neglect the syntactic relations between words, and thus it is hard for them to find the opinion words which are far away from the aspect term. To solve this problem, several recent researches (Zhang et al., 2019; Huang and Carley, 2019; Sun et al., 2019) leverage the graph based models to incorporate the syntactic structure of a sentence, and have shown better performance than those without considering syntactic relations.

Despite of their effectiveness, the seminal syntax based methods ignore the corpus level word co-occurrence information. Moreover, they do not distinguish the different types of syntactic dependency. We argue that both will incur information loss. (1) The frequently co-occurred words represent the collocations in linguistics. For example, in the sentence "*food was okay, nothing special*", the word pair "nothing special" occurs five times in the SemEval training set, denoting a negative polarity. Without such global information to counteract the positive polarity of "okay", syntax based methods will make wrong prediction on "food". (2) Each type of syntactic dependency denotes a specific relation. For example, in "*i like hamburgers*", "i-like" is a nsubj relation, and "like-hamburgers" is a dobj relation. If the nsubj relation and dobjs relation are

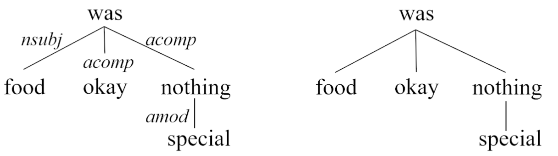
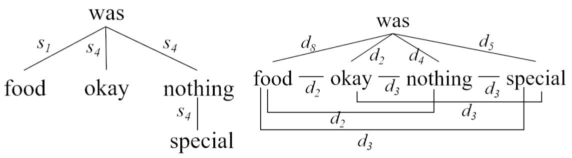
November 16–20, 2020. ©2020 Association for Computational Linguistics

treated equally, we are unable to differentiate the subject and the object of the action "like".

To tackle the above limitations, we propose a novel architecture which convolutes over hierarchical syntactic and lexical graphs. We first *employ a global lexical graph* to encode the corpus level word co-occurrence information, where nodes are words and the edge denotes the frequency between two word nodes in the training corpus. We then *build a concept hierarchy* on each of the syntactic and lexical graphs to distinguish different types of dependency relations or word co-occurrence relations. For example, the acomp relation "was-nothing" and the amod relation "nothing-special" are grouped into an adjective relation type, while the nsubj relation "food-was" will form another noun relation type. For illustration, we show in Figure 1 a sample sentence with its dependency tree and the corresponding lexical and syntactic graphs in our and other works (Zhang et al., 2019; Huang and Carley, 2019; Sun et al., 2019).



(a) dependency tree (b) syntactic graph by others



(c) our syntatic graph (d) our lexical graph

Figure 1: A sample of depedency tree and different graphs in our and other papers

It is clear from Fig.1 (b) that existing syntax integrated methods do not differentiate various types of dependency relations, as an edge simply represents that there is a relation between two nodes. In contrast, each edge in our syntactic graph (Fig.1 (c)) is attached with a label denoting the relation type. In addition, we construct a lexical graph (Fig.1 (d)) which also has a concept hierarchy to capture the various word co-occurrence relations. Finally, in order to let the syntactic and lexical graphs cooperate with each other, we design a bi-level interactive graph convolution network to fully exploit these two graphs.

We conduct extensive experiments on five SemEval datasets. Results demonstrate that our model achieves the state-of-the-art performance.

2 Related Work

Recent advances in aspect-level sentiment classification (ASC) focus on developing various types of deep learning models. We briefly review the neural models without considering syntax, and then go to the syntax based ones.

The neural models without considering syntax models can be mainly categorized into several types: LSTM based (Tang et al., 2016a; Wang et al., 2016; Ma et al., 2017), CNN based (Huang and Carley, 2018; Li et al., 2018), memory based (Tang et al., 2016b; Chen et al., 2017), and other hybrid methods (Weston et al., 2015; Xue and Li, 2018). For example, Zhang et al. (2016) use the gated neural network structures to model the interaction between the surrounding contexts and the target. Li et al. (2018) employ a CNN instead of attention to extract important features from the transformed word representations. Xue and Li (2018) combine the CNN and gating structure to extract aspect-specific information from contexts.

The syntactic information enables dependency information to be preserved in lengthy sentences, and helps shorten the distance between aspect and opinion words. There has long been research on incorporating syntactic information in document-level sentiment classification (Matsumoto et al., 2005; Ng et al., 2006; Nakagawa et al., 2010). Later, Dong et al. (2014); Nguyen and Shirai (2015); He et al. (2018); Salwa et al. (2018) also take the syntax structure of a sentence and or POS tags into account for aspect based sentiment analysis. Nevertheless, the effect of syntactical structure has not been fully exploited without the proper utilization of the dependencies along the syntactic paths.

More recently, several studies (Sun et al., 2019; Huang and Carley, 2019; Zhang et al., 2019) employ graph based models to integrate the syntactic structure. The basic idea is to transform the dependency tree into a graph, and then impose the graph convolutional networks (GCN) or graph attention networks (GAT) to propagate information from syntax neighbourhood opinion words to aspect words. There are also attempts (Tay et al., 2018; Yao et al., 2019) at exploiting the word co-occurrence information for sentiment analysis.

Unlike all the aforementioned methods, our model exploits both the syntactic and lexical graphs for capturing the dependency relations in a sentence and the word co-occurrence relations in the training corpus. Moreover, we construct the concept hierarchy for each graph, which can group relations with similar uses or meanings together and reduce noises. As we will show in our experiments, the introduction of hierarchy greatly boosts the performance.

3 Preliminary

Problem definition (ASC) Given a review sentence S = [w_1, ..., w_{a+1}, ..., w_{a+m}, ..., w_n] consisting of *n* words and a corresponding *m*-length aspect starting from the $(a+1)^{th}$ position, the aspect-level sentiment classification task ASC aims at identifying the sentiment polarity of the given aspect(s) in a sentence.

Hierarchical syntactic graph construction A syntactic graph (SG) has a node set V_s and an edge set E_s. Each node v in V_s is a word in the sentence and each edge e in E_s between two words denotes that they are syntactically related.

Existing syntax integrated methods for ASC (Sun et al., 2019; Huang and Carley, 2019; Zhang et al., 2019) do not utilize various types of dependency relations and an edge in their syntactic graph as shown in Fig.1 (b) simply denotes there exists a dependency relation between two words. As we pointed out in the introduction, each dependency relation represents a specific grammatical function that a word plays in a sentence and should be used in its own manner. However, since there are a good number of relations in the parsed tree, directly using one dependency relation as a type of edge in the graph may incur noises like a parsing error.

To solve this problem, we add a *syntactic concept hierarchy* R_s over the dependency relations. Specifically, we group 36 dependency relations into 5 relation types, including “noun”, “verb”, “adverb”, “adjective”, and “others”, denoted as s_1 .. s_5 in R_s, respectively.

In particular, since most aspect and opinion words are noun and adjective, respectively, they become two main types. Verb expresses an action, an event, or a state, and adverb modifies verbs and adjectives, thus they also become two types. All the remaining constitutes the “others“ type.

We then construct a *hierarchical syntactic graph* HSG based on the syntactic concept hierarchy. Specifically, HSG is denoted as $\{V_s, E_s, R_s\}$, where V_s, E_s, and R_s is a node set, an edge set, and a syntactic relation type set, respectively. Note that each edge in E_s is now attached with a label denoting the dependency relation type in R_s.

Hierarchical lexical graph construction *A global lexical graph* LG^T has a node set V^T and a edge set E^T. Each node v in V^T represents a word and each edge e in E^T denotes the co-occurrence frequency between two words in the training corpus whose vocabulary size is *N*.

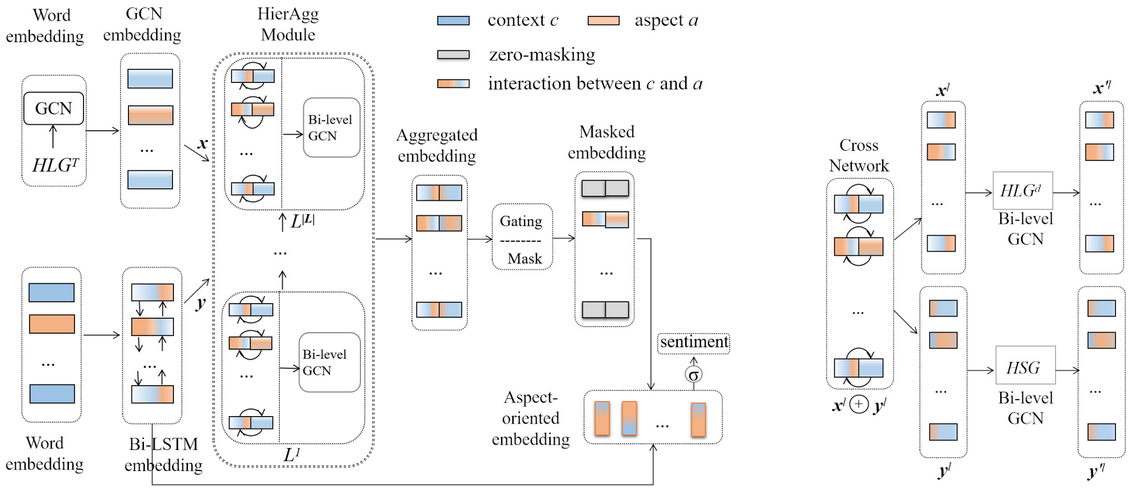
We then construct *a local lexical graph* LG^d for each sentence, where each node represents a word in the sentence and each edge denotes two words co-occur in the sentence. However, the edge is attached a same weight as that of the edge between two same words in LG^T. The rationale is to transfer the global word distribution information in LG^T into the local lexical graph LG^d.

The frequency of word co-occurrence in the corpus is highly skewed, where most word pairs occur one or two times, and a few of them have a large frequency. Clearly, the frequent word pairs should be treated differently from the rare ones. Hence we add a *lexical concept hierarchy* R_d over the word co-occurrence relations. To this end, we group the frequency of word pairs according to the log-normal distribution (Bhagat et al., 2018). Specifically, we use d_1 and d_2 to denote the word pair relation with the frequency of 2^0 and 2^1, and d_3, ..., d_7 to denote the word pair relation whose frequency falls in the interval of [2^k+1, 2^{k+1}] $(1 \leq k \leq 5)$. The last one d_8 denotes the lexical relation for all the word pairs whose frequency is larger than 2^6.

Finally we can construct a *hierarchical global lexical graph* HLG^T based on the lexical concept hierarchy, denoted as $\{V_d^T, E_d^T, R_d\}$, where V_d^T, E_d^T, and R_d is a node set, an edge set, and a lexical relation type set, respectively. Similarly, we have a *hierarchical local lexical graph* HLG^d = $\{V_d^d, E_d^d, R_d\}$, where V_d^d is identical to V_s.

4 Proposed Model

In this section, we present our proposed BiGCN model. We first show its architecture in Figure 2. As can be seen from Fig. 2 (a), BiGCN takes the global lexical graph and the word sequence as the input to get the initial sentence representation. It then introduces a HiarAgg module where the local lexical graph and syntactic graph interact with each other to refine the sentence representation. Finally, BiGCN obtains the aspect-oriented representation via the mask and gating mechanism for better predicting the sentiment polarity towards a specific



(a) Overall Framework

(b) The l^{th} layer in HierAgg module

Figure 2: Architecture of BiGCN model.

aspect in the sentence.

4.1 Getting Initial Sentence Representation

Let $\mathbf{E}_w \in \mathbb{R}^{|Vo| \times da}$ be the pre-trained word embedding, where $|Vo|$ is the vocabulary size and da is the dimension of word embedding. $\mathbf{E}_w$ is used to map the review sequence S with n words to word vectors $[\boldsymbol{e_1}, ..., \boldsymbol{e_{a+1}}, ..., \boldsymbol{e_{a+m}}, ..., \boldsymbol{e_n}] \in \mathbb{R}^{n \times da}$. We then propose two types of text representations for improving the sentence embedding. One is the GCN embedding based on our global lexical graph. The other is the Bi-LSTM embedding based on the bi-directional LSTM.

GCN Embedding Firstly, we wish to encode the corpus-specific lexical information into the review representation. For this target, we first build an embedding matrix $\mathbf{E}_{wt} \in \mathbb{R}^{N \times da}$ as the feature matrix for training corpus, where N is the vocabulary size for the training corpus. We then perform a standard GCN (Kipf and Welling, 2017) on the hierarchical global lexical graph HLG^T, and get a new embedding matrix $\mathbf{E}_{gcn} \in \mathbb{R}^{N \times dx}$. $\mathbf{E}_{gcn}$ is then used to form the GCN embedding of the review sequence S, i.e., $[\boldsymbol{x_1}, ..., \boldsymbol{x_{a+1}}, ..., \boldsymbol{x_{a+m}}, ..., \boldsymbol{x_n}] \in \mathbb{R}^{n \times dx}$ via a look-up table, denoted as $\boldsymbol{x}$ in Figure 2 (a).

Bi-LSTM Embedding Secondly, we encode the sequential information into the review representation following most of previous studies (Wang et al., 2016; Sun et al., 2019; Zhang et al., 2019). In addition, since the token closer to aspect may contribute more in judging the sentiment of the aspect (Gu et al., 2018), we calculate the absolute distance from each context word w_t to the corresponding aspect, and get a position sequence for S. Let $\mathbf{E}_p \in \mathbb{R}^{n \times dp}$ be the position embedding lookup table with random initialization, the position lookup layer maps the position sequence to a list of position embedding $[\boldsymbol{p_1}, ..., \boldsymbol{p_{a+1}}, ..., \boldsymbol{p_{a+m}}, ..., \boldsymbol{p_n}]$.

For each word w_t in S, its embedding is calculated as $\boldsymbol{e_t^p} = \boldsymbol{e_t} \oplus \boldsymbol{p_t} \in \mathbb{R}^{da+dp}$, where $\oplus$ denotes concatenation, $\boldsymbol{e_t}$ and $\boldsymbol{p_t}$ is pre-trained word embedding and the position embedding of the t^{th} word in S. The sentence S with the above representation is sent to a Bi-LSTM layer (Wang et al., 2016; Zhang et al., 2019). We omit the detail due to the space limitation. S is then transformed into a Bi-LSTM embedding $[\boldsymbol{y_1}, ..., \boldsymbol{y_{a+1}}, ..., \boldsymbol{y_{a+m}}, ..., \boldsymbol{y_n}] \in \mathbb{R}^{n \times dy}$, denoted as $\boldsymbol{y}$ in Figure 2 (a).

4.2 Refining Sentence Representation

With the the GCN embedding $\boldsymbol{x}$ and the Bi-LSTM embedding $\boldsymbol{y}$ as the initial sentence representation, we further leverage the local lexical graph and syntactic graph to get better representation for the sentence S. The basic idea is to let these two graphs interact with each other in a carefully designed HierAgg module. Briefly, HierAgg is a multi-layer structure, where each layer includes a cross network to fuse GCN and Bi-LSTM embedding and a Bi-level GCN to convolute on hierarchical syntactic and lexical graphs. The multi-layer structure ensures the collaboration of different types of information to be performed at different levels. This section gives the detail for one layer in HierAgg, as shown in Fig. 2 (b).

Cross Network To deeply fuse the GCN embedding $\boldsymbol{x}$ and Bi-LSTM embedding $\boldsymbol{y}$, we adopt the cross network structure (Wang et al., 2017), which is simple yet effective. In particular, we first concatenate $\boldsymbol{x}$ and $\boldsymbol{y}$ to form a fixed combination $\boldsymbol{f^0} \in \mathbb{R}^{dh}$, i.e., $\boldsymbol{f^0} = \boldsymbol{x} \oplus \boldsymbol{y}$. Then in each layer of the cross network, we use the following formula to update the fused embedding.

$$\boldsymbol{f^l} = \boldsymbol{f^0} \boldsymbol{f^{l-1}}^\top \boldsymbol{w^l} + \boldsymbol{b^l} + \boldsymbol{f^{l-1}}, \tag{1}$$

where l denotes the layer number (l=1,2,...,$|L|$), and $\boldsymbol{w^l}, \boldsymbol{b^l} \in \mathbb{R}^{dh}$ are the weight and bias parameters. The fused embedding $\boldsymbol{f^l}$ in the l^{th} layer is then detached into $\boldsymbol{x}^l$ and $\boldsymbol{y}^l$ from the original concatenation position, which will serve as the input node representation for two graphs in Bi-level GCN.

Bi-level GCN Since our syntactic and lexical graphs contain a concept hierarchy, a vanilla GCN cannot convolute over the graph with a labelled edge. To address this problem, we propose a bi-level GCN for aggregating different relation types. Given a sentence with its two graphs, we will perform a bi-level convolution using two aggregating operations.

The first aggregation (low-level): it aggregates the nodes with the same relation type to a virtual node, and then uses the same normalized hidden feature sum in the vanilla GCN (Kipf and Welling, 2017) as the aggregation function to obtain the embedding for the virtual node. Hence each relation type r has a representation $\tilde{\boldsymbol{h}}_{\boldsymbol{t}}^{\boldsymbol{l,r}}$, where l is the layer number and t is the target node for aggregation. For example, in Fig. 1 (c), "okay" and "nothing" have the same label and thus are aggregated into a virtual node "s_4" for the target node "was". Similarly, "food" itself is aggregated into a virtual node "s_1" for "was".

The second aggregation (high-level): it aggregates all virtual nodes together with their specific relation. The representation of the target word t is updated using the mean aggregation function over different relation types (virtual nodes):

$$\boldsymbol{h_t^l} = ReLU(\mathbf{W}_l \cdot (\oplus_r \tilde{\boldsymbol{h}}_{\boldsymbol{t}}^{\boldsymbol{l,r}})), \tag{2}$$

where $\oplus_r$ denotes the concatenation of the representations of different relation types, and $\mathbf{W}_l$ is the weight matrix in the l^{th}-layer.

We then get the refined sentence representation $\boldsymbol{x}'^l = [\boldsymbol{h_1^{l,d}}, ..., \boldsymbol{h_{a+1}^{l,d}},...,\boldsymbol{h_{a+m}^{l,d}},...,\boldsymbol{h_n^{l,d}}]$ and $\boldsymbol{y}'^l = [\boldsymbol{h_1^{l,s}},...,\boldsymbol{h_{a+1}^{l,s}},...,\boldsymbol{h_{a+m}^{l,s}},...,\boldsymbol{h_n^{l,s}}]$ after the first and second aggregations on lexical and syntactic graph, respectively, which will be used as the input of the next layer. Note that in the last layer in Hier-Agg module, we combine $\boldsymbol{x}'^L$ and $\boldsymbol{y}'^L$ to form an aggregated embedding $\boldsymbol{h^L} = \boldsymbol{x}'^L \oplus \boldsymbol{y}'^L$.

4.3 Generating Aspect-oriented Representation

For better predicting the sentiment polarity of an aspect, we propose to use a gating mechanism (Dauphin et al., 2017) to control the flow of sentiment information towards the given aspect:

$$\alpha_t = tanh(\boldsymbol{h^L} + \boldsymbol{h_a^l} \boldsymbol{W}_{g\alpha} + \boldsymbol{b}_{g\alpha}), \boldsymbol{h}'^L = \boldsymbol{h^L} * \alpha_t, \tag{3}$$

where $\boldsymbol{h_a^l}$ is the aspect in $\boldsymbol{h^L}$, $\boldsymbol{W}_{g\alpha}$, $\boldsymbol{b}_{g\alpha}$ are weights and bias, respectively, and $*$ is the element-wise product. We then mask non-aspect words and keep aspect words unchanged in the gated embedding $\boldsymbol{h}'^L$, and we get a zero-masked embedding $[0,...,\boldsymbol{h_{a+1}^{l'}},...,\boldsymbol{h_{a+m}^{l'}},...,0] \in \mathbb{R}^{dh}$.

Finally, we retrieve the important features that are semantically related to aspect words, and set the retrieval-based attention weights (Zhang et al., 2019) for each context word. The final representation $\boldsymbol{z}$ for the sentence is formulated as:

$$\theta_t = \sum_{i=1}^{n} \boldsymbol{y_t}^\top \boldsymbol{h_i^{l''}}, \quad \gamma_t = \frac{exp(\theta_t)}{\sum_{i=1}^{n} exp(\theta_i)}, \tag{4}$$

$$\boldsymbol{z} = \sum_{t=1}^{n} \gamma_t \boldsymbol{y_t}, \tag{5}$$

where $\boldsymbol{y_t} \in \mathbb{R}^{dy}$ is the Bi-LSTM embedding, $\boldsymbol{h_i^{l''}}$ is transformed from the zero-masked embedding $\boldsymbol{h_i^{l'}}$ via a fully connected layer to keep the same dimensionality as that of $\boldsymbol{y_t}$.

4.4 Model Training

After obtaining the aspect-oriented representation $\boldsymbol{z}$, we feed it into a fully connected layer and a softmax layer to project it into the prediction space:

$$\boldsymbol{u} = softmax(\boldsymbol{W_u z} + \boldsymbol{b_u}), \tag{6}$$

where $\boldsymbol{u}$ is a probability distribution of the prediction, $\boldsymbol{W_u}$ and $\boldsymbol{b_u}$ are the weight matrix and bias, respectively. Then the label of the highest probability is set as the final prediction $\hat{u}$.

The model is trained with the standard gradient descent algorithm by minimizing the cross-entropy loss on all training samples:

$$\zeta = -\sum_{i}^{J} u_i log \hat{u}_i + \lambda \|\Theta\|, \tag{7}$$

where J is the number of training samples, u_i and $\hat{u}_i$ is the ground truth and predicted label for the i^{th} sample, Θ represents all trainable parameters, and λ is the co-efficient of L2-regularization.

5 Experiments

5.1 Datasets and Settings

Datasets We evaluated our proposed model on five benchmark datasets. One is the Twitter dataset constructed by Dong et al. (2014). It consists of twitter posts. The other four datasets (Lap14, Rest14, Rest15, Rest16) are all from SemEval (Pontiki et al., 2014, 2015, 2016) tasks, which contain reviews on laptop and restaurant. Following previous studies (Tang et al., 2016b; Zhang et al., 2019), we remove the samples with conflicting polarities and those without explicit aspects in the sentences. The statistics for five datasets are shown in Table 1.

Table 1: Dataset statistics

Dataset		#Pos.	#Neu.	#Neg.
Twitter	Train	1561	3127	1560
	Test	173	346	173
Lap14	Train	994	464	870
	Test	341	169	128
Rest14	Train	2164	637	807
	Test	728	196	196
Rest15	Train	912	36	256
	Test	326	34	182
Rest16	Train	1240	69	439
	Test	469	30	117

Settings We initialize word embeddings using the 300-dimension GloVe vectors provided by Pennington et al. (2014). This is a standard setting commonly used in Huang and Carley (2019); Zhang et al. (2019); Sun et al. (2019). Moreover, since we use the position information, we use the same dimensionality 30 as that in Sun et al. (2019) for the position embedding for a fair comparison. We use spaCy toolkit to get dependency relations.

We use Adam as the optimizer with a learning rate of 0.001. The coefficient λ of L2-regularization is 10^5 and batch size is 32. Moreover, the layer number in our BiGCN module is set to 2, and we will examine its impacts later. The experimental results are obtained by averaging three runs with random initialization, where Accuracy and Macro-F1 are used as the evaluation metrics[1].

Baselines We compare our model with the following eight baselines.

(1) ATAE-LSTM (Wang et al., 2016) is a classic LSTM based model which explores the connection between an aspect and the content of a sentence with an attention-based LSTM.

(2) GCAE (Xue and Li, 2018) is a CNN based model which has two convolutional layers and their outputs are combined by the gating units.

(3) MemNet (Tang et al., 2016b) is a memory based method combining a neural attention model with an external memory to calculate the importance of each context word towards an aspect.

(4) RAM (Chen et al., 2017) uses multi-hops of attention layers and combines the outputs with a RNN for sentence representation.

(5) AF-LSTM (Tay et al., 2018) is an aspect fusion LSTM model learning the associative relationships between sentence words and the aspect.

(6) TD-GAT (Huang and Carley, 2019) proposes a graph attention network to explicitly utilize the dependency relationship among words.

(7) ASGCN (Zhang et al., 2019) employs a GCN over the dependency tree to exploit syntactical information and word dependencies.

(8) CDT (Sun et al., 2019) uses a GCN to model the structure of a sentence through its dependency tree. It also utilizes position information.

Among the baselines, the first four methods are classic models with typical neural structures like attention, LSTM, CNN, memory, and RNN. The middle one (AF-LSTM) exploits the word co-occurrence information. The bottom three methods are graph based and syntax integrated ones. We do not take TextGCN (Yao et al., 2019) as a baseline since it is developed for text or document level sentiment classification.

We re-produce the results for baselines if the authors provide the source code. For three methods (TD-GAT, AF-LSTM, and GCAE) with no released code, we implement them by ourselves using the optimal hyper-parameters settings reported in their papers. Since we do not use validation sets, the results for TD-GAT are higher than those in Huang and Carley (2019). The results for CDT (Sun et al., 2019) are lower than those in the original paper. CDT reports the best results among a certain number (100) of rounds. In our experiments, since we report the results over three runs with the random initialization, we stop training when the F1 score does not increase for a certain number (5) of rounds at one run. This stopping criterion is used for all methods for a fair comparison.

5.2 Results and Analysis

The comparison results for all methods are shown in Table 2. From these results, we make the follow-

TD-GAT	72.20	70.45	**75.63**	70.74	81.32	71.72	80.38	60.50	87.71	67.87
ASGCN	72.15	70.40	75.55	71.05	80.77	72.02	79.89	61.89	**88.99**	67.48
CDT	73.29	72.02	**75.63**	**72.01**	**83.10**	73.01	79.42	61.68	86.24	67.62
BiGCN	**74.16**	**73.35**	74.59	71.84	81.97	**73.48**	**81.16**	**64.79**	88.96	**70.84**

ing observations.

(1) Our proposed BiGCN model achieves the best results in terms of macro-F1 scores on all datasets. In particular, it gets an improvements of 3.12, 2.77, and 1.36 F1 score over the second best one on Rest16, Rest15, and Twitter dataset, respectively. Its accuracy scores are also among the best ones, and are only slightly worse than the baselines on Lap14 and Rest14, where the difference is tiny, i.e., 0.15 and 0.06.

(2) The graph based and syntax integrated methods (TD-GAT, ASGCN, and CDT) are much better than the upper five methods without considering syntax, showing that the dependency relations are beneficial to identify the sentiment polarity. This is consistent with the previous studies (Huang and Carley, 2019; Zhang et al., 2019; Sun et al., 2019). However, they are worse than our proposed BiGCN model. This proves that the lexical graph in our BiGCN also helps improve the performance.

(3) The AF-LSTM method exploits the word co-occurrences between the aspect and contexts by calculating their circular correlation or circular convolution and then inputting them into an attention layer. However, its performance does not always show improvements over other classic methods. This infers that a direct integration of word association information via an attention layer is insufficient to exploit the lexical relations.

5.3 Ablation Study

To examine the influence of each component in our BiGCN model, we conduct an ablation study and show the results in Table 3.

We first investigate the impacts of hierarchical lexical (M1) and syntactic graph (M2). Compared with the complete BiGCN, the performance of M1 and M2 both decrease, showing that one single graph is not as good as two interactive graphs. We also find that M1 and M2 have competitive results, indicating that they have their own contributions from the point view of lexicon and syntax.

We then show the effects of concept hierarchy by further removing the relation types from M1 and M2, resulting a basic lexical (M3) and syntactic graph (M4). We can see that the results on these basic graphs without the concept hierarchy are both worse than their counterparts (M1-M3, M2-M4). This clearly reveals the positive influence of our proposed concept hierarchy.

5.4 Case Study

To better understand how our BiGCN works, we present the case study on three testing examples. We visualize the attention scores, the predicted and the ground truth labels for these example. Due to the space limitation, we only present the results for RAM, AF-LSTM, TD-GAT, ASGCN, CDT, and BiGCN in Figure 3, where RAM is the top-performed classic neural model. AF-LSTM leverages the word co-occurrence information. TD-GAT, ASGCN, and CDT are three graph based models considering syntax information.

RAM is unable to make correct decision for all three examples due to the lack of syntax information. For the same reason, AF-LSTM also makes wrong prediction in the first sentence either. As can be seen from Fig. 3 (a), RAM and AF-LSTM emphasize "friendly". Our model and three syntax integrated methods TD-GAT, ASGCN, and CDT can identify the dummy word "*should*" in the first sentence, and thus correctly predict the negative polarity for the aspect "*staff*".

In the second sentence, Although AF-LSTM calculates the relations between the aspect and its context, the short distance between "*food*" and "*okay*" causes LSTM to assign the largest attention score to "*okay*". On the other hand, since "*okay*" and "*food*" are closely connected in the dependency tree, the strong positive polarity of "*okay*" prejudices the de-

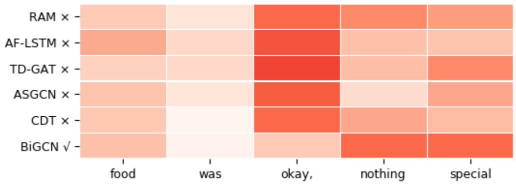
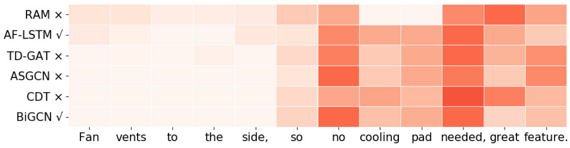
(a) aspect: *staff*, label: *negative*



(b) aspect: *food*, label: *neutral*



(c) aspect: *cooling pad*, label: *neutral*

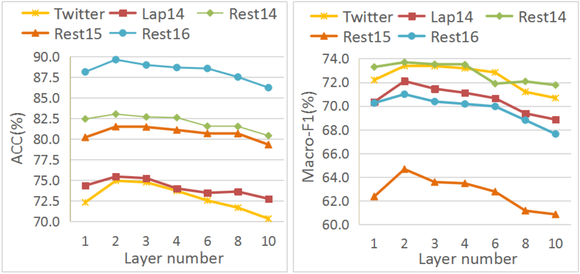
Figure 3: Visualization results for RAM, AF-LSTM, TD-GAT, ASGCN, CDT, and BiGCN, where a ✓ and × denotes the correct and wrong prediction, respectively.

cision of TD-GAT, ASGCN, and CDT. In contrast, with the help of global lexical information, our BiGCN model focuses on "*nothing special*" and correctly predict the neutral polarity for "*food*".

In the third sentence, the output from the parser connects "*no*" and "*cooling pad*" together. However, it also connects "*great*" with "*pad*", and "*needed*" with "*feature*", which results in the wrong prediction of TD-GAT, ASGCN and CDT. We notice that AF-LSTM can predict the polarity correctly. This is because AF-LSTM exploits the word association between "*no*" and "*needed*" which co-occur eight times in the training corpus. Similarly, with the help of such lexical information, our BiGCN model also highlights on "*no*" and "*needed*", and assigns the neutral polarity to "*cooling pad*". Note that this sentence has two aspects: fan and cooling pad. Since almost all models can make correct prediction for fan, we only present detailed analysis for cooling pad.

5.5 Impacts of Layer Number

One of the key contributions of our model is that the syntactic graph and lexical graph can interact on each other. The layer number in the HierAgg module denotes the number of interactions between two graphs. In this section, we examine the impacts of layer number l by varying it in [1, 2, 3, 4, 6, 8, 10]. The results are shown in Figure 4.



(a) (b)

Figure 4: Impacts of the layer number l.

It can be seen that our model achieves the best results with 2 or 3 layers. If only using 1 layer, the interaction between two graphs is not sufficient to produce good results. However, the performance does not always get improved with the increasing number of layers. This is because a large l value makes it hard to train the model. Moreover, a larger l introduces more parameters and results in a less generalizable model.

5.6 Analysis on Computational Cost

In this section, we compare the averaged training time over three runs of our BiGCN model with that of three typical baselines which are all graph based. The results are shown in Table 4.

It can be seen that the time cost of our model

Table 4: Running time of four methods.

Model	Twitter	Lap14	Rest14	Rest15	Rest16
ASGCN	600.43	52.34	110.04	40.67	59.42
CDT	584.93	49.96	100.43	37.56	62.14
TD-GAT	621.94	62.11	122.36	47.39	66.74
BiGCN	642.28	68.75	120.44	46.25	79.60

does not change much though we use two types of graphs. For example, on Rest14 and Rest15, the computational cost of our proposed BiGCN is less than that of TD-GAT. Even on the largest Twitter dataset, the ratio of increased time cost of our BiGCN to the most efficient CDT method is less than 10%.

6 Conclusions

In this paper, we propose a novel framework BiGCN to leverage the graph based methods for aspect level sentiment classification tasks. Besides the ordinary syntactic graph, we employ a lexical graph to capture the global word co-occurrence information in the training corpus. Furthermore, we build a concept hierarchy on each of the lexical and syntactic graphs, such that the functionally different types of relations in the graph can be treated separately. Finally, we design a HierAgg module to let the lexical and syntactic graphs work in a cooperative way. We conduct a set of experiments on five real world datasets. The results prove that our model achieves the state-of-the-art performance.

Abstract

Aspect-category sentiment analysis (ACSA) aims to predict sentiment polarities of sentences with respect to given aspect categories. To detect the sentiment toward a particular aspect category in a sentence, most previous methods first generate an aspect category-specific sentence representation for the aspect category, then predict the sentiment polarity based on the representation. These methods ignore the fact that the sentiment of an aspect category mentioned in a sentence is an aggregation of the sentiments of the words indicating the aspect category in the sentence, which leads to suboptimal performance. In this paper, we propose a Multi-Instance Multi-Label Learning Network for Aspect-Category sentiment analysis (AC-MIMLLN), which treats sentences as bags, words as instances, and the words indicating an aspect category as the key instances of the aspect category. Given a sentence and the aspect categories mentioned in the sentence, AC-MIMLLN first predicts the sentiments of the instances, then finds the key instances for the aspect categories, finally obtains the sentiments of the sentence toward the aspect categories by aggregating the key instance sentiments. Experimental results on three public datasets demonstrate the effectiveness of AC-MIMLLN [1].

1 Introduction

Sentiment analysis (Pang and Lee, 2008; Liu, 2012) has attracted increasing attention recently. Aspect-based sentiment analysis (ABSA) (Pontiki et al., 2014, 2015, 2016) is a fine-grained sentiment analysis task and includes many subtasks, two of which are aspect category detection (ACD) that detects the aspect categories mentioned in a sentence and aspect-category sentiment analysis (ACSA) that predicts the sentiment polarities with respect to the detected aspect categories. Figure 1 shows an example. ACD detects the two aspect categories, *ambience* and *food*, and ACSA predicts the negative and positive sentiment toward them respectively. In this work, we focus on ACSA, while ACD as an auxiliary task is used to find the words indicating the aspect categories in sentences for ACSA.

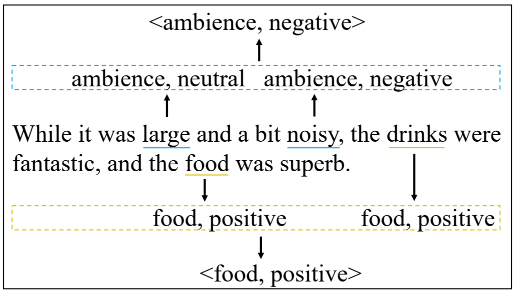

Figure 1: An example of ACD and ACSA. The underlined words are key instances, the labels of the key instances are in the dotted line boxes, and the labels of the sentence are in the angle brackets.

Since a sentence usually contains one or more aspect categories, previous studies have developed various methods for generating aspect category-specific sentence representations to detect the sentiment toward a particular aspect category in a sentence. To name a few, attention-based models (Wang et al., 2016; Cheng et al., 2017; Tay et al., 2018; Hu et al., 2019) allocate the appropriate sentiment words for the given aspect category. Xue and Li (2018) proposed to generate aspect category-specific representations based on convolutional neural networks and gating mechanisms. Since aspect-related information may already be discarded and aspect-irrelevant information may be retained in an aspect independent encoder, some existing methods (Xing et al., 2019; Liang et al., 2019) utilized the given aspect to guide the sentence encoding from

scratch. Recently, BERT based models (Sun et al., 2019; Jiang et al., 2019) have obtained promising performance on the ACSA task. However, these models ignored that the sentiment of an aspect category mentioned in a sentence is an aggregation of the sentiments of the words indicating the aspect category. It leads to suboptimal performance of these models. For the example in Figure 1, both "drinks" and "food" indicate the aspect category *food*. The sentiment about *food* is a combination of the sentiments of "drinks" and "food". Note that, words indicating aspect categories not only contain aspect terms explicitly indicating an aspect category but also contain other words implicitly indicating an aspect category (Cheng et al., 2017). In Figure 1, while "drinks" and "food" are aspect terms explicitly indicating the aspect category *food*, "large" and "noisy" are not aspect terms implicitly indicating the aspect category *ambience*.

In this paper, we propose a Multi-Instance Multi-label Learning Network for Aspect-Category sentiment analysis (AC-MIMLLN). AC-MIMLLN explicitly models the fact that the sentiment of an aspect category mentioned in a sentence is an aggregation of the sentiments of the words indicating the aspect category. Specifically, AC-MIMLLN treats sentences as bags, words as instances, and the words indicating an aspect category as the key instances (Liu et al., 2012) of the aspect category. Given a bag and the aspect categories mentioned in the bag, AC-MIMLLN first predicts the instance sentiments, then finds the key instances for the aspect categories, finally aggregates the sentiments of the key instances to get the bag-level sentiments of the aspect categories.

Our main contributions can be summarized as follows:

- We propose a Multi-Instance Multi-Label Learning Network for Aspect-Category sentiment analysis (AC-MIMLLN). AC-MIMLLN explicitly model the process that the sentiment of an aspect category mentioned in a sentence is obtained by aggregating the sentiments of the words indicating the aspect category.
- To the best of our knowledge, it is the first time to explore multi-instance multi-label learning in aspect-category sentiment analysis.
- Experimental results on three public datasets demonstrate the effectiveness of AC-MIMLLN.

2 Related Work

Aspect-Category Sentiment Analysis predicts the sentiment polarities with regard to the given aspect categories. Many methods have been developed for this task. Wang et al. (2016) proposed an attention-based LSTM network, which can concentrate on different parts of a sentence when different aspect categories are taken as input. Some new attention-based methods (Cheng et al., 2017; Tay et al., 2018; Hu et al., 2019) allocated more appropriate sentiment words for aspect categories and obtained bertter performance. Ruder et al. (2016) modeled the interdependencies of sentences in a text with a hierarchical bidirectional LSTM. Xue and Li (2018) extracted sentiment features with convolutional neural networks and selectively outputted aspect category related features with gating mechanisms. Xing et al. (2019), Liang et al. (2019) and Zhu et al. (2019) incorporated aspect category information into sentence encoders in the context modeling stage. Lei et al. (2019) proposed a human-like semantic cognition network to simulate the human beings' reading cognitive process. Sun et al. (2019) constructed an auxiliary sentence from the aspect category and converted ACSA to a sentence-pair classification task. Jiang et al. (2019) put forward new capsule networks to model the complicated relationship between aspect categories and contexts. The capsule networks achieved state-of-the-art results. Several joint models (Li et al., 2017; Schmitt et al., 2018; Wang et al., 2019; Li et al., 2019) were proposed to avoid error propagation, which performed ACD and ACSA jointly.

However, all these models mentioned above ignored that the sentiment of an aspect category discussed in a sentence is an aggregation of the sentiments of the words indicating the aspect category.

Multi-Instance Multi-Label Learning (MIMLL) (Zhou and Zhang, 2006) deals with problems where a training example is described by multiple instances and associated with multiple class labels. MIMLL has achieved success in various applications due to its advantages on learning with complicated objects, such as image classification (Zhou and Zhang, 2006; Chen et al., 2013), text categorization (Zhang and Zhou, 2008), relation extraction (Surdeanu et al., 2012; Jiang et al., 2016), etc. In ACSA, a sentence contains multiple words (instances) and expresses sentiments to multiple aspect categories (labels), so MIMLL is suitable for ACSA. However, as far as our knowledge, MIMLL has not been explored in ACSA.

Multiple instance learning (MIL) (Keeler and Rumelhart, 1992) is a special case of MIMLL, where a real-world object described by a number of instances is associated with only one class label. Some studies (Kotzias et al., 2015; Angelidis and Lapata, 2018; Pappas and Popescu-Belis, 2014) have applied MIL to sentiment analysis. Angelidis and Lapata (2018) proposed a Multiple Instance Learning Network (MILNET), where the overarching polarity of a text is an aggregation of sentence or elementary discourse unit polarities, weighted by their importance. An attention-based polarity scoring method is used to obtain the importance of segments. Similar to MILNET, our model also uses an attention mechanism to obtain the importance of instances. However, the attention in our model is learned from the ACD task, while the attention in MILNET is learned from the sentiment classification task. Pappas and Popescu-Belis (2014) applied MIL to another subtask of ABSA. They proposed a multiple instance regression (MIR) model to assign sentiment scores to specific aspects of products. However, i) their task is different from ours, and ii) their model is not a neural network.

3 Model

In this section, we describe how to apply the multi-instance multi-label learning framework to the aspect-category sentiment analysis task. We first introduce the problem formulation, then describe our proposed Multi-Instance Multi-Label Learning Network for Aspect-Category sentiment analysis (AC-MIMLLN).

3.1 Problem Formulation

In the ACSA task, there are N predefined aspect categories $A = \{a_1, a_2, ..., a_N\}$ and a predefined set of sentiment polarities $P = \{Neg, Neu, Pos\}$ (i.e., Negative, Neutral and Positive respectively). Given a sentence, $S = \{w_1, w_2, ..., w_n\}$ and the K aspect categories, $A^S = \{A_1^S, A_2^S, ..., A_K^S\}$, $A^S \subset A$, mentioned in S, the ACSA task predicts the sentiment polarity distributions of the K aspect categories, $p = \{p_1, p_2, ..., p_K\}$, where $p_k = \{p_{k_{Neg}}, p_{k_{Neu}}, p_{k_{Pos}}\}$. The multi-instance multi-label learning assumes that, for the k-th aspect category, p_k is an unknown function of the unobserved word-level sentiment distributions. AC-MIMLLN first produces a sentiment distribution p^j for each word and then combines these into a sentence-level prediction:

$$p^j = \hat{f}_{\theta_w}(w_j) \tag{1}$$

$$p_k = \hat{g}_{\theta_S}^k(p^1, p^2, ..., p^n) \tag{2}$$

3.2 Multi-Instance Multi-Label Learning Network for ACSA

In this section, we introduce our proposed Multi-Instance Multi-Label Learning Network for Aspect-Category sentiment analysis (AC-MIMLLN), which is based on the intuitive assumption that the sentiment of an aspect category mentioned in a sentence is an aggregation of the sentiments of the words indicating the aspect category. In MIMLL, the words indicating an aspect category are called the key instances of the aspect category. Specifically, AC-MIMLLN contains two parts, an attention-based aspect category detection (ACD) classifier and an aspect-category sentiment analysis (ACSA) classifier. Given a sentence, the ACD classifier as an auxiliary task generates the weights of the words for every aspect category. The weights indicate the probabilities of the words being the key instances of aspect categories . The ACSA classifier first predicts the sentiments of the words, then obtains the sentence-level sentiment for each aspect category by combining the corresponding weights and the sentiments of the words. The overall model architecture is illustrated in Figure 2. While the ACD part contains four modules: embedding layer, LSTM layer, attention layer and aspect category prediction layer, the ACSA part also consists of four components: embedding layer, multi-layer Bi-LSTM, word sentiment prediction layer and aspect category sentiment prediction layer. In the ACD task, all aspect categories share the embedding layer and the LSTM layer, and have different attention layers and aspect category prediction layers. In the ACSA task, all aspect categories share the embedding layer, the multi-layer Bi-LSTM, and the word sentiment prediction layer, and have different aspect category sentiment prediction layers.

Input: The input of our model is a sentence consisting of n words $S = \{w_1, w_2, ..., w_n\}$.

Embedding Layer for ACD: The input of this layer is the sentence. With an embedding matrix W_w, the sentence is converted to a sequence of vectors $X^D = \{x_1^D, x_2^D, ..., x_n^D\}$, where,$W_w \in R^{d \times |V|}$, d is the dimension of the word embeddings, and $|V|$ is the vocabulary size.

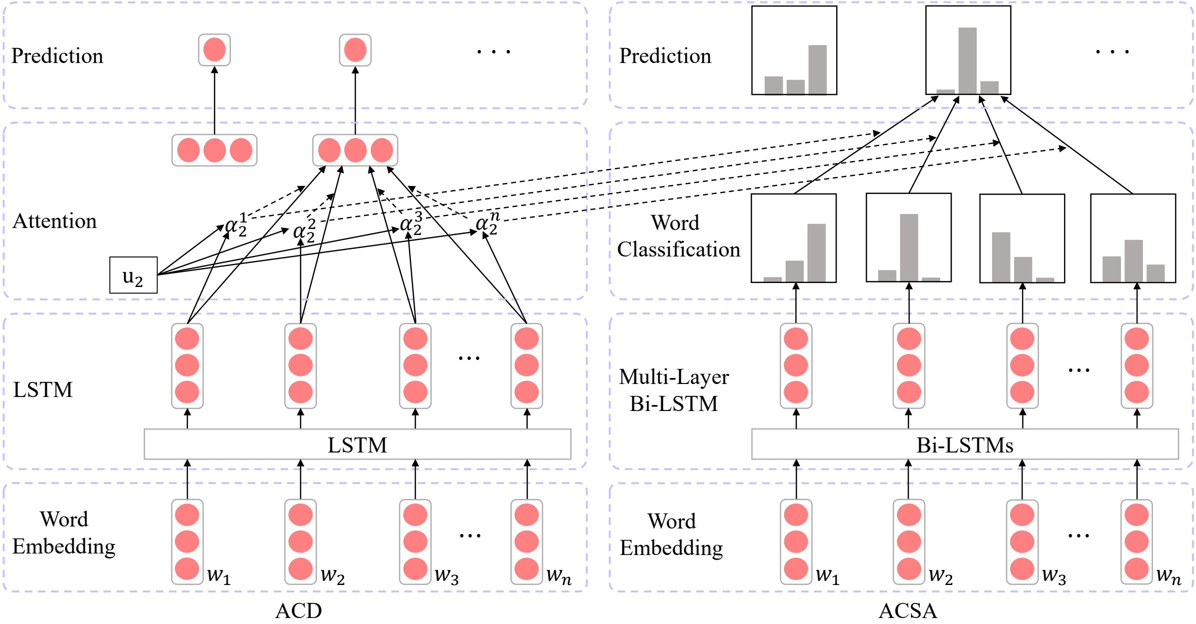

Figure 2: Overall architecture of the proposed method.

LSTM Layer: When LSTM (Hochreiter and Schmidhuber, 1997) is effective enough, attention mechanisms may not offer effective weight vectors (Wiegreffe and Pinter, 2019). In order to guarantee the effectiveness of the weights offered by attention mechanisms, we use a single-layer single-direction LSTM for ACD. This LSTM layer takes the word embeddings of the ACD task as input, and outputs hidden states $H = \{h_1, h_2, ..., h_n\}$. At each time step i, the hidden state h_i is computed by:

$$h_i = LSTM(h_{i-1}, x_i^D) \tag{3}$$

The size of the hidden state is also set to be d.

Attention Layer: This layer takes the output of the LSTM layer as input, and produce an attention (Yang et al., 2016) weight vector for each predefined aspect category. For the j-th aspect category:

$$M_j = tanh(W_j H + b_j), j = 1, 2, ..., N \tag{4}$$

$$\alpha_j = softmax(u_j^T M_j), j = 1, 2, ..., N \tag{5}$$

where $W_j \in R^{d\times d}$,$b_j \in R^d$,$u_j \in R^d$ are learnable parameters, and $\alpha_j \in R^n$ is the attention weight vector.

Aspect Category Prediction Layer: We use the weighted hidden state as the sentence representation for ACD prediction. For the j-th category:

$$r_j = H\alpha_j^T, j = 1, 2, ..., N \tag{6}$$

$$\hat{y}_j = sigmoid(W_j r_j + b_j), j = 1, 2, ..., N \tag{7}$$

where $W_j \in R^{d\times 1}$ and b_j is a scalar.

Embedding Layer for ACSA: For ease of reference, we use different embedding layers for ACD and ACSA. This embedding layer converts the sentence S to a sequence of vectors $X^C = \{x_1^C, x_2^C, ..., x_n^C\}$ with the help of the embedding matrix W_w.

Multi-Layer Bi-LSTM: The output of the embedding layer for ACSA are fed into a multi-layer Bidirectional LSTM (Graves et al., 2013) (Bi-LSTM). Each layer takes the output of the previous layer as input. Formally, given the hidden states of the $(l-1)$-th layer,$H^{l-1} = \{h_1^{l-1}, h_2^{l-1}, ..., h_n^{l-1}\}$, the l-th Bi-LSTM outputs hidden states $H^l = \{h_1^l, h_2^l, ..., h_n^l\}$. At each time step i, the hidden state h_i^l is computed by:

$$\overrightarrow{h_i^l} = \overrightarrow{LSTM}(\overrightarrow{h_{i-1}^l}, h_i^{l-1}) \tag{8}$$

$$\overleftarrow{h_i^l} = \overleftarrow{LSTM}(\overleftarrow{h_{i+1}^l}, h_i^{l-1}) \tag{9}$$

$$h_i^l = [\overrightarrow{h_i^l}; \overleftarrow{h_i^l}] \tag{10}$$

where $H^0 = \{x_1^C, x_2^C, ..., x_n^C\}$, $\overrightarrow{h_i^l} \in R^{d/2}$,$\overleftarrow{h_i^l} \in R^{d/2}$, $h_i \in R^d$, and $d/2$ denote the size of the hidden state of LSTM. The total number of Bi-LSTM layers is L.

Word Sentiment Prediction Layer: We use the hidden state h_i^L at the time step i of the L-th layer Bi-LSTM as the representation of the i-th word, and two fully connected layers are used to produce the i-th word sentiment prediction p^i:

$$p^i = W^2 ReLU(W^1 h_i^L + b^1) + b^2 \tag{11}$$

where $W^1 \in R^{d \times d}$, $W^2 \in R^{d \times 3}$, $b^1 \in R^d$, $b^2 \in R^3$ are learnable parameters. Note there is no softmax activation function after the fully connected layer, which lead it difficult to train our model.

Aspect Category Sentiment Prediction Layer: We obtain the aspect category sentiment predictions by aggregating the word sentiment predictions based on the weights offered by the ACD task. Formally, for the j-th aspect category, its sentiment p_j can be computed by:

$$p_j = softmax(\sum_{i=1}^{n} p^i \alpha_j^i) \tag{12}$$

where $p_j \in R^3$, and α_j^i indicates the weight of the i-th word about the j-th aspect category from the weight vector α_j offered by the ACD task.

Loss: For the ACD task [2], as each prediction is a binary classification problem, the loss function is defined by:

$$L_A(\theta_A) = -\sum_{j=1}^{N} y_j log\hat{y}_j + (1 - y_j) log(1 - \hat{y}_j) \tag{13}$$

For the ACSA task, only the loss of the K aspect categories mentioned in the sentence is included, and the loss function is defined by:

$$L_S(\theta_S) = -\sum_{j=1}^{K} \sum_{c \in P} y_{jc} log p_{jc} \tag{14}$$

We jointly train our model for the two tasks. The parameters in our model are then trained by minimizing the combined loss function:

$$L(\theta) = L_A(\theta_A) + \beta L_S(\theta_S) + \lambda \left\|\theta\right\|_2^2 \tag{15}$$

where β is the weight of ACSA loss, λ is the $L2$ regularization factor and θ contains all parameters of our model.

4 Experiments

4.1 Datasets

Rest14: The SemEval-2014 restaurant review (Rest14) (Pontiki et al., 2014) dataset has been widely used. Following previous works (Cheng et al., 2017; Tay et al., 2018; Hu et al., 2019), we remove samples with conflict polarities. Since there is no official development set for Rest14, we use the split offered by Tay et al. (2018).

Rest14-hard: Following Xue and Li (2018), we construct Rest14-hard. In Rest14-hard, training set and development set are same as Rest14's, while test set is constructed from the test set of Rest14. The test set of Rest14-hard only includes sentences containing at least two aspect categories with different sentiment polaritiess.

MAMS-ACSA: Since the test set of Rest14-hard is small, we also adopt the Multi-Aspect Multi-Sentiment dataset for Aspect Category Sentiment Analysis (denoted by MAMS-ACSA). MAMS-ACSA is released by Jiang et al. (2019), all sentences in which contain multiple aspect categories with different sentiment polarities.

We select Rest14-hard and MAMS-ACSA that we call hard datasets because most sentences in Rest14 contain only one aspect or multiple aspects with the same sentiment polarity, which makes ACSA degenerate to sentence-level sentiment analysis (Jiang et al., 2019). Rest14-hard and MAMS-ACSA can measure the ability of a model to detect multiple different sentiment polarities in one sentence toward different aspect categories. Statistics of these three datasets are given in Table 1.

4.2 Comparison Methods

We compare AC-MIMLLN with various baselines. (1) non-BERT models: GCAE (Xue and Li, 2018),

---

[2] ACD is an auxiliary task. Although AC-MIMLLN performs both ACD and ACSA, the aspect categories it detects (i.e., the results of ACD) are usually ignored in both training stage and testing stage. The reason is that our ACD classifier is simple, it can produce effective attention weights, but may not generate effective predictions for the ACD task. In this paper, we focus on ACSA and only evaluate the performance of AC-MIMLLN on ACSA.

Table 3: Results of the ACSA task on Rest14's aspect categories in terms of accuracy (%).

As-capsule (Wang et al., 2019) [3] and CapsNet (Jiang et al., 2019); (2) BERT (Devlin et al., 2019) based models: BERT (Jiang et al., 2019), BERT-pair-QA-B (Sun et al., 2019) and CapsNet-BERT (Jiang et al., 2019). We also provide the comparisons of several variants of AC-MIMLLN:

AC-MIMLLN – w/o mil generates aspect category-specific representations for the ACAC task. The representations are the weighted sum of the word representations based on the weights offered by the ACD task.

AC-MIMLLN-Affine replaces the LSTM in AC-MIMLLN with an affine hidden layer, which is used to evaluate the effectiveness of the attention in AC-MIMLLN (Wiegreffe and Pinter, 2019).

AC-MIMLLN-BERT replaces the embedding layer for ACSA and the multi-layer Bi-LSTM in AC-MIMLLN with the uncased basic pre-trained BERT. Since the overall sentiment of a sentence as context information is important for infering the sentiment of a particular aspect category, AC-MIMLLN-BERT also predicts the sentiment of the token "[CLS]" and assigns weight 1 to it. AC-MIMLLN-BERT takes "[CLS] sentence [SEP] aspect category [SEP]" as input like CapsNet-BERT.

4.3 Implementation Details

We implement our models in PyTorch (Paszke et al., 2017). We use 300-dimentional word vectors pre-trained by GloVe (Pennington et al., 2014) to initialize the word embedding vectors. The batch sizes are set to 32 and 64 for non-BERT models on the Rest14(-hard) dataset and the MAMS-ACSA dataset, respectively, and 16 for BERT-based models. All models are optimized by the Adam optimizer (Kingma and Ba, 2014). The learning rates are set to 0.001 and 0.00002 for non-BERT models and BERT-based models, respectively. We set $L = 3$, $\lambda = 0.00001$ and $\beta = 1$. For the ACSA task, we apply a dropout of $p = 0.5$ after the embedding and Bi-LSTM layers. For AC-MIMLLN-BERT, ACD is trained first then both of ACD and ACSA are trained together. For other models, ACD and ACSA are directly trained jointly. We apply early stopping in training and the patience is 10. We run all models for 5 times and report the average results on the test datasets.

4.4 Experimental Results

Experimental results are illustrated in Table 2. According to the experimental results, we can come to the following conclusions. First, AC-MIMLLN outperforms all non-BERT baselines on the Rest14-hard dataset and the MAMS-ACSA dataset, which indicates that AC-MIMLLN has better ability to detect multiple different sentiment polarities in one sentence toward different aspect categories. Second, AC-MIMLLN obtains +1.0% higher accuracy than AC-MIMLLN – w/o mil on the Rest14 dataset, +0.8% higher accuracy on the Rest14-hard dataset and +0.8% higher accuracy on the MAMS-ACSA dataset, which shows that the Multiple Instance Learning (MIL) framework is more suitable for

---

[3] As-capsule is also a multi-task model, which performs ACD and ACSA simultaneously like our model.

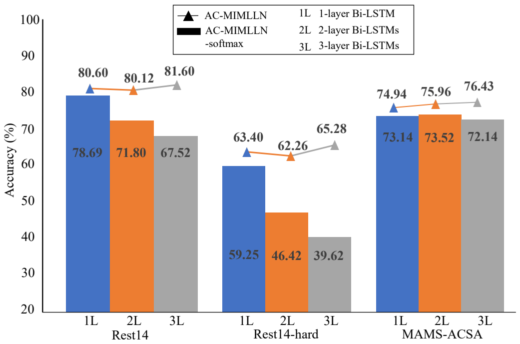

Figure 3: The impact of the number of Bi-LSTM layers and the softmax activation function.

the ACSA task. Third, AC-MIMLLN-BERT surpasses all BERT-based models on all three datasets, indicating that AC-MIMLLN can achieve better performance by using more powerful sentence encoders for ACSA. In addition, AC-MIMLLN can't outperform As-capsule on Rest14. The main reason is that AC-MIMLLN has poor perfmance on the aspect category *misc* (the abbreviation for *anecdotes/miscellaneous*) (see Table 3 and Figure 4 (f)).

4.5 Impact of Multi-Task Learning

AC-MIMLLN is a multi-task model, which performs ACD and ACSA simultaneously. Multi-task learning (Caruana, 1997) achieves improved performance by exploiting commonalities and differences across tasks. In this section, we explore the performance of AC-MIMLLN in different multi-task settings on the ACSA task. Specifically, we explore four settings: single-pipeline, single-joint, multi-pipeline and multi-joint. The "single" means that the ACSA task predicts the sentiment of one aspect category in sentences every time, while the "multi" means that the ACSA task predicts the sentiments of all aspect categories in sentences every time. The "pipeline" indicates that ACD is trained first, then ACSA is trained, while the "joint" indicates ACD and ACSA are trained jointly. The multi-joint is AC-MIMLLN.

Experimental results are shown in Table 5. First, we observe that, multi-* outperform all their counterparts, indicating modeling all aspect categories in sentences simultaneously can improve the performance of the ACSA task. Second, *-joint surpass *-pipeline on the Rest14-hard dataset and the MAMS-ACSA dataset, which shows that training ACD and ACSA jointly can improve the perfomance on hard datasets. Third, *-joint obtain worse perfomance on the Rest14 dataset than *-pipeline. One possible reason is that Rest14 is simple and *-joint have bigger model capacity than *-pipeline and overfit on Rest14.

4.6 Impact of Multi-layer Bi-LSTM Depth

In this section, we explore the effect of the number of the Bi-LSTM layers. Experiments results are shown in Figure 3, which also contains the results of AC-MIMLLN-softmax. AC-MIMLLN-softmax is obtained by adding the softmax activation function to the word sentiment prediction layer of AC-MIMLLN. We observe that, when the number of Bi-LSTM layer increases, AC-MIMLLN usually obtains better performance, and AC-MIMLLN-softmax obtains worse results. It indicates that AC-MIMLLN-softmax is hard to train when its complexity increases, while AC-MIMLLN can achieve better performance by using more powerful sentence encoders for ACSA.

4.7 Quality Analysis

In this subsection, we show the advantages of our model and analyze where the error lies in through

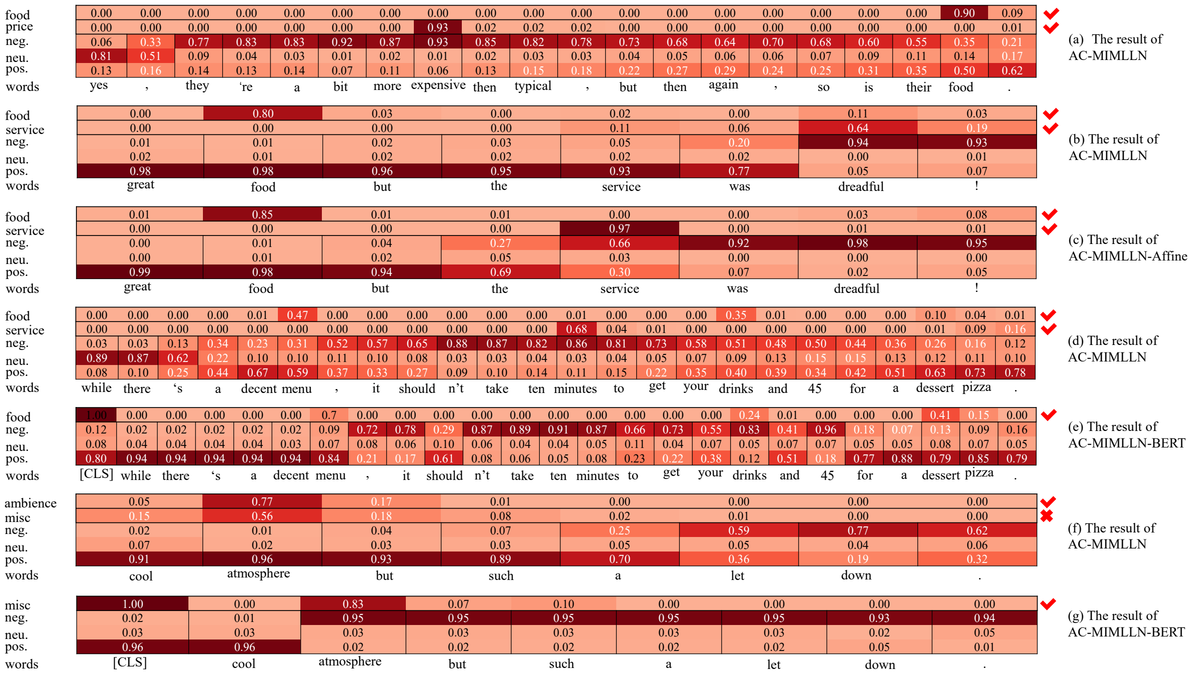

Figure 4: Visualization of the attention weights and the word sentiment prediction results. For each subfigure, the lines corresponding aspect categories show the attention weights offered by the ACD task, while the other three lines show the word sentiment distributions predicted by the ACSA task.

some typical examples and estimating the performance of our model detecting the key instances (KID) of the given aspect category and classifying the sentiments of the given key instances (KISC). We annotate the key instances for the aspect categories mentioned in sentences and their sentiment polarities on the test set of the three datasets. Models judge a word as a key instance if the weight of the word is greater than or equal to 0.1. Experimental results are illustrated in Table 4.

Case Study Figure 4 visualizes the attention weights and the word sentiment prediction results of four sentences. Figure 4 (a) shows that, our model accurately finds the key instances “expensive” for the aspect category *price* and “food” for *food*, and assigns correct sentiments to both the aspect categories and the key instances. Compared with previous models, which generate aspect category-specific sentence representations for the ACSA task directly (e.g. BERT-pair-QA-B) or based on aspect category-related sentiment words (e.g. As-capsule), our model is more interpretable.

In Figure 4, (b) and (c) show that, both AC-MIMLLN and AC-MIMLLN-Affine can correctly predict the sentiments of the aspect categories, *food* and *service*. While AC-MIMLLN-Affine accurately find the key instance “service” for *service*, AC-MIMLLN assigns weights to all the words in the text snippet “service was dreadful!”. This is because the LSTM-based ACD model in AC-MIMLLN can select useful words for both ACD and ACSA based on the context, which results in better performance (see Table 2). This also can explain why AC-MIMLLN has worse performance on detecting the key instances of the given aspect category than AC-MIMLLN-Affine (see Table 4).

Error Analysis In Figure 4 (d), the sentiments toward “drinks” and “dessert” (key instances of the aspect category *food*) should be neutral, however AC-MIMLLN assigns negative sentiment to ”drinks” and positive sentiment to ”dessert”. Figure 4 (e) shows AC-MIMLLN-BERT also assigns wrong sentiments to “drinks” and “dessert”. Table 4 shows that although AC-MIMLLN-BERT significantly improve the performance of KISC, it’s results are also less than 80% on the Rest14-hard dataset and the MAMS-ACSA dataset.

In Figure 4 (f), AC-MIMLLN wrongly predict the sentiment of the aspect category *misc*, because it finds the wrong key instances for *misc*. Compared to other aspect categories, it’s harder to decide which words are the key instances of *misc* for AC-MIMLLN, resulting in poor performance of AC-MIMLLN on the aspect category *misc*. Figure 4 (g) shows AC-MIMLLN-BERT correctly predict the sentiments of the aspect category *misc*, but also finds the wrong key instances for *misc*. Table 4 shows that all results on KID are less than 75%.

5 Conclusion

In this paper, we propose a Multi-Instance Multi-Label Learning Network for Aspect-Category sentiment analysis (AC-MIMLLN). AC-MIMLLN predicts the sentiment of an aspect category mentioned in a sentence by aggregating the sentiments of the words indicating the aspect category in the sentence. Experimental results demonstrate the effectiveness of AC-MIMLLN. Since AC-MIMLLN finds the key instances for the given aspect category and predicts the sentiments of the key instances, it is more interpretable. In some sentences, phrases or clauses rather than words indicate the given aspect category, future work could consider multi-grained instances, including words, phrases and clauses. Since directly finding the key instances for some aspect categories is ineffective, we will try to first recognize all opinion snippets in a sentence, then assign these snippets to the aspect categories mentioned in the sentence.

Abstract

Aspect sentiment classification, predicting the sentiment polarity of given aspects, has drawn extensive attention. Previous attention-based models emphasize using aspect semantics to help extract opinion features for classification. However, these works are either not able to capture opinion spans as a whole or capture variable-length opinion spans. In this paper, we present a neat and effective multiple CRFs based structured attention model that is capable of extracting aspect-specific opinion spans. The sentiment polarity of the target is then classified based on the extracted opinion features and contextual information. The experimental results on four datasets demonstrate the effectiveness of the proposed model, and our further analysis shows that our model can capture aspect-specific opinion spans.[1]

1 Introduction

Aspect Based Sentiment Analysis (ABSA) (Pang and Lee, 2008; Liu, 2012) is an extensively studied sentiment analysis task on a fine-grained semantic level, i.e., opinion targets explicitly mentioned in sentences. Previous ABSA studies focused on a few sub-tasks, such as Aspect Sentiment Classification (ASC) (Wang et al., 2016; Chen et al., 2017; Ma et al., 2018), Aspect Term Extraction (ATE) (Li et al., 2018b; He et al., 2017), Aspect and Opinion Co-Extraction (Liu et al., 2013; Wang et al., 2017; Xu et al., 2018; Dai and Song, 2019), E2E-ABSA (a joint task of ASC and ATE) (Li et al., 2019a; He et al., 2019; Li et al., 2019b), Aspect Sentiment Triplet Extraction (ASTE) (Peng et al., 2019; Xu et al., 2020), etc. ASC analyzes the sentiment polarity of given aspects/targets in a review. For example, consider the review sentence "***Food** is usually very good, though occasionally I worry about freshness of **raw vegetables** in side orders.*" This review mentions two aspects: **Food** and **raw vegetables**, and for ASC, the objective is to give a positive sentiment on **Food** and a negative sentiment on **raw vegetables**. Most of the previous works (Wang et al., 2016; Chen et al., 2017; Liu and Zhang, 2017; Yang et al., 2017; Li et al., 2018c; He et al., 2018; Li and Lu, 2019; Hu et al., 2019) adopt attention mechanism (Bahdanau et al., 2015) to capture the semantic relatedness among the context words and the aspect, and learn aspect-specific features for sentiment classification.

However, it is challenging for attention-based approaches to consider an opinion span as a whole during feature extraction because they are overreliant on neural models to learn the context-structural information and perform feature extraction over individual hidden representations. Previous work (Wang and Lu, 2018) engage structured attention networks (Kim et al., 2017), which extend the previous attention mechanism to incorporate structure dependencies, to model the interaction among context words, and perform soft-selections of word spans. In particular, they introduce two hand-coded regularizers to constrain the soft-selection process to attend to few short opinion spans. However, such regularizers disturb the structure dependencies, and their method is not capable of emphasizing aspect-specific opinion spans for sentiment classification.

To better capture opinion features for aspect sentiment classification, we propose the MCRF-SA model, which introduces multiple conditional random fields (CRF) (Lafferty et al., 2001) to structured attention model. While exploiting the advantages of structured attention mechanisms, our model avoids the regularizers by the complementarity among multiple CRFs. We also improve the

previous position decay function (Li et al., 2018a; Tang et al., 2019) to reduce the importance of context words that are further away from the aspect so as to emphasize aspect-specific opinion spans. Our multi-CRF layer with the effective decay function extracts aspect-specific features from different representation sub-spaces to overcome the previous limitations. The experimental results on the four datasets demonstrate the effectiveness of our model, and the analysis shows that the behaviors are in alignment with our intuition.

2 Model Description

Given a context sequence $\mathbf{w^c} = \{w_1, w_2, \ldots, w_n\}$ and a aspect sequence $\mathbf{w^a} = \{w_i, ..., w_j\}$ $(1 \leq i \leq j \leq n)$ which is a sub-sequence of $\mathbf{w^c}$, the goal of ASC is to predict sentiment polarity $y \in \{$*positive*, *negative*, *neutral*$\}$ over the given aspect. Our model is mainly constructed with a few neural layers, including an input layer, an aspect-specific contextualized representation layer, a position decay layer, a multi-CRF structured attention layer, and a sentiment classification layer. Figure 1 presents the architecture of our MCRF-SA model.

2.1 Input Layer

The input of our model consists of word embedding $\mathbf{w}_t^{word}$ and aspect indicator embedding $\mathbf{w}_t^{as}$. The aspect indicator embedding is to differentiate aspect words and context words and is randomly initialized. The input representation $\mathbf{x}_t$ is as follows:

$$\mathbf{x}_\mathrm{t} = [\mathbf{w}_t^{word};\ \mathbf{w}_t^{as}] \tag{1}$$

2.2 Aspect-Specific Contextualized Representation

We employ a bi-directional GRU (Cho et al., 2014) to generate the contextualized representation. Since the input representation has already contained the aspect information, the aspect-specific contextualized representation is obtained by concatenating the hidden states from both directions:

$$\mathbf{h}_\mathrm{t} = [\overrightarrow{\mathbf{h}}_t;\ \overleftarrow{\mathbf{h}}_t] \tag{2}$$

where $\overrightarrow{\mathbf{h}}_t$ is the hidden state from the forward GRU and $\overleftarrow{\mathbf{h}}_t$ is from the backward.

2.3 Position Decay

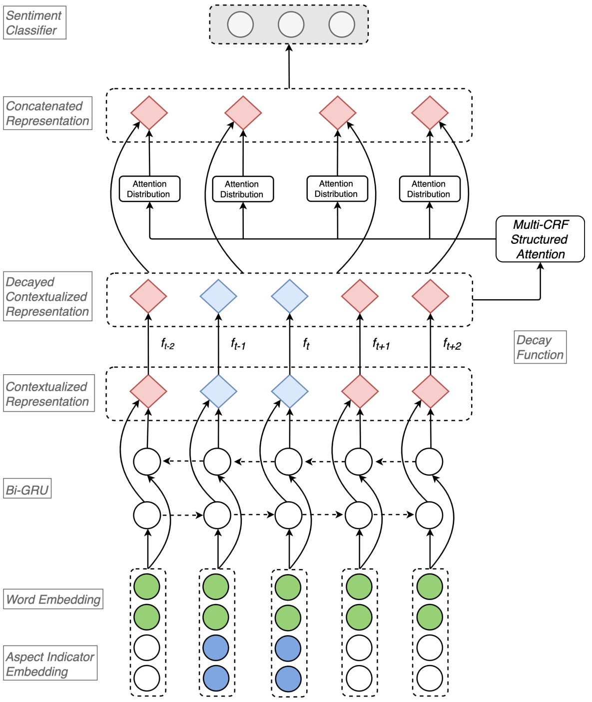

Figure 1: MCRF-SA Architecture.

Following the previous work (Li et al., 2018a; Zhang et al., 2019; Tang et al., 2019), we also use a position decay function to reduce the influence of the context words on the aspect as it goes further away from the aspect. We propose a higher-order decay function, which is more sensitive to distance, and the sensitivity can be tuned by γ on different datasets.

$$f(t) = \begin{cases} (\frac{L - i + t}{L})^\gamma & t < i \\ 1 & i \leq t \leq j \\ (\frac{L - t + j}{L})^\gamma & j < t \end{cases} \tag{3}$$

where i and j are the starting and ending position of an aspect, L is the maximum length of sentences across all datasets, γ is a hyper-parameter and a larger value enables more influence from the context words that are close to the aspect. Then, the decayed contextual word representation is as follows:

$$\mathbf{r}_t = f(t)\ \mathbf{h}_t \tag{4}$$

2.4 Multi-CRF Structured Attention

We use multiple linear-chain CRFs to intensively incorporate structure dependencies to capture the corresponding opinion spans of an aspect. In particular, we create a latent label (Wang and Lu, 2018) $z \in \{Yes,\ No\}$ to indicate whether each context word belongs to part of opinion spans. Similar to (Lample et al., 2016), given the sentence representation $\mathbf{x}$, the CRF is defined as:

$$P(\mathbf{z}|\mathbf{x}) = \frac{\exp(score(\mathbf{z}, \mathbf{x}))}{\sum_{\mathbf{z}'} \exp(score(\mathbf{z}', \mathbf{x}))} \tag{5}$$

where $score(\mathbf{z}, \mathbf{x})$ is a score function that is defined as the summation of transition scores and emission scores from the Bi-GRU:

$$score(\mathbf{z}, \mathbf{x}) = \sum_{t=0}^{n} T_{z_t, z_{t+1}} + \sum_{t=1}^{n} E_{\mathbf{t}, z_t} \quad (6)$$

where T is a transition matrix and $T_{z_t, z_{t+1}}$ denotes the transition score from label z_t to z_{t+1}. $E_{\mathbf{t}, z_t}$ denotes the emission score of label z_t at the t-th position, and the score is obtained from a linear layer, which takes $\mathbf{r}_t$ as input and returns a vector whose length is label size.

2.4.1 Marginal Inference

The latent labels introduced in the CRF layer show whether the word influences the given aspect's sentiment. Intuitively, we can understand that the marginal probabilities on the Yes label indicate the influence of the current context word on the aspect word's sentiment. By using the forward-backward algorithm, we calculate the marginal distribution of the latent label. With the marginal distribution, the sentence representation $\mathbf{s}$ is obtained:

$$\mathbf{s} = \sum_{t=1}^{n} P(z_t = Yes|\mathbf{x})\mathbf{r}_t \quad (7)$$

The final representation for classification is obtained by concatenating the sentence representations from all CRFs:

$$\mathbf{q} = [\mathbf{s}_1; \mathbf{s}_2; ...; \mathbf{s}_a] \quad (8)$$

where a is the number of CRFs.

2.5 Sentiment Classification

The sentence representation $\mathbf{q}$ is passed to a sentiment classier to obtain the distribution of sentiment polarities:

$$P(\mathbf{y}|\mathbf{q}) = \mathrm{Softmax}(W\mathbf{q} + \mathbf{b}) \quad (9)$$

where W and $\mathbf{b}$ are learnable parameters for the sentiment classifier layer. We learn model parameters by minimizing the negative log-likelihood.

3 Experiments

3.1 Experimental Setup

Our proposed MCRF-SA model is evaluated on four benchmark datasets: SemEval 2014 Task4 (Pontiki et al., 2014), SemEval 2015 Task12 (Pontiki et al., 2015) and SemEval 2016 Task 5 (Pontiki et al., 2016). Following the previous works (Tang et al., 2016; Chen et al., 2017; Wang and Lu, 2018; He et al., 2018), we remove a few examples that have conflicting labels. Detailed statistics of the datasets can be found in Table 1.

Dataset	**Train**			**Dev**			**Test**		
	#Pos.	#Neu.	#Neg.	#Pos.	#Neu.	#Neg.	#Pos.	#Neu.	#Neg.
14Rest	1796	539	666	368	94	139	728	196	196
14Lap	824	383	717	161	72	149	340	167	128
15Rest	808	29	228	147	5	44	340	28	195
16Rest	1106	54	406	191	9	60	474	29	127

Table 1: Statistics of datasets.

We use the 300d GloVe (Pennington et al., 2014) to initialize our word embeddings. One-sixth of instances are randomly selected from the original training dataset as the development dataset, and the model is only trained with the remaining data. With the development set, we tune our model hyperparameters using an open-source black-box tuner (Alberto and Giacomo, 2018). We set the hidden size of GRU to 32 or 64. The batch size is set to 64 or 96. The dropout rate is selected from 0.3 to 0.8, with a step size of 0.1. The dimension of the aspect indicator is selected from $\{50, 70, 90\}$. The value of γ in the position decay function is selected from $\{1,2,3\}$. The number of layer of GRU is selected from $\{1,2,3\}$. We adopt Adam (Kingma and Ba, 2014) to optimize our model with a learning rate of 0.008. All hyper-parameters are selected based on the best performance on the development set.

3.2 Baselines

Our MCRF-SA model is compared with the following methods[2]. SVM (Kiritchenko et al., 2014) is a support vector machine based method that integrates surface, lexicon, and parse features. ATAE-LSTM (Wang et al., 2016) is an LSTM (Hochreiter and Schmidhuber, 1997) based model, which has an extra attention to perform soft-selection over the context words. MemNet (Tang et al., 2016) introduces a deep memory network to implement attention mechanisms to learn the relatedness of context words towards the aspect. IAN (Ma et al., 2017) utilizes two LSTM based attention models to learn both context and aspect representations interactively. SA-LSTM-P (Wang and Lu, 2018) employs structured attention networks with multiple regularizers to capture the opinion spans for ASC. TNets (Li et al., 2018a) implements a context-preserving mechanism to get the aspect-specific word representations and uses a Convolutional Neu-

ral Network (CNN) (Lecun et al., 1998) layer to obtain the sentence representation. TNet-ATT (Tang et al., 2019) is an extension of TNet-LF, and it provides an attention supervision mining mechanism to improve the previous model. ASCNN and ASGCN (Zhang et al., 2019) use CNN and Graph Convolutional Network (GCN) (Kipf and Welling, 2017) to capture the long-range dependencies and syntactic information.

3.3 Experimental Results

Our proposed model shows significant improvements on the four datasets, Table 2 shows the performance comparisons. Our method outperforms SVM (Kiritchenko et al., 2014) by 2.7 and 7.15 *Acc.* score on 14Rest and 14Lap, respectively. This indicates that our neural approach extracts more effective features than hard-coded feature engineering. Compared to the attention-based methods – ATAE (Wang et al., 2016), MemNet (Tang et al., 2016), IAN (Ma et al., 2017), and TNet-ATT (Tang et al., 2019), our MCRF-SA model pays more attention to the aspect-specific opinion spans, which bring significant performance improvement on the four datasets.

We also compare our model with methods that focus on word segmentations for sentiment classification. Our method outperforms the previous regularizers guided structured attention model SA-LSTM-P (Wang and Lu, 2018) by more than 1.2 *Acc.* score on 14Rest and 14Lap. TNet-LF (Li et al., 2018a) and ASCNN (Zhang et al., 2019) employ CNN to evaluate word spans regarding how much it contributed to the sentiment, but the kernel size limits the length of the span. ASGCN (Zhang et al., 2019) employs GCN over the dependency tree to capture syntactic and dependency information. However, the performance heavily relies on the accuracy of the dependency trees. Our proposed multi-CRF structured attention along with the position decay function allows MCRF-SA to perform soft-selection of multiple aspect-specific opinion spans that influence the aspect's sentiment. The large performance gaps between our model and baseline models confirm the effectiveness of our proposed architecture. Such results also demonstrate that sentiment classification can benefit greatly from aspect-specific opinion spans.

Furthermore, we observe that the performance on 15Rest is not as good as the other three datasets. Such behavior is caused by the different distribution of positive, neutral, and negative sentiment between training and test set, shown in Table 1.

4 Analysis

4.1 Effect of Number of CRFs

To fully investigate the effect of the number of CRFs, we conduct additional experiments on 14Rest and 14Lap with the number of CRFs $\in \{1, 2, 3, ..., 16\}$. Figure 2 shows the experimental results. The model achieves the best performance when the number of CRFs equals to 4. Particularly, the performance becomes relatively plateau when a large number of CRFs is adopted. We believe this is because the sizes of the four benchmark datasets are relatively small, and an excessively large number of parameters may not be able to further extract

---

[3] We train their models with the default parameters and their released training data, and report the average results on our test sets from 3 runs. Note that these works did not release development sets.

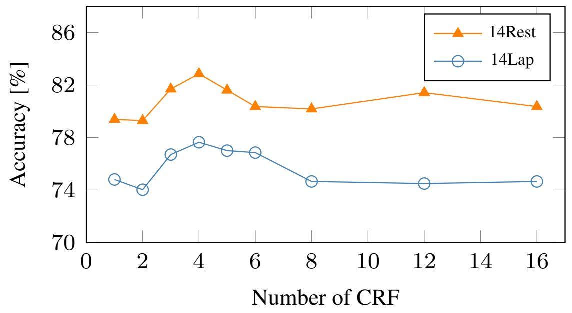

Figure 2: Effect of number of CRFs.

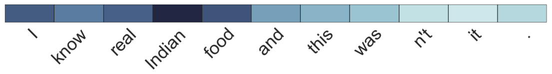
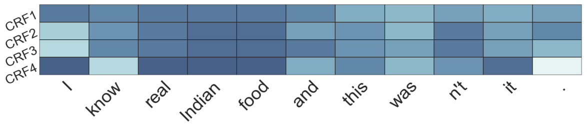


(a) SA-LSTM-P.



(b) MCRF-SA with 4 CRFs.

Figure 3: Marginal distributions of "Yes" label.

effective features.

4.2 Case Study and Error Analysis

Figure 3 shows the marginal distributions (Equation 5) of SA-LSTM-P (Wang and Lu, 2018) and our MCRF-SA model. The aspect for the given example is "*Indian food*" with negative sentiment, and only our model predicts correct sentiment. From Figure 3b heat map, the different marginal distributions on the four CRFs indicate that our model indeed captures different opinion features. It can be observed that MCRF-SA is able to attend to the two major opinion spans: *"real"* and *"n't"*. The SA-LSTM-P model returns positive sentiment as it focuses too much on wrong opinion words.

We also analyze some common errors from our MCRF-SA model, ASGCN, and TNet-ATT on the Lap14 dataset. We observe two major types of errors, and Table 3 shows the examples for error analysis. The first two sentences belong to the type 1 error and the last one presents a type 2 error. The first type of errors appear frequently in neutral cases. In general, the neural models cannot well differentiate if the negative expressions (e.g. "*cost*", "*shouldn't*", etc.) is associated with the target/aspect. The second type typically involve complicated sentence structures with non-trivial semantics, which requires advanced language understanding capability.

Case Study	MCRF-SA	ASGCN	TNet-ATT
1. When considering a Mac, look at the total cost of ownership and not just the initial **price tag**$_{\text{NEU}}$.	NEU	NEG$_{✗}$	NEG$_{✗}$
2. It shouldn't happen like that, I don't have any **design app**$_{\text{NEU}}$ open or anything .	NEG$_{✗}$	NEU	NEU
3. The smaller **size**$_{\text{POS}}$ was a bonus because of space restrictions.	NEG$_{✗}$	NEG$_{✗}$	NEG$_{✗}$

Table 3: The words highlighted in blue denote the given aspects, and gold sentiment labels are marked as subscripts. ✗ indicates incorrect prediction.

Models	14Rest		14Lap	
	Acc.	F_1	*Acc.*	F_1
MCRF-SA	82.86	73.78	77.64	74.23
– aspect indicator	79.02	66.96	72.76	67.56
– decay function	81.52	70.94	76.69	73.12
– structured attention	80.00	68.89	69.61	63.74

Table 4: Ablation Study.

4.3 Ablation Study

We examine the effectiveness of the major components of our MCRF-SA model, and Table 3 presents the ablation results on 14Rest and 14Lap datasets. Without the aspect indicator, our model becomes a sentence-level sentiment classification method which inevitably produces wrong predictions for sentences having multiple aspects with different sentiments. Removing the position decay function hurts the performance by 2.84 and 1.11 F_1 score on 14Rest and 14Lap, respectively. Lastly, without multi-CRF structured attention layer, the architecture becomes a simple Bi-GRU based model and the performance drops significantly by 4.89 and 10.49 F_1 points on 14Rest and 14Lap.

5 Conclusion

We propose a simple and effective MCRF-SA model to extract aspect-specific opinion span features. In particular, with the proposed multi-CRF structured attention layer and the effective position decay function, our model is capable of extracting various aspect-specific opinion span features from different representation sub-spaces. The experimental results demonstrate that our method effectively exploits the corresponding opinion features for sentiment classification. One future direction is to investigate how to integrate the two different attention mechanisms, namely the standard attention and structured attention for NLP applications.

Emotion-Cause Pair Extraction as Sequence Labeling Based on A Novel Tagging Scheme

Abstract

The task of emotion-cause pair extraction deals with finding all emotions and the corresponding causes in unannotated emotion texts. Most recent studies are based on the likelihood of Cartesian product among all clause candidates, resulting in a high computational cost. Targeting this issue, we regard the task as a sequence labeling problem and propose a novel tagging scheme with coding the distance between linked components into the tags, so that emotions and the corresponding causes can be extracted simultaneously. Accordingly, an end-to-end model is presented to process the input texts from left to right, always with linear time complexity, leading to a speed up. Experimental results show that our proposed model achieves the best performance, outperforming the state-of-the-art method by 2.26% ($p < 0.001$) in $F1$ measure.

1 Introduction

Emotion-cause pair extraction (ECPE) aims to extract all potential pairs of emotions and the corresponding causes from unannotated emotion texts, such as (c_3, c_1) and (c_3, c_2) in:

Ex.1 *A policeman visited the old man with the lost money,* $(c_1)|$ *and told him that the thief was caught.* $(c_2)|$ *The old man was very happy,* $(c_3)|$ *and deposited the money in the bank.* (c_4)

This task for pair extraction closely relates to the traditional emotion cause extraction task, which aims at identifying the causes for a given emotion expression. Many works (Gui et al., 2017; Li et al., 2018, 2019; Xu et al., 2019; Fan et al., 2019; Xia et al., 2019; Ding et al., 2019) related to emotion cause extraction have been published recently, and all of them are evaluated with the dataset released by Gui et al. (2016). However, it suffers that emotions must be annotated before extracting the causes, which is labor intensive and limits the applications in real-world scenarios.

Towards this issue, Xia and Ding (2019) presents a new task, namely emotion-cause pair extraction, to extract emotions and the corresponding causes together. In comparison, it is a more challenging task due to the inherent ambiguity and subtlety of emotions, especially when there is no annotation information provided before extraction. Following this task setting, they propose a two-step approach to solve this task. However, limited by the inherent drawback of pipelined framework, error propagation may occur from the first procedure to the second. Recent studies (Song et al., 2020; Tang et al., 2020) have focused on solving this task using multi-task learning framework (Caruana, 1993) with well-designed attention mechanism (Bahdanau et al., 2015), but they extract emotion-cause pairs by calculating a *pair matrix*, which is based on the likelihood of Cartesian product among all clauses in texts, thus leading to the computational cost is expensive, that is, the time complexity is $O(n^2)$.

In this paper, we define the joint emotion-cause pair extraction as a sequence labeling problem (Eger et al., 2017; Zheng et al., 2017), so that the emotion-cause structure can be integrated into an unified framework, including representation learning, pair extraction, and causality reasoning. The challenge is to also include emotion causality into the tagging scheme, i.e., the traditional BIO tagging is not suitable for this task. Targeting this problem, we design a novel tagging scheme with multiple labels which contain the information of causes and the triggered emotions associated with these causes, and we realize it by coding the distance between linked components into the tags. Accordingly, an end-to-end model based on this tagging scheme is presented to process the input sequences from left to right, consequently, reducing the number of

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3568–3573,
November 16–20, 2020.

potential pairs needed to be parsed and leading to a speed up.

Specifically, BERT (Devlin et al., 2019) is trained with the objective of masked language modeling and next-sentence prediction task, therefore, we base our model on the BERT to generate powerful, general-purpose linguistic representation for each clause. Then LSTMs (Hochreiter and Schmidhuber, 1997) will be applied to capture long-range dependencies among different clauses.

To summarize, our contribution includes:

- We frame the ECPE task as a sequence labeling problem and propose an end-to-end model based on a novel tagging scheme with multiple labels, thereby the emotion-cause structure can be extracted simultaneously.
- The proposed model incrementally processes the input sequences from left to right, always with linear time complexity.
- Performance evaluation shows the superiority and robustness of the proposed model compared to a number of competitive baselines.

2 Methodology

2.1 A Tagging Problem

We define $X = (x_1, x_2, \ldots, x_n)$ as an ordered clause sequence for an emotion text. There are several emotions and at least one cause corresponds to these emotions. The goal is to output all potential pairs where exist emotion causality. Due to the difficulty describing the emotion/cause at the word or phrase level (Chen et al., 2010), in this paper, the "emotion" and "cause" are refer to "emotion clause" and "cause clause" , respectively.

This research investigates such a problem by sequentially tagging each clause $x \in X$ with two-tuples label $y = (b, d) \in Y$, where $b \in \{\text{C}, \text{O}\}$ and $d \in \{-(n-1), \ldots, -1, 0, 1, \ldots, n-1, \perp\}$. Tag "C" represents the "Cause" tag which means the current clause is a cause clause, while tag "O" represent the "Other" tag, indicating the current clause is irrelevant to the final result. Moreover, d encodes the distance between the cause and the triggered emotion it relates to, e.g., "-1" denotes the **previous clause** is the related emotion, while "1" for the **subsequent clause**. The special symbol $\perp$ indicates when a particular slot is not filled, e.g., a non-cause clause (b=O) has no related emotion, thus it always associates with the symbol $\perp$. For example, we could incrementally label the text in **Ex.1** by sequence: $\{(C, 2), (C, 1), (O, \perp), (O, \perp)\}$.

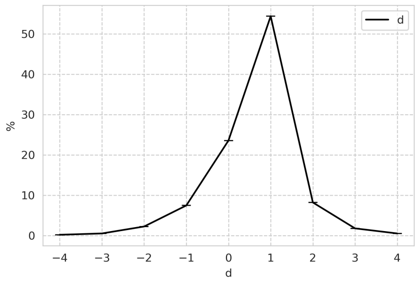

Figure 1: Distribution of distances d between emotions and causes in Gui et al. (2016) dataset.

While the total number of tags in Y is $N_t = 2 * (n-1) + 1 + 1$, which relies on the size of text X, resulting in the inconsistency during the training stage. Empirically, for emotion events, causes generally occur on positions very close to the emotions and occur frequently. As shown in Figure 1, in the dataset released by Gui et al. (2016), there are about 55% of all emotion-cause structures have distance "1", that is, the emotions behind the causes they attach to. Overall, around 95% of all emotion-cause distances lie in {-2, -1, 0, 1, 2}. Thus, we could let hyperparameter l to denote the left and right boundary which limits the scope of emotion corresponds to the current cause, i.e., $d \in \{-l, \ldots, -1, 0, 1, \ldots, l, \perp\}$. Then, we have total $N_t = 2 * l + 1 + 1$ tags, which keep consistent in the training stage.

2.2 The End-to-End Model

In this paper, the details of our model based on the novel tagging scheme will be described.

BERT Encoder Given an emotion text $X = (x_1, x_2, \ldots, x_n)$ consisting of n clauses and each clause $x_i = (w_{i1}, w_{i2}, \ldots, w_{ik})$ contains k words. We formulate each clause as a sequence $\hat{x}_i = ([\text{CLS}], w_{i1}, \ldots, w_{ik}, [\text{SEP}])$, where [CLS] is a special token that the final hidden state is used as the aggregate sequence features and [SEP] is a dummy token not used for this task. We first obtain the hidden representation as h_i = BERT($\hat{x}_i$) $\in \mathbb{R}^{d_h * |\hat{x}_i|}$ where d_h is the size of hidden dimension and $|\hat{x}_i|$ is the length of sequence $\hat{x}_i$. Then, the text X can be represented as $H_X = [h_1, h_2, \ldots, h_n]$, which will be fed into the LSTM encoder.

LSTM Encoder Based on the representation of H_X, a LSTM layer is performed to model the context-dependent information among different clauses. To summarize the information from both directions, we use bidirectional LSTM to exploit two parallel passes, this yields:

$$[\dots, \overrightarrow{\hat{h}_i}, \dots] = \overrightarrow{LSTM}_f([\dots, h_i, \dots]) \quad (1)$$

$$[\dots, \overleftarrow{\hat{h}_i}, \dots] = \overleftarrow{LSTM}_b([\dots, h_i, \dots]) \quad (2)$$

where $i \in [1, n]$, both $\overrightarrow{\hat{h}_i}$ and $\overleftarrow{\hat{h}_i} \in \mathbb{R}^{d_r * n}$, d_r is the hidden size of LSTMs. The two directional hidden states are concatenated as the final clause representation $\hat{h}_i = [\overrightarrow{\hat{h}_i}, \overleftarrow{\hat{h}_i}]$.

Training The representation $\hat{h}_i$ as the final feature for tag prediction and the model is trained by minimizing the cross entropy. Specifically,

$$p_i = \mathrm{softmax}(\mathrm{FFN}(\hat{h}_i)) \quad (3)$$

$$\mathcal{L} = -\sum_{j}^{|\mathbb{D}|} \sum_{i}^{n} y_i^{(j)} \log(p_i^{(j)}) + \frac{\lambda}{2} ||\theta||^2 \quad (4)$$

where FFN is a feed-forward neural network with the parameters randomly initialized, $|\mathbb{D}|$ is the size of training set, n is the length of text X_j. $y_i^{(j)}$ is the label of clause i in text X_j and $p_i^{(j)}$ is the normalized predictive probabilities of our special tags. Besides, θ denotes all the parameters in this model and λ is the coefficient of L_2-norm regularization.

3 Experiments

3.1 Experimental Setting

Dataset The only dataset released by Gui et al. (2016) is used to evaluate our proposed model. We also pre-process the whole dataset by following Xia and Ding (2019). In detail, there are 1746 samples with one emotion-cause pair, 177 samples with two pairs, and 22 samples with more than two pairs. Besides, the quartile information about clause number of per sample is also shown in Table 1. Moreover, we stochastically divide the corpus into a training/development/test set in a ratio of 8:1:1 and evaluate our method 20 times with different data splits to obtain statistically credible results.

Evaluation We adopt standard Precision(P), Recall (R) and F-measure ($F1$) to measure the performance and report the average results over 20 runs. Note that when we extract emotion-cause pairs, we obtain the emotions and causes for each text simultaneously. Thus, we also evaluate the performance of emotion extraction and cause extraction.

# of	Samples	quartile	Clauses
All	1945	1st quartile	11
1 pair	1746	2nd quartile	14
2 pairs	177	3rd quartile	18
$\geq$ 3 pairs	22	max clauses	73

Table 1: Statistical information about the dataset.

Hyperparameters Our proposed model is trained using Adam optimizer (Kingma and Ba, 2015), and the initial learning rate is set to 3e-5. We set the batch size to 4, the coefficient of L_2 term to 1e-2, the hidden size of all LSTMs and FFN to 256. We regularize our network using dropout with rate 0.5 and adopt BERT$_{Chinese}$ as the basis in this work[1]. We perform grid search over the emotion boundary $l \in \{1,2,3,4,5,6\}$. The model is trained 10 epochs in total and the highest $F1$-measure model on the development set is used to evaluate the test set.

Baselines In this paper, we compare our model with the following methods.

- **Indep**: Emotion extraction and cause extraction are trained independently. Then pairing them and eliminating the pairs that have no emotion causality; **Inter-CE**: The predictions of cause extraction are used to improve emotion extraction; **Inter-EC**: The predictions of emotion extraction are used to improve cause extraction. All of them are pipelined framework and proposed in Xia and Ding (2019).

- **E2EECPE** (Song et al., 2020): An end-to-end multi-task learning framework for constructing *pair matrix* through biaffine attention.

- **LAE-MANN** (Tang et al., 2020): The current state-of-the-art method using a multi-level attention mechanism based on LSTM or BERT encoder, denoted as **LML** and **LMB** here.

3.2 Main analysis

The experimental results are shown in Table 2. **Indep** yields the lowest performance, because it ignores the fact that emotions and causes are usually mutually indicative. **Inter-CE** and **Inter-EC** benefit from this interaction information, thus get

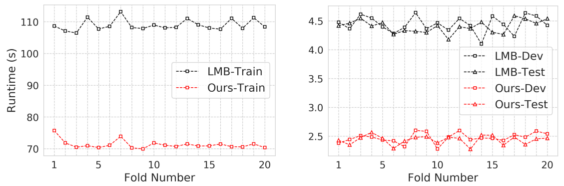
3	77.39	**70.18**	**67.76**
4	77.14	69.68	67.28
5	76.99	69.87	67.16
6	76.11	68.95	66.42

Table 3: $F1$ scores with different emotion scope limitation over all the tasks.

better performance. Meanwhile, the joint models (**E2EECPE**, **LML**, **LMB**) have better performance compared to the previous pipelined methods by reducing error propagation. Specifically, **LML** outperforms **E2EECPE** by capturing mutual interdependence between emotions and causes using a multi-level attention mechanism, and **LMB** further improves the performance based on BERT embeddings. Our model performs worse on emotion extraction, because it inherently learns to detect causes firstly, then identifies emotions through distance tag. Overall, our model achieves better performance compared to the previous methods, significantly improves cause extraction by 5.15% and emotion-cause pair extraction by 2.26% in $F1$-measure with $p < 0.001$. The reason may be that our model always processes the texts with linear time complexity, instead of based on Cartesian product, which the time complexity is $O(n^2)$, thereby greatly reducing the search space.



(a) In training stage. (b) In inference stage.

Figure 2: Comparison of running time between LMB and our model in training/inference stage (s/epoch).

3.3 Emotion Scope Limitation Analysis

It is intuitive that the larger emotion scope is allowed, the more situations are involved. In this section, we evaluate the power of distance limitation l for this task, and set the number of l from 1 to 6. Results are shown in Table 3. With the increasing scope of emotion, the performance improves. However, when the scope of emotion is more than 3, the performance decreases, because the larger emotion scope is set, the larger search space is. As such, we choose $l = 3$ in our final model since it gives the best performance in our experiments.

3.4 Runtime Analysis

Theoretically, our proposed model always labels the input texts from left to right with linear time complexity, but all the previous end-to-end model is $O(n^2)$ time complexity. Nevertheless, we still perform a further experiment to confirm this superiority empirically. For simplicity and efficiency, we only conduct runtime analysis between **LMB** and ours, since **LMB** is also based on BERT and is the current state-of-the-art method. Figure 2 shows the running time consumed by models per epoch in different data folds. The results suggest that our model is 36% and 44% faster than **LMB** in training and inference stage respectively, indicating the efficiency of the proposed method.

4 Conclusion

In this paper, we consider the emotion-cause pair extraction as a sequence labeling problem and propose an end-to-end model based on a novel tagging scheme with multiple labels. The proposed model is capable of integrating the emotion-cause structure into a unified framework, so that emotions with the related causes can be extracted simultaneously. Moreover, the proposed model parses the input texts in order from left to right, greatly reducing the search space, leading to a speed up. Experimental results demonstrate the effectiveness and robustness of the proposed method on a benchmark dataset. In the future, we will explore the extension of this approach to achieve full coverage.

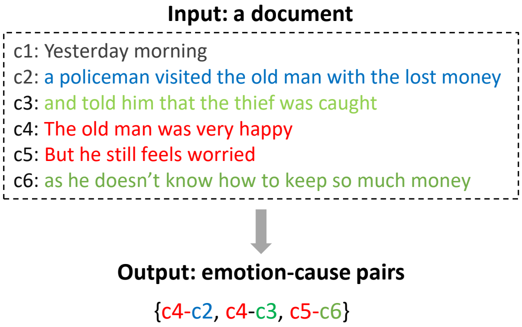
Abstract

Emotion-cause pair extraction (ECPE) is a new task that aims to extract the potential pairs of emotions and their corresponding causes in a document. The existing methods first perform emotion extraction and cause extraction independently, and then perform emotion-cause pairing and filtering. However, the above methods ignore the fact that the cause and the emotion it triggers are inseparable, and the extraction of the cause without specifying the emotion is pathological, which greatly limits the performance of the above methods in the first step. To tackle these shortcomings, we propose two joint frameworks for ECPE: 1) multi-label learning for the extraction of the cause clauses corresponding to the specified emotion clause (CMLL) and 2) multi-label learning for the extraction of the emotion clauses corresponding to the specified cause clause (EMLL). The window of multi-label learning is centered on the specified emotion clause or cause clause and slides as their positions move. Finally, CMLL and EMLL are integrated to obtain the final result. We evaluate our model on a benchmark emotion cause corpus, the results show that our approach achieves the best performance among all compared systems on the ECPE task.

1 Introduction

With the rapid growth of social media, emotion analysis of online text has received much attention in recent years. Unlike most studies that focused on the detection and classification of emotions, (Lee et al., 2010) first proposed the emotion cause extraction (ECE) task, which aims to extract the stimulus behind emotions. (Gui et al., 2016a) released a public corpus and defined the ECE task as a fine-grained emotion analysis task, where the goal is to judge for each clause in the document whether it is the corresponding cause, given the annotation of emotions. This corpus has received a lot of attention in subsequent research and has become a benchmark dataset for the ECE task (Gui et al., 2017; Li et al., 2018; Yu et al., 2019; Xu et al., 2019; Ding et al., 2019; Xia et al., 2019). However, there are several inherent shortcomings in the setting of the ECE task: firstly, the need for emotion annotation greatly limits the practical applications of the ECE task; secondly, the way of annotating emotions before extracting causes ignores the fact that emotions and causes are mutually indicative. To solve these problems, we have proposed the emotion-cause pair extraction (ECPE) task in (Xia and Ding, 2019), with the goal to extract the potential pairs of emotions and corresponding causes in the document.



Input: a document

c1: Yesterday morning
c2: a policeman visited the old man with the lost money
c3: and told him that the thief was caught
c4: The old man was very happy
c5: But he still feels worried
c6: as he doesn't know how to keep so much money

Output: emotion-cause pairs

{c4-c2, c4-c3, c5-c6}

Figure 1: An example showing the emotion-cause pair extraction (ECPE) task.

Figure 1 shows an example of the ECPE task. The input is a document, which has been split into six clauses. Clauses c4 and c5 are both emotion clauses, which contain the emotion expression "happy" and "worried", respectively. C4 has two corresponding cause clauses: clause c2 ("a policeman visited the old man with the lost money") and clause c3 ("and told him that the thief was caught"). C5 has one corresponding cause clause c6 ("as he doesnt know how to keep so much money"). The

November 16–20, 2020.

output is a set of all emotion-cause pairs in the document: {c4-c2, c4-c3, c5-c6}.

The existing ECPE solutions use a two-step framework. Step1 independently extracts the emotion clause set and the cause clause set in the document. Step2 first applies a Cartesian product to the two sets to obtain candidate emotion-cause pairs, and then train a binary classifier to determine whether each candidate pair contains a causal relationship. However, the above methods ignore the fact that the cause and the emotion it triggers are inseparable, and the extraction of the cause without specifying the emotion is pathological, which greatly limits the performance of the above methods in the first step.

In this paper, we transform the ECPE task into the emotion-pivot cause extraction problem in the sliding window. Specifically, we assume that all clauses in the document are emotion clauses and introduce an emotion-oriented sliding window centered on each emotion clause in the document. Then we use a multi-label learning framework inside each sliding window to extract one or more cause clauses that can be paired with the current emotion clause (CMLL). Taking Figure 1 as an example, the clauses c1, c2, $\cdots$, c6 are respectively used as the centers of the emotion-oriented sliding windows, and multi-label learning is performed in each window to extract the corresponding cause clauses: the results for clause c1,c2,c3, and c6 are empty; the result for clause c4 is {c2, c3}; and the result for clause c5 is {c6}. These emotion clauses are then paired with their corresponding cause clauses to get the final emotion-cause pair set: {c4-c2, c4-c3, c5-c6}.

On the other hand, we can also transform the ECPE task into the cause-pivot emotion extraction problem in the sliding window by building a cause-oriented sliding window centered on each cause clause in the document. Then we use a multi-label learning framework inside each sliding window to extract one or more emotion clauses that can be paired with the current cause clause (EMLL).

The above two methods are dual, that is, when we perform emotion-cause pair extraction, we can use emotion clauses as the pivot to extract the corresponding cause clauses, and we can also use the cause clauses as the pivot to extract the corresponding emotion clauses. We get the final emotion-cause pairs based on the combination of these two predictions.

We evaluate our model on a benchmark emotion cause corpus, the results show that our approach achieves the best performance among all compared systems on the ECPE task.

2 Related Work

(Lee et al., 2010) first proposed the emotion cause extraction (ECE) task to extract the causes behind a given emotion expression in text. They constructed a small-scale dataset and proposed a rule-based ECE solution. Based on the same corpus, (Chen et al., 2010) proposed a multi-label approach, which can not only detect the multi-clause causes, but also capture the long-distance information. After that, many follow-up work conducted ECE exploration on their own corpus and proposed new ECE solutions based on rules (Neviarouskaya and Aono, 2013; Li and Xu, 2014; Gao et al., 2015a,b; Yada et al., 2017), traditional machine learning methods (Russo et al., 2011; Gui et al., 2014; Ghazi et al., 2015; Song and Meng, 2015), and deep learning models (Cheng et al., 2017).

(Gui et al., 2016a,b; Xu et al., 2017) constructed an open ECE dataset based on Sina City News, and redefined the ECE task as a clause level binary classification problem. They proposed to solve the ECE task by event-driven emotion cause extraction methods. In recent years, this dataset has received more and more attention and has become a benchmark dataset for ECE, and many deep learning solutions based on this corpus have been proposed in the follow-up researches (Gui et al., 2017; Li et al., 2018; Yu et al., 2019; Xu et al., 2019; Ding et al., 2019; Xia et al., 2019).

The traditional ECE tasks have several inherent shortcomings. First, the need for emotion annotations limits its practical applications. Second, annotating emotions before extracting causes ignores the mutual indication of emotions and causes. To solve these shortcomings, we proposed the emotion-cause pair extraction (ECPE) task in (Xia and Ding, 2019), with the aim to extract all pairs of emotion clauses and corresponding cause clauses in the document. We have further proposed a two-step framework to solve this new task: the first step extracts independent sets of emotion clauses and cause clauses, the second step uses the Cartesian product to obtain candidate emotion-cause pairs and introduces a binary classifier to filter out pairs that do not contain causality.

However, the above method does not directly

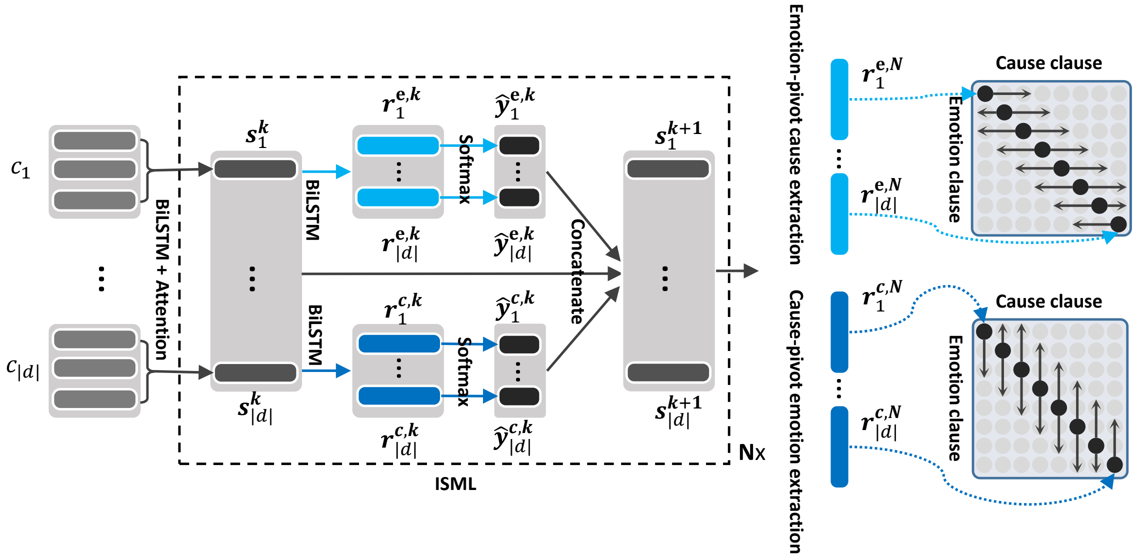

Figure 2: Overview of the ECPE-MLL model.

model the extraction of emotion-cause pairs, and the mistakes made in the first step will propagate to the second step. To deal with these problems, we have proposed an end-to-end approach which extracts emotion-cause pairs through 2D representation, interaction, and prediction (Ding et al., 2020). (Fan et al., 2020) proposed a transition-based model to transform the ECPE task into a procedure of parsing-like directed graph construction. (Wei et al., 2020) designed a joint neural approach which models the inter-clause relations with graph attention and tackles emotion-cause pair extraction from a ranking perspective. In contrast, in this paper, we propose a joint framework to solve the ECPE task by sliding window multi-label learning.

It should be noted that (Chen et al., 2018) also identifies emotions and causes together, while the task of this paper is different from ours. The main difference is that their task is a joint task of emotion cause extraction and emotion classification (rather than emotion expression extraction), which is based strictly on the condition that the emotion expressions should be annotated in advance. While ours performs automatic extractions of emotion expressions and causes, as well as their pairs.

3 Approach

3.1 Task Definition

Before describing our method, we first give the formal definition of the emotion-cause pair extraction (ECPE) task. The input is a document containing multiple clauses $d = [c_1, c_2, \cdots, c_{|d|}]$, the goal of ECPE is to extract a set of emotion-cause pairs in d:

$$P = \{\cdots, c^{\mathrm{e}}\text{-}c^{\mathrm{c}}, \cdots\}, \tag{1}$$

where c^{e} is an emotion clause and c^{c} is the corresponding cause clause.

3.2 Emotion-pivot Cause Extraction

We propose to solve the ECPE task by a sliding window multi-label learning scheme (ECPE-MLL), as shown in Figure 2. First, we assume that all clauses in the document are emotion clauses, and build an emotion-oriented sliding window centered on each emotion clause. Then, in each window, we use the emotion clause as the pivot to extract the corresponding one or more cause clauses based on multi-label learning (CMLL). As the example mentioned in section 1, the results of multi-label learning can be naturally transformed into emotion-cause pairs. Finally, by processing multiple sliding windows, we can get the emotion-cause pairs in the entire document.

3.2.1 Emotion-oriented Sliding Window Encoding

The purpose of emotion-oriented sliding window encoding is to obtain emotion-specific clause representations, which are used as features for emotion-pivot cause extraction. Specifically, we introduce the emotion extraction and cause extraction subtasks, and propose the iterative synchronized multi-task learning (ISML) model to solve these two subtasks.

The input is a document contains multiple clauses: $d = [c_1, c_2, \cdots, c_{|d|}]$, and each clause also contains multiple words $c_i = [w_{i,1}, w_{i,2}, ..., w_{i,|c_i|}]$. We use a hierarchical network with two layers to encode the document. The lower layer uses a BiLSTM to encode each clause c_i in the document independently and obtains the clause representation $\mathbf{s}_i$ by attention mechanism.

The upper layer is composed of a module that can be iterated multiple times. We abbreviate the model in which the upper layer is iterated N times as ISML-N. In each iteration of the upper layer, we introduce two components for emotion extraction and cause extraction, and obtain the prediction results of the two subtasks respectively. The predictions of subtasks in the current iteration will assist in the prediction of subtasks in subsequent iterations to achieve deep interactions between emotions and causes.

Specifically, in the k-th iteration of the upper layer, both components for emotion extraction and cause extraction take the clause representation $(\mathbf{s}_1^k, \mathbf{s}_2^k, \cdots, \mathbf{s}_{|d|}^k)$ as input (in particular, $\mathbf{s}_i^k = \mathbf{s}_i$ when $k = 1$), and use two clause level Bi-LSTM to obtain the emotion-specific representation $\mathbf{r}_i^{\mathrm{e},k}$ and cause-specific representation $\mathbf{r}_i^{\mathrm{c},k}$ for each clause c_i, respectively. The emotion distribution $\mathbf{y}_i^{\mathrm{e},k}$ and cause distribution $\mathbf{y}_i^{\mathrm{c},k}$ of the clause c_i are predicted as follows:

$$\hat{\mathbf{y}}_i^{\mathrm{e},k} = \mathrm{softmax}(\mathbf{W}^{\mathrm{e}}\mathbf{r}_i^{\mathrm{e},k} + \mathbf{b}^{\mathrm{e}}), \tag{2}$$

$$\hat{\mathbf{y}}_i^{\mathrm{c},k} = \mathrm{softmax}(\mathbf{W}^{\mathrm{c}}\mathbf{r}_i^{\mathrm{c},k} + \mathbf{b}^{\mathrm{c}}). \tag{3}$$

Finally, we can get the input for the next iteration $(\mathbf{s}_1^{k+1}, \mathbf{s}_2^{k+1}, \cdots, \mathbf{s}_{|d|}^{k+1})$, where

$$\mathbf{s}_i^{k+1} = \mathbf{s}_i^k \oplus \hat{\mathbf{y}}_i^{\mathrm{e},k} \oplus \hat{\mathbf{y}}_i^{\mathrm{c},k}. \tag{4}$$

It should be noted that we introduce the supervision of emotion extraction and cause extraction for each iteration. Therefore, the total loss of the ISML model for a document d is the sum of the losses of N iterations:

$$L^{\text{ISML-}N} = \sum_{t=1}^{N} L_t, \tag{5}$$

$$L_t = -\sum_{i=1}^{|d|} \mathbf{y}_i^{\mathrm{e}} \cdot \log(\hat{\mathbf{y}}_i^{\mathrm{e},t}) - \sum_{i=1}^{|d|} \mathbf{y}_i^{\mathrm{c}} \cdot \log(\hat{\mathbf{y}}_i^{\mathrm{c},t}), \tag{6}$$

where $\mathbf{y}_i^{\mathrm{e}}$ and $\mathbf{y}_i^{\mathrm{c}}$ are emotion and cause annotation of clause c_i, respectively.

3.2.2 Emotion-pivot Cause Extraction based on Multi-label learning

Formally, we assume c_i is an emotion clause, and introduce a multi-label classifier to judge whether the clauses $c_{i-|w|}, \cdots, c_{i-1}, c_i, c_{i+1}, \cdots, c_{i+|w|}$ are corresponding cause clauses. The dimension of multi-label is $(|w| * 2 + 1)$, where $|w|$ is the size of window, which indicates the farthest distance between current emotion clause and the candidate cause clauses. Therefore, the multi-label cause annotation of each clause c_i can be represented as a $(|w| * 2 + 1)$ dimensional vector: $\mathbf{y}_i^{\mathrm{cml}} = [y_i^{\mathrm{cml}_{-|w|}}, \cdots, y_i^{\mathrm{cml}_0}, \cdots, y_i^{\mathrm{cml}_{|w|}}]$, where $y_i^{\mathrm{cml}_j} = 1$ if c_i-c_{i+j} is annotated as an emotion-cause pair, and $y_i^{\mathrm{cml}_j} = 0$ otherwise.

In order to implement multi-label classification of $(|w| * 2 + 1)$ candidate cause clauses for emotion clause c_i, we use emotion specific clause representation $\mathbf{r}_i^{\mathrm{e},N}$ as the feature and introduce $(|w| * 2 + 1)$ logistic functions to predict a probability $\{p(y_i^{\mathrm{cml}_j} = 1|c_i), j = -|w|, \cdots, 0, \cdots, |w|\}$ for each candidate cause clause:

$$p(y_i^{\mathrm{cml}_j} = 1|c_i) = \hat{y}_i^{\mathrm{cml}_j} = \frac{1}{1 + e^{\mathbf{W}^{\mathrm{cml}_j}\mathbf{r}_i^{\mathrm{e},N} + \mathbf{b}^{\mathrm{cml}_j}}}, \tag{7}$$

$$p(y_i^{\mathrm{cml}_j} = 0|c_i) = 1 - \hat{y}_i^{\mathrm{cml}_j}, \tag{8}$$

where $\mathbf{W}^{\mathrm{cml}_j}$ and $\mathbf{b}^{\mathrm{cml}_j}$ are the parameters for logistic regression. It should be noted that c_i-c_{i+j} is predicted as an emotion-cause pair only when $\hat{y}_i^{\mathrm{cml}_j} > 0.5$. For a given document d, the loss of CMLL is defined as the following joint binary cross entropy loss:

$$L^{\mathrm{CMLL}} = -\textstyle\sum_{i=1}^{|d|}\sum_{j=-|w|}^{|w|}(y_i^{\mathrm{cml}_j} \cdot \log\hat{y}_i^{\mathrm{cml}_j} + (1 - y_i^{\mathrm{cml}_j}) \cdot \log(1 - \hat{y}_i^{\mathrm{cml}_j})). \tag{9}$$

3.3 Cause-pivot Emotion Extraction

Dual with the method proposed in section 3.2, we can also transform the ECPE task into the cause-pivot emotion extraction problem in the sliding window. Specifically, we assume that all clauses in the document are cause clauses, and build a cause-oriented sliding window centered on each cause clause. Then, in each window, we use the cause clause as a pivot to extract the corresponding one or more emotion clauses based on multi-label learning (EMLL).

Formally, we assume c_i is a cause clause, and introduce a multi-label classifier to judge whether the clauses $c_{i-|w|}, \cdots, c_{i-1}, c_i, c_{i+1}, \cdots, c_{i+|w|}$ are corresponding emotion clauses. The dimension of multi-label is $(|w| * 2 + 1)$. Therefore, the multi-label emotion annotation of each clause c_i can be represented as a $(|w| * 2 + 1)$ dimensional vector: $\mathbf{y}_i^{\mathrm{eml}} = [y_i^{\mathrm{eml}_{-|w|}}, \cdots, y_i^{\mathrm{eml}_0}, \cdots, y_i^{\mathrm{eml}_{|w|}}]$, where $y_i^{\mathrm{eml}_j} = 1$ if c_{i+j}-c_i is annotated as an emotion-cause pair, and $y_i^{\mathrm{eml}_j} = 0$ otherwise.

The process of multi-label classification for the EMLL model is similar as CMLL. We use cause specific clause representation $\mathbf{r}_i^{\mathrm{c},N}$ obtained in section 3.2.1 as the feature and introduce $(|w| * 2 + 1)$ logistic functions to predict a probability $\hat{y}_i^{\mathrm{eml}_j} = \{p(y_i^{\mathrm{eml}_j} = 1|c_i), j = -|w|, \cdots, 0, \cdots, |w|\}$ for each candidate emotion clause. And c_{i+j}-c_i is predicted as an emotion-cause pair only when $\hat{y}_i^{\mathrm{eml}_j} > 0.5$. For a given document d, the loss of EMLL is defined as the following joint binary cross entropy loss:

$$L^{\mathrm{EMLL}} = -\sum_{i=1}^{|d|}\sum_{j=-|w|}^{|w|}(y_i^{\mathrm{eml}_j} \cdot \log\hat{y}_i^{\mathrm{eml}_j} + (1 - y_i^{\mathrm{eml}_j}) \cdot \log(1 - \hat{y}_i^{\mathrm{eml}_j})). \tag{10}$$

3.4 Dual Emotion-Cause Pair Extraction

For a candidate emotion-cause pair c_p-c_q, where $p, q \in \{1, \cdots, |d|\}, p - q \in [-|w|, |w|]$, both CMLL and EMLL predict a probability of whether c_p-c_q is a valid emotion-cause pair: $\hat{y}_p^{\mathrm{cml}_{q-p}}$ and $\hat{y}_q^{\mathrm{eml}_{p-q}}$. We adopt three strategies to integrate these two predictions:

- Average probability. c_p-c_q is predicted as an emotion-cause pair only when $(\hat{y}_p^{\mathrm{cml}_{q-p}} + \hat{y}_q^{\mathrm{eml}_{p-q}})/2 > 0.5$.
- Logical AND. c_p-c_q is predicted as an emotion-cause pair only when $\hat{y}_p^{\mathrm{cml}_{q-p}} > 0.5$ AND $\hat{y}_q^{\mathrm{eml}_{p-q}} > 0.5$.
- Logical OR. c_p-c_q is predicted as an emotion-cause pair only when $\hat{y}_p^{\mathrm{cml}_{q-p}} > 0.5$ OR $\hat{y}_q^{\mathrm{eml}_{p-q}} > 0.5$.

The final loss of our model for a document d is a weighted sum of L^{ISML}, L^{CMLL} and L^{EMLL} with L2-regularization term as follows:

$$L = \lambda_1 L^{\mathrm{ISML}\text{-}N} + \lambda_2 L^{\mathrm{CMLL}} + \lambda_3 L^{\mathrm{EMLL}} + \lambda_4 ||\theta||^2, \tag{11}$$

where $\lambda_1, \lambda_2, \lambda_3, \lambda_4 \in (0, 1)$ are weights, θ denotes all the parameters in this model.

The performances using different integration methods are given in the experiment section.

4 Experiments

4.1 Dataset and Metrics

We conducted experiments on the data set provided by (Xia and Ding, 2019) to verify the effectiveness of our model. For fair comparisons with (Xia and Ding, 2019), we use the same ratio to split the data that 90% are randomly selected for training and the remaining are used for testing. Similarly, we repeat the experiments 20 times and report the average result.

We use the precision, recall, and F1 score defined in (Xia and Ding, 2019) as evaluation metrics for the ECPE task as well as two sub-tasks: emotion extraction and cause extraction.

4.2 Experimental Settings

We use the same word embeddings as (Xia and Ding, 2019). The dimension of word embedding is set to 200. The number of hidden units in BiLSTM for all our models is set to 100. The size of the window in the multi-label learning is set to 3.

In the training phase, we use stochastic gradient descent (SGD) algorithm and Adam optimizer. The batch size and learning rate are set to 32 and 0.005, respectively. The weights $\lambda_1, \lambda_2, \lambda_3$ in formula 11 are all set to 1. For regularization, we apply dropout to word embeddings and perform L2 constraints over the softmax parameters. The dropout rate and L2-norm regularization are set to 0.5 and 1e-5, respectively. The code has been made publicly available on Github[1].

4.3 Overall Performance

Table 1 shows the experimental results of our models and baseline methods on the ECPE task as well as two subtasks (emotion extraction and cause extraction).

ECPE-2Steps refers to the two-step framework proposed in our previous work (Xia and Ding, 2019), which first performs individual emotion extraction and cause extraction via multi-task learning, and then conducts emotion-cause pairing and filtering. Specifically, there are three kinds of multi-task learning settings: Indep, Inter-CE, and Inter-EC. Indep perform emotion extraction and cause

Table 1: Performance of our models and baseline models (Xia and Ding 2019) using precision, recall, and F1-measure as metrics on the ECPE task as well as the two sub-tasks.

extraction independently. While Inter-CE/Inter-EC uses the predictions of cause/emotion extraction to improve emotion/cause extraction.

ECPE-MLL is a joint framework proposed in this paper, which re-formalizes the ECPE task as a multi-label learning problem. In order to obtain emotion specific and cause specific clause representations for multi-label classification, we explored four multi-task learning settings. In addition to the ISML model proposed in this paper, we also explored the Indep, Inter-CE, and Inter-EC model. It should be noted that the results of our models on the ECPE task are based on Logical OR integration of EMLL and CMLL, as it performs best in all integration methods.

In order to simplify the description, we abbreviate the ECPE-2Steps and ECPE-MLL methods based on different settings as 2Steps-* and MLL-*. Among the previous methods, 2Steps-Indep is a baseline model and performs the worst on the ECPE task. 2Steps-Inter-EC uses the prediction of emotion extraction to enhance cause extraction, which improves the performance of cause extraction and ECPE tasks, and becomes the state-of-the-art model.

Compared to 2Steps-Inter-EC, our model MLL-ISML-6 has achieved substantial improvements on the ECPE, emotion extraction and cause extraction tasks (F1 scores have increased by 6.12%, 2.7%, and 4.43% on these three tasks, respectively), which proves the effectiveness of our method as a whole. We will discuss the effects of each part of our model in sections 4.4, 4.5, and 4.6.

4.4 ECPE-MLL vs. ECPE-2Steps

In order to verify the advantages of our proposed joint model ECPE-MLL compared to the ECPE-2Steps model, we discard the ISML module and use Indep, Inter-CE, and Inter-EC for emotion/cause encoding. The experimental results are shown in Table 1.

On the ECPE task, compared with the 2Steps-* models using the same emotion/cause encoding settings, our proposed MLL-* models achieve large improvements in the recall rate (Specifically, the recall rates of MLL-Indep, MLL-Inter-CE, and MLL-Inter-EC are 11.78%, 9.13%, and 5.52% higher than 2Steps-Indep, 2Steps-Inter-CE, and 2Steps-Inter-EC, respectively), which further lead to a significant increase in F1 score. This indicates that our methods can extract more emotion-cause pairs than the previous methods.

In the emotion extraction and cause extraction subtasks, the MLL-Indep, MLL-Inter-CE and MLL-Inter-EC methods are also better than 2Steps-Indep, 2Steps-Inter-CE, and 2Steps-Inter-EC respectively. We attribute these improvements to multi-task learning, as we additionally introduced two multi-label learning tasks for emotion-cause pair extraction.

The above results show that compared with the two-step framework, our proposed multi-label learning framework for emotion-cause extraction has great advantages and potential.

4.5 The Effectiveness of Iterative Synchronized Multi-task Learning

Table 1 shows the performance of the MLL-ISML-N model with different number of iterations. It should be noted that the MLL-ISML-1 model and the MLL-Indep model are equivalent, so we do not repeat its results in the table.

The MLL-ISML-1 model does not model the correlation between emotion and cause, so its perfor-

Approach	CMLL			EMLL

Table 2: Performance of the CMLL, EMLL models and their integrated predictions on the ECPE task.

mance on the three tasks is the worst compared to other MLL-* models. As the number of iterations increases, the performance of the MLL-ISML-N model on all three tasks is generally getting better, especially when the number of iterations is increased from 1 to 2. One possible reason is that MLL-ISML-2 first introduced the interaction between emotion and cause. When the number of iterations is increased to 6, MLL-ISML-N achieves optimal performance on all three tasks.

In addition, MLL-ISML-2 achieves better performance than MLL-Inter-CE on the emotion extraction task, and better performance than MLL-Inter-EC on the cause extraction task, which shows that the single use of emotion extraction to help cause extraction and the use of cause extraction to help emotion extraction are not as effective as using them simultaneously.

The above results show that compared with the Inter-EC and Inter-CE models, our proposed ISML model can better utilize the interaction between emotion and cause, and significantly improve the performance of ECPE-MLL on three tasks.

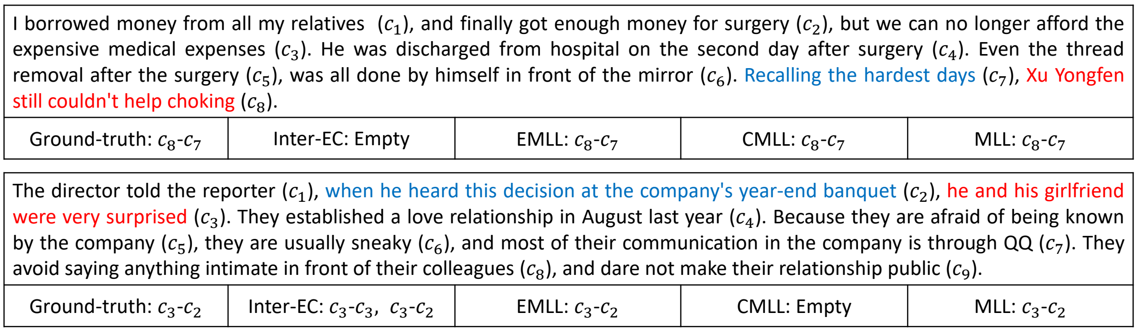
4.6 The Effectiveness of CMLL, EMLL, and Integrated Prediction

Table 2 shows the performance of the CMLL, EMLL models and their integrated predictions on the ECPE task using different emotion/cause encoding settings. For simplicity, we refer to these models based on different settings as CMLL-*, EMLL-*, AP-*, LAND-*, and LOR-*, for example, EMLL-Indep and LOR-Indep.

First of all, it can be seen that without integrated prediction, CMLL-* and EMLL-* alone can already perform very well. When under the same emotion/cause encoding setting, EMLL-* can obtain better performance in F1 score than CMLL-* in most cases. An interesting result is that CMLL-Inter-CE performs far better than CMLL-Inter-EC, and EMLL-Inter-EC performs far better than EMLL-Inter-CE. One possible explanation is that better emotion specific clause representation contributes to the performance of CMLL-*, better cause specific clause representation is beneficial to the performance of EMLL-*.

We now use CMLL-* and EMLL-* as the baselines and explore the effects of different integration methods under the same emotion/cause encoding setting.

- Average Probability. AP-* does not perform significantly better or worse than CMLL-* and EMLL-*.
- Logical AND. The recall rate and F1 score of LAND-* are lower than CMLL-* and EMLL-*, but the precision is higher than them.
- Logical OR. The recall rate of LOR-* is higher than that of CMLL-* and EMLL-*, but the precision score is lower than them. On the whole, the F1 score of LOR-* is mostly higher than CMLL-* and EMLL-*.



I borrowed money from all my relatives (c_1), and finally got enough money for surgery (c_2), but we can no longer afford the expensive medical expenses (c_3). He was discharged from hospital on the second day after surgery (c_4). Even the thread removal after the surgery (c_5), was all done by himself in front of the mirror (c_6). Recalling the hardest days (c_7), Xu Yongfen still couldn't help choking (c_8).				
Ground-truth: c_8-c_7	Inter-EC: Empty	EMLL: c_8-c_7	CMLL: c_8-c_7	MLL: c_8-c_7

The director told the reporter (c_1), when he heard this decision at the company's year-end banquet (c_2), he and his girlfriend were very surprised (c_3). They established a love relationship in August last year (c_4). Because they are afraid of being known by the company (c_5), they are usually sneaky (c_6), and most of their communication in the company is through QQ (c_7). They avoid saying anything intimate in front of their colleagues (c_8), and dare not make their relationship public (c_9).				
Ground-truth: c_3-c_2	Inter-EC: c_3-c_3, c_3-c_2	EMLL: c_3-c_2	CMLL: Empty	MLL: c_3-c_2

Figure 3: Case study between Inter-EC and our models.

Approach	Emotion-Cause Pair Ext.		
	P	R	$F1$
MLL-Indep-AS	0.6762	0.6288	0.6505
MLL-Inter-CE-AS	0.6733	0.6374	0.6538
MLL-Inter-EC-AS	0.6755	0.6374	0.6540
MLL-ISML-6-AS	0.6800	0.6388	0.6578

Table 3: Performance of our models on the ECPE task when auxiliary supervisions of emotion extraction and cause extraction are removed.

The above results show that, compared to EMLL-* and CMLL-* alone, LOR-* is a better choice when we need a model with a higher recall rate and F1 score. When we need a model with a higher precision score, then LAND-* is a better choice.

4.7 The Effectiveness of Auxiliary Supervision

We explored the effectiveness of auxiliary supervisions of emotion extraction and cause extraction by removing them from our models. For simplicity, we refer to the model without auxiliary supervisions as '*-AS'. The results are shown in Table 3 (based on Logical OR integration method).

For the MLL-(Indep/Inter-CE/Inter-EC) models, removing the auxiliary supervisions did not lead to a decrease in their performance on the ECPE task, but resulted in a consistent improvement (though not much). These results indicate that our joint models do not rely on independent emotion and cause extraction. However, for the MLL-ISML-6 model, its performance is significantly reduced when the auxiliary supervisions are removed. This is intuitive because the ISML model cannot work normally without auxiliary supervisions. Nevertheless, it still outperforms MLL-Indep-AS.

4.8 Case Analysis

Figure 3 shows the advantages of our models (all using ISML-6 settings) over the Inter-EC (using 2 step framework) model through two examples in the test set. In the first example, the Inter-EC model failed to extract the emotion-cause pair c_8-c_7. In contrast, our EMLL and CMLL models successfully identified this pair. We found this situation is quite common in the test set, which ultimately leads to a significant increase in the recall rate of our model compared to Inter-EC.

In the second example, Inter-EC extracted two emotion-cause pairs: c_3-c_3 and c_3-c_2, where the latter is correct and the former is wrong. By observing the results of the first step in Inter-EC, we found that c_3 is predicted to be an emotion clause, c_2 and c_3 are predicted to be cause clauses. The filter ultimately failed to eliminate the invalid pair c_3-c_3. In contrast, our models are more "cautious", EMLL did not output other pairs after predicting the correct one, CMLL did not even output any pairs. The MLL model uses the union of the output of EMLL and CMLL to identify as many emotion-cause pairs as possible. These situations make our models have higher precision performance than the Inter-EC model, and make the MLL model more robust than EMLL and CMLL models.

5 Conclusion

The emotion-cause pair extraction (ECPE) task is a new direction in emotion analysis. To overcome the shortcomings of the existing two-step approach, we propose a sliding window multi-label learning scheme. Specifically, we assume that all clauses in the document are emotion clauses, and build an emotion-oriented sliding window centered on each of them. Then, in each window, we use the emotion clause as a pivot to extract the corresponding one or more cause clauses based on multi-label learning (CMLL). At the same time, we propose the dual form of CMLL, i.e., EMLL, which uses the cause clauses as the pivot to extract the corresponding emotion clauses. The final predictions are obtained by integrating the results of CMLL and EMLL. We evaluated our model on a benchmark emotion cause dataset, and the experimental results show that our method has achieved a substantial improvement over the state-of-the-art method.

A Experimental Results with BERT

We explored the effect of using pre-trained BERT (Devlin et al., 2019) as the clause encoder in ECPE-MLL. The results are shown in Table 4.

Specifically, we follow (Liu and Lapata, 2019) to feed the entire document into pre-trained BERT. Each clause in the document is expanded to start with the word “[CLS]” and end with the word “[SEP]”. We also assign interval segment embeddings E_A or E_B to each clause c_i depending on whether i is odd or even. The input representation of each word is the sum of three parts: word embedding, position embedding, and segment embedding. The representations of all clauses in the document can be obtained by gathering the representations of all corresponding “[CLS]” tokens. After that, we use two clause level transformers to obtain the emotion-specific representation and cause-specific representation for each clause, respectively.

Approach	Emotion Ext.		
	P	R	$F1$
ECPE-MLL	0.8582	0.8429	0.8500
ECPE-MLL(BERT)	0.8608	0.9191	0.8886

Approach	Cause Ext.		
	P	R	$F1$
ECPE-MLL	0.7248	0.6702	0.6950
ECPE-MLL(BERT)	0.7382	0.7912	0.7630

Approach	Emotion-Cause Pair Ext.		
	P	R	$F1$
ECPE-MLL	0.7090	0.6441	0.6740
ECPE-MLL(BERT)	0.7700	0.7235	0.7452

Table 4: Performance of our models with/without pre-trained BERT encoder on the ECPE task as well as the two sub-tasks.

Our model is built based on this implementation: https://github.com/google-research/bert, and is initialized using the pre-trained BERT model “BERT-Base, Chinese”. We apply the linear warmup and linear decay mechanism to the learning rate. The batch size and initial learning rate are set to 8 and 2e-5, respectively. It should be noted that we use the fixed learning rate 2e-3 for the parameters in the logistic regression layer. Readers can refer to the source code for more implementation details.

The experimental results in Table 4 show that the performance of our model on three tasks can be greatly improved by using BERT as the clause encoder. In particular, the recall rate on the cause extraction subtask has increased by 12%, indicating that the pre-trained language models have great potential in the emotion cause related tasks.

Multi-modal Multi-label Emotion Detection with Modality and Label Dependence

Abstract

As an important research issue in the natural language processing community, multi-label emotion detection has been drawing more and more attention in the last few years. However, almost all existing studies focus on one modality (e.g., textual modality). In this paper, we focus on multi-label emotion detection in a multi-modal scenario. In this scenario, we need to consider both the dependence among different labels (label dependence) and the dependence between each predicting label and different modalities (modality dependence). Particularly, we propose a multi-modal sequence-to-set approach to effectively model both kinds of dependence in multi-modal multi-label emotion detection. The detailed evaluation demonstrates the effectiveness of our approach.

1 Introduction

Emotion detection is to predict emotion categories, such as *angry*, *happy*, and *surprise*, expressed by an utterance of a speaker and has largely encompassed a variety of applications, such as online chatting (Galik and Rank, 2012; Zhang et al., c), news analysis (Li et al., 2015; Zhu et al., 2019) and dialogue systems (Ghosal et al., 2019; Zhang et al., d). Over the last few years, there has been a substantial body of research on emotion detection (Abdul-Mageed and Ungar, 2017; Zhou et al., 2019; Zhang et al., a), where a considerable amount of work has focused on multi-label emotion detection (Li et al., 2015; Yu et al., 2018; Ying et al., 2019).

Basically, emotion detection is a multi-label classification problem since one utterance naturally tends to involve more than one emotion category. However, classifying instances with multiple possible categories is sometimes much more difficult than classifying instances with a single label. One main challenge is how to model the **label dependence** in the classification approach. For example, in the utterance as shown in Figure 1, both the *Sad* and *Disgust* emotions are more likely to exist, rather than the conflicting emotions of *Sad* and *Happy*. Recent studies, such as (Yang et al., 2019) and (Xiao et al., 2019), have begun to address this challenge.

Figure 1: An example of multi-modal instance with multi-label emotion categories in a video segment.

However, almost all existing studies in multi-label emotion detection focus on one modality (e.g., textual modality). Only very recently, the research community has become increasingly aware of the need on multi-modal emotion detection (Zadeh et al., 2018b) due to its wide potential applications, e.g., with the massively growing importance of analyzing conversations in speech (Gu et al., 2019) and video (Majumder et al., 2019). In this study, we aim to tackle multi-modal multi-label emotion detection. Compared with single modality, multi-modal multi-label emotion detection needs to well model the contribution of different modalities for each label since each modality has a different impact on expressing emotion. For example, from the textual modality as shown in Figure 1, while we may only infer the *Sad* emotion, we are more

November 16–20, 2020.

likely to infer the *Disgust* emotion instead from the visual modality. Meanwhile, the acoustic modality may not help label prediction in this case. Therefore, besides the label dependence, it is important and challenging to effectively model another dependence, namely the **modality dependence**.

In this paper, we address the above challenges in multi-modal multi-label emotion detection by proposing a multi-modal seq2set (MMS2S) approach to model both the modality and label dependence simultaneously. Specifically, while the conditional generation framework naturally models the label dependence by predicting the next emotion label upon other potential labels, we propose Multi-head soft modality attention at each predicting step inside the emotion decoder to capture the modality dependence. First, we adopt three single-modal encoders based on Transformer to capture the single-modal characteristics of the textual, visual and acoustic modalities, respectively. Then, we make the given emotion representation attend to three intra-modal sequences from encoders inside the emotion decoder and leverage multi-head soft modality attention to control the different contributions of different modalities for each potential emotion prediction. Finally, we train our proposed model by maximizing the probabilities of top K sequences and predict all potential emotion labels by finding the most likely emotion label set.

Systematical evaluation on a public multi-modal multi-label emotion dataset, i.e., CMU-MOSEI, shows that our approach significantly outperforms several state-of-the-art baselines.

2 Related Work

As an interdisciplinary research field, emotion detection has been drawing more and more attention in both natural language processing and multi-modal communication (Zadeh et al., 2018c). In the NLP community, almost all existing studies of multi-label emotion detection rely on special knowledge of emotion, such as context information (Li et al., 2015), cross-domain transferring (Yu et al., 2018) and external resource (Ying et al., 2019). In fact, when there is no special knowledge (Kim et al., 2018), it can be normally handled by multi-label text classification approaches. In the multi-modal community, related studies normally focus on single-label emotion task and the studies for multi-label emotion task are much less and limited to be transformed to multiple binary classification (Zadeh et al., 2018b; Wang et al., 2019; Akhtar et al., 2019; Chauhan et al., 2019). In the following, we give an overview of multi-label emotion/text classification and multi-modal emotion detection.

Multi-label Emotion/Text Classification. Recent studies normally cast multi-label emotion detection task as a classification problem and leverage the special knowledge as auxiliary information (Yu et al., 2018; Ying et al., 2019). These approaches may not be easily extended to those tasks without external knowledge. At this time, the multi-label text classification approaches can be quickly applied to emotion detection. There have been a large number of representative studies for that. Kant et al. (2018) leverage the pre-trained BERT to perform multi-label emotion task and Kim et al. (2018) propose an attention-based classifier that predicts multiple emotions of a given sentence. More recently, Yang et al. (2018) propose a sequence generation model and Yang et al. (2019) leverage a reinforced approach to find a better sequence than a baseline sequence, but it still relies on the pre-trained seq2seq model with a pre-defined order of ground-truth.

Different from above studies, we focus on multi-label emotion detection in a multi-modal scenario by considering the modality dependence besides the label dependence. To the best of our knowledge, this is the first attempt to perform multi-label emotion detection in a multi-modal scenario.

Multi-modal Emotion Detection. Recent studies on multi-modal emotion detection largely depend on multi-modal fusion framework to perform binary classification within each emotion category. Recently, Wang et al. (2019) introduce a recurrent attended variation embedding network for multi-modal language analysis with non-verbal shifted word representation. Tsai et al. (2019) employ the Transformer-based architecture to capture the long-range interactions inside and across different modalities. However, they still cast the multi-label emotion detection as multiple binary classification problems.

Different from above studies, we focus on multi-modal emotion detection in a multi-label scenario by considering the label dependence besides the modality dependence. To the best of our knowledge, this is the first attempt to perform multi-modal emotion detection in a multi-label scenario.

3 Data Pre-processing

We extract low-level handcrafted features from three modalities. First of all, we align the three modalities by extracting the exact utterance timestamp of each word using P2FA (Yuan and Liberman, 2008). Since words are considered as the basic semantic units of language, we use the interval duration of each word as a time-step. Then, we calculate the expected video and audio features by taking the expectation of their feature values over the word time interval (Zadeh et al., 2018a; Zhang et al., b). On this basis, we process the information of the three modalities as follows.

Textual Modality. The GloVe word embeddings (Pennington et al., 2014) are used to represent the words from manual transcripts. Then, we get the text sequence $X^T = [x_1^T, x_2^T, \cdots, x_m^T]$ with dimension $m \times d^T$.

Visual modality. The library Facet [1] is used to extract a set of visual features including facial action units, facial landmarks, head pose, gaze tracking and HOG features (Zadeh et al., 2018c) to form a sequence of facial gesture throughout time. Then, we get the visual sequence $X^V = [x_1^V, x_2^V, \cdots, x_m^V]$ with dimension $m \times d^V$.

Acoustic Modality. The COVAREP software (Degottex et al., 2014) is used to extract acoustic features including 12 Mel-frequency cepstral coefficients (MFCCs), pitch, voiced/unvoiced segmenting features (Drugman and Alwan, 2011), glottal source parameters (Drugman et al., 2012), peak slope parameters and maxima dispersion quotients (Kane and Gobl, 2013). Then, we get the acoustic sequence $X^A = [x_1^A, x_2^A, \cdots, x_m^A]$ with dimension $m \times d^A$.

4 Multi-modal Seq2Set for Multi-modal Multi-label Emotion Detection

4.1 Problem Description

In this section, we define some notations and describe the multi-modal multi-label emotion detection (MMED) task. Given the label space with L labels $\mathcal{L} = \{l_1, l_2, \cdots, l_L\}$, the textual, visual and acoustic sequences, i.e., X^T, X^V and X^A containing m time steps respectively, the task is to assign a subset $\boldsymbol{y}$ containing L' labels in the label space $\mathcal{L}$, i.e., $\{y_1, y_2, \cdots, y_{L'}\}$. Unlike traditional single-label classification where only one label is assigned to each sample, each sample in the MMED task can have multiple labels. In previous studies (Yang et al., 2018, 2019), from the perspective of sequence generation, the MMED task can be modeled as finding an optimal label sequence $\boldsymbol{y}^*$ that maximizes the conditional probability $p(\boldsymbol{y}^*|X^T, X^V, X^A)$. Although sequence decoding by conditioned on previous steps can effectively capture the dependence among an output sequence, all possible emotion labels of an utterance are a set rather than a fixed sequence. Therefore, we adopt a conditional set generation mechanism, which maximizes the log-likelihood as follows:

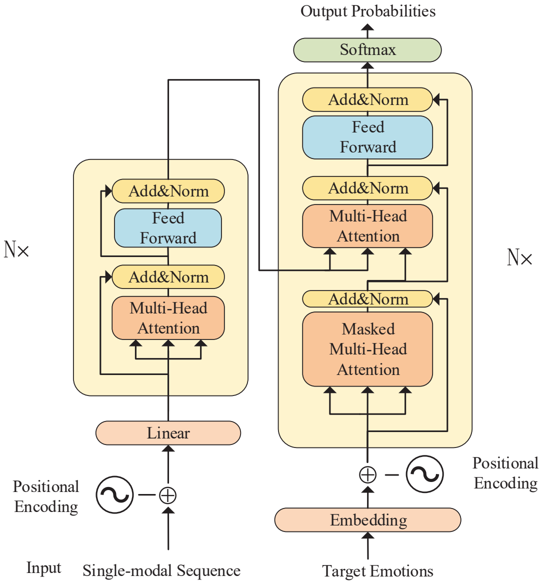

Figure 2: The architecture of a standard Transformer (Vaswani et al., 2017) for sequence to sequence learning.

$$\sum_{i=1}^{Num} log \sum_{\mathrm{s} \in \pi(\boldsymbol{y}^i)} p(\mathrm{s}|(X^T)^i, (X^V)^i, (X^A)^i) \quad (1)$$

where Num denotes the total number of multi-modal samples in the dataset. $\pi(\boldsymbol{y}^i)$ stands for all permutations of the label set $\boldsymbol{y}^i$ of the i-th sample.

4.2 Background

Since our approach is based on Transformer architecture, we give a brief description of a standard Transformer (Vaswani et al., 2017) for seq2seq learning as shown in Figure 2.

The encoder is composed of a stack of N identical layers, each of which has two sub-layers. The first sub-layer is a multi-head self-attention network, and the second one is a position-wise fully connected feed-forward network. A residual connection (He et al., 2016) is employed around each

---

[1] https://imotions.com/emotient/

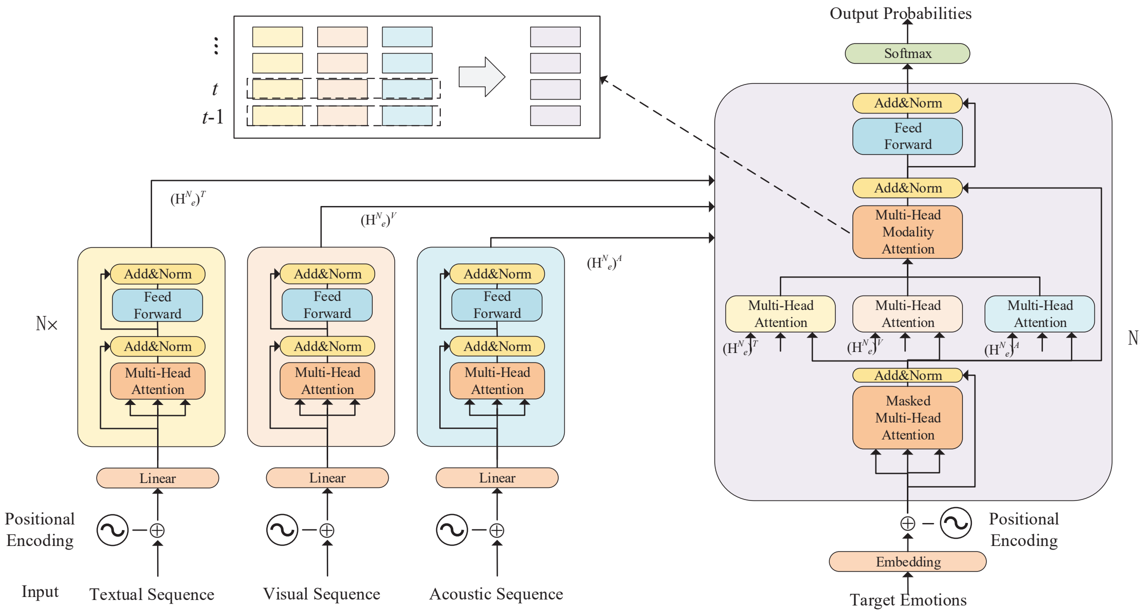

Figure 3: The overview of multi-modal seq2set.

sub-layer, followed by layer normalization (Ba et al., 2016). Formally, the output of the first sub-layer C_e^n and the second sub-layer H_e^n at n-th layer are sequentially calculated as:

$$C_e^n = \mathrm{LN}(\mathrm{SATT}(H_e^{n-1}) + H_e^{n-1}) \quad (2)$$
$$H_e^n = \mathrm{LN}(\mathrm{FFN}(C_e^n) + C_e^n) \quad (3)$$

where $\mathrm{LN}(\cdot)$, $\mathrm{SATT}(\cdot)$, and $\mathrm{FFN}(\cdot)$ are layer normalization, multi-head self-attention mechanism, and feed-forward network with ReLU activation, respectively. The subscript e denotes the encoding part.

The decoder is also composed of a stack of N identical layers. In addition to two sub-layers in each decoder layer, the decoder inserts a third sub-layer D_d^n to perform attention over the output of the encoder H_e^N:

$$C_d^n = \mathrm{LN}(\mathrm{SATT}(H_d^{n-1}) + H_d^{n-1}) \quad (4)$$
$$D_d^n = \mathrm{LN}(\mathrm{ATT}(C_d^n, H_e^N) + C_d^n) \quad (5)$$
$$H_d^n = \mathrm{LN}(\mathrm{FFN}(C_d^n) + C_d^n) \quad (6)$$

where $\mathrm{ATT}(C_d^n, H_e^N)$ denotes attending the top output of encoder H_e^N with C_d^n as query. The subscript d denotes the decoding part. The top layer output of the decoder H_d^N is used to generate the final output sequence.

4.3 Multi-modal Seq2Set Approach

Figure 2 shows the overall architecture of our proposed Multi-Modal Seq2Set (MMS2S) approach. Note that the novel decoding module can well handle the modality and label dependence by soft modality attention and conditional label generation.

Multi-modal Sequences Encoding. We first build three independent Transformer-based encoders to capture the temporal information and self-modal dynamics in each modality. Formally,

$$(H_e^N)^M = \mathrm{Trans}_e^M(X^M) \quad (7)$$

where $M \in \{T, V, A\}$ denotes the symbol of modality. $(H_e^N)^M \in \mathbb{R}^{m \times d_m}$ denotes the final output of the encoder for modality M and Trans_e^M denotes a Transformer-based encoder function for modality M.

From the multi-modal sequences encoding module, we can obtain the feature sequence of each modality: $(H_e^N)^T$, $(H_e^N)^V$ and $(H_e^N)^A$.

Multi-Head Modality Attention. All modality-specific sequences are simultaneously fed into the decoding module. For each decoding step, the decoder attends to the encoding representation of each modality independently. Formally,

$$C_d^n = \mathrm{LN}(\mathrm{SATT}(H_d^{n-1}) + H_d^{n-1}) \quad (8)$$
$$(C_{d\to e}^n)^M = \mathrm{ATT}(C_d^n, (H_e^N)^M) \quad (9)$$

Then, we can obtain three contextual sequences from decoder attending to encoders: $(C_{d\to e}^n)^T$, $(C_{d\to e}^n)^V$ and $(C_{d\to e}^n)^A$. We leverage multi-head modality attention over three sequences to control different contribution of different modalities at each step for feature matrix $(C_{d\to e}^n)_t =$

Algorithm 1 Training Procedure for MMS2S

```
Input: Multi-modal Multi-label Dataset $(X^i, \boldsymbol{y}^i)$, $X^i = ((X^T)^i, (X^V)^i, (X^T)^i)$, $i = 1, 2, \cdots, Num$;
Output: Trained parameters of MMS2S model ;
for each batch do
    for each $(X^i, \boldsymbol{y}^i)$ in a batch do
        Get top $K$ sequences by beam search and their probabilities:
        $\{\mathrm{s}_1^i, \cdots, \mathrm{s}_K^i; p(\mathrm{s}_1^i|X^i), \cdots, p(\mathrm{s}_K^i|X^i)\}$;
    end for
    Update model parameters by maximizing:
    $\sum_{(X^i,\boldsymbol{y}^i)\in batch} log \sum_{\mathrm{s}\in\{\mathrm{s}_1^i,\cdots,\mathrm{s}_K^i\}} p(\mathrm{s}|X^i)$
end for
```

$[(\mathrm{C}^n_{d\to e})^T_t, (\mathrm{C}^n_{d\to e})^V_t, (\mathrm{C}^n_{d\to e})^A_t] \in \mathbb{R}^{3\times d_m}$. Formally,

$$\mathrm{C}_t = \mathrm{SATT}((\mathrm{C}^n_{d\to e})_t) \qquad (10)$$

$$(\mathrm{C}^n_d)'_t = W_s(\mathrm{C}^T_t \oplus \mathrm{C}^V_t \oplus \mathrm{C}^A_t) \qquad (11)$$

where $\mathrm{C}_t = [\mathrm{C}^T_t, \mathrm{C}^V_t, \mathrm{C}^A_t] \in \mathbb{R}^{3\times d_m}$ denotes the temporary multi-modal hybrid representation at t-th step. $(\mathrm{C}^n_d)'_t \in \mathbb{R}^d_m$ denotes the feature vector by soft modality weighting the t-th step. $W_s \in \mathbb{R}^{d_m\times 3d_m}$ is a trainable matrix to scale the dimension of multi-modal hybrid representation. $\oplus$ denotes the concatenating operation.

Subsequently, as the normal propagation, the adaptive contextual sequence is fed into the feed-forward layer,

$$\mathrm{D}^n_d = \mathrm{LN}((\mathrm{C}^n_d)' + \mathrm{C}^n_d) \qquad (12)$$

$$\mathrm{H}^n_d = \mathrm{LN}(\mathrm{FFN}(\mathrm{C}^n_d) + \mathrm{C}^n_d) \qquad (13)$$

Emotion Prediction. Finally, the top output of decoder $\mathrm{Z} = \mathrm{H}^N_d \in \mathbb{R}^{m'\times d_m}$ is used to predict all potential emotions via linear and softmax layer. Formally,

$$p_t = \mathrm{softmax}(\mathrm{Z}_t W_p + I_t) \qquad (14)$$

where $W_p \in \mathbb{R}^{d_m\times L}$, is a trainable weight matrix. $I_t \in \mathbb{R}^L$ is the mask vector that is used to prevent the decoder from predicting repeated labels:

$$(I_t)_k = \begin{cases} -\infty & \text{if label } l_k \text{ has been predicted} \\ 0 & \text{otherwise} \end{cases} \qquad (15)$$

Training by Top K Sequences. We approximate the objective of Eq. 1 by only considering the top K highest probability sequences produced by our model. We leverage a variant of beam search (Qin et al., 2019) for sets with width K. In particular, the search candidates in each step are restricted to only labels in the golden set. This approximates inference procedure is carried out repeatedly before each batch training step to find highest probability sequences for all training instances occurring in that batch. Algorithm 1 shows the detailed procedure.

Algorithm 2 Testing Procedure for MMS2S

```
Input: Multi-modal Instance $X$, $X = (X^T, X^V, X^T)$;
Output: Predicted Emotion Label Set $\hat{\boldsymbol{y}}$;
Obtain $K$ highest probability sequences by beam search: $\{\mathrm{s}_1, \cdots, \mathrm{s}_K\}$;
Map each sequence $\mathrm{s}_k$ to the corresponding set $\boldsymbol{y}_k$ and remove duplicate sets (if any);
for each $\boldsymbol{y}_k$ do
    Get top $K$ sequences associated with $\boldsymbol{y}_k$ and their probabilities by beam search:
    $\{\mathrm{s}'_1, \cdots, \mathrm{s}'_K; p(\mathrm{s}'_1|X), \cdots, p(\mathrm{s}'_K|X)\}$;
    Set probability is approx. by summing up:
    $p(\boldsymbol{y}_k|X) \approx \sum_{\mathrm{s}\in\{\mathrm{s}'_1,\cdots,\mathrm{s}'_K\}} p(\mathrm{s}|X)$;
end for
$\hat{\boldsymbol{y}} = argmax_{\boldsymbol{y}_k} p(\boldsymbol{y}_k|X)$
```

Testing by Most Probable Set. Different from the previous approach of directly using most probable sequence as a set based on a pre-defined baseline (Yang et al., 2019) , we instead aim to find the most likely set, which involves summing up probabilities for all its permutations. Algorithm 2 shows the detailed procedure. Note that both the training and testing procedures allow our model to be far more freedom on label order.

5 Experimentation

In this section, we systematically evaluate our approach to multi-modal multi-label emotion detection.

5.1 Experimental Settings

Dataset. We use the largest available multi-modal emotion benchmark dataset, i.e., CMU-MOSEI (Zadeh et al., 2018b) in our evaluation. The dataset is segmented into utterances with three modalities, i.e., the textual, visual and acoustic modalities, while the emotion categories contain *happiness*, *sadness*, *anger*, *fear*, *disgust* and *surprise*. The average words of utterance-level video clips are

Multi-label	Number	Emotion	Number
None	3372	*Happiness*	12240
One	11050	*Surprise*	1892
Two	5526	*Sadness*	5918
Three	2084	*Anger*	4933
Four	553	*Disgust*	3680
Five	84	*Fear*	2286
Six	8	-	-

Table 1: The statistics on the CMU-MOSEI dataset.

19.1 and the average number of emotion labels per sample is 1.6. The training, validation and test data are all the same with the split videos and utterances available in the public SDK[2]. Table 1 shows the brief statistics of the samples with multiple labels.

Implementation Details. We implement our approach via Pytorch toolkit (torch-0.4.1) with a piece of GTX 1080 Ti. Following (Zadeh et al., 2018b), the textual input dimension d^T is set to 300, the visual input dimension d^V is set to 35 and the acoustic input dimension d^A is set to 74. The hidden size d_m in the encoders and decoder is 512. The number of heads in SATT and ATT is 8.

During training, we train each model for a fixed number of epochs 50 and monitor its performance on the validation set. Once the training is finished, we select the model with the best F_1 score on the validation set as our final model and evaluate its performance on the test set. We adopt cross-entropy as the loss function and use the Adam (Kingma and Ba, 2014) optimization method to minimize the loss over the training data. For the hyper-parameters of the Adam optimizer, we set the learning rate as 0.001 with two momentum parameters of β_1 and β_2, 0.9 and 0.999 respectively. The beam size K is set to be 5 at both training and inference stages. To motivate future research, the code will be released via github [3].

Evaluation Metrics and Significance Test. In our study, we employ three evaluation metrics to measure the performances of different approaches to multi-modal multi-label emotion detection, i.e., multi-label Accuracy (*Acc*), Hamming Loss (*HL*) and micro F_1 measure (F_1). These metrics have been popularly used in some multi-label classification problems (Li et al., 2015; Yang et al., 2019; Aly et al., 2019; Wu et al., 2019).

Note that smaller Hamming Loss corresponds to better classification quality, while larger Accuracy and F_1 measure corresponds to better classification quality. Besides, through scipy[4], the paired t-test is performed to test the significance of the difference between two approaches, with a default significant level of 0.05.

5.2 Baselines

For a thorough comparison, we implement various baseline approaches in three groups:

Multi-label Classification Approaches. In this group, the baselines use different approaches to deal with the multi-label issue without considering the modality dependence issue. Specifically, in these approaches, the multi-modal inputs are early fused (simply concatenated) as a new input. (1) **BR**[5] (Shen et al., 2004), which transforms the multi-label task into multiple single-label binary classification problems by ignoring the correlations between labels. (2) **CC**[5] (Read et al., 2011), which transforms the multi-label task into a chain of binary classification problems and takes high-order label correlations into consideration. (3) **RAkEL**[5] (Tsoumakas et al., 2011), which improves the Label Powerset (Tsoumakas and Katakis, 2007) with breaking the initial set of labels into a number of small random subsets and training a corresponding classifier. (4) **AC**[6] (Kim et al., 2018), which consists of a self-attention module and multiple CNNs enabling it to imitate human's two-step procedure of analyzing emotions from sentences: comprehend and classify. (5) **LSAN**[7] (Xiao et al., 2019), which takes advantage of label semantic information to determine the semantic connection between labels and document for constructing label-specific document representation. This approach is considered as the state-of-the-art in multi-label text classification. (6) **DRS2S**[8] (Yang et al., 2019), which leverages deep reinforcement learning to find a most probable sequence as the target label set based on a pre-trained sequence-to-sequence model of RNN. This approach is also considered as the state-of-the-art in multi-label text classification.

Multi-modal Classification Approaches. In this group, the baselines use different approaches to deal with the multi-modal issue without considering the label dependence issue. Specifically, in these approaches, a linear layer of L dimensions

with $sigmoid$ activation is used to predict the emotions. (7) **GMFN**[2] (Zadeh et al., 2018b), which explicitly models the multi-modal interactions by capturing uni-modal, bi-modal and tri-modal interactions. (8) **RAVEN**[9] (Wang et al., 2019), which models the fine-grained structure of nonverbal subword sequences and dynamically shifts word representations based on nonverbal cues. This approach is considered as the state-of-the-art in multi-modal language analysis. (9) **MulT**[10] (Tsai et al., 2019), which addresses long-range dependencies between elements across modalities in an end-to-end manner. This approach is considered as the state-of-the-art in multi-modal emotion detection.

Ablated Approaches. (10) **MMS2S w/o M**, a variation of our approach, which replaces the multi-head modality attention with simply concatenation. (11) **MMS2S w/o L**, a variation of our approach, which replaces the decoder with $sigmoid$ activation for L dimension.

5.3 Experimental Results

Comparison with the multi-modal and multi-label classification approaches. Table 2 shows the results of different approaches to multi-modal multi-label emotion detection. From this table, we can see that (1) the classical multi-label approaches **BR**, **CC** and **RAkLA** perform much worse than the deep learning baselines **AC**, **LSAN** and **DRS2S**. For instance, **DRS2S** outperforms **RAkLA** by 19.4%, 16.1% and 12.6% with respect to *Acc*, *HL* and F_1, respectively. This indicates that the approaches with deep representation do have more advantages than the classical approaches towards multi-label problem. (2) The baselines of multi-modal classification outperform the baselines of text-based multi-label classification in most cases. Especially, **MulT** performs much better than **LSAN** and **DRS2S** in terms of all metrics. This is mainly due to the fact that multi-modal data need to well model the intra-modal and inter-modal dynamics and the early fusion approaches inevitably result in performance loss. (3) Among all the approaches, our proposed **MMS2S** performs best in terms of all metrics. The t-test demonstrates that our approach significantly outperforms **LSAN**, **DRS2S**, , **and MulT**, respectively (p-value < 0.05).

Ablation Study. To further demonstrate the importance of modeling modality and label dependence, we do not model either the modality (**MMS2S w/o M**) or the label dependence (**MMS2S w/o L**). From Table 2, we observe that not modeling either the modality or the label dependency significantly decreases the performance. This illustrates the effectiveness of our approach in modeling the two types of dependence.

5.4 Analysis

Impact of random label order. We investigate the impact of random label order as ground-truth for our proposed **MMS2S** and a previous text-based seq2set approach **DRS2S** (Yang et al., 2019) as shown in Table 3. We can observe that **DRS2S** largely depends on the pre-defined knowledge of label order (such as descending order of label frequency). While, our approach performs well with random label order as ground-truth, suggesting that our approach indeed generates an adaptive emotion label set rather than a sequence for each sample.

Single-modal approach vs. multi-modal approach. To illustrate the necessity of multi-modal approach for multi-label emotion detection, we also evaluate single-modal approach via sequence-to-set training and testing, namely **SMS2S**, which aims at modeling a single modality while ignoring the other two. Table 4 compares the performance of SMS2S and MMS2S approaches. From this ta-

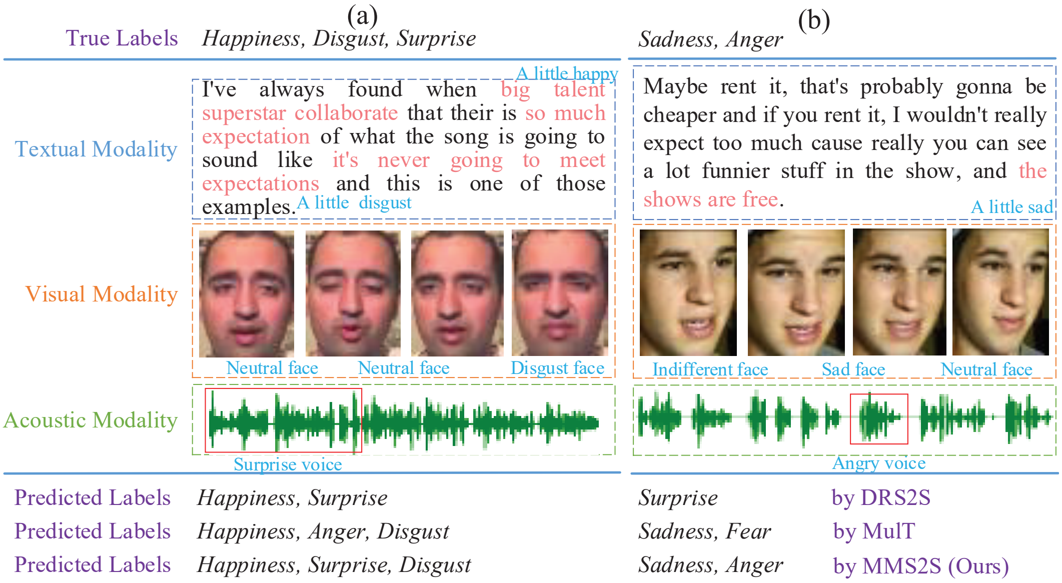
---

[9] https://github.com/victorywys/RAVEN

[10] https://github.com/yaohungt/Multimodal-Transformer

Approach	Modality	*Accuracy*	*Hamming Loss*	F_1 *measure*	*Precision*	*Recall*
SMS2S	Text	0.438	0.216	0.492	0.561	0.438
	Vision	0.396	0.221	0.440	0.505	0.390
	Audio	0.395	0.219	0.451	0.552	0.381
MMS2S	Text&Vision&Audio	**0.475**	**0.182**	**0.560**	**0.576**	**0.545**

Table 4: Performance of single-modal and multi-modal seq2set approaches.



I've always found when big talent superstar collaborate that their is so much expectation of what the song is going to sound like it's never going to meet expectations and this is one of those examples.

Maybe rent it, that's probably gonna be cheaper and if you rent it, I wouldn't really expect too much cause really you can see a lot funnier stuff in the show, and the shows are free.

Figure 4: Two cases of the predicted labels by **DRS2S**, **MulT** and **MMS2S**.

ble, we observe that **SMS2S** with textual modality outperforms the counterparts with the other two modalities, suggesting that the textual modality contains more useful information than the others. Moreover, our **MMS2S** achieves the highest performance, suggesting that both the visual and the acoustic modalities could be useful complement to the textual modality. This is consistent with our motivation that different modality plays different roles in emotion expressing.

Case Study. To further demonstrate the effectiveness of our multi-modal seq2set approach, Figure 4 presents two examples with predicted emotions by **MMS2S**, and two representative baselines **DRS2S** and **MulT**. We take the case (a) as an example: although **DRS2S** can accurately detect two emotions of the ground-truth, it leaves the *Disgust* emotion. This is mainly because early fusion without modality dependence results in different modalities information confusion so that it may be difficult for **DRS2S** to infer all the correct emotions. In contrast, **MulT** can detect the *Disgust* emotion and obtain three emotions. But it gives a wrong prediction of *Anger*. Obviously, *Happiness* and *Anger* are conflicting emotions. This indicates that **MulT** completely ignores the label dependence. However, from both cases, we observe that our **MMS2S** can obtain all correct emotions by properly modeling modality dependence and label dependence.

6 Conclusion

In this paper, we propose a multi-modal sequence-to-set approach to simultaneously handle the modality and label dependence in multi-modal multi-label emotion detection. Our approach can not only model the dependence between each label and different modalities, but also model the dependence among multiple labels of a sample. The detailed evaluation demonstrates that our proposed model significantly outperforms several state-of-the-art baselines.

In our future work, we will extend our approach to more multi-modal multi-label scenarios, such as intention detection in video conversations and aspect analysis in multi-modal reviews. Furthermore, we would like to investigate other approaches (e.g., graph-based neural network) to better model the modality and label dependence in multi-modal multi-label emotion detection.

Abstract

Aspect-based sentiment analysis (ABSA) aims to predict the sentiment towards a specific aspect in the text. However, existing ABSA test sets cannot be used to probe whether a model can distinguish the sentiment of the target aspect from the non-target aspects. To solve this problem, we develop a simple but effective approach to enrich ABSA test sets. Specifically, we generate new examples to disentangle the confounding sentiments of the non-target aspects from the target aspect's sentiment. Based on the SemEval 2014 dataset, we construct the Aspect Robustness Test Set (ARTS) as a comprehensive probe of the aspect robustness of ABSA models. Over 92% data of ARTS show high fluency and desired sentiment on all aspects by human evaluation. Using ARTS, we analyze the robustness of nine ABSA models, and observe, surprisingly, that their accuracy drops by up to 69.73%. We explore several ways to improve aspect robustness, and find that adversarial training can improve models' performance on ARTS by up to 32.85%.[1]

1 Introduction

Aspect-based sentiment analysis (ABSA) is an advanced sentiment analysis task that aims to classify the sentiment towards a specific aspect (e.g., *burgers* or *fries* in the review "Tasty *burgers*, and crispy *fries*."). The key to a strong ABSA model is it is sensitive to *only* the sentiment words of the target aspect, and therefore not be interfered by the sentiment of any non-target aspect. Although state-of-the-art models have shown high accuracy on existing test sets, we still question their robustness. Specifically, given the *prerequisite* that a model outputs correct sentiment polarity for the test example, we have the following questions:

(Q1) If we reverse the sentiment polarity of the target aspect, can the model change its prediction accordingly?

(Q2) If the sentiments of all non-target aspects become opposite to the target one, can the model still make the correct prediction?

(Q3) If we add more non-target aspects with sentiments opposite to the target one, can the model still make the correct prediction?

A robust ABSA model should both meet the prerequisite and have affirmative answers to all the questions above. For example, if a model makes the correct sentiment classification (i.e., positive) for *burgers* in the original sentence "Tasty *burgers*, and crispy fries", it should flip its prediction (to negative) when seeing the new context "Terrible *burgers*, but crispy fries". Hence, these questions together form a probe to verify if an ABSA model has high ***aspect robustness***.

Unfortunately, existing ABSA datasets have very limited capability to probe the *aspect robustness*. For example, the Twitter dataset (Dong et al., 2014) has only one aspect per sentence, so the model does not need to discriminate against non-target aspects. In the most widely used SemEval 2014 Laptop and Restaurant datasets (Pontiki et al., 2014), for 83.9% and 79.6% instances in the test sets, the sentiments of the target aspect, and all non-target aspects are all the same. Hence, we cannot decide whether models that make correct classifications attend only to the target aspect, because they may also wrongly look at the non-target aspects, which are *confounding factors*. Only a small portion of the test set can be used to answer our target questions proposed in the beginning. Moreover, when we test on the subset of the test set (59 instances in Laptop, and 122 instances in Restaurant) where the target aspect sentiment differs from all non-target aspect sentiments (so that the confounding

SubQ.	Generation Strategy	Example
Prereq.	**Source**: The original sample from the test set	Tasty **burgers**, and crispy fries. (Tgt: burgers)
Q1	**RevTgt**: Reverse the sentiment of the *target* aspect	Terrible **burgers**, but crispy fries.
Q2	**RevNon**: Reverse the sentiment of the *non-target* aspects with originally the same sentiment as target	Tasty **burgers**, but soggy fries.
Q3	**AddDiff**: Add aspects with the *opposite* sentiment from the target aspect	Tasty **burgers**, crispy fries, but poorest service ever!

Table 1: The generation strategies and examples of the prerequisite (Prereq) and three questions (Q1)-(Q3). Each example are annotated with the **target aspect (Tgt)**, and altered sentence parts.

factor is disentangled), the best model (Xu et al., 2019a) drops from 78.53% to 59.32% on Laptop and from 86.70% to 63.93% on Restaurant. This implies that the success of previous models may over-rely on the confounding non-target aspects, but not necessarily on the target aspect only. However, *no* datasets can be used to analyze the aspect robustness more in depth.

We develop an automatic generation framework that takes as input the original test instances from SemEval 2014, and applies three generation strategies showed in Table 1. New test instances generated by RevTgt, RevNon, and AddDiff can be used to answer the questions (Q1)-(Q3), respectively. The generated new instances largely overlap with the content and aspect terms of the original instances, but manage to disentangle the confounding sentiment polarity of non-target aspects from the target, as showed in the examples in Table 1. In this way, we produce an “all-rounded” test set that can test whether a model robustly captures the target sentiment instead of other irrelevant clues.

We enriched the laptop dataset by 294% from 638 to 1,877 instances and the restaurant dataset by 315% from 1,120 to 3,530 instances. By human evaluation, more than 92% of the new aspect robustness test set (ARTS) shows high fluency, and desired sentiment on all aspects. Our ARTS test set is in line with other recent works on NLP challenge sets (McCoy et al., 2019; Gardner et al., 2020). Using our new test set, we analyze the aspect robustness of nine existing models. Experiment results show that their performance degrades by up to 55.64% on Laptop and 69.73% on Restaurant. We also use our generation strategy to conduct adversarial training and find it improves aspect robustness by at least 11.87% and at most 35.37% across various models.

The contributions of our paper are as follows:

1. We develop simple but effective automatic generation methods that generate new test instances (with over 92% accuracy by human evaluation) to challenge the aspect robustness.
2. We construct ARTS, a new test set targeting at aspect robustness for ABSA models, and propose a new metric, Aspect Robustness Score.
3. We probe the aspect robustness of nine models, and reveal up to 69.73% performance drop on ARTS compared with the original test set.
4. We provide several solutions to enhance aspect robustness for ABSA models, including adversarial training detailed in Section 5.4.

2 Data Generation

As shown in Table 1, we aim to build a systematic method to generate all possible aspect-related alternations, in order to remove the confounding factors in the existing ABSA data. In the following, we will introduce three different ways to disentangle the sentiment of the target aspect from sentiments of non-target aspects.

2.1 RevTgt

The first strategy is to generate sentences that reverse the original sentiment of the target aspect. The word spans of each aspect's sentiment of SemEval 2014 data are provided by (Fan et al., 2019a). We design two methods to reverse the sentiment, and one additional step of conjunction adjustment on top of the two methods to polish the resulting sentence.

Strategy	Example
Flip Opinion	It's **light** and **easy** to transport. → It's **heavy** and **difficult** to transport.
Add Negation	The menu **changes** seasonally. → The menu **does not change** seasonally.
Adjust Conjunctions	The food is good, **and** the decor is **nice**. → The food is good, **but** the decor is **nasty**.

Table 2: Three strategies and examples of RevTgt.

Strategy	Example
Original sentence & sentiment	It has great food and a reasonable price, but the service is poor. **(Tgt) food:+** **price:+** **service:−** **overall:○**
RevNon	
Flip same-sentiment non-target aspects (and adjust conjunctions)	It has great food **but** an **unreasonable** price, **and** the service is poor.
Exaggerate opposite-sentiment non-target aspects	It has great food **but** an **unreasonable** price, **and** the service is **extremely** poor. **(Tgt) food:+** **price:−** **service:−−** **overall:−**

Table 3: The generation process of RevNon. The target aspect (Tgt), and sentiments of all aspects are annotated.

Flip Opinion Words Suppose we have the sentence "*Tasty* **burgers** and crispy fries," where the sentiment term for the target aspect is *Tasty*. We aim to generate a new sentence that flips the sentiment *Tasty*. A baseline approach is antonym replacement by looking up WordNet (Miller, 1995). However, due to polysemy, the simple lookup is very likely to derive an inappropriate antonym and cause incompatibility with the context. Among the retrieved set of antonyms, we only keep words with the same Part-of-Speech (POS) tag as original, using the stanza package[2] which takes the context into account by the state-of-the-art neural network-based model.[3] Lastly, in the case of multiple antonyms, we prioritize the words that are already in the existing vocabulary, and then randomly select an antonym from the candidate set.

Add Negation As the above strategy of flipping by the antonym is constrained by whether appropriate antonyms are available. For those cases without suitable antonyms, including long phrases, we add negation according to the linguistic features. In most cases, the sentiment expression is an adjective or verb term, so we simply add negation (i.e., "not") in front of it. If the sentiment term is not an adjective or verb, we add negation to its closest verb. For example, in Table 2, there are no available antonyms for "change" in the original example "The menu **changes** seasonally.", so we simply negate it as "The menu **does not change** seasonally."

Adjust Conjunctions As pinpointed in Section 1, 79.6∼83.9% of the original test data of SemEval 2014 (Pontiki et al., 2014) have the same sentiment for all aspects. A possible result of reverting one aspect's sentiment is that the other aspects' sentiments will be opposite to the altered one. So we need to adjust the conjunctions for language fluency. If the two closest surrounding sentiments of a conjunction word have the same polarity, then cumulative conjunctions such as "and" should be applied; otherwise, we should adopt adversative conjunctions such as "but." In the example in Table 2, after flipping the sentiment, we derive the example "The food is good, **and** the decor is nasty" which is very unnatural, so we replace the conjunction "and" with "but," and thus generate the example "The food is good, **but** the decor is nasty."

2.2 RevNon

Changing the target sentiment by RevTgt can test if a model is sensitive enough towards the target-aspect sentiment, but we need to further complement this probe by perturbing the sentiments of the non-target aspects (RevNon). As showed in Table 3, for all the non-target aspects with the same sentiment as the target aspect's, we reverse their sentiments using the same method as RevTgt. And for all the remaining non-target aspects, whose sentiments are already opposite from the target sentiment, we exaggerate the extent by randomly adding an adverb (e.g., "very", "really" and "extremely") from a dictionary of adverbs of degree that is collected based on the training set. The resulting test example will be a solid proof of the ABSA quality, because only the target aspect has the desired sentiment, and all non-target aspects have been flipped to or exaggerated with the opposite sentiment.

2.3 AddDiff

The first two strategies, RevTgt and RevNon, have explored how the sentiment changes of existing aspects will challenge an ABSA model, and AddDiff further investigate if adding more non-target aspects can confuse the model. Moreover, the existing SemEval 2014 test sets have only on average 2 aspects per sentence, but the real-world applications can have more aspects. With these

---

[2] `https://stanfordnlp.github.io/stanza/`

[3] For the candidate filter, we do not use GPT-2 perplexity because its low accuracy, e.g., 38.4% on a random sample set. And its output is also less interprettable than the POS filter.

motivations, we develop AddDiff as follows.

We first form a set of aspect expressions AspectSet[4] by extracting all aspect expressions from the entire dataset. Specifically, for each example in the dataset, we first identify each sentiment term (e.g., "reasonable" in "Food at a reasonable price") and then extract its linguistic branch as the aspect expression (e.g., "at a reasonable price") by pretrained constituency parsing (Joshi et al., 2018). Table 4 shows several examples of AspectSet in the restaurant domain.

Sentiment	Aspect Expression
Positive	staff is *friendly* and *knowledgeable*
	desserts are *out of this world*
	texture is a *velvety*
Negative	service is *severely slow*
	dining experience is *miserable*
	tables are *uncomfortably close*

Table 4: Example aspect expressions from AspectSet of the restaurant domain.

Using the AspectSet, we randomly sample 1-3 aspects that are not mentioned in the original test sample and whose sentiments are different from the target aspect's, and then append these to the end of the original example. For example, "Great food and best of all GREAT beer!" $\xrightarrow{\text{AddDiff}}$ "Great food and best of all GREAT beer, *but management is less than accommodating, music is too heavy, and service is severely slow*." In this way, AddDiff enables the advanced testing of whether the model will be confused when there are more irrelevant aspects with opposite sentiments.

3 ARTS Dataset

3.1 Overview

Our source data is the most[5] widely used ABSA dataset, SemEval 2014 Laptop and Restaurant Reviews (Pontiki et al., 2014).[6] We follow (Wang et al., 2016; Ma et al., 2017; Xu et al., 2019a) to remove instances with conflicting polarity and only keep positive, negative, and neutral labels. We use the train-dev split as in (Xu et al., 2019a). The resulting Laptop dataset has 2,163 training, 150 validation, and 638 test instances, and Restaurant has 3,452 training, 150 validation, and 1,120 test instances.

Building upon the original SemEval 2014 data, we generate enriched test sets of 1,877 instances (294% of the original size) in the laptop domain, and 3,530 instances (315%) in the restaurant domain using generation method introduced in Section 2. The statistics of our ARTS test set are in Table 5. (A more detailed explanations of the number of instances generated by each strategy is in Appendix A.1.)

	Laptop	Restaurant
Original Test Set	638	1,120
Enriched Test Set	1,877	3,530
Relative Size	294.20%	315.17%
	Fluency Check	
Accepted Instances	1,732	3,260
Fixed Instances	145	270
Acceptance Rate	92.27%	92.35 %
Inter-Agreement	91.10%	92.69%
	Sentiment Check	
Accepted Instances	1,763	3,362
Fixed Instances	114	168
Acceptance Rate	93.93%	95.24%
Inter-Agreement	94.14%	95.61%

Table 5: Overall statistics of the ARTS test set and results of fluency and sentiment checks.

3.2 Quality Inspection

We conduct human evaluation to validate the generation quality of our ARTS dataset on two criteria:

1. **Fluency**: Does the generated sentence maintain the fluency of the source sentence?
2. **Sentiment Correctness**: Does the sentiment of each aspect have the desired polarity?

- RevTgt: Is the target sentiment reversed?
- RevNon: For non-target aspects with originally the same sentiment as the target, is it reversed? For the rest, are they exaggerated?
- AddDiff: Is the target sentiment unchanged?

Each task is completed by two native-speaker judges. We first calculate the inter-agreement rate of the human annotators, and then resolve the divergent opinions on samples that they disagree with. We accept the samples that both judges considered as correct or are resolved to be correct after our check. Finally, we ask the annotators to fix the rejected samples by minimal edit which does not

---

[4] The full AspectSet is available on our GitHub.

[5] We surveyed deep learning-based ABSA papers from 2015 to 2020 at top conferences (ACL, EMNLP, NAACL, NeurIPS, ICLR, ICML, AAAI, IJCAI). Among the 63 ABSA papers, 50 use SemEval 2014 Laptop and Restaurant, which is the top 1 widely used dataset.

[6] `http://alt.qcri.org/semeval2014/task4/`

change the aspect term or the sentence meaning, but satisfies both criteria.

Fluency Check The evaluation results on fluency are showed in Table 5. Most samples (92.27% of Laptop and 92.35% of Restaurant test sets) are accepted as fluent text. The inter-agreement rate between the two human judges is also high, 91.10% and 92.69% on the two datasets.

Sentiment Check We also evaluate the sentiment correctness of the generated text. Note that for REVNON, we count the samples with all "yes" answers as accepted samples. Overall, the acceptance rate of the generated samples is 93.93% on Laptop and 95.24% on Restaurant, along with inter-agreement rates of over 94.14% on both datasets.

3.3 Dataset Analysis

After checking the quality of our enriched ARTS test set, we analyze the dataset characteristics and make comparisons with the original test sets.

	Laptop		**Restaurant**	
	Ori	ARTS	Ori	ARTS
#Words/Sent	18.56	22.27	19.37	23.15
Vocab Size	1565	1746	2197	2451
Labels				
Positive	341	883	728	1953
Negative	128	587	196	1104
Neutral	169	407	196	473
#Positive/#Negative	2.66	1.5	3.71	1.77
Aspect-Related Challenge				
#Aspects/Sent	2.05	2.75	2.57	3.28
Opp. Nontgt ≥ 1	16%	59%	20%	67%
Opp. Nontgt = All	9%	38%	11%	42%
#Opp. Nontgt/Sent	0.23	1.16	0.27	1.39

Table 6: Characteristics of the ARTS test sets in comparison to the Original ("Ori") Laptop and Restaurant test sets.

For *general statistics*, we can see from Table 6 that the sentence length in the new test set is on average 4 words more than the original, and the vocabulary size is also larger by around two hundred. *For the label distribution*, we can see that the new test set has an increasing number of all labels, and especially balances the ratio of positive-to-negative labels from the original 2.66 to 1.5 on Laptop, and from 3.71 to 1.77 on Restaurant.

For the *aspect-related challenge* in the test set, the new test set, first of all, has a larger number of aspects per sentence than the original. Our test set also features the higher disentanglement of the target aspect from the non-target aspects that have the same sentiment as the target: the portion of samples with at least one non-target aspects of sentiments different from the target is 59∼67%, and on average 45% higher than the original test sets. And the portion of the most challenging samples where all non-target aspects have sentiments different from the target one on the new test set is on average 30% more than that of the original test set. The average number of non-target aspects with opposite sentiments per sample in the new test set is on average 5 times that of the original set.

3.4 Aspect Robustness Score (ARS)

As mentioned in Section 1, a model is considered to have high aspect robustness if it satisfies both the prerequisite and all three questions (Q1)-(Q3). So we propose a novel metric, Aspect Robustness Score (ARS), that counts the correct classification of the source example and all its variations (REVTGT, REVNON, and ADDDIFF) as one unit of correctness. Then we apply the standard calculation of accuracy. Note that the three variations correspond to questions (Q1)-(Q3), respectively.

4 Evaluating ABSA Models

We use our enriched test set as a comprehensive test on the aspect robustness of ABSA models.

4.1 Models

For a comprehensive overview of the ABSA field, we conduct extensive experiments on models with a variety of neural network architectures.

TD-LSTM: (Tang et al., 2016a) uses two Long Short-Term Memory Networks (LSTM) to encode the preceding and following contexts of the target aspect (inclusive) and concatenate the last hidden states of the two LSTMs to make the sentiment classification.

AttLSTM: Wang et al. (2016) apply an Attention-based LSTM on the concatenatation of the aspect and word embeddings of each token.

GatedCNN: Xue and Li (2018) use a Gated Convolutional Neural Networks (CNN) that applies a Tanh-ReLU gating mechanism to the CNN-encoded text with aspect embeddings.

MemNet: Tang et al. (2016b) use memory networks to store the sentence as external memory and calculate the attention with the target aspect.

GCN: Aspect-specific Graph Convolutional Networks (GCN) (Zhang et al., 2019a) first applies

GCN over the syntax tree of the sentence and then imposes an aspect-specific masking layer on its top.

BERT: Xu et al. (2019a) uses a BERT-based baseline (Devlin et al., 2019) and takes as input the concatenation of the aspect term and the sentence.

BERT-PT: Xu et al. (2019a) post-train BERT on other review datasets such as Amazon laptop reviews (He and McAuley, 2016) and Yelp Dataset Challenge reviews, and finetune on ABSA tasks.

CapsBERT: (Jiang et al., 2019) encode the sentence and the aspect term with BERT, and then feed it into Capsule Networks to predict the polarity.

BERT-Sent: For more in-depth analysis, we also implement a sentence classification baseline. BERT-Sent takes as input sentences without aspect information, and predicts the "global" sentiment. We use it because if other ABSA models fails to pay attention to aspects, they will degenerate to a sentence classifier. If so, they will resemble BERT-Sent, which performs well on original tests and badly on ARTS. So BERT-Sent is a reference to check degenerated aspect-level models.

4.2 Implementation Details

For all existing models, we use the authors' official implementation. For our self-proposed BERT-Sent, we use Adam optimizer with a learning rate of 5e-5, weight decay of 0.01, and batch size of 32. We apply the l_2 regularization with $\lambda = 10^{-4}$, and train 50 epochs. Note that the tokenization of the ASTS dataset is the same as the original SemEval 2014, as we prepared the new test set by inverting the NLTK tokenization rules we used when applying the generation strategies.[7]

4.3 Results on ARTS

We list the accuracy[8] of the nine models on the Laptop and Restaurant test sets in Table 7. For *Entire Test-New* in Table 7, accuracy is calculated using ARS. Supplementary to ARS, Table 7 also decomposes ARS into single-strategy scores (the right three columns) by splitting the entire ARTS test set into three subsets according to the corresponding data generation techniques. Each of the single-strategy scores explains from one perspective the reason for large performance drop in ARS, which will be elaborated later.

Overall Performance On the entire test set, we can see that the accuracy of all models on the original test set is very high, achieving up to 78.53% on Laptop and 86.70% on Restaurant, but it drops drastically ($\downarrow$69%$\sim\downarrow$25%) on our new test sets.

Performance of Different Models From the overall performance on our new test set, we can see that BERT models on average are more robust to the aspect-targeted challenges that our new test set poses. The most effective model BERT-PT scores the best on both original accuracy and robustness. It has 53.29% ARS on Laptop and 59.29% on Restaurant. However, the accuracy of non-BERT models on average drops drastically to under 30% by over $\downarrow$50%.

Performance on Different Subsets We list in detail the performance of each model on the three subsets of our new test set: REVTGT, REVNON, and ADDDIFF. They correspond to the three questions (Q1)-(Q3). REVTGT on average induces the most performance drop, as it requires the model to pay precise attention to the target sentiment words. REVNON makes the performance of the sentence classifier BERT-Sent drops the most by up to $\downarrow$45.93%, and the model CapsBERT also drops by up to $\downarrow$39.26%. The last subset ADDDIFF causes most non-BERT models to drop significantly, indicating that these models are not robust enough against an increased number of non-target aspects, which should have been irrelevant.

Laptop vs. Restaurant The performance drop on Restaurant is higher than that on Laptop. There are two possible reasons: (1) the original performance on restaurant is higher, and (2) the new test set is more challenging in the Restaurant domain. We verify this by calculating the relative drop ($\frac{\text{new}-\text{old}}{\text{old}}$) in addition to the reported absolute values of the change. The relative drop on Laptop is 64.76%, which is higher than 60.36% on Restaurant. For the laptop dataset, both the lower original performance and the larger relative decrease of performance might be due to the nature of the dataset. For example, Laptop restaurant has far fewer training data than Restaurant, which makes the models less accurate originally and weaker on ARTS.

5 Analysis

5.1 Variations of Generation Strategies

Combining Multiple Strategies Each sample in the ARTS test set is generated by one of the three

---

[7] We used the metanl package to detokenize: `https://github.com/commonsense/metanl`.

[8] For ABSA, accuracy is the standard metric to be reported (Wang et al., 2016; Xue and Li, 2018; Tang et al., 2016b).

[9] CapsBERT hand-crafted the Capsule Guided Routing specifically for the restaurant domain, so it fails significantly.

Table 7: Model accuracy on Laptop and Restaurant data. We compare the accuracy on the **Ori**ginal and our **New** test sets (*Ori* → *New*), and calculate the *change* of accuracy. Besides the Entire Test Set, we also list accuracy on subsets where the generation strategies RevTgt, RevNon and AddDiff can be applied. The accuracy of *Entire Test-New* is calculated using ARS. $\star$ indicates whether the performance drop is statistically significant (with p-value ≤ 0.05 by Welch's t-test).

strategies. However, it is also worth exploring whether combining several strategies can make a more challenging probe on the aspect robustness of ABSA models. As a case study, we analyze the model robustness against test samples generated by the combination of RevNon+AddDiff. By comparing the performance decrease caused by RevNon+AddDiff in Table 8 and by only RevNon and AddDiff in Table 7, we can see that the accuracy of each model decreases by a much larger extent on RevNon+AddDiff than either of RevNon and AddDiff. The performance drop by the RevNon+AddDiff subset is almost the sum of RevNon and AddDiff in most cases, and sometimes larger than the sum, for example, in the case of BERT-PT on Laptop where the sum of the performance drop by the two separate strategies 9.63%+2.82% is smaller than the combined strategy's 14.81%.

Model	Laptop	Restaurant
	Ori → New (Change)	Ori → New (Change)
MemNet	82.22 → 72.59 (↓09.63)	84.46 → 50.90 (↓33.56)*
GatedCNN	84.44 → 59.26 (↓25.18)*	87.84 → 53.83 (↓34.01)*
AttLSTM	85.93 → 51.85 (↓34.08)*	86.26 → 38.06 (↓48.20)*
TD-LSTM	83.70 → 68.89 (↓14.81)*	88.51 → 65.99 (↓22.52)*

BERT-PT	93.33 → 78.52 (↓14.81)*	92.57 → 78.60 (↓13.97)*
Average	87.57 → 55.14 (↓32.43) *	88.96 → 57.26 (↓31.70)*

Table 8: The accuracy of each model on the original test set and the new test set generated by RevNon+AddDiff in laptop and restaurant domains.

AddDiff with More Aspects Some strategies such as AddDiff can be parameterized by k, where k is the number of additional non-target aspects to be added. We select three models (the best, the worst, and an average-performing one), and plot their accuracy on test samples generated by AddDiff(k) on Laptop in Figure 1. As k gets larger, the test samples become more difficult. The sentence classification baseline BERT-Sent drops drastically, BERT-PT remains high, and GCN lies in the middle.

5.2 How to Effectively Model the Aspect?

An important usage of our ARTS is to understand what model components are key to aspect robustness. We list the aspect-specific mechanisms of all models according to the ascending order of their ARS on Laptop dataset in Table 9. We can see that for BERT-based models, BERT-PT, which is further trained on large review corpora, gets the best accuracy and aspect robustness. More complicated structures like CapsBERT underperforms the basic BERT by 25.08%.

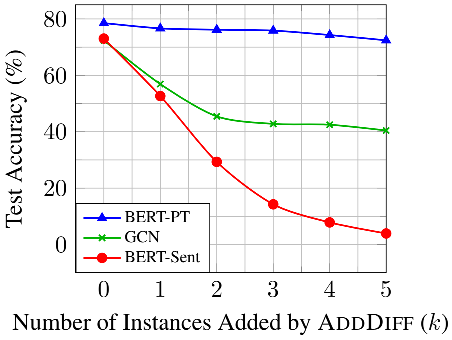

Figure 1: Accuracy of BERT-PT, GCN, and BERT-Sent on the test samples in the laptop domain generated by ADDDIFF(k) where k varies from 1 to 5.

Model	ARS	Asp+W Emb	Posi-Aware	Asp Att
AttLSTM	9.87	✓	✗	✓
GatedCNN	10.34	✓	✗	✓
MemNet	16.93	✗	✗	✓
GCN	19.91	✗	✓	✓
TD-LSTM	22.57	✗	✓	✗
CapsBERT	25.86	✗	✗	✓
BERT	50.94	✗	✗	✗
BERT-PT	53.29	✗	✗	✗

Table 9: Models in the ascending order of their ARS on Laptop. We list their aspect-specific mechanisms, including concatenating the aspect and word embeddings (Asp+W Emb), position-aware mechanism for aspects (Posi-Aware), and attention using the aspect (Asp Att). We highlight ✓ for Posi-Aware as it is the most related to aspect robustness for non-BERT models.

Among the non-BERT models, the aspect position-aware models TD-LSTM and GCN are the most robust, as they have a stronger sense of the location of the target aspect in a sentence. On the contrary, the other models with poorer robustness (9.87%∼16.93% in Table 9) only use mechanisms such as aspect-based attention, or concatenating the aspect embedding to the word embedding.

To summarize, the main takeaways are

- For BERT models, additional pretraining is the most effective.
- For non-BERT models, explicit position-aware designs lead to more aspect robustness.

5.3 Does a More Diverse Training Set Help?

A recent dataset, Multi-Aspect Multi-Sentiment (MAMS) (Jiang et al., 2019), is collected from the same data source as the SemEval 2014 Restaurant dataset (Ganu et al., 2009). However, its sentences are more complicated, each having at least two aspects with different sentiment polarities.

We use this dataset to inspect whether a stronger training set can help improve aspect robustness.

Training and Testing on MAMS Table 10a checks the aspect robustness of models trained on MAMS using the original MAMS test set (O→O) and the new test set that we produced by applying the same generation strategies to its test set (O→N). Models trained and tested on MAMS have a smaller decrease rate than those on the Restaurant dataset. This shows that a more challenging training set can make models more robust.

Training on MAMS and Testing on Restaurant As MAMS and Restaurant are collected from the same source data, we test whether MAMS-trained models perform well on the new test set of Restaurant (in the column "MAMS→N" of Table 10b). We can see that all models trained on MAMS are more robust than those trained on the Restaurant dataset. For example, the accuracy of BERT and BERT-PT on the new test set is lifted up to 62.77%.

5.4 Does Adversarial Training Help?

Although the MAMS described in Section 5.3 provides a training set with diversity, it remains difficult to improve aspect robustness for other domains, or future new datasets. Therefore, we propose a flexible method, adversarial training, for aspect robustness, which is applicable to any given dataset.

We conducted adversarial training on the Laptop and Restaurant datasets, and analyze its effect in Table 10b. Specifically, for the column "Adv→N", we generated an additional training set by applying the three proposed strategies on training data, then trained models on the augmented data obtained by combining the original training data and this newly generated data, and finally evaluated on the ARTS test data. This practice follows Table 7 of (Zhang et al., 2019b) which is a similar stream of work as ours for the paraphrasing domain.

In both Restaurant and Laptop domains, adversarial training (Adv→N) leads to significant performance improvement than only training on the original datasets (O→N). On the Restaurant datasets, adversarial training is even more effective than training on MAMS, because our generated data instances comprehensively covered all possible perturbations of the non-target aspects, and naturally collected datasets might not be comparable.

6 Error Analysis for Data Generation

We analyze the error types in the subset of ARTS that was fixed by human judges. Two most significant error types are wrong antonyms (∼2%), such

Model	MAMS	
	O→O	O→N
MemNet	70.51	37.80
GatedCNN	66.02	32.93
AttLSTM	67.14	39.67
TD-LSTM	77.62	49.25
GCN	76.95	47.98
BERT-Sent	49.25	10.48
CapsBERT	83.38	60.18
BERT	84.51	61.38
BERT-PT	85.10	64.37

(a) Accuracy of each model trained on the MAMS **O**riginal training data and evaluated on the **O**riginal test data (O→O), as well as the **N**ew test set generated by our models (O→N).

Restaurant				Laptop		
O→O	O→N	MAMS→N	Adv→N	O→O	O→N	Adv→N
75.18	21.52	24.02	37.95	64.42	16.93	31.82
76.96	13.13	18.48	37.50	65.67	10.34	41.85
75.98	14.64	22.32	48.66	67.55	9.87	42.63
78.12	30.18	41.60	62.76	68.03	22.57	54.86
77.86	24.73	46.51	61.52	72.41	19.91	56.43
80.62	10.89	12.95	45.80	73.04	17.40	53.92
83.66	55.36	61.43	75.80	76.80	25.86	61.23
83.04	54.82	62.77	74.82	77.59	50.94	65.67
86.70	59.29	62.77	74.64	78.53	53.29	66.93

(b) Accuracy of each model trained on the **O**riginal data and evaluated on the **O**riginal test set (O→O), and the **N**ew test set (O→N), as well as that trained on the **Adv**ersarial data and evaluated on the **N**ew test set (Adv→N). For Restaurant, we also test models trained on **MAMS** dataset and tested on the **N**ew test set of Restaurant (MAMS→N).

Table 10: Improvements on the new test set using different training data.

as "the weight of the laptop is light→dark", and negation which causes grammatical errors (∼1.1%). In future work, we can fix the latter by applying a grammatical error correction system on top of our generation. Also, RevTgt and RevNon cannot be applied to 1.4∼6.6% instances with complicated sentiment expressions which rely on commonsense. For example, "a 2-hour wait" is negative bust too difficult to alter in our current generation framework. It needs more advanced models such as text style transfer (Shen et al., 2017; Jin et al., 2019b).

7 Related Work

Robustness in NLP Robustness in NLP has attracted extensive attention in recent works (Hsieh et al., 2019; Li et al., 2016). As a popular method to probe the robustness of models, adversarial text generation becomes an emerging research field in NLP. Techniques include adding extraneous text to the input (Jia and Liang, 2016), character-level noise (Belinkov and Bisk, 2018; Ebrahimi et al., 2018), and word replacement (Alzantot et al., 2018; Jin et al., 2019a). Using the adversarial generation techniques, new adversarial test sets are proposed for several tasks such as paraphrasing (Zhang et al., 2019b) and entailment (Glockner et al., 2018; McCoy et al., 2019).

Aspect-Based Sentiment Analysis ABSA has emerged as an active research area recently. Early works hand-craft sentiment lexicons and syntactic features for rule-based classifiers (Vo and Zhang, 2015; Kiritchenko et al., 2014). Recent neural network-based models use architectures such as LSTM (Tang et al., 2016a), CNN (Xue and Li, 2018), Attention mechanisms (Wang et al., 2016), Capsule Network (Jiang et al., 2019), and the pretrained model BERT (Xu et al., 2019a). Similar to the motivation in our paper, some work shows preliminary speculation that the current ABSA datasets might be downgraded to sentence-level sentiment classification (Xu et al., 2019b).

8 Conclusion

In this paper, we proposed a simple but effective mechanism to generate test instances to probe the aspect robustness of the models. We enhanced the original SemEval 2014 test sets by 294% and 315% in laptop and restaurant domains. Using our new test set, we probed the aspect robustness of nine ABSA models, and discussed model designs and better training that can improve the robustness.

Acknowledgments

We appreciate Professor Rada Mihalcea for her insights that helped us plan this research, Pengfei Liu for valuable suggestions on writing, and Yuchun Dai for helping to code some functions in our annotation tool. We also want to convey special thanks to Mahi Shafiullah and Osmond Wang for brilliant suggestions on the wording of the title. A Appendices

A.1 Test Set Generation Details

In our main paper, we mentioned that the size of our enriched ARTS test set is 294% of the original Laptop data size, and 315% of the original Restaurant test data size. These two ratios should ideally be both 400%, because there are three generation strategies, plus one original sentence. However, this gap is because not every original test sentence can qualify for every generation strategy. The number of instances generated by each strategy is shown in Table **??**.

Although AddDiff can apply to all test cases, the other two strategies, REVTGT and REVNON, cannot apply to all instances. For REVTGT and REVNON, we need to flip opinion words, so we can only apply these two strategies on instances with explicit opinion words. The number of opinion words is the main bottleneck for REVTGT. Specifically, Fan et al. (2019b) provide opinion words for 466 instances of Laptop, and 846 instances of Restaurant. Since REVTGT is applicable to these instances, the number of new test instances in ARTS generated by REVTGT are the same as the number of opinion word-available instances.

In addition to the opinion word constraint, REVNON has some further requirements. We filter out instances with only one aspect (224 in Laptop, and 263 in Restaurant), as well as instances where the opinion words of the target aspect are overlapped with the opinion words of the non-target aspect (102 in Laptop and 132 in Restaurant). Also we did not consider instances of which all the sentiment of non-target aspects are neutral (4 in Laptop, and 7 in Restaurant).

Modeling Content Importance for Summarization with Pre-trained Language Models

Abstract

Modeling *content importance* is an essential yet challenging task for summarization. Previous work is mostly based on statistical methods that estimate word-level salience, which does not consider semantics and larger context when quantifying importance. It is thus hard for these methods to generalize to semantic units of longer text spans. In this work, we apply *information theory* on top of *pre-trained language models* and define the concept of importance from the perspective of *information amount*. It considers both the semantics and context when evaluating the importance of each semantic unit. With the help of pre-trained language models, it can easily generalize to different kinds of semantic units (n-grams or sentences). Experiments on CNN/Daily Mail and New York Times datasets demonstrate that our method can better model the importance of content than prior work based on F1 and ROUGE scores.

1 Introduction and Related Work

Text summarization aims to compress long document(s) into a concise summary while maintaining the salient information. It often consists of two critical subtasks, *important information identification* and *natural language generation* (for abstractive summarization). With the advancements of large pre-trained language models (PreTLMs) (Devlin et al., 2019; Yang et al., 2019), state-of-the-art results are achieved on both natural language understanding and generation. However, it is still unclear how well these large models can estimate "content importance" for a given document.

Previous studies for modeling importance are either *empirical-based*, which implicitly encode importance during document summarization, or *theory-based*, which often lacks support by empirical experiments (Peyrard, 2019). Benefiting from the large-scale summarization datasets (Nallapati et al., 2016; Narayan et al., 2018), data-driven approaches (Nallapati et al., 2017; Paulus et al., 2018; Zhang et al., 2019) have made significant progress. Yet most of them conduct the information selection implicitly while generating the summaries. It lacks theory support and is hard to be applied to low-resource domains. In another line of work, structure features (Zheng and Lapata, 2019), such as centrality, position, and title, are employed as proxies for importance. However, the information captured by these features can vary in texts of different genres.

To overcome this problem, theory-based methods (Louis, 2014; Peyrard, 2019; Lin et al., 2006) aim to formalize the concept of importance, and develop general-purpose systems by modeling the background knowledge of readers. This is based on the intuition that humans are good at identifying important content by using their own interpretation of the world knowledge. Theoretical models usually rely on *information theory* (IT) (Shannon, 1948). Louis (2014) uses Dirichlet distribution to represent the background knowledge and employs Bayesian surprise to find novel information. Peyrard (2019) instead models the importance with entropy, assuming the important words should be frequent in the given document but rare in the background.

However, statistical method is only a rough evaluation for informativity, which largely ignores the effect of semantic and context. In fact, the information amount of units is not only determined by frequency, but also by its semantic meaning, context, as well as reader's background knowledge. In addition, bag-of-words approaches are difficult to generalize beyond unigrams due to the sparsity of n-grams when n is large.

In this paper, we propose a novel and general-purpose approach to model content importance for

---

November 16–20, 2020.

summarization. We employ *information theory* on top of *pre-trained language models*, which are expected to better capture the information amount of semantic units by leveraging their meanings and context. We argue that *important content contains information that cannot be directly inferred from context and background knowledge*. Large pre-trained language models are suitable for our study since they are trained from large-scaled datasets consisting of diverse documents and thus containing a wide range of knowledge.

We conduct experiments on popular summarization benchmarks of CNN/Daily Mail and New York Times corpora, where we show that our proposed method can outperform prior importance estimation models. We further demonstrate that our method can be adapted to model semantic units of different scales (n-grams and sentences).

2 Methodology

In this section, we first estimate the amount of information by using information theory with pre-trained language models (§2.1 and §2.2), where we consider both the context and semantic meaning of a given text unit. We then propose a formal definition of importance for text summarization from a perspective of information amount (§2.3).

2.1 Information Theory

Information theory (IT), as invented by Shannon (1948), has been used on *words* to quantify their "informativity". Concretely, IT uses the frequency of semantic units x_i to approximate the probability $P(x_i)$ and uses negative logarithm of frequency as the measurement for information, which is called *self-info*[1]:

$$I(x_i) = -\log_2 P(x_i) \tag{1}$$

It approximates the information amount of a unit (e.g. word) in a given corpus.

However, traditional IT suffers from the sparsity problem of longer n-grams and also ignores semantics and context. Advanced compression algorithms in IT (Hirschberg and Lelewer, 1992) attempt to model the context to better estimate the information amount. But due to the sparsity, they can only count up to third-order statistics. Statistical methods are nearly impossible to reliably calculate the probability of x_i conditioned on its context, e.g., $P(x_i|\cdots, x_{i-1}, x_{i+1}, \cdots)$, as the number of combinations of the context can be explosive.

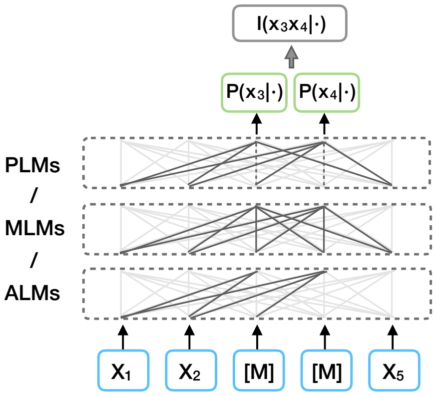

Figure 1: Information amount evaluation with language models. Here we take a subsequence x_3x_4 as example. [M] denotes mask and PLMs/MLMs/ALMs are three different options for language models. $I(x_3x_4|\cdot) = -\log[P(x_3|\cdot)P(x_4|\cdot)]$, where conditions for different models are omitted for brevity.

2.2 Using Language Models in Information Theory

With the development of deep learning, neural language models can efficiently predict the probability of a specified unit, such as a word or a phrase, given its context, which makes it feasible to calculate high-order approximation for the information amount.

We thus propose to use neural language models to replace the statistical models for estimating the information amount of a given semantic unit. Language models can be categorized as follows, and we present information estimation method for each as shown in Fig. 1.

Auto-regressive Language Model (ALM) (Bengio et al., 2000) is the most commonly used probabilistic model to depict the distribution of language, which is usually referred as unidirection LM (UniLM). Given a sequence of tokens $x_{0:T} = [x_0, x_1, \cdots, x_T]$, UniLMs use leftward content to estimate the conditional probability for each token: $P(x_t|x_{<t}) = g_{\text{UniLM}}(x_{<t})$, where g_{UniLM} denotes a neural network for language model and $x_{<t}$ represents the sequence from x_0 to x_{t-1}. Then the joint probability of a subsequence is factorized as:

$$P(x_{m:n}|x_{<m}) = \prod_{t=m}^{n} P(x_t|x_{<t}) \tag{2}$$

After applying Eq. (1) to both sides of Eq. (2), we can obtain the information amount of the subse-

---

[1] The unit of information is "bit", with base of 2. In the rest of this paper, we omit base 2 for brevity.

quence conditioned on its context as:

$$I(x_{m:n}|x_{<m}) = \sum_{t=m}^{n} I(x_t|x_{<t}) \tag{3}$$

Masked Language Model (MLM) is proposed by Taylor (1953) and combined with pre-training by Devlin et al. (2019) to encode bidirectional context. MLM masks a certain number of tokens from the input sequence, then predicts these tokens based on the unmasked ones. The conditional probability of a masked token x_t can be estimated as: $P(x_t|x_{\neq t}) = \mathrm{g}_{\mathrm{MLM}}(x_{\neq t})$, where $\neq t$ indicates that the t-th token is masked. Information amount of a given subsequence of the input is calculated as:

$$I(x_{m:n}|x_{\notin[m:n]}) = \sum_{t=m}^{n} I(x_t|x_{\notin[m,n]}) \tag{4}$$

Since MLMs encode both leftward and rightward context, intuitively, it can better estimate the information of current tokens than UniLMs.

Permutation Language Model (PLM) is proposed by (Yang et al., 2019) to combine ALMs and MLMs, by considering the dependency between the masked tokens as well as overcoming the problem caused by discrepancy of pre-training and fine-tuning in MLMs. It models the dependency of the tokens by maximizing the expected likelihood of all possible permutations of factorization orders. The probability prediction can be formalized as: $P(z_t|z_{<t}) = \mathrm{g}_{\mathrm{PLM}}(z_{<t})$ where z denotes a possible permutation sequence of input. Information of a subsequence is estimated as:

$$I(z_{m:n}|z_{<m}) = \sum_{t=m}^{n} I(z_t|z_{<t}) \tag{5}$$

2.3 Modeling Importance with Pre-trained Language Model

We argue that important content should be hard to be predicted based on background knowledge only; it should be also difficult to be inferred from the context. Moreover, detecting important content is to find the most informative part from the input. As described in (Shann, 1989), the information amount is a quantification of the uncertainty we have for the semantic units. But the degree of uncertainty is relative to reader's *background knowledge*. The less knowledge the reader has, the more uncertainty the source shows.

We thus employ pre-trained language models, which contain a wide range of knowledge, to represent background knowledge. If a semantic unit is frequently mentioned in the training corpus, it will get *high probability* during inference and thus *low information amount*. We further propose a notion of **importance** as the information amount conditional on the background knowledge:

$$\mathrm{Imp}(x_i|X - x_i, K) = -\log P_{LM_K}(x_i|X - x_i) \tag{6}$$

where $X - x_i$ means the context excluding[2] the unit x_i from input X and K denotes the knowledge encoded in the pre-trained model. In practice, when calculating the importance of a semantic unit, we first exclude all its occurrences from the input document, and let the PreTLMs predict the probability of each occurrence, based on which the information amount is calculated. As the same unit may appear at multiple positions in the input, summation is used as the final value of information amount.

Based on our notion of importance, a summarization model is to maximize the overall importance of a subset $\mathbf{x}$ of the input X, with a length constraint, such as $\sum_{x_i \in \mathbf{x}} |x_i| < l_{max}$:

$$\arg\max_{\mathbf{x} \subset X} \mathrm{Imp}(\mathbf{x}) = \sum_{x_i \in \mathbf{x}} \mathrm{Imp}(x_i|X - x_i, K) \tag{7}$$

3 Experimental Setups

Semantic Units and Tasks. Our theory can be generalized for evaluating the importance for any scale of semantic units. To verify the effectiveness of our theory, we instantiate the semantic unit with three common forms: **unigram**, **bigram** and **sentence**. In this way, our method can also be regarded as a general unsupervised information extraction system, serving as a keyphrase extraction or sentence-level extractive summarization model. As our method exploits the existed PreTLMs and needs no additional training, it has the potential of benefiting the low-resource languages and domains.

In *unigram* scenario, we simply instantiate semantic unit x_i as a token w_t and calculate its importance with $\mathrm{Imp}(w_t) = -\log P(w_t|w_{\neq t}, K)$. For evaluation, top-$k$ important ones are selected and F_1 score is calculated by comparing against the reference, where the value of k is set by grid search.

Importance of *bigrams*, e.g., $x_i = w_t w_{t+1}$, can be represented as a joint probability of two tokens: $\mathrm{Imp}(w_t w_{t+1}) = -\log P(w_t w_{t+1}|w_{t \notin [t,t+1]}, K)$. Same as unigrams, F_1 score is computed to evaluate the accuracy.

By extending the formula of bigram importance to longer sequences, we get importance definition

---

[2] MLMs hide targets by replacing them with special tokens, PLMs use attention masks, and ALMs only see leftward context.

Table 1: Results of importance modeling. UNI./BI. denote unigram and bigram. R-1/R-2/R-L are ROUGE-1, ROUGE-2 and ROUGE-L respectively. Best results per metric are in bold. Among our models (bottom), Imp yields significantly higher scores on all metrics except when using unigrams as semantic unit and with sentences (based on R-1) on NYT (Welch's t-test, p<0.05).

for a *sentence* as: $\mathrm{Imp}(s_i) = I(s_i|w_{\notin s_i}, K) = -\log P(s_i|w_{\notin s_i}, K)$. For evaluation, we select a subset of sentences with Eq. (7) and calculate the ROUGE scores (Lin, 2004) against reference summary. The length constraints for CNN/DM and NYT are set to 105 and 95 tokens respectively.

Datasets. We evaluate our method on the test set of two popular summarization datasets: CNN/Daily Mail (abbreviated as CNN/DM) (Nallapati et al., 2017) and New York Times (Sandhaus, 2008). Following See et al. (2017)[3], we use the non-anonymized version that does not replace the name entities, which is most commonly used in recent work. We preprocess them as described in (Paulus et al., 2018). For unigram experiments, we remove all the stop words and punctuation in the reference summaries and treat the notional words as the predicting targets. For bigram, we first collect all the bigrams in source document and then discard the ones containing stop words or punctuation. The rest bigrams are employed as the predicting targets.

Comparisons. We compare our method with two types of models: (1) the methods that estimate importance for n-grams. We consider TF·IDF, a numerical statistic to reflect how important a term is to a document, and STM (Peyrard, 2019), a simple theoretic model for content importance based on statistical information theory. (2) unsupervised models for extractive summarization. We adopt centrality-based models LexRank (Erkan and Radev, 2004), TextRank (Mihalcea and Tarau, 2004) and TextRank+BERT (Zheng and Lapata, 2019), a frequency-based model SumBasic (Ani Nenkova, 2005), and BayesianSR (Louis, 2014) which scores words or sentences with Bayesian surprise.

4 Results

We conduct extensive experiments with pre-trained models[4] in all three types of language models, including ALM: GPT-2 (Radford et al., 2019); MLMs: BERT (Devlin et al., 2019), and DistillBert (Sanh et al., 2019); PLMs: XLNet (Yang et al., 2019).

As shown in Table 1, our method Imp consistently outperform prior models. Among comparisons, we can see that theory-based methods, STM and BayesianSR, achieve better results. This is because they have statistics estimated for background distribution, which helps filter out common words. The significant advantage of our method verifies our hypothesis that pre-trained language models better characterize the background knowledge, which in turn more precisely calculate the importance of each semantic unit. Moreover, our methods have a more significant improvement on bigram-level prediction than unigram-level. This is due to the fact that Imp-based models overcome the sparsity issue, where they can evaluate the importance of a phrase by considering its semantic meaning and context.

---

[3] `https://github.com/JafferWilson/Process-Data-of-CNN-DailyMail`

[4] We use the implementations and parameters from `huggingface.co/transformers/index.html`

Surprisingly, our method can also generalize to sentence-level semantic units and serve as an unsupervised extract-based model for summarization. Our models achieve significantly higher ROUGE scores than previous work by average 2.02. This observation inspires a potential future direction for sentence-level importance modeling based on background knowledge as well as context information.

We also compare the performance of PreTLMs in different categories. MLMs, including BERT and DISTILLBERT, have the best overall performance, since they are able to encode bidirectional context. PLM, i.e. XLNet, is slightly inferior to MLMs because the probabilities of the words are related to the order of their permutation, which may hurt importance estimation by our method.

5 Future Work

In the future work, we would like to fine-tune the current language models on the target of $\max P(x_i|X - x_i)$ to better align with the interpretation of information theory. Currently, the PreTLMs mostly mask the text randomly, which still differ from our current method's objective.

Background knowledge also deserves further investigation. The background knowledge of our methods comes from the pre-training process of language models, suggesting that the information distribution largely depends on the training data. Meanwhile, most PreTLMs are trained with Wikipedia or books, which may affect the determination of content importance from text with different styles. So domain-specific knowledge, such as genres or topics, can be included in the future work.

6 Conclusion

We propose to use large pre-trained language models to estimate the information amount of given text units, by filtering out the background knowledge as encoded in the large models. We show that the large pre-trained models can be used as unsupervised methods for content importance estimation, where significant improvement over nontrivial baselines is achieved on both keyphrase extraction and sentence-level extractive summarization tasks.

Abstract

Evaluation of a document summarization system has been a critical factor to impact the success of the summarization task. Previous approaches, such as ROUGE, mainly consider the informativeness of the assessed summary and require human-generated references for each test summary. In this work, we propose to evaluate the summary qualities without reference summaries by unsupervised contrastive learning. Specifically, we design a new metric which covers both linguistic qualities and semantic informativeness based on BERT. To learn the metric, for each summary, we construct different types of negative samples with respect to different aspects of the summary qualities, and train our model with a ranking loss. Experiments on Newsroom and CNN/Daily Mail demonstrate that our new evaluation method outperforms other metrics even without reference summaries. Furthermore, we show that our method is general and transferable across datasets.

1 Introduction

Recently, there has been great success in automatic text summarization and generation (Huang et al., 2020; LeClair et al., 2020; Chen et al., 2020). To better compare and improve the performance of models, evaluation for such systems has been a problem of interest. The selection of evaluation metrics will greatly affect the assessed quality of a generated summary and thus affect the evaluation of summarization models.

The most ideal metric is definitely human judgement, which is often treated as the gold standard. But human evaluation is time-consuming and labor-intensive, an automatic evaluation metric that cannot only save human resources but also simulate the ability of human judgement is of crucial importance.

Most of the existing automatic evaluation methods assess a summary by comparing it with reference texts written by humans. Some of them are model-free and simply use hand-crafted matching functions to calculate the similarity between the candidate summary and the reference (Papineni et al., 2002; Lin and Och, 2004; Banerjee and Lavie, 2005). These methods consider both the reference and the candidate as a sequence of tokens or n-gram blocks. For instance, as the de facto standard evaluation metric, ROUGE (Lin and Och, 2004) calculates the n-gram overlap between the machine-generated summaries and reference summaries. Although these methods have the advantage of interpretability and efficiency, they are found to correlate poorly with human evaluation (Novikova et al., 2017).

To reduce the requirement of exact word matching, some recent work tried to match the reference and the candidate summary in the embedding space of words or sentences (Zhang et al., 2020; Clark et al., 2019; Zhao et al., 2019). For instance, BERTScore (Zhang et al., 2020) uses contextual word embeddings generated by BERT and performs a greedy matching to obtain the maximum cosine similarity between two texts. These methods are proved to correlate better with human judgement than ROUGE on many datasets, which demonstrates the effectiveness of using contextual embeddings.

However, the aforementioned methods all have some intrinsic drawbacks: these methods always need at least one human-generated reference to assess a candidate summary. References written by humans are costly to obtain. In addition, most of them only consider the semantic similarities with references, i.e. semantic qualities of the summaries, which ignores the linguistic qualities and other important aspects. In this paper, we propose a new unsupervised contrastive learning framework for auto-

matically evaluating the summary qualities without comparing with reference summaries or training with human ratings. Specifically, we design an evaluator to consider both linguistic and semantic aspects of a summary. Then for each of the aspect we create a set of negative samples by perturbing the training samples. We compare the scores of original training samples and the negative samples to obtain the contrastive loss function and learn the evaluator. The experiments on Newsroom and CNN/Daily Mail demonstrate that our new evaluation method has much higher correlation with human judgement.

We summarize our contributions as follows:

- We develop a new unsupervised method for summary quality evaluation which considers both linguistic and semantic aspects.
- We creatively make negative samples with respect to our evaluation metric and train the evaluator by contrastive learning.
- Our evaluator requires no reference summaries or human ratings but achieves the best performance on single-document summarization datasets, and the trained evaluator can be easily used across different datasets.

2 Related Work

2.1 Existing Evaluation Metrics

2.1.1 Reference-based Metrics

Most of the existing automatic metrics for summarization evaluation assess a model-generated summary (i.e. the candidate) by comparing it with a human-authored summary (i.e. the reference).

Some metrics are model-free and their scoring basis are often easy to interpret (Papineni et al., 2002; Lin and Och, 2004; Banerjee and Lavie, 2005). For instance, as the most widely used metric for summarization evaluation, ROUGE (Lin and Och, 2004) measures the co-occurrence of n-grams or substrings between the reference and the candidate.

Most of the model-based methods (Zhang et al., 2020; Zhao et al., 2019; Clark et al., 2019) compare the embeddings of the reference and the candidate. BERTSCore (Zhang et al., 2020) uses pretrained BERT contextual embeddings (Devlin et al., 2019) and performs a greedy matching to obtain the maximum cosine similarity between embeddings of tokens in the two texts. Clark et al. (2019) proposed metrics based on sentence mover's similarity (SMS) by leveraging sentence-level embeddings for evaluating multi-sentence texts. MoverScore (Zhao et al., 2019) combines n-gram contextual embeddings and Earth Mover's Distance. BERTScore can be viewed as a special case of MoverScore. NUBIA (Kané et al., 2020) considers three aspects of features of the reference-candidate pairs and aggregates the extracted features using a neural network regressor.

These metrics have a common drawback that the evaluation is based on costly human-authored references. To assess the quality of a generated text summary, we need to obtain a corresponding ground-truth reference.

2.1.2 Reference-free Metrics

Some work discussed how to evaluate the quality of generated text in the reference-free setting (Louis and Nenkova, 2013; Peyrard et al., 2017; Peyrard and Gurevych, 2018; Shimanaka et al., 2018; Xenouleas et al., 2019; Sun and Nenkova, 2019; Böhm et al., 2019; Chen et al., 2018; Gao et al., 2020). Louis and Nenkova (2013), Peyrard et al. (2017) and Peyrard and Gurevych (2018) leveraged regression models to fit human judgement. RUSE (Shimanaka et al., 2018) use sentence embeddings generated by three different models and aggregate them using a MLP regressor. Xenouleas et al. (2019) proposed a method that also uses a regression model to predict the scores, while the predictions are based on hidden representations generated using BERT (Devlin et al., 2019) as the encoder. However, these methods require ratings assigned by human annotators as training data which are also costly to obtain. In contrast, our method is *unsupervised* and requires no human ratings for training.

Sun and Nenkova (2019) discussed both reference-based and reference-free settings for summarization evaluation. Their method basically converts both the generated text and the text for comparison (denoted as T) into hidden representations using encoders like ELMo (Peters et al., 2018) and calculates the cosine similarity between them, T in the reference-based setting and the reference-free setting stands for the human-authored reference text and the source document text, respectively. However, the experiment results show that their method's correlation with human ratings is lower than ROUGE, especially in the reference-free setting. Chen et al. (2018) designed a Question-Answering based method to compare the content difference of two texts. Although this method provides a novel perspective and the evaluation basis is easy to interpret, the results show that it has not achieved better performance than ROUGE considering the lower correlation with human ratings.

SUPERT generates pseudo references and evaluates the quality of the test summaries by calculating word mover's distance between the pseudo reference summaries and the test summaries (Gao et al., 2020). It is similar to MoverScore (Zhao et al., 2019) which uses the human-authored references instead of pseudo references. However, SUPERT mainly focuses on multi-document summarization evaluation, and its performance is inevitably worse than MoverScore.

The work closest to our model is an evaluation method for natural language generation (NLG) systems proposed by Zhou and Xu (2020). They implemented the sample-level evaluation by comparing a pair of texts. However, their method requires a set of different NLG systems and they need to generate weak supervision sample pairs from different checkpoints of a system. For testing, they also need to compare different samples to obtain a comparison score. In contrast, our model focuses on summarization evaluation; we do not need generated texts from many systems and different checkpoints of a system: all our negative samples are created by modifying the existing summaries; and in the test phase no comparison between different summaries is needed.

2.2 Dimensions of Evaluation

We investigated a few summarization datasets. As shown in Table 1, different datasets consider different evaluation dimensions. We observed that these dimensions can be roughly divided into three classes: the semantic quality (Semantic), the linguistic quality (Linguistic), and other dimensions that can be hardly classified (Else). In this paper, we design our method to cover both dimensions of semantic quality and linguistic quality.

3 Method

As shown in the previous section, two of the most important factors that impact the summary qualities are linguistic quality and semantic quality. Linguistic quality indicates how natural the generated summary is; it generally includes the fluency of each sentence, the coherence of entities/consecutive sentences, and the correctness of grammars. Semantic quality indicates whether a summary expresses the most important information of the original documents; it generally includes informativeness, relevance, and redundancy, etc. We consider both aspects and design our method in the following sections. Our model architecture is shown in Figure 1. The figure contains two parts, first we design our evaluator to assign scores to summaries based on a BERT encoder. Then we create negative samples and use a contrastive learning framework to train the evaluator.

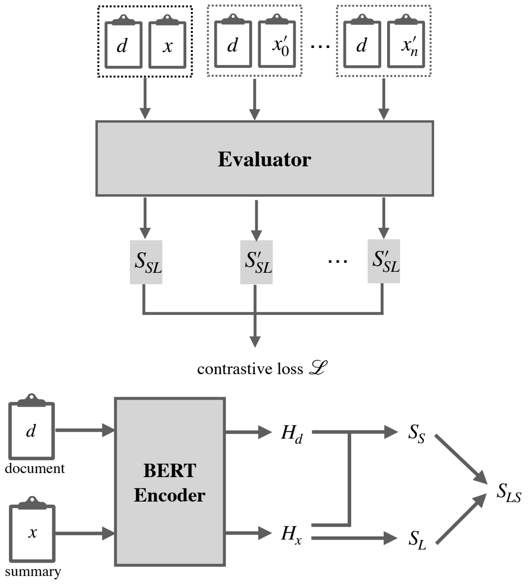

Figure 1: Model Framework. The top figure describes the framework for contrastive learning, where for each document x, we create different types of negative samples and compare them with x to get a ranking loss. The bottom figure is the evaluator which generates the final evaluation score. For short, here we use S_S, S_L and S_{LS} to indicate S_Score, L_Score and LS_Score.

3.1 Evaluating Semantic Quality

To better evaluate the semantic quality, we utilize the contextualized embeddings of BERT (Devlin et al., 2019). BERT takes in a sequence which always starts with a special classification token `[CLS]` as input, and outputs the representation of this sequence. Each token has its own hidden state. The hidden state corresponding to `[CLS]` is supposed to aggregate information from the whole sequence. We design our evaluation model as follows.

Formally, let S_x and S_d be the sequence of tokens in the summary x and the source document d from which x is generated. A sequence of tokens is encoded into a sequence of token embeddings H by the BERT encoder.

$$H_x = \text{BERT}(S_x) \tag{1}$$

$$H_d = \text{BERT}(S_d) \tag{2}$$

In order to avoid the requirement of a reference summary, similar to (Sun and Nenkova, 2019), we measure the semantic quality of the target summary x by calculating the semantic similarity between x and its source document d. Thus the semantic quality score is:

$$S\_Score(x) = Sim(H_d^0, H_x^0), \tag{3}$$

where Sim refers to cosine similarity, H^0 denotes the hidden state corresponding to token `[CLS]`.

3.2 Evaluating linguistic quality

For a summary x and its sequence of tokens S_x, the exact operations to obtain its linguistic quality score are as follows.

We first use the BERT encoder to get the representation of the summary x.

$$H_x = \text{BERT}(S_x), \tag{4}$$

where $H_x \in \mathbb{R}^{N \times K}$, N is the sequence length and K means the hidden size of the BERT encoder. Then we calculate the probability of the sequence based on this representation.

$$P_x = \text{softmax}\left(W_1^\top\left(\sigma(W_0^\top H_x)\right)\right), \tag{5}$$

where $W_0 \in \mathbb{R}^{K \times K}$ and $W_1 \in \mathbb{R}^{K \times V}$ denotes two weight parameters and we omit biases here. V stands for the vocabulary size. σ is an activation function, which is GELU in our experiments. A softmax operation is applied to every token's embeddings to predict a probability distribution at each position in the sequence. Here we use p_x^i to represent the probability of the i-th token to be the same as S_x^i. Motivated by the perplexity, the linguistic quality of x can be calculated as:

$$L\_Score(x) = \frac{1}{|x|}\sum_i^n log\ p_x^i \tag{6}$$

3.3 Evaluating Both Dimensions

In order to capture both the linguistic and semantic aspects, we develop our final metric by linearly combining the S_Score and L_Score. We call it LS_Score, which is a trade-off between the semantic score and linguistic score.

$$LS\_Score(x) = \alpha L\_Score(x) + \beta S\_Score(x) \tag{7}$$

The α and β are used to scale the L_Score and the S_Score. In our experiments we fix $\alpha = 0.01$ and $\beta = 1$ to scale the L_Score and the S_Score.

Original summary:

Kristina Patrick from Alaska filmed her German Shepherd Pakak performing a very skillful trick. Footage shows the pup taking the ball from her mouth with her paws and holding it up high in the air to admire it. She then carefully lowers it back down to the starting point.

Negative samples:

1. delete words

Patrick $\wedge$ from Alaska filmed her German Shepherd Pakak performing a very skillful trick. Footage shows the pup taking the $\wedge$ from her $\wedge$ with her paws and holding it up high in the air to $\wedge$ it. She then carefully lowers it back down to the starting point.

2. add sentences

Kristina Patrick from Alaska filmed her German Shepherd Pakak performing a very skillful trick. Footage shows the pup taking the ball from her mouth with her paws and holding it up high in the air to admire it. She then carefully lowers it back down to the starting point. ~~PAKAK 's owner says she loves playing with balls.~~

3. disorder words

Kristina Patrick skillful Alaska filmed her performing Shepherd a German Pakak very from trick. Footage shows the pup taking the ball from admire mouth with and paws her holding it up high her to air the in it. She then back lowers it carefully to down the starting point.

Table 2: An example of negative sampling.

3.4 Contrastive Training

To alleviate the requirement of reference summaries as well as given human evaluation scores, we develop a new unsupervised training framework via contrastive learning. Intuitively, for a given good summary, if we make some noise, e.g. disordering the words/sentences, we can easily create a summary with worse quality. Then we can compare these two summaries to get a contrastive loss. In practice, we can use human generated summaries in the training data as the "good" summaries, however, they can also be replaced with other good machine-generated summaries. We do not require any reference summaries in the test phase, i.e. for a candidate summary without known reference summaries we can also predict a score for it. That increases the flexibility and generalizability of our evaluation method.

Given a base summary r, assume we make some noise and get a set of negative samples $\hat{X}_r$, we formulate a ranking loss function as follows:

$$Loss = \sum_{r\in\mathcal{R}} \sum_{\hat{x}\in\hat{X}_r} max(0, 1-(LS\_Score(r) - LS\_Score(\hat{x}))) \quad (8)$$

where $\mathcal{R}$ denotes the set of original summaries in the training set and $\hat{X}_r$ is the set of corresponding noisy variants of a training sample r. For a batch of $(r, \hat{X}_r)$, we obtain their scores predicted by an evaluation model and then update model parameters (including fine-tuning BERT) using the gradients of the loss function . In this way, we train the model to better distinguish between good and bad summaries.

Since we evaluate the summaries from two different aspects, for each aspect we create different types of noisy samples. For semantic quality, one straightforward strategy is to randomly remove some words or sentences in the original summary to get a new negative sample. Obviously the created new summary will encounter information loss compared to the original one, so its evaluator score will be lower. In our experiments, we randomly select 20% words (with no consideration of word types) to delete. We do not delete entire sentences because most of the summaries have only very few sentences (as shown in Table 3, the average number of sentences in a reference is 1.43 and 3.88 in Newsroom and CNN/Daily Mail, respectively), thus deleting sentences will cause too much information loss, which doesn't benefit the model's ability to distinguish good from bad.

In addition, we do not want the generated summaries to have too much redundant information. So we create another type of negative samples by adding redundant sentences. The redundant sentences are chosen randomly from the original document. Firstly we extract sentences from the original document. Then we filter out the sentences that are most similar to each sentence in the reference. At last, we randomly sample the redundant sentences from the remaining sentences in the reference.

For linguistic quality, the negative samples can be generated by either disordering the words/sentences or deleting words. Both of the operations will lead to loss of coherence or fluency. So the negative sampling strategy in this case is as follows: 1) randomly rotating the order of sentences or the order of words within a sentence. 2) randomly deleting some of the words in the original summary. Note that the second strategy is also used in generating noisy samples for semantic quality, but our LS_Score combines both semantic and linguistic quality, so we do not explicitly discriminate the two aspects for this type of negative samples.

Table 2 shows three examples of our negative samples, each of which represents one type of negative samples respectively. By differentiating the original summaries and the negative samples we enforce our evaluator to capture various aspects of the summary quality. The trained evaluator can then be used for evaluating summaries with unknown references. In our experiments, we generate only one negative sample per type of operations for each base summary, i.e. each base summary has 3 negative samples.

4 Experiments

We conduct our experiments to answer the following questions:

- Does our contrastive learning method obtain better performance over other baselines even without reference summaries?
- Can our evaluator capture the expected aspects of summary qualities, and does it outperform others under the same contrastive learning framework?
- Is our method generalizable to different datasets? That is, how does it perform if we train the metric on one dataset and test on another one?

4.1 Experimental Settings

The encoder in our experiments to convert token sequence into embeddings is BERT (Devlin et al., 2019). We simply use a pretrained BERT model `bert-base-uncase` which has 12 layers, a hidden size of 768, 12 attention heads and 110M parameters in total.[1] Our model is implemented based on the HuggingFace Transformers.[2] The max length of sequence we use for BERT encoding is 512, so we truncate the sequence longer than 510 tokens (despite the special tokens `[CLS]` and `[SEP]`).[3].

Table 3: Datasets statistics

4.2 Datasets

We conduct empirical studies on two benchmark single-document summarization datasets. These datasets both have original documents, their corresponding human-authored summaries (i.e. references) and also some model-generated summaries that are manually rated in several dimensions, so we can compare different evaluation methods by their correlation with human ratings.

Newsroom. Proposed by Grusky et al. (2018), this summarization dataset includes 1.3 million documents and human-written summaries. In this corpus, there are only 420 summaries with human ratings. These summaries are generated by 7 different extractive or abstractive summarization systems. Each document-summary pair is evaluated by three human raters in four dimensions (`coherence`, `fluency`, `informativeness`, and `relevance`). We take the mean score of three raters as the groundtruth human score for each summary. We use these summaries with human ratings as our test data. In order to prevent information leakage in the training process, we select our training data (108,802 document-reference pairs) with no overlapped reference summaries with the test data. It means we do not use any reference summaries in our test data for training. The data statistics are shown in Table 3.

[1] `https://github.com/google-research/bert`

[2] `https://github.com/huggingface/transformers`

[3] Our code is publicly available at `https://github.com/whl97/LS-Score.git`

CNN/Daily Mail. This dataset was first proposed by Hermann et al. (2015) using news documents for question answering research and was subsequently extended to the area of summarization by Nallapati et al. (2016). Chaganty et al. (2018) provided human scores for 2,513 references and system-generated summaries in three dimensions (`overall`, `fluency` and `redundancy`). We use 1,996 summaries generated by 4 systems for testing and 10,932 document-reference pairs for training. Similarly, there is no overlap of reference summaries between the training data and test data. Table 3 shows the data statistics of the training data.

For both datasets, in the training data, we randomly selected 95% of sentence-pairs for training and the remaining 5% for validation.

4.3 Baselines

We adopt the following metrics as our baselines. Since this paper focuses on unsupervised approaches, we do not compare with the metrics training with human ratings.

ROUGE. This metric has been the most frequently used automatic metric for summarization evaluation. It evaluates the quality of a summary by comparing it to a human-authored reference. The essence of the comparison is to measure the overlapping units (such as n-gram or word sequences) between the summary and the reference (Lin and Och, 2004).

METEOR. Proposed by Banerjee and Lavie (2005), this metric evaluates a candidate string by measuring the harmonic mean of unigram-precision and unigram-recall between the candidate string and a reference string.

BERTScore. This metric was proposed by Zhang et al. (2020), it utilizes token-level contextual embeddings generated by a pretrained language model (here we use BERT). The evaluation score is calculated by computing similarity between the embeddings of the summary to evaluate and the reference. The BERTScore includes three metrics R (recall), P (precision)and F (F1 score).

WMS/SMS/S+WMS. Kusner et al. (2015) proposed word mover's distance (WMD) to calculate the minimum cost of moving a sequence into the other. They treat each sequence as a bag of words and each word is represented by its word embeddings. The WMD can then be transformed into a similarity (WMS) (Clark et al., 2019). On the basis of **WMS**, (Clark et al., 2019) (2019) designed to measure the similarity of two sequences by calculating sentence mover's distance to enhance the ability of evaluating multi-sentence texts. They introduced two metrics: sentence mover's distance (**SMS**) and sentence and word mover's distance (**S+WMS**). **SMS** uses sentence embeddings instead of word embeddings and represents each sequence as a bag of sentences and **S+WMS** combines both sentence and word embeddings and represents each sequence as a bag of both sentences and words.

MoverScore. Also inspired by WMD, Zhao et al. (2019) represented both the reference and the candidate text as a sequence of n-gram embeddings and calculate the WMD between two sequences. We report the result of the best models described in their paper that use a BERT pretrained on MNLI dataset to generate the n-gram embeddings and PMeans as the aggregator.

BERT+Cos+Ref. This metric uses BERT as the encoder and calculates the cosine similarity between the embeddings of the reference and the candidate summary.

BERT+Cos+Doc. This metric is similar to **BERT+Cos+Ref**, but it measures the similarity between the source document and the candidate summary. This is the only *reference-free metric* in the baselines.

4.4 Experiment Results

The usual practice of evaluating a summarization evaluation metric is to measure its average summary-level correlation with human judgements,

	Overall	**Grammar**	**Redundancy**

i.e. to measure the correlation between the predicted scores and the human scores across all the test summaries. We evaluate our methods on the aforementioned two datasets. We implemented our final model (LS_Score with contrastive learning), as we introduced in 3.3. For each dataset, we train our models on the document-reference pairs in the training data, and test on the machine-generated summaries without comparing with reference summaries.

4.4.1 Comparison with Other Methods

The Spearman correlations between different evaluation methods and human evaluation in four dimensions on Newsroom are shown in Table 4. Even though most of baselines are with reference summaries, our reference-free evaluator (LS_Score) still achieves best correlations in all of the different dimensions. By capturing both the semantic quality and semantic quality in the evaluator's scoring function as well as our negative sampling strategies, our method outperforms other previous metrics a lot in both linguistic dimensions (`coherence`, `fluency`) and semantic dimensions (`informativeness`, `relevancy`). Especially, it is also superior to another unsupervised reference-free method, BERT+Cos+Doc.

Furthermore, we observe that BERT+Cos+Doc achieves a better overall performance on Newsroom as compared to BERT+Cos+Ref. This is probably due to the short lengths of the summaries on the Newsroom dataset (mostly one sentence). A possible explanation is that the short reference summaries fail to capture all the important information of original documents. As a result, directly comparing with document representations will suffer much less information loss.

Table 5 shows the Spearman correlations on CNN/Daily Mail. As mentioned before, this dataset focuses more on evaluating the linguistic quality of summaries. One interesting comparison is between our model and BERTScore-R. On `redundancy` BERTScore-R is comparable but its `grammar` ratings is much worse than ours, which also leads to a worse overall performance.

4.4.2 Ablation Study for Evaluator Selection

We further conduct experiments to show the benefit of using our evaluator. A commonly used BERT-based evaluator is to add a linear regressor to the BERT representations (Xenouleas et al., 2019). We implement an evaluator (called BERT+Linear) that also uses a linear regressor to map the BERT embeddings of summaries into a score. We train this evaluator under our contrastive learning framework with the same negative samples, and compare its results with ours. Table 6 and Table 7 show the comparison results, and our model is superior to BERT+Linear a lot in most cases. One thing worth mentioning is that this ablation model already obtained better results than most of the baselines in Table 4 and Table 5, which further demonstrate the power of our contrastive learning framework.

	Coh.	**Flu.**	**Inf.**	**Rel.**
Bert+Linear	0.4213	0.4511	0.3075	0.3400

LS_Score	**0.3342**	0.2664	**0.2875**

Table 7: Ablation studies on CNN/Daily Mail. The models use the same contrastive learning framework but different evaluators.

4.4.3 Cross-dataset Transferability

Although the generated summaries are from documents not included in the training data, we still do experiments to further verify the transferability of our methods by training on one dataset and testing on the other dataset's test data. The performance of our method trained on CNN/Daily Mail and tested on Newsroom is shown in Table 8, and the one trained on Newsroom and tested on CNN/Daily Mail are presented in Table 9. We call this model LS_Score_cross. For easy comparison, we also take some values in Table 4 and Table 5. As shown in Table 8 and 9, the cross-data training makes the performance of LS_Score_cross slightly lower than the original LS_Score in most cases, but it still outperform all other baselines. This shows that our evaluation method is very flexible to be used. Even trained on different datasets, it can still achieve very good results.

5 Conclusion

In this paper, we propose a new evaluation method in the field of text summarization. We found that the quality of a summary can be evaluated in two separate dimensions: semantic quality and linguistic quality. Since human-authored references used in most of the existing metrics are costly, we investigate automatic evaluation metrics in an unsupervised reference-free setting. Leveraging powerful representations of BERT, our methods achieve the highest performance on two datasets. Although our experiments are only on single-document summarization datasets, our method can also be also extended to evaluation of multi-document summarization with slight changes, especially in the part of semantic quality evaluation.

Abstract

Sentence-level extractive text summarization is substantially a node classification task of network mining, adhering to the informative components and concise representations. There are lots of redundant phrases between extracted sentences, but it is difficult to model them exactly by the general supervised methods. Previous sentence encoders, especially BERT, specialize in modeling the relationship between source sentences. While, they have no ability to consider the overlaps of the target selected summary, and there are inherent dependencies among target labels of sentences. In this paper, we propose HAHSum (as shorthand for **H**ierarchical **A**ttentive **H**eterogeneous Graph for Text **Sum**marization), which well models different levels of information, including words and sentences, and spotlights redundancy dependencies between sentences. Our approach iteratively refines the sentence representations with redundancy-aware graph and delivers the label dependencies by message passing. Experiments on large scale benchmark corpus (CNN/DM, NYT, and NEWSROOM) demonstrate that HAHSum yields ground-breaking performance and outperforms previous extractive summarizers.

1 Introduction

Single document extractive summarization aims to select subset sentences and assemble them as informative and concise summaries. Recent advances (Nallapati et al., 2017; Zhou et al., 2018; Liu and Lapata, 2019; Zhong et al., 2020) focus on balancing the salience and redundancy of sentences, i.e. selecting the sentences with high semantic similarity to the gold summary and resolving the redundancy between selected sentences. Taking Table 1 for example, there are five sentences in a document, and each of them is assigned one salience score and one label indicating whether this sentence should be contained in the extracted summary. Although *sent1*, *sent3*, and *sent4* are assigned high salience score, just *sent3* and *sent4* are selected as the summary sentences (with label 1) because there are too much redundancy information between unselected *sent1* and selected *sent3*. That is to say, whether one sentence could be selected depends on its salience and the redundancy with other selected sentences. However, it is still difficult to model the dependency exactly.

Salience	Label	Sentence
sent1: 0.7	0	Deanna Holleran is charged in murder.
sent2: 0.1	0	Jackson County Prosecutor Jean Peters Baker announced today.
sent3: 0.7	1	Deanna Holleran faces a charge of traffic accident.
sent4: 0.7	1	The fatal traffic accident is a murder.
sent5: 0.2	0	It took the life of Marianna Hernandez near 9th Hardesty.
Summary:		Woman faces a charge of murder for a fatal traffic accident.

Table 1: Simplified News from Jackson County Prosecutor. **Salience** score is an approximate estimation derived from semantic and **Label** is converted from gold summary to ensure the concision and accuracy of the extracted summaries.

Most of the previous approaches utilize autoregressive architecture (Narayan et al., 2018; Mendes et al., 2019; Liu and Lapata, 2019; Xu et al., 2020), which just models the unidirectional dependency between sentences, i.e., the state of the current sentence is based on previously sentence labels. These models are trained to predict the current sentence label given the ground truth labels of the previous sentences, while feeding the predicted labels of the previous sentences as input in inference phase. As we all know, the autoregressive paradigm faces error propagation and exposure bias problems (Ranzato et al., 2015). Besides, reinforcement learning is also introduced to consider the semantics of extracted summary (Narayan et al., 2018; Bae et al.,

2019), which combines the maximum-likelihood cross-entropy loss with the rewards from policy gradient to directly optimize the evaluation metric for the summarization task. Recently, the popular solution is to build a summarization system with two-stage decoder. These models extract salient sentences and then rewrite (Chen and Bansal, 2018; Bae et al., 2019), compress (Lebanoff et al., 2019; Xu and Durrett, 2019; Mendes et al., 2019), or match (Zhong et al., 2020) these sentences.

Previous models generally use top-k strategy as an optimal strategy: for different documents, the number of selected sentences is constant which conflicts with the real world. For example, almost all previous approaches extract three sentences from the source articles (top-3 strategy (Zhou et al., 2018; Liu and Lapata, 2019; Zhang et al., 2019b; Xu et al., 2020)), although 40% documents in CNN/DM contain more or less than 3-sentences oracle summary. That's because these approaches are difficult to measure the salience and redundancy simultaneously with error propagation. Notably, Mendes et al. (2019) introduces the length variable into the decoder and Zhong et al. (2020) can choose any number of sentences by match candidate summary in semantic space.

In order to address above issues, we construct the source article as a hierarchical heterogeneous graph (HHG) and propose a Graph Attention Net (Veličković et al., 2018) based model (HAHSum) to extract sentences by simultaneously balancing salience and redundancy. In HHG, both words and sentences are constructed as nodes, the relations between them are constructed as different types of edges. This hierarchical graph can be viewed as a two-level graph: word-level and sentence-level. For word-level graph (word-word), we design an **Abstract Layer** to learn the semantic representation of each word. Then, we transduce the word-level graph into the sentence-level one, by aggregating each word to its corresponding sentence node. For sentence-level graph (sentence-sentence), we design a **Redundancy Layer**, which firstly pre-labels each sentence and iteratively updates the label dependencies by propagating redundancy information. The redundancy layer restricts the scale of receptive field for redundancy information, and the information passing is guided by the ground-truth labels of sentences. After obtaining the redundancy-aware sentence representations, we use a classifier to label these sentence-level nodes with a threshold. In this way, the whole framework extracts summary sentences simultaneously instead of autoregressive paradigm, taking away the top-k strategy.

The contributions of this paper are as below: 1) We propose a hierarchical attentive heterogeneous graph based model(HAHSum) to guide the redundancy information propagating between sentences and learn redundancy-aware sentence representation; 2) Our architecture is able to extract flexible quantity of sentences with a threshold, instead of top-k strategy; 3) We evaluate HAHSum on three popular benchmarks (CNN/DM, NYT, NEWSROOM) and experimental results show that HAHSum outperforms the existing state-of-the-art approaches. Our source code will be available on Github [1].

2 Related Work

2.1 Extractive Summarization

Neural networks have achieved great success in the task of text summarization. There are two main lines of research: abstractive and extractive. The abstractive paradigm (Rush et al., 2015; See et al., 2017; Celikyilmaz et al., 2018; Sharma et al., 2019) focuses on generating a summary word-by-word after encoding the full document. The extractive approach (Cheng and Lapata, 2016; Zhou et al., 2018; Narayan et al., 2018) directly selects sentences from the document to assemble into a summary.

Recent research work on extractive summarization spans a large range of approaches. These work usually instantiate their encoder-decoder architecture by choosing RNN (Nallapati et al., 2017; Zhou et al., 2018), Transformer (Wang et al., 2019; Zhong et al., 2019b; Liu and Lapata, 2019; Zhang et al., 2019b) or Hierarchical GNN (Wang et al., 2020) as encoder, autoregressive (Jadhav and Rajan, 2018; Liu and Lapata, 2019) or non-autoregressive (Narayan et al., 2018; Arumae and Liu, 2018) decoders. The application of RL provides a means of summary-level scoring and brings improvement (Narayan et al., 2018; Bae et al., 2019).

2.2 Graph Neural Network for NLP

Recently, there is considerable amount of interest in applying GNN to NLP tasks and great success has been achieved. Fernandes et al. (2019) applied

---

[1] http://github.com/coder352/HAHSum

sequence GNN to model the sentences with named entity information. Yao et al. (2019) used two-layer GCN for text classification and introduced a well-designed adjacency matrix. GCN also played an important role in Chinese named entity (Ding et al., 2019). Liu et al. (2019) proposed a new contextualized neural network for sequence learning by leveraging various types of non-local contextual information in the form of information passing over GNN. These studies are related to our work in the sense that we explore extractive text summarization by message passing through hierarchical heterogeneous architecture.

3 Methodology

3.1 Problem Definition

Let $S = \{s_1, s_2, ..., s_N\}$ denotes the source document sequence which contains N sentences, where s_i is the i-th sentence of document. Let T denotes the hand-crafted summary. Extractive summarization aims to produce summary $S^* = \{s^*_1, s^*_2, ..., s^*_M\}$ by selecting M sentences from S, where $M \leq N$. Labels $Y = \{y_1, y_2, ..., y_N\}$ are derived from T, where $y_i \in \{0, 1\}$ denotes whether sentence s_i should be included in the extracted summary. Oracle summary is a subset of S, which achieves the highest ROUGE score calculated with T.

3.2 Graph Construction

In order to model the redundancy relation between sentences, we use a heterogeneous graph which contains multi-granularity levels of information to represent a document, as shown in Figure 1. In this graph, there are three types of nodes: named entity, word, and sentence. To reduce semantic sparsity, we replace text spans of `Named Entity` by anonymized tokens (e.g. [Person_A], [Person_B], [Date_A]). `Word` node is the original textual item, representing word-level information. Different from DivGraphPointer (Sun et al., 2019), which aggregates identical words into one node, we keep each word occurrence as one node to avoid the confusion of different contexts. Each `Sentence` node corresponds to one sentence and represents the global information of one sentence.

We also define four types of edges to represent various structural information in HAHSum:

1. We connect sequential named entities and words in one sentence using directed `Next` edges.
2. We connect one named entity node or word node to one sentence node with directed `In` edge if the named entity or word occurs in this sentence.
3. We connect two named entity nodes with undirected `Same` edge if they are the same named entity.
4. We connect two sentence nodes with undirected `Similar` edge if they have trigram overlapping.

The topological structure of graph can be represented by adjacency matrix A, where the bool-type element is indicating whether there is an edge between nodes. Because HAHsum contains multi-granularity levels of information, it can be divided into three subgraphs: the word-level, word-sentence, and sentence-level subgraph. So, we define three adjacency matrices: A_{word} is used for the word-level graph, constructed by `Entity` node, `Word` node, `Next` edge and `Same` edge. $A_{word-sent}$ is used for the word-sentence graph, constructed by three types of nodes and `In` edge. A_{sent} is used for sentence-level graph, constructed by `Sentence` node and `Similar` edge. By propagating the information from word-level to sentence-level graph, we can obtain the sentence representation and model the redundancy between sentences.

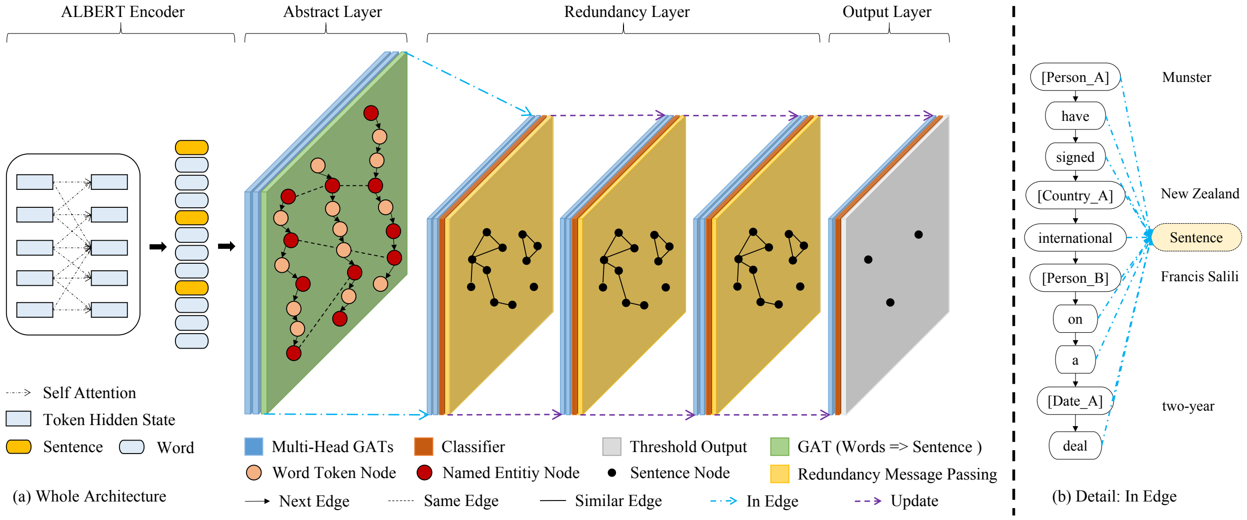
Generally, the message passing over graphs can be achieved in two steps: aggregation and combination, and this process can be conducted multiple times (referred as layers or hops in GNN literature) (Tu et al., 2019). Therefore, we iteratively update the sentence nodes representation with redundancy message passing which will be described in the following sections.

3.3 Graph Attention Network

To represent graph structure A and node content X in a unified framework, we develop a variant of Graph Attention Network (GAT) (Veličković et al., 2018). GAT is used to learn hidden representations of each node by aggregating the information from its neighbors, with the attention coefficients:

$$e_{ij} = \text{LeakReLU}(a(Wx_i || Wx_j)) \qquad (1)$$

where $W \in \mathbb{R}^{d \times d}$ is a shared linear transformation weight matrix for this layer, $||$ is the concatenation operation, and $a \in \mathbb{R}^{2d}$ is a shared attentional weight vector.



(a) Whole Architecture

(b) Detail: In Edge

Figure 1: Overview of Hierarchical Attentive Heterogeneous Graph

To make the attention coefficients easily comparable across different nodes, we normalize them as follows:

$$\alpha_{ij} = \text{softmax}(e_{ij}) = \frac{\exp(e_{ij})}{\sum_{k \in \mathcal{N}_i} \exp(e_{ik})} \qquad (2)$$

where $\mathcal{N}_i$ denotes the neighbors of node i according to adjacency matrix A.

Then, the normalized attention coefficients are used to compute a linear combination of features.

$$x'_i = \sigma(\sum_{j \in \mathcal{N}_i} \alpha_{ij} W x_j) + W' x_i \qquad (3)$$

where W' is used to distinguish the information between x_i and its neighbors.

3.4 Message Passing

Shown in Figure 1, HAHSum consists of ALBERT Encoder, Abstract Layer, Redundancy Layer, and Output Layer. We next introduce how the information propagates over these layers.

3.4.1 ALBERT Encoder

In order to learn the contextual representation of words, we use a pre-trained ALBERT (Lan et al., 2019) for summarization and the architecture is similar to BERTSUMEXT (Liu and Lapata, 2019). The output of ALBERT encoder contains word hidden states h^{word} and sentence hidden states h^{sent}. Specifically, ALBERT takes subword units as input, which means that one word may correspond to multiple hidden states. In order to accurately use these hidden states to represent each word, we apply an average pooling function to the outputs of ALBERT.

3.4.2 Abstract Layer

The abstract layer contains three GAT sublayers which are described in Section 3.3: two for word-level graph and one for word-sentence transduction. The first two GAT sublayers are used to learn the hidden state of each word based on its two-order neighbors inspired by Kipf and Welling[2017],

$$\mathcal{W} = \text{GAT}(\text{GAT}(h^{word}, A_{word}), A_{word}) \qquad (4)$$

where A_{word} denotes the adjacency matrix of the word-level subgraph, and $\mathcal{W}$ denotes the hidden state of the word nodes.

The third GAT sublayer is to learn the initial representation of each sentence node, derived from the word hidden states:

$$[\mathcal{W}, \mathcal{S}_{abs}] = \text{GAT}([\mathcal{W}, h^{sent}], A_{word-sent}) \qquad (5)$$

where $A_{word-sent}$ denotes the adjacency matrix of the word-sentence subgraphs, and $\mathcal{S}_{abs}$ (abs is for abstract) is the initial representation of sentence nodes.

3.4.3 Redundancy Layer

The BERT encoder and abstract layer specialize in modeling salience with overall context representation of sentences, while it is powerless for redundancy information with dependencies among target labels. So, redundancy layer aims to model the redundancy, by iteratively updating the sentence representation with redundancy message passing, and this process is supervised by ground-truth labels.

This layer only deals with sentence-level information $\mathcal{S} = \{h_1, h_2, ..., h_N\}$ and iteratively updates it L times with classification scores:

$$\widetilde{\mathcal{S}}^l_{re} = \text{GAT}(\text{GAT}(\mathcal{S}^l_{re}, A_{sent}), A_{sent})$$
$$P(y_i = 1|\widetilde{\mathcal{S}}^l_{re}) = \sigma(\text{FFN}(\text{LN}(\tilde{h}^l_i + \text{MHAtt}(\tilde{h}^l_i)))) \tag{6}$$

where $\mathcal{S}^0_{re} = \mathcal{S}_{abs}$ (re is for redundancy) and we get $\mathcal{S}^L_{re}$ at the end, W_c, W_r are weight parameters, FFN, LN, MHAtt are feed-foreard network, layer normalization and multi-head attention layer.

We update $\tilde{h}^l_i$ by reducing the redundancy information g^l_i, which is the weighted summation of neighbors information:

$$\begin{aligned} g^l_i &= \frac{1}{|\mathcal{N}_i|} \sum_{j \in \mathcal{N}_i} P(y_j = 1|\widetilde{\mathcal{S}}^l_{re}) * \tilde{h}^l_j \\ h^{l+1}_i &= W^l_c * \tilde{h}^l_i - \tilde{h}^{lT}_i W^l_r \tanh(g^l_i) \\ \mathcal{S}^{l+1}_{re} &= (h^{l+1}_1, h^{l+1}_2, ..., h^{l+1}_{|S|}) \end{aligned} \tag{7}$$

where $\mathcal{N}_i$ is redundancy receptive field for node i, according to A_{sent}.

Specifically, we employ a gating mechanism (Gilmer et al., 2017) for the information update, so that: 1) to avoid GNN smoothing problem; 2) the original overall information from ALBERT is accessible for the ultimate classifier.

$$\begin{aligned} \tilde{h}^{l'}_i &= W^l_c * \tilde{h}^l_i - \tilde{h}^{lT}_i W^l_r \tanh(g^l_i) \\ p^l_g &= \sigma(f^l_g([\tilde{h}^l_i; \tilde{h}^{l'}_i])) \\ h^{l+1}_i &= \tilde{h}^l_i \odot p^l_g + \tilde{h}^{l'}_i \odot (1 - p^l_g) \end{aligned} \tag{8}$$

where $\odot$ denotes element-wise multiplication.

3.5 Objective Function

Previous approaches for modeling the salience and redundancy is autoregressive, where observations from previous time-steps are used to predict the value at current time-step:

$$P(Y|S) = \prod_{t=1}^{|S|} P(y_t|S, y_1, y_2, ..., y_{t-1}) \tag{9}$$

The autoregressive models have some disadvantages: 1) the error in inference will propagate subsequently, 2) label y_t is generated just depend on previous sentences $y_{<t}$ rather than considering bidirectional dependency, and 3) it is difficult to decide how many sentences to extract.

Datasets	avg.doc length		avg.summary length	
	words	sentences	words	sentences
CNN	760.50	33.98	45.70	3.59
DailyMail	653.33	29.33	54.65	3.86
NYT	800.04	35.55	45.54	2.44
Newsroom (Ext)	605.44	28.78	40.95	1.90

Table 2: Data Statistics: CNN/Daily Mail, NYT, Newsroom

Our HAHSum predicts these labels simultaneously:

$$P(Y|S) = \prod_{t=1}^{|S|} P(y_t|S, \mathcal{S}_{abs}, \mathcal{S}_{re}) \tag{10}$$

where we extract flexible quantity of sentences with a threshold instead of top-k. For L classifiers in our model, we train them simultaneously with different proportions. For each training pair (X, Y) and the predicted $\hat{Y}$, the loss function is formalized as follows:

$$\begin{aligned} \mathcal{L} = -\sum_{l=0}^{L} \frac{L+l}{2L} \sum_{i=1}^{|S|} \{ & y_i \log P(\hat{y}_i|\widetilde{\mathcal{S}}^l_{re}) + \\ & (1 - y_i) \log(1 - P(\hat{y}_i|\widetilde{\mathcal{S}}^l_{re}))\} \end{aligned} \tag{11}$$

4 Experiments Setting

4.1 Benchmark Datasets

As shown in Table 2, we employ three datasets widely-used with multiple sentences summary (CNN/DM (Hermann et al., 2015), NYT (Sandhaus, 2008), and NEWSROOM (Grusky et al., 2018)). These summaries vary with respect to the type of rewriting operations, e.g., CNN/DM and NYT prefer to the abstractive approaches and Newsroom(Ext) is genuinely extractive. We employ the greedy method to obtain ground-truth sentence labels (Nallapati et al., 2017).

CNN/DailyMail: We use the standard splits for training, validation, and test (90,266/1,220/1,093 for CNN and 196,96/12,148/10,397 for DailyMail) (Liu and Lapata, 2019). Input documents are truncated to 768 BPE tokens, with anonymized entities and processed by Stanford CoreNLP.

NYT: Following previous work (Zhang et al., 2019b; Xu and Durrett, 2019), we use 137,778, 17,222 and 17,223 samples for training, validation, and test, respectively. Input documents were truncated to 768 BPE tokens too. Note that there are different division for NYT (Durrett et al., 2016; Liu and Lapata, 2019) and several models are not evaluated on NYT officially (See et al., 2017; Mendes et al., 2019), so we re-train and evaluate them on NYT with the source code from Github.

Newsroom(Ext): We employ the extractive part of Newsroom with same divisioin method (Mendes et al., 2019) for training/validation/test (331,778/36,332/36,122). Input documents are truncted to 768 BPE tokens.

4.2 Evaluation Metric & Parameter Settings

Metric: ROUGE (Lin, 2004) is the standard metric for evaluating the quality of summaries. We report the ROUGE-1, ROUGE-2, and ROUGE-L of HAHSum by *ROUGE-1.5.5.pl*, which calculates the overlap lexical units of extracted sentences and ground-truth.

Graph Structure: For abstract layer, we extract the named entities (`[Person]`, `[Date]`, `[Country]`, `[Buildings]`, `[Monetary]`) using CoreNLP, and replace them by anonymized tokens. Similar to Fernandes et al. (2019), we have tried to add dependency parse edges and they didn't show significant benefits, owing to the facts that 1) the dependency tree is substantially a permutation sequential structure, with little advancements for original information; 2) the performance is influenced by the accuracy of the upstream annotators. We have tried the iteration steps of $[1, 2, 3, 5]$ for updating redundancy layer, and $L = 3$ is the best value in experiment result.

Parameters: We employ pre-trained 'albert-xxlarge-v2'[2] and reuse the implementation of PreSumm[3]. We train our model (with about 400M parameters) one day for 100,000 steps on 2 GPUs(Nvidia Tesla V100, 32G) with gradient accumulation every two steps. We select the top-3 checkpoints according to the evaluation loss on validation set and report the averaged results on the test set. Adam with $\beta_1 = 0.9$, $\beta_2 = 0.999$ is used as optimizer and learning rate schedule follows the strategies with warming-up on first 10,000 steps (Vaswani et al., 2017). The final threshold in extraction is 0.65 for CNN/DM, 0.58 for NYT and 0.64 for Newsroom, with the highest ROUGE-1 score individually. A higher threshold will be with more concise summary and the lower threshold will return more information.

4.3 Baselines

Extractive Methods: **Oracle** is the extracted summary according to the ground-truth labels. **Lead** is a base method for extractive text summarization that chooses first several sentences as a summary. **SummaRuNNer** takes content, salience, novelty, and position of each sentence into consideration when deciding if a sentence should be included in the extractive summary. **PN-BERT** tries to employ the unsupervised transferable knowledge. **BERTSUMEXT** applies pre-trained BERT in text summarization and proposes a general framework for both extractive and abstractive models. **MATCHSUM** is a two-stage method for extract-then-match, and the first-stage is BERTSUMEXT.

Abstractive Methods: **ABS** is the normal architecture with RNN-based encoder and decoder. **PGC** augments the standard Seq2Seq attentional model with pointer and coverage mechanisms. **TransformerABS** employs Transformer in text summarization. **MASS** proposes masked Seq2Seq pre-training for encoder-decoder. **UniLM** presents unified pre-trained language model, that can be fine-tuned for summarization. **BART**, and **ProphetNet** are pre-trained on large unlabeled data and perform excellent performance with Transformer architecture. **PEGASUS** proposes Transformer-based models with extracted gap-sentences for abstractive summarization.

Specifically, these Transformer-based approaches are divided into `Base` and `Large` versions, according to the layers of Transformer.

5 Analysis

5.1 Rouge Scores

The experiment results on three benchmark datasets are shown in Table 3. There are ignored positions for Newsroom(Ext), which is designed for extractive approaches, eliminating the demanding of abstractive ones. It is obvious that HAHSum almost outperforms all the baselines across most of the evaluation metrics. For CNN/DM, there is little gap between the performance of extractive and abstractive architectures, particularly demonstrating the popularity and generality of this dataset. While NYT prefers to abstractive methods, and NEWSROOM(Ext) is constructed by extracting sentences

Table 3: Automatic Evaluation or ROUGE

directly. For extractive approaches, HAHSum, MATCHSUM, and BERTSUMEXT are outstanding with the power of pre-trained BERT-like models. For abstractive methods, these variants of Transformer perform extremely with deep architectures and large-scale unlabeled corpus.

HAHSum outperforms all other extractive approaches for that: 1) HAHSum achieves improvements to mitigate the redundancy bias by measuring salience and redundancy simultaneously, while this would not be possible with any framework in the autoregressive literature because salience and redundancy are treated as two different processes due to the dependency among target labels. 2) The promising results of heterogeneous sequence-graph models outperform pure sequence models. Sequence encoders with a graph component can reason about long-distance relationships in weakly structured data such as text, which requires non-trivial understanding of the input, while attentive sequential architectures prefer to calculate the relevance merely.

5.2 Ablation Studies

We propose several strategies to improve the performance by relieving the semantic sparsity and redundancy bias, including abstract layer(AL), the iterative redundancy layer(RL), and pre-trained ALBERT. To investigate the influence of these factors, we conduct the experiments and list the results in Table 4. Significantly, AL is more important than RL, for the reason that there are lots of meaningless named entities. Besides, RL mechanism enlarges the advantage of extraction without top-*k* strategy, for there are more than 40% documents in CNN/DM contains more or less than 3-sentences oracle summary. As shown in Table 6, HAHSum predicts sequence exactly with two sentences, same as the oracle summary. While BERTSUMEXT extracts top-3 sentences strictly, in spite of the inaccurateness and redundancy.

Models	R-1	R-2	R-L
HAHSum	**44.68**	**21.30**	**40.75**
w/o AL	44.35	20.98	40.49

5.3 Human Evaluation for Summarization

It is not enough only relying on the ROUGE evaluation for a summarization system, although the ROUGE correlates well with human judgments (Owczarzak et al., 2012). To evaluate the performance of HAHSum more accurately, we design

Models	1st	2nd	3rd	4th	5th	MeanR
SummaRuNNer	0.14	0.27	0.24	0.22	0.13	2.93
BERTSUMEXT	0.20	0.28	0.31	0.16	0.05	2.58
MATCHSUM	0.24	0.36	0.16	0.15	0.09	2.49
HAHSum	0.45	0.34	0.18	0.03	0.00	2.24
Ground-Truth	0.70	0.21	0.05	0.04	0.00	1.43

Table 5: Human evaluation on Daily Mail.

an Amazon Mechanical Turk experiment based on ranking method. Following Cheng and Lapata (2016); Narayan et al. (2018); Zhang et al. (2019b), firstly, we randomly select 40 samples from Daily Mail test set. Then the human participants are presented with a original document and a list of corresponding summaries produced by different model systems. Participants are requested to rank these summaries (ties allowed) by taking informativeness (Can the summary capture the important information from the document) and fluency (Is the summary grammatical) into account. Each document is annotated by three different participants separately.

Following the previous work, the input article and ground truth summaries are also shown to the human participants in addition to the four model summaries (SummaRuNNer, BERTSUMEXT, MATCHSUM and HAHSum). From the results shown in Table 5, we can see that HAHSum is better in relevance compared with others.

5.4 Visualization

We visualize the learned embedding of word and sentence nodes in a two-dimensional space by applying the t-SNE algorithm. We randomly select 500 continuous word nodes (approximately 30 sentences in a document) and 1000 sentence nodes from BERTSUMEXT and HAHSum separately. As shown in Figure 2, for word nodes, the darkness determines it's position in one document; while for sentence nodes, red points are the sentences with label 1, and green points are with label 0. The result shows: 1) It is amazing that sentence-level summarization constrains word representations to be shared across whole sentence, and there are obviously word clusters in BERTSUMEXT; 2) The word clusters are more distinct and meaningful in HAHSum equipped with abstract layer and GAT; 3) Intuitively, the redundancy layer has particularly strong representation power and generalizability, for that oracle sentence nodes in HAHSum are easy to identify, without autoregressive formalism used for capturing sentence-level redundancy.

6 Conclusion

In this paper, we propose hierarchical attentive heterogeneous graph, aiming to advance text summarization by measuring salience and redundancy simultaneously. Our approach model redundancy information by iteratively update the sentence information with message passing in redundancy-aware graph. As a result, HAHSum produces more focused summaries with fewer superfluous and the performance improvements are more pronounced on more extractive datasets.

Abstract

We consider the problem of better modeling query-cluster interactions to facilitate query focused multi-document summarization. Due to the lack of training data, existing work relies heavily on retrieval-style methods for assembling query relevant summaries. We propose a *coarse-to-fine* modeling framework which employs progressively more accurate modules for estimating whether text segments are relevant, likely to contain an answer, and central. The modules can be independently developed and leverage training data if available. We present an instantiation of this framework with a trained *evidence* estimator which relies on distant supervision from question answering (where various resources exist) to identify segments which are likely to answer the query and should be included in the summary. Our framework[1] is robust across domains and query types (i.e., long vs short) and outperforms strong comparison systems on benchmark datasets.

1 Introduction

Query Focused Multi-Document Summarization (QFS; Dang 2006) aims to create a short summary from a set of documents that answers a specific query. It has various applications in personalized information retrieval and recommendation engines where search results can be tailored to an information need (e.g., a user might be looking for an overview summary or a more detailed one which would allow them to answer a specific question).

Neural approaches have become increasingly popular in single-document text summarization (Nallapati et al., 2016; Paulus et al., 2018; Li et al., 2017b; See et al., 2017; Narayan et al., 2018; Gehrmann et al., 2018), thanks to the representational power afforded by deeper architectures and the availability of large-scale datasets containing hundreds of thousands of document-summary pairs (Sandhaus, 2008; Hermann et al., 2015; Grusky et al., 2018). Unfortunately, such datasets do not exist in QFS, and one might argue it is unrealistic they will ever be created for millions of queries, across different domains, and languages. In addition to the difficulties in obtaining training data, another obstacle to the application of end-to-end neural models is the size and number of source documents which can be very large. It is practically unfeasible (given memory limitations of current hardware) to train a model which encodes all of them into vectors and subsequently generates a summary from them.

In this paper we propose a coarse-to-fine modeling framework for extractive QFS which incorporates a *relevance* estimator for retrieving textual segments (e.g., sentences or longer passages) associated with a query, an *evidence* estimator which further isolates segments likely to contain answers to the query, and a *centrality* estimator which finally selects which segments to include in the summary. The vast majority of previous work (Wan et al., 2007; Wan, 2008; Wan and Xiao, 2009; Wan and Zhang, 2014) creates summaries by ranking textual segments (usually sentences) according to their relationship (e.g., similarity) to other segments *and* their relevance to the query. In other words, relevance and evidence estimation are subservient to estimating the centrality of a segment (e.g., with a graph-based model). We argue that disentangling these subtasks allows us to better model the query and specialize the summaries to specific questions or topics (Katragadda and Varma, 2009). A coarse-to-fine approach is also expedient from a computational perspective; at each step the model processes a decreasing number of segments (rather than entire documents), and as a result is insensitive to the original input size and more scalable.

Our key insight is to treat evidence estimation as a question answering task where a cluster of po-

November 16–20, 2020.

tentially relevant documents provides support for answering a query (Baumel et al., 2016). Advantageously, we are able to train the evidence estimator on existing large-scale question answering datasets (Rajpurkar et al., 2016; Joshi et al., 2017; Yang et al., 2018), alleviating the data paucity problem in QFS. Existing QFS systems (Wan et al., 2007; Wan, 2008; Wan and Xiao, 2009; Wan and Zhang, 2014) employ classic retrieval techniques (such as TF-IDF) to estimate the affinity between query-sentence pairs. Such techniques can handle short keyword queries, but are less appropriate in QFS settings where query narratives can be long and complex. We argue that a trained evidence estimator might be better at performing *semantic matching* (Guo et al., 2016) between queries and document segments. To this effect, we experiment with two popular QA settings, namely answer sentence selection (Heilman and Smith, 2010; Yang et al., 2015) and machine reading comprehension (Rajpurkar et al., 2016) which operates over passages than isolated sentences. In both cases, our evidence estimators take advantage of powerful pre-trained encoders such as BERT (Devlin et al., 2019), to better capture semantic interactions between queries and text units.

Our contributions in this work are threefold: we propose a coarse-to-fine model for QFS which we argue allows to introduce trainable components taking advantage of existing datasets and pre-trained models; we capitalize on the connections of QFS with question answering and propose different ways to effectively estimate the query-segment relationship; we provide experimental results on several benchmarks which show that our model consistently outperforms strong comparison systems across domains (news articles vs. medical text) and query types (long narratives vs. keywords).

2 Related Work

Existing research on query-focused multi-document summarization largely lies on extractive approaches, where systems usually take as input a set of documents and select the sentences most relevant to the query for inclusion in the summary.

In Figure 1(a), we provide a sketch of classic centrality-based approaches which have generally shown strong performance in QFS. Under this framework, all sentences within a document cluster, together with their query relevance, are jointly considered in estimating centrality. A variety of approaches have been proposed to enhance the way relevance and centrality are estimated ranging from incorporating topic-sensitive information (Wan, 2008; Badrinath et al., 2011; Xu and Lapata, 2019), predictions about information certainty (Wan and Zhang, 2014), manifold-ranking algorithms (Wan et al., 2007; Wan and Xiao, 2009; Wan, 2009), and Wikipedia-based query expansion (Nastase, 2008). More recently, Li et al. (2015) estimate the salience of text units within a sparse-coding framework by additionally taking into account reader comments (associated with news reports). Li et al. (2017a) use a cascaded neural attention model to find salient sentences, whereas in follow-on work Li et al. (2017b) employ a generative model which maps sentences to a latent semantic space while a reconstruction model estimates sentence salience. There are also feature-based approaches achieving good results by optimizing sentence selection under a summary length constraint (Feigenblat et al., 2017).

In contrast to previous work, our proposal does not simultaneously perform segment selection and query matching. We introduce a coarse-to-fine approach that incorporates progressively more accurate components for selecting segments to include in the summary, making model performance relatively insensitive to the number and size of input documents. Drawing inspiration from recent work on QA, we take advantage of existing datasets in order to reliably estimate the relationship between the query and candidate segments. We focus on two QA subtasks which have attracted considerable attention in the literature, namely *answer sentence selection* which aims to extract answers from a set of pre-selected sentences (Heilman and Smith, 2010; Yao et al., 2013; Yang et al., 2015) and *machine reading comprehension* (Rajpurkar et al., 2016; Welbl et al., 2018; Yang et al., 2018), which aims at answering a question after processing a short text passage (Chen, 2018).

QA and QFS are related but ultimately different tasks. QA aims at finding the *best* answer in a span or sentence, while QFS extracts a *set* of sentences based on user preferences and the content of the input documents under a length budget (Wan, 2008; Wan and Zhang, 2014). QA questions are often short and fact-based while QFS narratives can be longer and more complex (see the example in Section 3) and as a result simply localizing an answer within a cluster is not optimal.

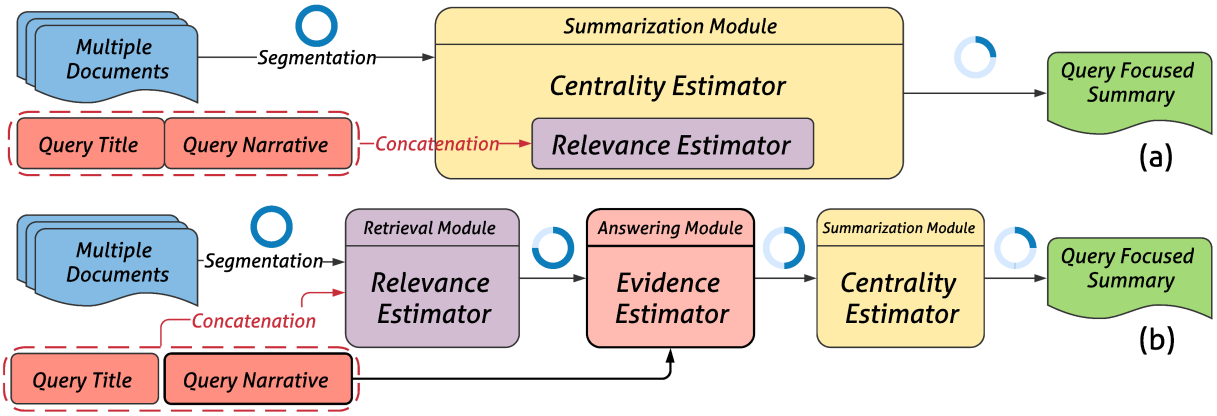

Figure 1: Classic (a) and proposed framework (b) for query-focused summarization. The classic approach involves a relevance estimator nested within a summarization module while our framework takes document clusters as input, and *sequentially* processes them with three individual modules (relevance, evidence, and centrality estimators). The blue circles indicate a coarse-to-fine estimation process from original articles to final summaries where modules gradually discard segments (i.e., sentences or passages). With regard to evidence estimation, we adopt pretrained BERT (Devlin et al., 2019) which is further fine-tuned with distant signals from question answering.

3 Problem Formulation

Let $\mathcal{Q}$ denote an information request and $\mathcal{D} = \{d_1, d_2, \ldots, d_M\}$ a set of topic-related documents. It is often assumed (e.g., in DUC competitions) that $\mathcal{Q}$ consists of a short title (e.g., *Amnesty International*) highlighting the topic of interest, and a query narrative which is considerably longer and detailed (e.g., *What is the scope of operations of Amnesty International and what are the international reactions to its activities?*).

We illustrate our proposed framework in Figure 1(b). We first decompose documents into segments, i.e., passages or sentences, and retrieve those which are most relevant to query $\mathcal{Q}$ (Relevance Estimator). Then, a trained estimator quantifies the semantic match between selected segments and the query (Evidence Estimator) to further isolate segments for consideration in the output summary (Centrality Estimator). We propose two variants of our evidence estimator; a context agnostic variant infers evidence scores over individual sentences, while a context aware one infers evidence scores for tokens within a passage which are further aggregated into sentence-level evidence. Passages might allow for semantic relations to be estimated more reliably since neighboring context is also taken into account.

3.1 Relevance Estimator

Our QFS system operates over documents within a cluster which we segment into sentences. The latter serve as input to the context agnostic evidence estimator. For the context aware variant, we obtain passages with a sliding window over continuous sentences in the same document.

During inference, we first retrieve the top k^{IR} answer candidates (i.e., sentences or passages) which are subsequently processed by our evidence estimator. We do this following an *adaptive* method that allows for a variable number of segments to be selected for each query. Specifically, for the ith query-cluster pair, we first rank all segments in the cluster based on term frequency with respect to the query, and determine k_i^{IR} such that it reaches a fixed threshold $\theta \in [0, 1]$. Formally, k_i^{IR}, the number of retrieved segments, is given by:

$$k_i^{\text{IR}} = \max_k \sum_{j=1}^{k} r_{i,j} < \theta \qquad (1)$$

where $r_{i,j}$ is the relevance score for segment j (normalized over segments in the ith cluster). Although we adopt term frequency as our relevance estimator, there is nothing in our framework which precludes the use of more sophisticated retrieval methods (Dai and Callan, 2019; Akkalyoncu Yilmaz et al., 2019). We investigated approaches based on term frequency-inverse sentence frequency (Allan et al., 2003) and BM25 (Robertson et al., 2009), however, we empirically found that they are inferior, having a bias towards shorter segments which are potentially less informative for summarization.

3.2 Evidence Estimator

We argue that relevance matching is not sufficient to capture the semantics expressed in the query narrative and its relationship to the documents in the cluster. We therefore leverage distant supervision signals from existing QA datasets to train our evidence estimator and use the trained estimators to rerank answer candidates selected from the retrieval module. For the ith cluster, we select the top $\min\{k^{\text{QA}}, k_i^{\text{IR}}\}$ candidates as answer evidence (where k^{QA} is tuned on the development set).

Sentence Selection Let $\mathcal{Q}$ denote a query (in practice a sequence of tokens) and $\{\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_N\}$ the set of candidate answers (also token sequences) obtained from the retrieval module. Our learning objective is to find the correct answer(s) within this set. We concatenate query $\mathcal{Q}$ and candidate sentence $\mathcal{S}$ into a sequence `[CLS]`, $\mathcal{Q}$, `[SEP]`, $\mathcal{S}$, `[SEP]` to serve as input to a BERT encoder (we pad each sequence in a minibatch of L tokens). The `[CLS]` vector serves as input to a single layer neural network to obtain the distribution over positive and negative classes:

$$p_0^{(i)} = \frac{1}{Z} \exp\left(t_i^{\intercal} W_{:,0}\right), p_1^{(i)} = \frac{1}{Z} \exp\left(t_i^{\intercal} W_{:,1}\right) \quad (2)$$

where $Z = \sum_c \exp\left(t_i^T W_{:,c}\right)$ and matrix $W \in \mathbb{R}^{d\times 2}$ is a learnable parameter. We use a cross entropy loss where 1 denotes that a sentence contains the answer (and 0 otherwise):

$$\mathcal{L} = -\sum_{i=1}^{N} (y \log p_1^{(i)} + (1-y) \log p_0^{(i)}). \quad (3)$$

We treat the probability of the positive class as evidence score $q = p_1^{(i)} \in (0,1)$ and use it to rank all retrieved segments for each query.

Span Selection A span selection model allows us to capture more faithfully the answer, its local context and their interactions. Again, let $\mathcal{Q}$ denote a query token sequence and $\mathcal{P}$ a passage token sequence. Our training objective is to find the correct answer span in $\mathcal{P}$. Similar to sentence selection, we concatenate the query $\mathcal{Q}$ and the passage $\mathcal{P}$ into a sequence `[CLS]`, $\mathcal{Q}$, `[SEP]`, $\mathcal{P}$, `[SEP]` and pad it to serve as input to a BERT encoder. Let $T = [t_i]_{i=1}^{N}$ denote the contextualized vector representation of the entire sequence obtained from BERT. We feed T into two separate dense layers to predict probabilities $p_{\mathcal{S}}$ and $p_{\mathcal{E}}$:

$$p_{\mathcal{S}}^{(i)} = \frac{\exp\left(t_i^{\intercal} w_{\mathcal{S}}\right)}{\sum_j \exp\left(t_j^{\intercal} w_{\mathcal{S}}\right)} \quad (4)$$

$$p_{\mathcal{E}}^{(i)} = \frac{\exp\left(t_i^{\intercal} w_{\mathcal{E}}\right)}{\sum_j \exp\left(t_j^{\intercal} w_{\mathcal{E}}\right)} \quad (5)$$

where $w_{\mathcal{S}}$ and $w_{\mathcal{E}}$ are two learnable vectors denoting the beginning and end of the (answer) span, respectively. During training we optimize the log-likelihood of the correct start and end positions. For passages without any correct answers, we set these to 0 and default to the `[CLS]` position.

At inference time, to allow comparison of results across passages, we remove the final softmax layer over different answer spans. Specifically, we first calculate the (unnormalized) start and end scores for all tokens in a sequence:

$$u = \exp\left(T w_{\mathcal{S}}\right), v = \exp\left(T w_{\mathcal{E}}\right). \quad (6)$$

And collect sentence scores from token scores as follows. For each sentence starting at token i and ending at token j, we obtain score matrix Q via:

$$\tilde{Q} = \left(u_{[i:j]} v_{[i:j]}^{\intercal} A\right)^{\frac{1}{2}} \quad (7)$$

$$Q = \tanh(\tilde{Q}) \quad (8)$$

where we collect all possible span scores within a sentence in matrix S where $S_{i',j'}$ denotes the span score from token i' to token j' ($i \leq i' < j' \leq j$). Matrix A is an upper triangular matrix masking all illegitimate spans whose end comes before the start. The $\tanh$ function scales the magnitude of extreme scores (e.g., scores over 100 or under 0.01), as a means of reducing the variance of $\tilde{Q}$. And finally, we use max pooling to obtain a scalar score q:

$$q = \text{max-pool}(Q) \in (0,1). \quad (9)$$

It is possible to produce multiple evidence scores for the same sentence since we use overlapping passages; we select the score with the highest value in this case.

Ensemble Selection We can also build an ensemble by linearly interpolating evidence scores from the two estimators based on sentence selection and span extraction. Let $(\mathcal{E}^{\mathcal{S}}, q^{\mathcal{S}})$ and $(\mathcal{E}^{\mathcal{P}}, q^{\mathcal{P}})$ denote the selected sentence sets and their evidence scores produced by the sentence selection estimator and span extraction estimator, respectively. We obtain the ensemble score for sentence e via:

$$q_e = \begin{cases} \mu * q_e^{\mathcal{S}} + (1-\mu) * q_e^{\mathcal{P}} & e \in \mathcal{E}^{\mathcal{S}} \cap \mathcal{E}^{\mathcal{P}} \\ \mu * q_e^{\mathcal{S}} & e \in \mathcal{E}^{\mathcal{S}} \wedge e \notin \mathcal{E}^{\mathcal{P}} \\ -\infty & e \notin \mathcal{E}^{\mathcal{S}} \end{cases} \tag{10}$$

where the coefficient was set to $\mu = 0.9$.

3.3 Centrality Estimator

Graph Construction Inspired by Wan (2008), we introduce as our centrality estimator an extension of the well-known LEXRANK algorithm (Erkan and Radev, 2004), which we modify to incorporate the evidence estimator introduced in the previous section.

For each document cluster, LEXRANK builds a graph $G = (\mathcal{V}, \mathcal{E})$ with nodes $\mathcal{V}$ corresponding to sentences and (undirected) edges $\mathcal{E}$ whose weights are computed based on similarity. Specifically, matrix E represents edge weights where each element $E_{i,j}$ corresponds to the transition probability from vertex i to vertex j. The original LEXRANK algorithm uses TF-IDF (Term Frequency Inverse Document Frequency) to measure similarity; since our framework operates over sentences rather than "documents", we use TF-ISF (Term Frequency Inverse Sentence Frequency), with ISF defined as:

$$\text{ISF}(w) = 1 + \log(|C|/\text{SF}(w)) \tag{11}$$

where C is the total number of sentences in the cluster, and $\text{SF}(w)$ is the number of sentences in which w occurs.

We integrate our evidence estimator into the original transition matrix as:

$$\tilde{E} = \phi * [\tilde{q}; ...; \tilde{q}] + (1-\phi) * E \tag{12}$$

where $\phi \in (0,1)$ controls the extent to which query-specific information influences sentence selection for the summarization task; and $\tilde{q}$ is a distributional evidence vector which we obtain after normalizing the evidence scores $q \in \mathbb{R}^{1\times|V|}$ obtained from the previous module ($\tilde{q} = q/\sum_v^{|V|} q_v$).

Summary Generation In order to decide which sentences to include in the summary, a node's centrality is measured using a graph-based ranking algorithm (Erkan and Radev, 2004; Xu and Lapata, 2019). Specifically, we run a Markov chain with $\tilde{E}$ on G until it converges to stationary distribution e^* where each element denotes the salience of a sentence. In the proposed algorithm, e^* jointly expresses the importance of a sentence in the document *and* its semantic relation to the query as modulated the evidence estimator and controlled by ϕ. We rank sentences according to e^* and select the top k^{Sum} ones, subject to a budget (e.g., 250 words). To reduce redundancy, we apply the diversity algorithm proposed in Wan (2008) which penalizes the salience of sentences according to their overlap with those already selected to appear in the summary. We also remove the sentences which have high cosine similarities (i.e., ≥ 0.6) with any sentence already included in the summary (Cao et al., 2015; Angelidis and Lapata, 2018).

4 Experimental Setup

Datasets We performed QFS experiments on the DUC 2005-2007 benchmarks and the **T**opically **D**iverse QFS dataset (TD-QFS; Baumel et al. 2016). DUC benchmarks contain long query narratives over 50 clusters with 32–25 documents each, and cover multiple domains. TD-QFS focuses on medical texts, contains short keyword queries over 4 clusters with 185 documents each. As a result, TD-QFS clusters are less topically concentrated, with larger amounts of query-irrelevant information (Baumel et al., 2016). Although our approach is motivated by the desire to better model long and complex queries, experiments on TD-QFS examine whether it generalizes to out-of-domain queries and clusters. We used DUC 2005 as a development set to optimize hyperparameters and evaluated performance on DUC 2006-2007 and TD-QFS. A summary of the characteristics of these datasets

Sentence Selection	
Question	What bird family is the owl?
Candidate Sentences	**Owls are a group of birds that belong to the order strigiformes, constituting 200 extant bird of prey species.** Most are solitary and nocturnal, with some exceptions (e.g., the northern hawk owl). Owls hunt mostly small mammals, insects, and other birds, although a few species specialize in hunting fish. They are found in all regions of the earth except antarctica, most of greenland and some remote islands. Owls are characterized by their small beaks and wide faces, and are divided into two families: the typical owls, strigidae; and the barn-owls, tytonidae.
Span Selection (answerable)	
Question	By what main attribute are computational problems classified utilizing computational complexity theory?
Context	Computational complexity theory is a branch of the theory of computation in theoretical computer science that focuses on classifying computational problems according to their **inherent difficulty**, and relating those classes to each other. A computational problem is understood to be a task that is in principle amenable to being solved by a computer, which is equivalent to stating that the problem may be solved by mechanical application of mathematical steps, such as an algorithm.
Answer	**inherent difficulty**
Span Selection (unanswerable)	
Question	What was the name of the 1937 treaty?
Context	Other legislation followed, including the Migratory Bird Conservation Act of 1929, a 1937 treaty prohibiting the hunting of right and gray whales, and the **Bald Eagle Protection Act** of 1940. These later laws had a low cost to society: the species were relatively rare and little opposition was raised.
Plausible Answer	**Bald Eagle Protection Act**

Table 3: Examples for two types of question answering datasets for evidence estimation: answer sentence selection and span selection. **Red** denotes answers while **blue** denotes a plausible answer to the question that cannot be answered from the given context. We use the union of WikiQA (Yang et al., 2015) and TrecQA (Heilman and Smith, 2010) for answer sentence selection and SQuAD 2.0 (Rajpurkar et al., 2016) for span selection. SQuAD 2.0 contains both answerable and unanswerable questions and we show one example for each of them.

is provided in Table 1.

We used three datasets for training our evidence estimator, including WikiQA (Yang et al., 2015), TrecQA (Yao et al., 2013), and SQuAD 2.0 (Rajpurkar et al., 2018). WikiQA and TrecQA are benchmarks for answer sentence selection while SQuAD 2.0 is a popular machine reading comprehension dataset (which we used for span selection). Compared to SQuAD, WikiQA and TrecQA are smaller and we therefore integrate them for model training (Yang et al., 2019). We show statistics for QA datasets in Table 2 and examples in Table 3.

Implementation Details We used the publicly released BERT model[2] and fine-tuned it on our QA tasks. Considering the maximum input length BERT allows (512 tokens) and the query narrative (which in DUC is fairly long), we set the maximum passage size to 8 sentences (with maximum sentence length of 50 tokens). To ensure all sentences are properly contextualized, we used a stride size of 4 sentences to create overlapping passages. Details on model training and optimization are provided in Appendix A.

Evaluation Following standard practice in DUC evaluations, we used ROUGE as our automatic evaluation metric[3] (Lin and Hovy, 2003) We report F1 for ROUGE-1 (unigram-based), ROUGE-2 (bigram-based), and ROUGE-SU4 (based on skip bigram with a maximum skip distance of 4).

We also evaluated model summaries in a judgment elicitation study via Amazon Mechanical Turk. Native English speakers (self-reported) were asked to rate query-summary pairs on two dimensions: *Succinctness* (does the summary avoid unnecessary detail and redundant information?) and *Coherence* (does the summary make logical sense?). The ratings were obtained using a five point Likert scale. In addition, participants were asked to assess the *Relevance* of the summary to the query. Crowdworkers read a summary and for each sentence decided whether it is relevant (i.e., whether it provides an answer to the query), irrelevant (i.e., it does not answer the query), and partially relevant (i.e., it is not clear it directly answers the query). Relevant sentences were awarded

a score of 5, partially relevant ones a score of 2.5, and 0 otherwise. Sentence scores were averaged to obtain a relevance score for the whole summary.

5 Results

Automatic Evaluation Our results on DUC are summarized in Table 4. The first block reports upper bound performance (Gold) which we estimated by treating a (randomly selected) reference summary as the output of a hypothetical system and comparing it against the remaining (three) ground truth summaries. Oracle uses reference summaries as queries to retrieve summary sentences, and Lead returns all lead sentences (up to 250 words) of the most recent document.

The second block in Table 4 compares our model to various *graph-based* approaches which include: LexRank (Erkan and Radev, 2004), a widely used unsupervised method based on Markov random walks. LexRank is query-free, it measures relations between all sentence pairs in a cluster and sentences recommend other similar sentences for inclusion in the summary. GRSum (Wan, 2008), a Markov random walk model that integrates query-relevance into a **G**raph **R**anking algorithm; and CTSum (Wan and Zhang, 2014) which is based on GRSum but additionally considers sentence **C**er**T**ainty information in ranking.

The third group in the table shows the performance of *autoencoder-based* neural approaches. C-Attention (Li et al., 2017a) is based on **C**ascaded attention with sparsity constraints for compressive multi-document summarization. VaeSum (Li et al., 2017b) employs a generative model based on **VA**riational auto**E**ncoders (Kingma and Welling, 2013; Rezende et al., 2014) and a data reconstruction model for sentence salience estimation. VAESum represents the state-of-the-art amongst neural systems on DUC.[4] The salience estimation module is further integrated in an integer linear program which selects VPs and NPs to create the final summary.

The last block in Table 4 presents different variants of our query-focused summarizer which we call QuerySum. We show automatic results with distant supervision based on isolated $\mathcal{S}$entences (QuerySum$_{\mathcal{S}}$), $\mathcal{P}$assages (QuerySum$_{\mathcal{P}}$), and an ensemble model (QuerySum$_{\mathcal{S}+\mathcal{P}}$) which combines both. As can be seen, our models outperform strong comparison systems on both DUC test sets: QuerySum$_{\mathcal{S}}$ achieves the best R-1 while QuerySum$_{\mathcal{P}}$ achieves the best R-2 and R-SU4. Perhaps unsurprisingly, both models fall behind the human upper bound.

Our results on the TD-QFS dataset are summarized in Table 5. In addition to Lead and LexRank, we compared to KLSum, the best performing system on this dataset (Baumel et al., 2016). KLSum selects a subset of sentences from retrieved candidates by minimizing the Kullback-Leibler Divergence between the unigram distribution in the selected sentences and the source cluster. QuerySum$_{\mathcal{S}}$ and our ensemble model achieve superior results across all ROUGE metrics.

Human Evaluation For the DUC benchmarks, participants assessed summaries created by

---

[4] Similar to our experimental setting, its hyperparameters are optimized on a development set. For fair comparison, we leave aside a few symbolic approaches that take advantage of query expansion techniques, and task-specific predictors such as position bias.

DUC	Rel	Suc	Coh	All
Lead	$3.75^{\triangleright\dagger\circ}$	$3.60^{\dagger\circ}$	$4.27^{\triangleright}$	$3.96^{\dagger\circ}$
VAESum	4.28	$3.62^{\dagger\circ}$	$4.05^{\dagger\circ}$	$4.03^{\dagger\circ}$
QuerySum	**4.32**	$\mathbf{3.93}^{\triangleright}$	$\mathbf{4.27}^{\triangleright}$	$\mathbf{4.22}^{\triangleright}$
Gold	4.36	$3.93^{\triangleright}$	$4.35^{\triangleright}$	$4.26^{\triangleright}$

TD-QFS	Rel	Suc	Coh	All
Lead	$3.97^{\triangleright\dagger\circ}$	3.93°	4.04°	$3.98^{\dagger\circ}$
KLSum	4.24°	4.13°	4.00°	4.12°
QuerySum	**4.47**	$\mathbf{4.13}^{\circ}$	4.02°	$\mathbf{4.21}^{\circ}$
Gold	$4.60^{\triangleright}$	$4.41^{\triangleright\dagger}$	$4.33^{\triangleright\dagger}$	$4.45^{\triangleright\dagger}$

Table 6: Human evaluation results on DUC (above) and TD-QFS (below): average **Rel**evance, **Suc**cinctness, **Coh**erence ratings; **All** is the average across ratings; $\triangleright$: sig different from VAESum or KLSum; †: sig different from QuerySum; °: sig different from Gold (at $p < 0.01$, using a pairwise t-test).

VAESum[5], a neural state-of-the-art system, QuerySum, and the Lead baseline. For TD-QFS, we evaluated summaries created by KLSum, QuerySum, and Lead. We also included a randomly selected Gold standard summary as an upper bound. We sampled 20 query-cluster pairs from DUC (2006, 2007; 10 from each set), and 20 pairs from TD-QFS (5 from each cluster). We collected three responses per query-summary pair.

Table 6 shows the ratings for each system. As can be seen, participants find QuerySum summaries on DUC more relevant and with less redundant information compared to Lead and VAESum. Our multi-step estimation process also produces more coherent summaries (as coherent as Lead) even though coherence is not explicitly modeled. Overall, participants perceive QuerySum summaries as significantly better ($p < 0.01$) compared to Lead and VAESum (see Appendix B for examples of system output). QuerySum is also considered as the best performing system across metrics on TD-QFS. This further demonstrates the robustness of our system on unseen domains and query types.

Ablation Studies We also conducted ablation experiments to verify the effectiveness of the proposed coarse-to-fine framework. We present results in Table 7 when individual modules are removed. In the −Relevance setting, all text segments (i.e., sentences or passages) in a cluster are given as input to the evidence estimator module. The −Evidence setting treats all retrieved segments as evidence for summarization. Note that since our summarizer operates on sentences, we can only assess this configuration with the QuerySum$_{\mathcal{S}}$ model; we take the top k^{QA} sentences from the retrieval module as evidence. The −Centrality setting treats the (ranked) output of the evidence estimator as the final summary. For the sake of brevity, we report results on DUC-2007 and TD-QFS (DUC-2006 follows a very similar pattern).

Systems	DUC 2007			TD-QFS		
	R-1	R-2	R-SU4	R-1	R-2	R-SU4
QuerySum$_{\mathcal{S}}$	42.9	11.6	16.7	44.4	16.2	20.8
−Relevance	↓1.5	↓1.4	↓1.2	↓2.7	↓3.9	↓3.0
−Evidence	↓0.3	↓0.4	↓0.4	↓0.7	↓0.4	↓0.2
−Centrality	↓2.3	↓1.3	↓1.3	↓0.9	↓1.1	↓0.9
QuerySum$_{\mathcal{P}}$	43.4	11.2	16.5	43.5	14.8	19.7
−Relevance	↓0.2	↑0.2	↑0.1	↓4.2	↓5.4	↓4.8
−Centrality	↓3.2	↓2.1	↓2.0	↓3.3	↓3.5	↓3.3

Table 7: Ablation results (absolute performance decrease/increase denoted by ↓/↑).

As can be seen, removing the retrieval module leads to a large drop in the performance of QuerySum$_{\mathcal{S}}$. This indicates that the (deep) semantic matching model trained for sentence selection can get distracted by noise which a (shallow) relevance matching model can help pre-filter. Interestingly, on DUC, when the matching model is trained on passages, the retrieval module seems more or less redundant, there is in fact a slight improvement in R-2 and R-SU4 (see row QuerySum$_{\mathcal{P}}$, − Relevance in Table 7). This suggests that the evidence estimator trained on passages is more robust and captures the semantics of the query more faithfully. Moreover, since it takes contextual signals into account, it is able to recognize irrelevant information and unanswerability is explicitly modeled. We show in Figure 2 how ROUGE-2 varies over k^{IR} best retrieved segments. We compare three different types of query settings, the short *title*, the *narrative*, and the *full* query with both the title and the narrative. As expected, recall increases with k^{IR} (i.e., when more evidence is selected) and then finally converges. For both sentence and passage retrieval settings, the full query achieves best performance over k^{IR}, with the narrative being most informative when it comes to relevance estimation.

Performance also drops in Table 7 when the evidence estimator is removed (see QuerySum$_{\mathcal{S}}$, −Evidence in Table 7). In Figure 3, we plot how ROUGE-2 varies with increasing k^{QA} when the evidence component is estimated on passages and sentences for the full model. As can be seen, the model trained on passages surpasses the model

---

[5] We are grateful to Piji Li for providing us with the output of their system.

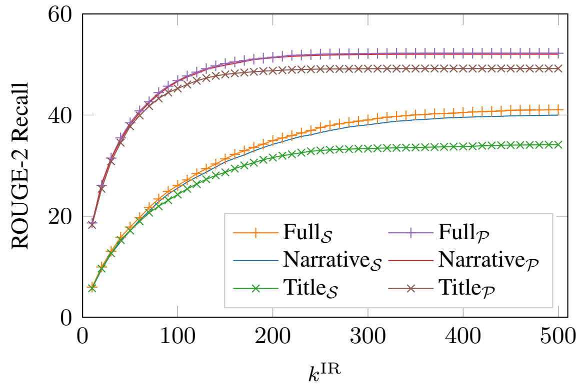

Figure 2: Performance (ROUGE-2 Recall) over k^{IR} best retrieved segments (development set). $\mathcal{S}$ and $\mathcal{P}$ refer to sentence and passage retrieval, respectively. *Full* is the concatenation of the query title and narrative.

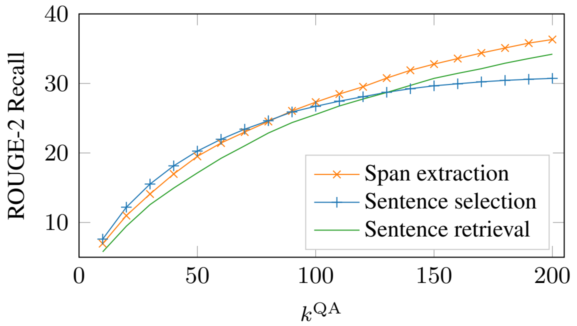

Figure 3: Performance (ROUGE-2 Recall) over k^{QA} best evidence sentences selected by estimators trained on sentences and passages (development set).

trained on sentences roughly when $k^{\mathrm{QA}} = 80$. For comparison, we also show the performance of the retrieval module by treating the top sentences as evidence. The retrieval curve is consistently under the passage curve, and under the sentence curve when $k^{\mathrm{QA}} < 140$. Since the quality of top sentences directly affects the quality of the summarization module, this further demonstrates the effectiveness of evidence estimation in terms of reranking retrieved segments.

Finally, Table 7 shows that the removal of the centrality estimator decreases performance even when the query and appropriate evidence are taken into account. This suggests that the centrality estimator further learns to select important summary worthy sentences from the available evidence. Interestingly, the gain on the DUC datasets is slight but considerable on TD-QFS, suggesting that in less topically concentrated clusters where multiple high-quality answers can be available, the soft discrimination between answer candidates based on their answerability can be useful during the final summary sentence selection.

6 Conclusions

In this work, we proposed a coarse-to-fine estimation framework for query focused multi-document summarization. We explored the potential of leveraging distant supervision signals from Question Answering to better capture the semantic relations between queries and document segments. Experimental results across datasets show that the proposed model yields results superior to competitive baselines contributing to summaries which are more relevant and less redundant. We have also shown that disentangling the tasks of relevance, evidence, and centrality estimation is beneficial allowing us to progressively specialize the summaries to the semantics of the query. In the future, we would like to generate abstractive summaries following an unsupervised approach (Baziotis et al., 2019; Chu and Liu, 2019) and investigate how recent advances in open domain QA (Wang et al., 2019; Qi et al., 2019) can be adapted for query focused summarization.

A Implementation Details

We used the publicly released BERT model[6] and fine-tuned it on our QA tasks with 4 GTX 1080TI GPUs with 11GB memory. For the answer sentence selection model, BERT was fine-tuned with a learning rate of 3×10^{-6} and a batch size of 16 for 3 epochs (Yang et al., 2019). For span selection, we adopted a learning rate of 3×10^{-5} and a batch size of 64 for 5 epochs. During inference, the confidence threshold for the relevance estimator was set to $\theta = 0.75$ (Kratzwald and Feuerriegel, 2018) for both sentence and passage retrieval. For the evidence estimator, k^{QA} was tuned on the development set. We obtained 90 and 110 evidence sentences from the sentence selection and span selection models, respectively. For the centrality estimator, the influence of the query was set to $\phi = 0.15$ (Wan, 2008; Wan and Zhang, 2014).

The TD-QFS dataset used in this work is publicly available at `https://www.cs.bgu.ac.il/~talbau/TD-QFS/dataset.html`. DUC 2005-2007 datasets can be requested from NIST: `https://www-nlpir.nist.gov/projects/duc/data.html`.

B Summary Outputs

We show in Table 8 and Table 9 system outputs for one cluster in DUC 2006 and 2007, respectively.

---

[6] `https://github.com/huggingface/pytorch-transformers`

Query: Crime and Law Enforcement in China. Give examples of criminal activity in China. Name those involved, if possible. What is China doing to fight crime?

Gold: In 1996, China began cracking down on crime. Extensive investigations and citizen tips led to hundreds of arrests for such crimes as drug trafficking; firearms, ammunition and explosives manufacturing, sales, smuggling and possession; burglary and robbery; murder; hooliganism; kidnapping; racketeering; gambling; and blackmail. The perpetrators are often gangs of thieves and criminals, and members of international criminal gangs operating between China and Hong Kong or China and Macau. In 1998, 60% of criminal suspects arrested were minors. Chinese authorities broke up a Hong Kong-based gang operating between Hong Kong and the mainland. Its leader was tried, convicted, and sentenced to death in China. Chinese authorities apprehended members of a Macau gang in its Guangdong Province. As part of its ”Strike Hard national crime-fighting campaign, China agreed to participate in the UN Commission on Crime Prevention and Criminal Justice. China revised its criminal and procedural laws and enacted new laws. Its Criminal Law was amended to include terrorist crime, organized crime, money-laundering, illegal immigrant trafficking, and environment-related crimes. China signed legal assistance agreements with 28 countries and extradition agreements with ten. China pledged increased cross-border anti-crime cooperation and urged Portugal to take tougher measures against gang-related crime in preparation for the 1999 handover of the Portuguese colony. After the handover, China will station troops in Macau to better fight organized criminal activity there. The Chinese government pledges to increase efforts to crack down on corruption, smuggling, and other economic crimes as well as criminal acts in 2000.

Lead: Members of a criminal gang in Foshan city of south China’s Guangdong province, which was controlled by a larger and more notorious gang in neighboring Macao, have been apprehended by local police. Police arrested 28 people who have been involved in more than 30 cases of blackmail, gambling, illegal use of guns and other crimes. The gambling cases involved more than 50 million yuan (about six million U.S. dollars) of illicit money. Police also seized a number of guns and ammunition, including eight military pistols. The gang was established by Zeng Qiqiang in 1996, as a branch of the “Shuifang Bang”, a large criminal gang in Macao. The gang in Foshan, with more than 100 members, used to help the “Shuifang Bang” run its gambling operations and collect money from people by force. To date, the provincial public security department of Guangdong and the local police in Foshan have completely uprooted the gang which seriously threatened the security of Foshan and Macao.

VAESum: Police working with Hong Kong authorities had arrested 18 members of the gang in southern Guangdong province, which is adjacent to Hong Kong. As a reputed local crime boss fights his death sentence in China, reports Thursday said Hong Kong officials had previously asked mainland counterparts to consider sparing the lives of territory residents convicted of capital offenses in China. A police chief of a southern Chinese city where a reputed Hong Kong crime boss is on trial has stepped up security following assassination threats by gang members. Gang members loyal to “Big Spender” Cheung Tze-keung have put a 4 million Hong Kong dollar (U.S. dlrs 512,000 million) price tag for the death of Guangzhou police chief Zheng Guoqiang. The arrests are the latest in a series by Chinese and Hong Kong police to crack down on criminal activities related to 43-year-old Hong Kong gang boss Cheung Tze-keung, alias “Big Spender”. Charges against the reputed gangsters center around the killing of a mainland Chinese businessman and a Hong Kong resident, armed robberies, smuggling explosives into Hong Kong, and the kidnapping of the two Hong Kong businessmen for more than 1.6 billion Hong Kong dollars (U.S. dlrs 205 million) in ransom. Hong Kong officials would appeal on grounds that the mainland had no jurisdiction over Cheung’s case since many of Cheung’s alleged crimes, including kidnappings of two Hong Kong tycoons, were committed in Hong Kong. 18 were Hong Kong residents and 14 were from mainland China.

QuerySum: Zhang Fusen, head of the Chinese delegation, told the fifth session of the UN commission on Crime Prevention and Criminal Justice (CCPCJ) that China will participate in united nations activities in crime prevention and criminal justice. China has revised the criminal law and criminal procedure law, promulgated and enforced new laws such as the lawyers’ law and the law on administrative punishment to strengthen the judicial guarantee for human rights during that period of time, the paper says. As a reputed local crime boss fights his death sentence in china, reports Thursday said Hong Kong officials had previously asked mainland counterparts to consider sparing the lives of territory residents convicted of capital offenses in China. China is ready to strengthen cooperation with other countries and international organizations in combating and preventing organized transnational crime, a senior Chinese official said here today. Zhang said that in the past few years, China’s law enforcement authorities cracked numerous cases in southeast china involving killing, kidnapping and racketeering by members of criminal gangs which entered china from overseas. Statistics show that in 1996, courts throughout the country sentenced 322,382 criminal offenders who had seriously endangered public security by committing crimes of violence, crimes involving the use of guns, and gang-related crimes. Speaking at the opening ceremony of the seventh world conference of Asia Crime Prevention Foundation (ACPF), deputy procurator-general of the supreme people’s procuratorate of China Liang Guoqing called for enhancing cooperation among asian countries to fight crimes and set up a crime prevention regime.

Table 8: System outputs for cluster D0621C in DUC 2006. The gold summary answers the query covering four main aspects (denoted with different colors): (1) general facts and vision; (2) criminal activities in southeastern China, including HongKong and Macau; (3) international corporations; (4) law revision and enforcement. Our system produces more diverse content that represents these aspects compared to other systems.

Query	Describe the activities of Morris Dees and the Southern Poverty Law Center.
Gold	Morris Dees is a co-founder and leader of the Southern Poverty Law Center, located in Montgomery, Alabama. It was founded to battle racial bias and has expanded its efforts by tracking hate crimes and the increasing spread of racist organizations across the US. ”Teaching Tolerance” is a major program of the Center. Under that program, a magazine promoting interracial and intercultural understanding goes to more than 400,000 teachers. Other publications of the Center include the magazine ”Intelligence Report” and pamphlets ”Ten Ways to Fight Hate” and ”Fighting Hate at School”. Dees has determined that the civil courts are an effective forum in which to attack and destroy hate groups. He has used the civil lawsuit like a ”Buck Knife, carving financial assets out of hate group leaders”. Some skeptics thought that Dees sought out victims of hate groups to profit from their tragedy. However, Dees does not charge the groups and the Center estimates that it collects only 2% on successful judgments. Dees has a perfect record in the major lawsuits he has prosecuted. Successful judgments include one for $21.5M against a South Carolina branch of the Ku Klux Klan for burning the Macedonia Baptist Church. Others include $6.3M against Aryan Nation’s leader Richard Butler and $7M against a Klan group that killed a black man in Mobile, Alabama. The Center operates mostly on contributions that in the late 1990s have increased to around $100 Million annually.
Lead	Spokane, Wash. (AP) – facing eviction from its compound in northern Idaho, the aryan nations may move its annual white supremacist gathering to Pennsylvania next year. The news was posted on the Neo-Nazi group’s web site Friday, a week after the group was slapped with a $6.3 million judgment in a civil lawsuit. The compound is scheduled to be seized on sept. 29 and the assets sold to satisfy a portion of the judgment due to two people who sued the group after they were assaulted by aryan nations’ guards. The notice was the first indication that the lawsuit, brought by the southern poverty law center, may drive the group out of Idaho. ”I have been asked if I would continue to host the yearly national congress and my answer was, of course, an astounding yes!” wrote august B. Kreis III, web master for the Aryan nations and a posse comitatus leader in Pennsylvania. Kreis wrote that if the compound is lost, the Aryan nations ”National Congress 2001” would be planned for a site near ulysses, pa. Aryan nations leader Richard Butler declined to talk with reporters Friday. He is appealing the judgment to the Idaho supreme court, but that appeal is not expected to halt the seizure of the group’s 20-acre compound north of Hayden lake. Morris Dees, the civil rights lawyer who led the plaintiffs’ legal team, has said he expected the judgment to bring a quick end to the aryan nations and its racist, anti-semitic message.
VAESum	A state jury in northern Idaho Thursday ordered leaders of the Aryan nations to pay more than $6 million to the victims of an attack two years ago by men who were serving as security guards at the group’s compound near here. Coeur d’Alene, Idaho – issuing a verdict that civil rights organizations hope will bankrupt one of the nation ’s largest white-supremacist groups and limit its ability to preach hate. Aryan nations leader Richard Butler vowed Saturday he will not leave northern Idaho, despite a $6.3 million judgment against his racist organization. Coeur d’Alene, idaho – Morris S. Dees JR. , who has won a series of civil rights suits against the Ku Klux Klan and other racist groups in a campaign to put them out of business, came to court here Monday to try to seize the Aryan nations compound that has nurtured white supremacists for more than 20 years. Her son who were attacked by Aryan nations guards outside the white supremacist group’s north Idaho headquarters. One of two men convicted of assaulting a woman and her son outside the headquarters of the Aryan nations denied being a member of the white supremacist group Thursday during testimony in a civil rights case filed against them, the aryan nations and the group’s founder, Richard Butler. Morris Dees, co-founder of the southern poverty law center in Montgomery, Ala., has said he intends to take everything the aryan nations owns to pay the judgment, including the sect’s name.
QuerySum	Morris Dees, the co-founder of the southern poverty law center in Montgomery, Ala., and one of the attorneys for the plaintiffs, said he intended to enforce the judgment, taking everything the Aryan nations owns, including its trademark name. Dees, founder of the southern poverty law center, has won a series of civil right suits against the Ku Klux Klan and other racist organizations in a campaign to drive them out of business. But since co-founding the southern poverty law center in 1971, Dees has wielded the civil lawsuit like a buck knife, carving financial assets out of hate group leaders who inspire followers to beat, burn and kill. In a lawsuit that goes to trial Monday, attorney Morris Dees of the southern poverty law center is representing a mother and son who were attacked by security guards for the white supremacist group. The southern poverty law center tracks hate groups, and intelligence report covers right-wing extremists. Over the last two decades, the southern poverty law center has taken the Ku Klux Klan and other hate groups to court, starting with a successful suit against the invisible empire Klan, which in 1979 attacked a group of peaceful civil rights marchers in Decatur, Ala. He said Gilliam also told the informant someone should kill the FBI sniper who killed the wife of white supremacist randy weaver during an 11-day standoff in 1992 at Ruby Ridge, Idaho, along with civil rights lawyer Morris Dees of the Montgomery-based southern poverty law center.

Table 9: System outputs for cluster D0701A in DUC 2007. The gold summary answers the query covering three main aspects (denoted with different colors): (1) Southern Poverty Law Center and its activities; (2) Morris Dees and his activities; (3) representative successful lawsuits. For this document cluster, summarization systems are prone to extract unnecessary lawsuit details, which indirectly relate to the given query but are not the query focus. Our system contains more summary-worthy facts that succinctly respond to the given query compared to other systems.

Pre-training for Abstractive Document Summarization by Reinstating Source Text

Abstract

Abstractive document summarization is usually modeled as a sequence-to-sequence (SEQ2SEQ) learning problem. Unfortunately, training large SEQ2SEQ based summarization models on limited supervised summarization data is challenging. This paper presents three sequence-to-sequence pre-training (in shorthand, STEP) objectives which allow us to pre-train a SEQ2SEQ based abstractive summarization model on unlabeled text. The main idea is that, given an input text artificially constructed from a document, a model is pre-trained to reinstate the original document. These objectives include sentence reordering, next sentence generation and masked document generation, which have close relations with the abstractive document summarization task. Experiments on two benchmark summarization datasets (i.e., CNN/DailyMail and New York Times) show that all three objectives can improve performance upon baselines. Compared to models pre-trained on large-scale data ($\geq$160GB), our method, with only 19GB text for pre-training, achieves comparable results, which demonstrates its effectiveness. Code and models are public available at `https://github.com/zoezou2015/abs_pretraining`.

1 Introduction

Automatic document summarization is the task of condensing a document into its shorter form with important content preserved, which requires wide-coverage understandings of the document, rather than specific words or phrases. This task can be typically classified into two categories: extractive and abstractive document summarization. Extractive summarization (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2018a) aims to extract important sentences from the input document and concatenates such extracted sentences as the corresponding output summary. Thus, the relative orders of the selected sentences in the summary is the same as their relative orders in the input document. Differently, abstractive summarization (Nallapati et al., 2016; See et al., 2017; Paulus et al., 2018) rewrites the source text and generates the corresponding summary which may contain novel words and phrases not featured in the input. The output summary is closely related to the input document. Also, summary sentences, paraphrased from the input by the abstractive summarizers, might have a different relative order compared to the source text. In other words, contents of the original document may be *reordered* in its summary. Such a phenomena is defined as *content reordering* (see Section 3.2 for detailed definition). Statistically, we observed that around 40% instances of the training split of our summarization dataset have this content reordering phenomena. Therefore, it is necessary to design a model that is capable of reordering content. However, as far as we know, relatively rare prior work has studied this for abstractive summarization.

Abstractive summarization is usually framed as a sequence-to-sequence (SEQ2SEQ) learning problem (Nallapati et al., 2016; See et al., 2017). In this paper, we adopt the SEQ2SEQ Transformer (Vaswani et al., 2017), which has been demonstrated to be the state-of-the-art for SEQ2SEQ modeling (Vaswani et al., 2017; Ott et al., 2019). Recent studies (Song et al., 2019; Dong et al., 2019; Lewis et al., 2019; Zhang et al., 2019a; Raffel et al., 2019) have proven effectiveness of pre-trained SEQ2SEQ Transformer models on the natural language generation tasks, such as abstractive summarization.

Based on the above observations, with regard to abstractive summarization, this work proposes

November 16–20, 2020.

three **s**equence-**t**o-s**e**quence **p**re-training (in shorthand, STEP) objectives which can be used to pre-train a SEQ2SEQ model on unlabeled text, namely Sentence Reordering (SR), Next Sentence Generation (NSG), and Masked Document Generation (MDG). All three objectives are designed to reinstate the original source text. SR learns to recover a document with randomly shuffled sentences. Given the first segment of a document, NSG generates the next segment of the original document. MDG learns to recover a masked document to its original form.

After pre-training a model with our proposed objective(s) on unlabeled documents, we fine-tune it on supervised summarization datasets (i.e., CNN/DailyMail and New York Times). Experiments show that, even pre-training on documents from the training split of a summarization dataset, our method can improve performance upon a heavily tuned large SEQ2SEQ Transformer model which already includes a strong pre-trained encoder by a large margin. By involving more data (19GB) for pre-training, the performance is further improved. Compared to models pre-trained with much more data ($\geq$160GB), we can still achieve comparable or even higher ROUGE scores.

2 Related Work

Extractive Summarization This task aims to find the informative sentences in a document as its summary. This task is usually viewed as a sentence ranking problem (Kupiec et al., 1995; Conroy and O'leary, 2001) using scores from a binary (sequence) classification model, which predicts whether a sentence is in the summary or not. Extractive neural models (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2018b; Zhang et al., 2018) employ hierarchical LSTMs/CNNs as the feature learning part of the binary (sequence) classifier, which largely outperform discrete feature based models (Radev et al., 2004; Filatova and Hatzivassiloglou, 2004; Nenkova et al., 2006). Very recently, the feature learning part was replaced again with pre-trained Transformer encoders (Zhang et al., 2019b; Liu and Lapata, 2019) that lead to another huge performance gain. However, extractive models have their own limitations. For example, the extracted sentences might be too long and redundant. Besides, manually written summaries in their nature are abstractive. Therefore, we focus on abstractive summarization in this paper.

Abstractive Summarization This task aims to generate a summary by rewriting a document, which is a SEQ2SEQ learning problem. SEQ2SEQ attentive LSTMs (Hochreiter and Schmidhuber, 1997; Bahdanau et al., 2015) are employed in Nallapati et al. (2016) that have been extended with copy mechanism (Gu et al., 2016), coverage model (See et al., 2017) and reinforcement learning (Paulus et al., 2018). Liu and Lapata (2019) used a SEQ2SEQ Transformer model with only its encoder initialized with a pre-trained Transformer encoder (i.e., BERT; Devlin et al. 2019). This work proposes to pre-train the decoder together with the encoder and then initialize both the encoder and decoder of a summarization model with the pre-trained Transformer model.

There is also a line of work that bridges extractive and abstractive models with attention mechanisms (Gehrmann et al., 2018; Hsu et al., 2018) and reinforcement learning (Chen and Bansal, 2018), while our model is simpler.

Pre-training Pre-training methods draw a lot of attentions recently. Peters et al. (2018) and Radford et al. (2019) pre-trained LSTM and Transformer using language modeling objectives. To leverage the context in both directions, BERT (Devlin et al., 2019) is trained with the masked language modeling and next sentence prediction objectives. SpanBERT (Joshi et al., 2020) applied only the masked language modeling objective that masks contiguous random spans, rather than random tokens. XLNet (Yang et al., 2019) proposed a permutation language modeling objective that removes the independence assumption of masked tokens in BERT. RoBERTa (Liu et al., 2019) extends BERT with more training data and better training strategies. The above models focus on pre-training an encoder or a decoder, while we propose methods to pre-train a SEQ2SEQ model (i.e., the encoder together with the decoder) for abstractive summarization.

Dong et al. (2019) (UniLM) proposed a unified language model that can be used for both natural language understanding and generation tasks, which is pre-trained using masked, unidirectional and SEQ2SEQ language modeling objectives. The encoder and decoder parameters are shared. By contrast, we pre-train a SEQ2SEQ Transformer with separate parameters for the encoder and decoder. Song et al. (2019) (MASS) proposed a method to pre-train a SEQ2SEQ Transformer by masking a span of text and then predicting the masked tokens. Their pre-training task is similar to our MDG task, but we apply a different masking strategy and predict the original text. Song et al. (2019) tested their model on sentence-level tasks (e.g., machine translation and sentence compression), while we aim to solve document-level tasks (e.g., abstractive document summarization). Lewis et al. (2019) (BART) adopted the combination of text infilling and sentence permutation as a single objective for SEQ2SEQ Transformer pre-training. Differently, we propose three objectives and use them individually. Specifically, MDG replaced each selected token with a masked token in the input sequence. Raffel et al. (2019) (T5) studies different pre-training objectives, model architectures, and unlabeled datasets. ProphetNet (Yan et al., 2020) predicts the next n tokens simultaneously. Zhang et al. (2019a) (PEGASUS) proposed to remove/mask sentences from an input document and learn to generate such removed/masked sentences for pre-training, while NSG predicts the following sentences of the input sequence and MDG masks randomly selected tokens.

3 Proposed Method

3.1 Sequence-to-Sequence Learning

In this work, the task of abstractive document summarization is modeled as a SEQ2SEQ learning problem. We adopt the SEQ2SEQ Transformer architecture (Vaswani et al., 2017). Given a document $X = (x_1, x_2, \ldots, x_{|X|})$ paired with its summary $Y = (y_1, y_2, \ldots, y_{|Y|})$, we aim to learn the model parameters θ and estimate the conditional probability:

$$P(Y|X;\theta) = \prod_{t=1}^{|Y|} p(y_t|y_{<t}; X; \theta) \qquad (1)$$

where $y_{<t}$ stands for all tokens before position t (i.e., $y_{<t} = (y_1, y_2, \ldots, y_{t-1})$). Given the whole training set $(\mathcal{X}, \mathcal{Y})$, this model can be trained by maximizing the log-likelihood of the training document-summary pairs:

$$\mathcal{L}(\theta; \mathcal{X}, \mathcal{Y}) = \sum_{(X,Y)\in(\mathcal{X},\mathcal{Y})} \log P(Y|X;\theta) \qquad (2)$$

We first pre-train the SEQ2SEQ Transformer model on the unlabeled text using our proposed pre-training objectives (see Section 3.2) and then fine-tune it on the document-summary dataset.

3.2 Pre-training Objectives

Automatic abstractive summarization requires comprehensive understanding of the input document and rewrites the source text into its shorter form, where the summary is closely related to the input, retaining important contents. Also, rewriting the document may result in content reordering.

Now, we define ***content reordering*** as follows. For each document-summary pair, we first map each sentence in the summary to its corresponding sentence in the document by maximizing the ROUGE score (see Appendix A more details). If the relative orders of sentences in the summary are different from the relative orders of their mapped sentences in the original document, we count this as one content reordering. According to the statistics on the training split of our summarization dataset, contents of the original documents are *reordered* in their summaries for 40% of cases, approximately.

The above observations motivate us to propose sequence-to-sequence pre-training objectives that are capable of pre-training a SEQ2SEQ model serving the abstractive summarization task.

Sentence Reordering In sentence reordering (SR), we first divide an unlabeled document into multiple sentences based on full stops. Let us change the notation of a document slightly in this paragraph. Let $X = (S_1||S_2||\ldots||S_m)$ denote a document, where S_i is a sentence, m is the number of sentences, and $||$ refers to sentence concatenation. The sentence index order in X can be represented as $\mathcal{O} = (1, 2, \ldots, m)$. We then shuffle the document by sentences. In other words, the items in the order $\mathcal{O}$ are rearranged and we obtain a shuffled order $\mathcal{O}_S = (a_1, a_2, \ldots, a_m)$, where $1 \leq a_i \leq m$, $1 \leq a_j \leq m$, and $a_i \neq a_j$ for any $i, j \in [1, m]$ and $i \neq j$. Concatenating sentences following $\mathcal{O}_S$, we obtain a *shuffled* document $\hat{X}_S = (S_{a_1}||S_{a_2}||\ldots||S_{a_m})$. A SEQ2SEQ model takes as input the shuffled document $\hat{X}_S$ and is pre-trained to reinstate the original one X, as demonstrated in Figure 1. The training objective is calculated as:

$$\mathcal{L}(\theta; \mathcal{X}) = \sum_{X\in\mathcal{X}} \log P(X|\hat{X}_S;\theta)$$

There are several reasons why we design this objective. First, a summary of a document usually consists of multiple sentences. We expect that the model is pre-trained to learn to generate

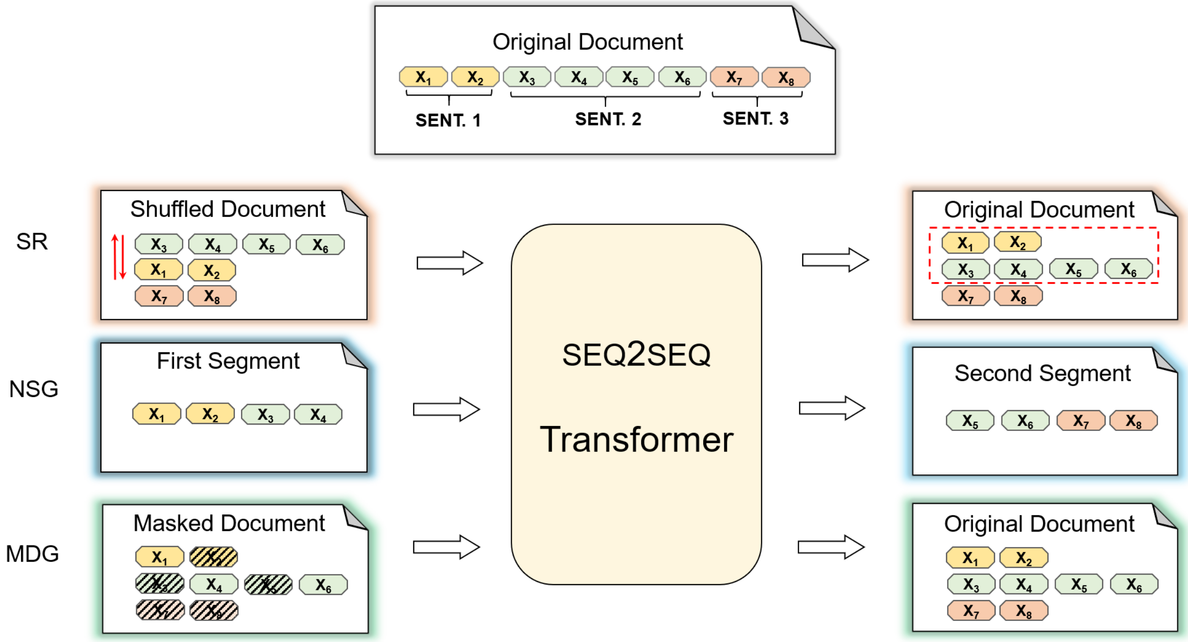

Figure 1: Assume a document $(x_1, x_2, \cdots, x_8)$ contains three sentences (i.e., SENT. 1, SENT. 2 and SENT. 3). A SEQ2SEQ Transformer model can be pre-trained with our proposed objective. It takes the transformed document (i.e., a shuffled document, the first segment of a document, or a masked document) as input and learns to recover the original document (or part of the original document) by generation. SR: Sentence Reordering; NSG: Next Sentence Generation; MDG: Masked Document Generation.

long and coherent summaries (across sentences). The output of the objective (i.e., the original document) also contains multiple sentences. Second, as we discussed earlier, sentence reordering (or content reordering) is necessary for summarization. Third, abstractive summary requires reproducing factual details (e.g., named entities, figures) from the source document. We also expect the model to learn to copy tokens.

Note that document rotation[1] is a special case of sentence reordering with a significant amount of partially ordered sentences, which we believe is a simpler objective. In this work, we only consider the general case of sentence reordering.

Next Sentence Generation Next Sentence Generation (NSG) uses one span of text in a document to predict its next span of text, which leverages the natural order of text, as shown in Figure 1. Specifically, we split a document into two segments (i.e., $\hat{X}_{G_1}$ and $\hat{X}_{G_2}$). Note that each segment might contain multiple sentences. Intuitively, in a document, sentences are highly correlated with their preceding sentences due to the context dependent nature of documents or language. Our intention is to learn to generate multiple sentences and also learn to focus on input text, which fits the document summarization task, since either a document or its summary usually includes multiple sentences and they are closely related. The training objective is calculated as:

$$\mathcal{L}(\theta; \mathcal{X}) = \sum_{X=(\hat{X}_{G_1}||\hat{X}_{G_2}), X\in\mathcal{X}} \log P(\hat{X}_{G_2}|\hat{X}_{G_1}; \theta)$$

We do not make constraints that the split point must be the position right after a full-stop symbol, which ensures full sentences for each segment. Instead, the split point can be at any position within the document, which may lead to incomplete sentences in segments. We intend to force the model to understand input text without complete information. Similarly, as a common wisdom in abstractive summarization, documents, as input, are truncated to a fixed number of tokens, which may also contain incomplete sentences. This setting allows to reduce mismatches between the pre-training and fine-tuning input.

---

[1] A document is randomly divided into two fragments $X = (F_1||F_2)$ using full stops. The rotated document is $\hat{X}_R = (F_2||F_1)$. Document rotation recovers X using $\hat{X}_R$.

Masked Document Generation The third objective is Masked Document Generation (MDG) that learns to reinstate a document with a masked span of tokens (see Figure 1). A document is denoted as $X = (x_1, x_2, \cdots, x_{|X|})$. We randomly sample the length of the span l from a discrete uniform distribution $\mathcal{U}(a, b)$ (a and b are distribution parameters) and the span starting position k from another discrete uniform distribution $\mathcal{U}(1, |X| - l + 1)$. Thus, $\mathcal{M} = (x_k, x_{k+1}, \cdots, x_{k+l-1})$ is the text span to be masked. Let $\hat{X}_M$ denote the document after the application of our masking strategy. The training objective is calculated as:

$$\mathcal{L}(\theta; \mathcal{X}) = \sum_{X \in \mathcal{X}} \log P(X | \hat{X}_M; \theta)$$

One straightforward masking strategy is to replace each token residing in $\mathcal{M}$ with a special `[MASK]` token. However, we refrain from doing so because of the following two reasons. Usually, `[MASK]` tokens will not appear in downstream tasks. Second, similar to SR, avoiding replacing every token with `[MASK]` also helps our model learn the ability of copying tokens from the input while preserving the ability of generating novel tokens. Thus, in the sub-sequence $\mathcal{M}$, each token is processed with one of the three strategies: 1) replaced with the `[MASK]` token; 2) replaced with a random token; 3) remains unchanged. Inspired by BERT (Devlin et al., 2019), for 80% of selected tokens, we follow strategy 1). In 10% of cases, we employ strategy 2) and we use strategy 3) for the remaining 10% of cases.

During pre-training, we consider two settings. **Setting one:** pre-training a model with one single objective, i.e., SR, NSG or MDG, resulting in three different pre-trained models. **Setting two**: employing all three objectives. For each training batch, we randomly choose one objective and each objective is used for $1/3$ of the training time, obtaining one model (i.e., ALL, see Section 5).

For better reference, we name our model as STEP (i.e., **s**equence-**t**o-s**e**quence **p**re-training) that can be used to denote a SEQ2SEQ model pre-trained using our proposed objective(s).

3.3 Fine-tuning

After a SEQ2SEQ model is pre-trained, we fine-tune the model on abstractive document summarization datasets. In other words, we continue to train the model on the document-summary pairs.

4 Experimental Setup

4.1 Datasets

CNNDM The CNNDM dataset contains news articles and the associated highlights (i.e., summaries) collected from the CNN and Daily Mail Online websites[2]. Articles were collected starting in April 2007 for CNN and June 2010 for Daily Mail, both until the end of April 2015. The validation data is from March 2015, and the test data from April 2015 (Hermann et al., 2015). Following previous work (See et al., 2017; Liu and Lapata, 2019), we use the non-anonymized version of CNNDM. Specifically, we preprocessed the dataset with the publicly available scripts[3] provided by See et al. (2017) and obtained 287,226 document-summary pairs for training, 13,368 for validation and 11,490 for test.

NYT The NYT dataset (Sandhaus, 2008) is a collection of articles along with multi-sentence summaries written by library scientists. Following the preprocessing procedures described in (Durrett et al., 2016; Liu and Lapata, 2019), the test set is constructed by including all articles published on January 1, 2007 or later, which contains 9,076 articles. The remaining 100,834 articles are split into a training set of 96,834 examples and a validation set of 4,000 examples. Following (Durrett et al., 2016), we also removed articles whose summaries contain less than 50 words from the test set, and the resulting test set contains 3,452 examples.

GIGA-CM To pre-train our model with the objectives introduced in Section 3.2, following the procedures in Zhang et al. (2019b), we created the GIGA-CM dataset, which contains only unlabeled documents. The training set of GIGA-CM is composed of 6,521,658 documents sampled from the English Gigaword dataset[4] and the training documents in CNNDM, resulting in 19GB text for pre-training. We used the 13,368 documents in the validation split of CNNDM as the validation set. Note that the Gigaword dataset overlaps with the NYT dataset and we therefore excluded the test set of NYT from the training set of GIGA-CM.

Table 1 lists the number of document-summary pairs (for CNNDM and NYT) and unlabeled documents (for GIGA-CM). For CNNDM, NYT and

Dataset	Training	Validation	Test
CNNDM	287,226	13,368	11,490
NYT	96,834	4,000	9,076
GIGA-CM	6,521,658	13,368	-

Table 1: The number of document-summary pairs (for CNNDM and NYT) and unlabeled documents (for GIGA-CM).

GIGA-CM datasets, we segmented and tokenized documents and/or summaries (GIGA-CM only contains documents) using the Stanford CoreNLP toolkit (Manning et al., 2014). We further applied the UTF8 based BPE (Sennrich et al.; Radford et al., 2019) to reduce the vocabulary size. As a common wisdom in abstractive summarization, documents and summaries in CNNDM and NYT are usually truncated to 512 and 256 tokens, respectively.

We leverage unlabeled documents differently for different pre-training objectives. We first split each document into 512-token pieces if it contains more than 512 tokens (pieces or documents with less than 512 tokens are removed). In SR and MDG, we use the piece after transformation to predict its original form. We set the minimum and maximum masked length $a = 100$ and $b = 256$ in MDG individually. In NSG, each piece is used to predict its next 256 tokens.

4.2 Implementation Details

As mentioned in Section 3, we adopt the SEQ2SEQ Transformer model (Vaswani et al., 2017) as our backbone architecture. The purpose of releasing large pre-trained models is to reuse so that the community can avoid high computational costs. Hence, similar to previous work (Liu and Lapata, 2019), our encoder is initialized with a pre-trained model, i.e., RoBERTa$_{\text{LARGE}}$ model[5] (Liu et al., 2019), and therefore they share the same architecture. Specifically, the encoder is a 24-layer Transformer. Each layer has 16 attention heads and its hidden size and feed-forward filter size are 1,024 and 4,096, respectively. The decoder is shallower with 6 layers and is randomly initialized. The number of total trainable model parameters is 585M. The hidden size and number of attention head of the decoder are identical to those of the encoder, but the feed-forward filter size is 2,048. We use a smaller filter size in the decoder to reduce the computational and memory cost. The dropout rates of all layers in the encoder are set to 0.1 and all dropout rates in the decoder are set to 0.3. Our models are optimized using Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$. The other optimization hyper-parameters for pre-training and fine-tuning are different. In the pre-training stage, the encoder is initialized with a pre-trained model while the decoder is randomly initialized. Therefore, similar to Liu and Lapata (2019), we used two separate optimizers for the encoder and decoder. The peak learning rates of the encoder and decoder are set to $2e-5$ and $1e-4$ with 10,000 warmup steps, respectively. We also adopted the same learning rate schedule strategies as in Vaswani et al. (2017). We used smaller batch sizes for datasets with less examples (i.e., 1,024 for GIGA-CM, 256 for CNNDM and 128 for NYT) to ensure each epoch has sufficient number of model updates. We trained our models until their convergence of validation perplexities (around 30 epochs on GIGA-CM, 60 epochs on CNNDM and 40 epochs on NYT). One epoch on GIGA-CM takes around 24 hours with 8 Nvidia Tesla V100 GPUs. The time costs for different pre-training objectives are close.

We highlight the parameters used in the fine-tuning stage that are different from the pre-training stage. Others remain the same. The learning rates for both the encoder and decoder are set to 2e-5 with 4,000 warmup steps, since both the encoder and decoder are already pre-trained. We trained our models for 30 epochs on CNNDM and 50 epochs on NYT, respectively. We selected the best model with regard to ROUGE score on the validation set. During decoding, similar to Liu and Lapata (2019); Dong et al. (2019), we applied beam search with beam size of 5. We also conducted experiments on the validation set of CNNDM with different beam sizes (i.e., 1 to 10). According to ROUGE-L, beam=5 is indeed optimal. Detailed results with different beam sizes are included in the Appendix B. Following Paulus et al. (2018), we also blocked repeated trigrams during beam search and tuned the minimum summary length on the validation set in the range of $[30, 80]$. The search range of minimum summary length was empirically set according to the summaries of training split of CNNDM, where the average and medium minimum lengths are both around 55. We used step size of 5 to get quick feedback. Similar

---

[5] We tried RoBERTa$_{\text{BASE}}$ and obtained inferior results.

to the pre-training process, the datasets with less instances were fine-tuned with smaller batch sizes (i.e., 64 for NYT and 768 for CNNDM).

5 Results

5.1 Automatic Evaluation

We used ROUGE (Lin, 2004) to measure the quality of different summarization model outputs. We reported full-length F1 based ROUGE-1, ROUGE-2 and ROUGE-L scores on CNNDM, while we used the limited-length recall based ROUGE-1, ROUGE-2 and ROUGE-L on NYT, following Durrett et al. (2016). The ROUGE scores are computed using the `ROUGE-1.5.5.pl` script[6].

Models in Comparison Lead3 is a baseline which simply takes the first three sentences of a document as its summary. BERTExt (Liu and Lapata, 2019) is an extractive model fine-tuned on BERT (Devlin et al., 2019) that outperforms other extractive systems. PTGen (See et al., 2017), DRM (Paulus et al., 2018), and DCA (Celikyilmaz et al., 2018) are Seq2Seq learning based models extended with copy and coverage mechanism, reinforcement learning, as well as deep communicating agents individually. BottomUp (Gehrmann et al., 2018) assisted summary generation with a word prediction model. BERTAbs (Liu and Lapata, 2019) and UniLM (Dong et al., 2019) are both pre-training based models and are trained based on BERT (Devlin et al., 2019). We also implemented four abstractive models as our baselines. Transformer-S2S is a 12-layer Seq2Seq Transformer with random initialization. When we replaced the encoder of Transformer-S2S with RoBERTa$_{\text{BASE}}$ or RoBERTa$_{\text{LARGE}}$ (Liu et al., 2019), we obtain two baselines, RoBERTa$_{\text{BASE}}$-S2S and RoBERTa-S2S, respectively. Following Liu et al. (2019), we further train the RoBERTa$_{\text{LARGE}}$ on the documents of training split of CNNDM for 60 epochs, same as the number of epochs for our models (indicated as "In-domain"). We replaced the encoder of Transformer-S2S with this further trained model, resulting in RoBERTa$_{\text{CONT}}$-S2S.

Table 2: Results on the test split of CNNDM using full-length F1 based ROUGE-1 (R-1), ROUGE-2 (R-2) and ROUGE-L (R-L). $*$ indicates significant improvements ($p < 0.05$ measured with the ROUGE script) compared to models in the first two blocks.

Results on CNNDM The results on the CNNDM are listed in Table 2. The first and second blocks show results of previous extractive and abstractive models, respectively. Results of ours are all listed in the third block. RoBERTa$_{\text{BASE}}$-S2S outperforms Transformer-S2S by nearly 2 ROUGE points. RoBERTa-S2S further improves the performance. This shows the effectiveness of the pre-trained encoders.

Then, we study the effects of different pre-training objectives (see Section 3.2). We first pre-train a Seq2Seq Transformer model (the sizes of our model and RoBERTa-S2S are identical) on unlabeled documents of CNNDM training split to get quick feedback[7], denoted as "STEP (In-domain)". From the top part of the third block in Table 2, we can see that Sentence Reordering (SR), Next Sentence Generation (NSG) and Masked Document Generation (MDG) can all improve RoBERTa$_{\text{BASE}}$-S2S and RoBERTa-S2S significantly measured by the ROUGE script[8]. Interestingly, even though we merely use the in-domain training split (around 1GB), our method still significantly outperforms UniLM (Dong et al., 2019) that is pre-trained on 16GB data. Compared to STEP (In-domain) (e.g., pre-training with SR)

Table 3: Results on the test set of NYT dataset using limited-length recall based ROUGE. $*$ indicates significant improvements ($p < 0.05$ measured with the ROUGE script) to models in the first two blocks.

with ROBERTA$_{\text{CONT}}$-S2S, although the encoders of such two models are pre-trained on the same corpus for the same epochs, our model achieves better performance. This shows that the performance gains mainly result from our proposed objectives for pre-training the decoder together with the encoder. Training RoBERTa longer may improve understanding tasks (Liu et al., 2019), but no evidence shows longer training time for RoBERTa may improve generation performance.

When we pre-train the SEQ2SEQ model on even larger dataset (i.e., GIGA-CM in the size of 19GB), indicated as STEP (GIGA-CM), the results are further improved and our method outperforms all models under comparison, as listed in the bottom part of Table 2.

Results on NYT Table 3 presents results on NYT dataset. Following the same evaluation protocol as Durrett et al. (2016), we adopted the limited-length recall based ROUGE, where we truncated the predicted summaries to the length of the gold ones. Again, the first and second blocks show results of previous extractive and abstractive models, respectively. Results of our models are listed in the third block. Similar to the trends in CNNDM, our method leads to significant performance gains (with $p < 0.05$).

Comparisons among Objectives Among all three pre-training objectives, SR works slightly better than the other two objectives (i.e., NSG and MDG). We also tried to randomly use all the three objectives during training with 1/3 probability each (indicated as ALL). Interestingly, we observed that, in general, ALL outperforms all three objectives when employing unlabeled documents of training splits of CNNDM or NYT, which might be due to limited number of unlabeled documents of the training splits. After adding more data (i.e., GIAG-CM) for pre-training, SR consistently achieves the highest ROUGE-2 on both CNNDM and NYT. We conclude that SR is the most effective pre-training objective for abstractive summarization since sentence reordering objective fits content reordering and it requires comprehensively understanding a document in a wide coverage, going beyond individual words and sentences, which is highly close to the essence of abstractive document summarization.

Model	Corpus Size	R-1	R-2	R-L
T5	750GB	43.52*	**21.55***	40.69*
PEGASUS (C4)	750GB	43.90	21.20	40.76*

STEP	19GB	44.03	21.13	41.20

Table 4: Results on the CNNDM test split of models pre-trained on different corpora. $*$ indicates significant differences from our model.

We put the performance of our models on the validation splits of CNNDM and NYT in the Appendix B.

Comparison to Models Pre-trained with Large-scale Corpora It is worth noting that several models have been released recently, which are pre-trained using various corpora much larger than ours, as listed in Table 4 (top part). T5 (Raffel et al., 2019) introduced C4 (750GB) as its pre-training corpus. PEGASUS$_{\text{LARGE}}$ has two versions that are pre-trained on C4 and HugeNews (3,800GB), respectively. Both BART (Lewis et al., 2019) and ProphetNet (160GB) (Yan et al., 2020) are pre-trained on a 160GB corpus introduced by Liu et al. (2019). We compare our best preforming model STEP (i.e., pre-training on the GIGA-CM dataset using SR objective) with such models and focus on the performance on the CNNDM which is the well-known benchmark for abstractive summarization. We highlight the highest ROUGE scores in Table 4 using bold font and use the symbol $*$ to indicate the models that perform significantly different from STEP. Both T5 and PEGASUS (HugeNews) achieve significantly higher ROUGE-2 scores than our model. However, we obtain higher ROUGE-1 and ROUGE-L scores. On the other hand, we also consider models pre-trained on the relatively small-scale corpus. Following BERT (Devlin et al., 2019), both ProphetNet (16GB) (Yan et al., 2020) and UniLM (Dong et al., 2019) use the same 16GB text for pre-training. As listed in Table 4 (bottom part), our model significantly outperforms such two models.

5.2 Human Evaluation

Since summaries generated by abstractive models may produce disfluent or ungrammatical outputs, we also evaluated abstractive systems by eliciting human judgements. We compared our best preforming model (i.e., pre-training on the GIGA-CM dataset using SR objective) with human references (denoted as Gold), as well as several strong baselines whose system outputs are available to us, including RoBERTa-S2S, and two pre-training based models, i.e., BERTAbs (Liu and Lapata, 2019) and UniLM (Dong et al., 2019)[9]. 50 documents are randomly sampled from the test split of CNNDM. 10 participants are presented with a document and a list of outputs generated by different abstractive summarization systems. Then they are asked to rank the outputs of these systems from best to worst according to informativeness (*does the summary capture the informative part of the document?*), fluency (*is the summary grammatical?*), and succinctness (*does the summary express the document clearly in a few words?*) We report the proportions of system rankings and mean rank (lower is better) in Table 5. The output of STEP is selected as the best for the 23% of cases and we obtained lower mean rank than all systems except for Gold, which shows the participants' preference for our model. We further converted ranking numbers into ratings (i.e., rank i is converted into $6-i$) and applied the student t-test on the ratings. Ours is significantly better than all other systems (except for Gold) in comparison with $p < 0.05$. However, it still lags behind human. One possible reason is that our system (as well as other systems) only takes the first 512 tokens of a long document as input and thus may lose information residing in the following tokens.

Systems	1st	2nd	3rd	4th	5th	MR
BERTAbs	0.11	0.15	0.17	0.26	0.31	3.50
UniLM	0.12	0.16	0.20	0.24	0.29	3.43
RoBERTa-S2S	0.17	0.21	0.20	0.20	0.21	3.07
STEP	0.23	0.23	0.23	0.18	0.14	2.77
Gold	0.37	0.25	0.20	0.12	0.05	2.12

Table 5: Human evaluation results: proportions of system rankings. MR: mean rank (the lower the better).

Qualitative analysis with generated examples are illustrated in the Appendix C.

6 Conclusion

We proposed three sequence-to-sequence pre-training objectives, including sentence reordering, next sentence generation, and masked document generation. All those objectives have relations with abstractive summarization task and are designed based on reinstating the source text. A SEQ2SEQ model for abstractive document summarization can be pre-trained using such objectives and then fine-tuned on the summarization dataset. Compared to models pre-training on the even larger corpora ($\geq$160GB), our method, with only 19GB for pre-training, can still achieve comparable and even better performance. In the future, we would like to investigate other objectives to pre-train SEQ2SEQ models for abstractive summarization.

A Additional Setup Details

Statistics for Content Reordering Recall that it is not an unusual case that a human rewrites a document to summarize its most important information yet does not track the ordering in which how such information is described in the document. This phenomena is defined as ***content reordering*** as follows. For each document-summary pair, we first map each sentence in the summary to one sentence in the document by maximizing the ROUGE-2 score. If the relative orders of sentences in the summary are different from the relative orders of their mapped sentences in the original document, we count this as one content reordering.

We did statistics of such cases over the training and validation splits of CNNDM dataset. To be specific, we borrow the sentence annotations from extractive summarization (Zhang et al., 2018; Zhou et al., 2018; Zhang et al., 2019b) that consider extractive summarization as a sentence classification task. The sentences in a document that maximize ROUGE-2 score (Lin, 2004) against the human references are labeled as `True` while other sentences are assigned `False`. Like previous extractive summarization systems (Zhang et al., 2018, 2019b), we also concatenate sentences with label `True` in a document as its associated summary. For each sentence in a summary, we search for its string closet sentence in its associated document according to the count of overlapped bigrams. We found that, for some instances, the relative orders of sentences in the summary is not consistent with the relative orders of their closet sentences appearing in the document. In practice, we found that 38.1% instances in the training split and 40.5% instances in the validation set have this phenomenon.

B Additional Results

Results on Validation Set The performance of our proposed models on the validation splits of CNNDM and NYT are listed in Table 8 and 9, respectively.

Results on Validation Set of CNNDM with different beam sizes Table 6 lists the ROUGE-L

Beam Size	1	2	3	4	5	6	7	8	9	10
ROUGE-L	41.16	41.78	41.85	41.87	**41.88**	41.83	41.84	41.83	41.82	41.83

Table 6: ROUGE-L results on the validation set of CNNDM with different beam sizes.

Table 9: Results on the validation set of NYT dataset using limited-length recall based ROUGE.

results on the validation set of CNNDM with different beam sizes for the beam search during decoding. Beam size of 5 gives the highest ROUGE-L score. Thus, we use beam$=5$ in this work.

Results on XSum Different from CNNDM and NYT, XSum consists of 226,711 online news articles extracted from British Broadcasting Corporation (BBC), each annotated with a short, one-sentence news summary, answering the question “What is the article about?”. The same split (204,045/11,332/11,334 for training/validation/testing) and preprocessing procedures described in the work of Narayan et al. (2018a) are adopted to make direct comparisons.

STEP	43.02	20.11	35.34

Table 10: Results on the test split of XSum using full-length F1 based ROUGE-1 (R-1), ROUGE-2 (R-2) and ROUGE-L (R-L).

Table 10 lists results on the XSum. Here, we report our model pre-trained using SR objective on the in-domain pre-training corpus, indicated as “STEP”. As we can see that, after pre-training, STEP does not give performance gain. One possible reason is that the summary of XSum contains only one sentence. The SR objective might not be helpful for this dataset.

Results on GLUE We also apply the encoder of our best performing model to the GLUE tasks (**?**), as listed in Table 7. Compared to RoBERTa (Liu et al., 2019), the encoder of our best performing model does not consistently achieve higher results, which demonstrates that the improvements of our models on the abstractive summarization task do not come from a better encoder.

C Examples of System Outputs

Table 11 and 12 demonstrate three output examples of various systems, including BERTAbs (Liu and Lapata, 2019), UniLM (Dong et al., 2019), gold standard summaries (human references, denoted as Gold), the RoBERTa-S2S baseline, and our best performing model. Table 11 shows an example that the outputs of systems BERTAbs and UniLM copied a sentence from the input article, while our model generates summaries by rewriting sentences. Table 12 lists an instance, where the summary generated by the system UniLM contains an incomplete sentence.

Article	(CNN) In response to reports of big banks threatening to withhold campaign funds from Senate Democrats, Sen. Elizabeth Warren last week offered a defiant response: ”Bring it on.” Warren said she isn't going to slack off on her calls for breaking up banks and other measures to rein in Wall Street. As Hillary Clinton prepares to officially launch her presidential campaign this month, she will need to make a choice about how much to highlight issues relating to economic inequality. Former Maryland Gov. Martin O'Malley, who is also running for the Democratic nomination, is trying to steal Clinton's thunder by talking about the problems of disproportionate wealth. In other words, there are many signs that Democrats are planning to take on the big issue of economic inequality. But in other recent news , the likelihood that New York's Chuck Schumer will replace Harry Reid as leader of the Senate Democrats means the dreams of a more economically leftward party are crashing into political reality. While Schumer has been a very effective Democrat and skilled legislative leader, he is also a Wall Street Democrat who has spent much of his time courting and protecting powerful financial interests who run one of the dominant industries in his state. He is not alone. Even at his most progressive moments, President Barack Obama relied on Wall Street donations for both of his campaigns. Despite all the talk from conservatives about left-wing ”socialism” in the White House, the financial community has been willing to open its coffers to Democrats without much concern, even in the 2012 election. ***Democratic populism can't really work within the current campaign finance system***. The enormous pressures for parties to raise funds in campaigns has for many decades created pressure on Democrats, despite their political base, to court big donors. During the 1980s, California Democrat Tony Coelho, serving as the chairman of the Democratic Congressional Campaign Committee and then as majority whip, made a strong appeal to savings and loans executives before the crash of the industry to catch up to Republicans who had been outflanking them in raising money. The Democrats were, and have continued to, losing their traditional base of campaign support – organized labor – which had been a central source of campaign muscle since the 1930s, providing money and campaign assistance during campaigns. Without organized labor to serve as their foundation and with the pressure for raising private funds increasing, many Democrats concluded they needed business by their side. Democrats running for president have made the same kind of choices. In 2008, Obama disappointed many supporters upon becoming the first president to abandon the post-Watergate public finance system for campaigns altogether, preferring to raise money himself for the general campaign. While small donors were enormously important to his victories, so too were business and Wall Street executives. At the height of the financial crash, when public sentiment had clearly turned against Wall Street, the administration agreed to a financial regulation bill (Dodd-Frank) that was structured in such a way as to give powerful interests more than enough opportunity to limit the bite over the coming years. Wall Street, with an army of counsel, succeeded in eroding the impact of the legislation. Not only does the acceptance of our campaign finance system limit the policy choices Democrats can make, but it also greatly damages the party's brand name. As The Washington Post reported, the scandal that might bring down New Jersey Democratic Sen. Robert Menendez is the first involving large scale super PAC donations. At the heart of the story is almost $600,000 that physician Salomon Melgen gave to Senate Majority PAC, possibly in exchange for favors. This is not simply some sort of accommodation of Democrats to the corporate system. They don't have much of a choice. Without these funds, they won't be able to compete. In this election cycle, independent campaign donors are causing a huge stir. In conservative circles, the Koch brothers and their allies are throwing around enormous amounts of money to candidates who will support their deregulatory agenda. Individual donors such as Las Vegas gambling magnate Sheldon Adelson are causing ripples every time candidates speak, pressuring them to adjust their agenda. Democrats have found their own magnates for political support, such as Tom Steyer and George Soros. This is why campaign finance reform is so important, Without Congress changing the fundamental dynamics, there won't be much room for populism to thrive. Even if Democrats select someone like a Elizabeth Warren as their candidate or Hillary Clinton decides to move sharply to the left on economic policy, there won't be much room for reform when the time of governance actually starts. The Democratic Party needs Wall Street more than it needs to take a stand against Wall Street. Those are the facts on the ground. If Democrats really want to take on Wall Street and tackle economic inequality, they first have to bring about reform of the campaign finance system. If campaigns were publicly funded or there were more stringent limits on independent expenditures, Wall Street would have much more trouble achieving disproportionate influence. Reform could level the playing field. More often than not, campaign finance reform is an issue that gets sidetracked with little more than some pro forma words of support. A more populist economic agenda that revolved around progressive taxation and substantial public assistance to strengthen the middle class can only work in a different kind of political system. If things stay the same, Democrats can only continue to win elections by turning to their corporate and financial base of support.
BERTAbs	julian zelizer: sen.elizabeth warren said she isn't going to slack off on her call for breaking up banks. he says the likelihood that new york's chuck schumer will replace harry reid as leader of the senate democrats. zelizer: ***democratic populism can't really work within the current campaign finance system***

Article	(CNN) Hillary Clinton is finally announcing her candidacy for the 2016 presidential election. Although she has watched her standing in the polls sag in recent months, there is likely to be a boost in the days that follow the announcement. For Democrats, there is ample reason to be excited about Clinton’s run for the presidency. She is certainly one of the strongest candidates in many decades. She brings to the table extensive political and policy experience, a combination of skills that is often lacking. She has been through some of the roughest partisan wars and emerged stronger than ever before. She has a keen sense about the nature of the modern news media, how to use it to her advantage and how to survive scandal frenzies. She is a hardened, tough partisan who will not shy away from Republican attack. Americans have many positive memories of Clinton name, given the booming economy of the late 1990s during Bill Clinton’s presidency. If Hillary Clinton puts together an effective campaign, she could be unbeatable in the Democratic primaries as well as in the general election. However, during the buildup to her final decision, some of her weaknesses have also been exposed. Clinton doesn’t want to end up like Vice President Al Gore in 2000. Although he did relatively well in the final election (with many Americans believing that he did actually defeat George W. Bush) he didn’t generate much energy once the campaign started. Although he too was touted as a ”perfect” candidate who was the ideal person for the job, something seemed stiff and inauthentic when he actually hit the trail. He seemed to freeze when the television cameras were rolling. Gore had trouble connecting with voters, and he seemed to remake his image constantly. His biggest asset ended up being that he was viewed as the inevitable nominee, rather than what he actually stood for. Clinton must avoid following Gore’s path. She suffered this fate in the 2008 primaries and can’t afford to do so again. She needs to do more than rest on the perception that her candidacy is inevitable and on her record of experience. That is not enough. More important is for her to put forth an exciting vision about what she would stand for in the White House. Voters thirst for signs of greatness when they pick their presidents, even if they are savvy enough to understand that the reality of a polarized Washington will probably limit her ability to achieve bold change. A recent story in The Washington Post suggests that her advisers are aware of this potential liability. After the announcement, they are going to avoid big rallies and events and instead concentrate on smaller events where she will meet with voters directly in states such as Iowa and New Hampshire. Clinton also will have to contend with doubts about her authenticity. In his first day on the campaign trail, Sen. Rand Paul immediately tapped into these concerns by raising questions about whether she could be trusted. That question has dogged the Clintons ever since they came onto the national political scene in the late 1980s. Their greatest virtue, their immense skills as politicians , has often come back to haunt them. Bill Clinton was attacked as ”slick Willie” by members of both parties for the perception that he would say anything to win and Hillary Clinton has faced similar criticism. When she tried to distance herself from her vote for the use of force in Iraq , many Democrats didn’t buy her critique of President George W. Bush’s foreign policies and went for Barack Obama instead. When she conducted her ”listening tour” of New York before running for the Senate, many voters saw it as a manufactured effort to hide the fact she was running for office as an outsider. When she explained that there was nothing to the recent stories about her use of a private email server rather than her State Department email, some felt that even if the story was relatively minor it indicated that she wasn’t always telling us what she was really about. Even if she isn’t hiding anything, she often gives that appearance. During the next few months, Clinton will also have to connect with her party’s base. The ongoing speculation about Sen. Elizabeth Warren of Massachusetts has suggested that the most active part of the Democratic Party is not that enthused with Clinton’s candidacy. While they will probably vote for her, they are not very motivated and don’t trust that she will stand for Democratic values. She will need to address these concerns, not through her style but through her agenda. Voters will want to hear her talking about issues such as tougher financial regulation and policies to diminish economic inequality as well as her positions on race and policing. She will also need to make clear that she has heard voters on being too hawkish about going to war and give clear indications about how she would handle a nuclear agreement with Iran. Clinton will also have to contend with the gender bias that still exists in the electorate at large. Without any doubt she will be subject to questions and comments – about her appearance, for instance – that won’t be aimed at male candidates. Part of her candidacy is itself an effort to break down these remaining vestiges of political sexism. But the struggle will be tough. Finally, and this relates to the last challenge, Clinton will have to contend with her husband. To be sure he can be an immense force on the campaign trail, one of the most compelling Democrats of our generation. But he can also be liability. As she learned in 2008 , Bill Clinton is not always easy to control. When he speaks his mind, as he did in dismissive comments about Obama’s candidacy, it can often work against her. The fund-raising records of the Clinton Foundation will also raise questions about conflict of interest, and ongoing stories about his personal life, as was the case when Monica Lewinsky returned to the media a few months ago, could re-emerge on the campaign trail. Whether that is fair or not is beside the point: Everything is fair game on the modern campaign trail. Hillary Clinton has the potential to be a hugely successful presidential candidate. But she and her campaign team will need to address the multiple questions and weaknesses that have become clear in recent months.
BERTAbs	julian zelizer: hillary clinton is finally announcing her candidacy for the 2016 presidential election. zelizer: she has been through some of the roughest partisan wars and emerged stronger than ever before. he says she is a hardened, tough partisan who will not shy away from republican attack

Learning from Context or Names?
An Empirical Study on Neural Relation Extraction

Abstract

Neural models have achieved remarkable success on relation extraction (RE) benchmarks. However, there is no clear understanding which type of information affects existing RE models to make decisions and how to further improve the performance of these models. To this end, we empirically study the effect of two main information sources in text: **textual context** and **entity mentions (names)**. We find that (i) while context is the main source to support the predictions, RE models also heavily rely on the information from entity mentions, most of which is type information, and (ii) existing datasets may leak shallow heuristics via entity mentions and thus contribute to the high performance on RE benchmarks. Based on the analyses, we propose an entity-masked contrastive pre-training framework for RE to gain a deeper understanding on both textual context and type information while avoiding rote memorization of entities or use of superficial cues in mentions. We carry out extensive experiments to support our views, and show that our framework can improve the effectiveness and robustness of neural models in different RE scenarios. All the code and datasets are released at `https://github.com/thunlp/RE-Context-or-Names`.

1 Introduction

Relation extraction (RE) aims at extracting relational facts between entities from text, e.g., extracting the fact (SpaceX, `founded by`, Elon Musk) from the sentence in Figure 1. Utilizing the structured knowledge captured by RE, we can construct or complete knowledge graphs (KGs), and eventually support downstream applications like question answering (Bordes et al., 2014), dialog systems (Madotto et al., 2018) and search engines (Xiong et al., 2017). With the recent advance of deep learning, neural relation extraction (NRE) models (Socher et al., 2012; Liu et al., 2013; Baldini Soares et al., 2019) have achieved the latest state-of-the-art results and some of them are even comparable with human performance on several public RE benchmarks.

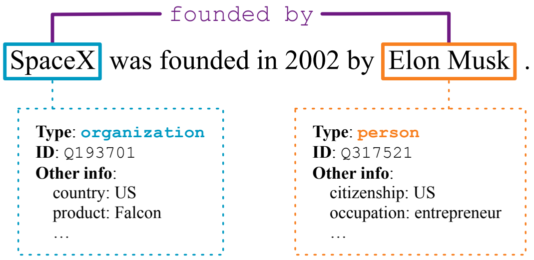

Figure 1: An example for the information provided by textual context and entity mentions in a typical RE scenario. From mentions, we can acquire type information and link entities to KGs, and access further knowledge about them. The IDs in the figure are from Wikidata.

The success of NRE models on current RE benchmarks makes us wonder *which type of information these models actually grasp to help them extract correct relations*. The analysis of this problem may indicate the nature of these models and reveal their remaining problems to be further explored. Generally, in a typical RE setting, there are two main sources of information in text that might help RE models classify relations: textual context and entity mentions (names).

From human intuition, **textual context** should be the main source of information for RE. Researchers have reached a consensus that there exist interpretable patterns in textual context that express relational facts. For example, in Figure 1, "... *be founded* ... *by* ..." is a pattern for the relation `founded by`. The early RE systems (Huffman, 1995; Califf and Mooney, 1997) formalize patterns into string templates and determine relations by

November 16–20, 2020.

matching these templates. The later neural models (Socher et al., 2012; Liu et al., 2013) prefer to encode patterns into distributed representations and then predict relations via representation matching. Compared with rigid string templates, distributed representations used in neural models are more generalized and perform better.

Besides, **entity mentions** also provide much information for relation classification. As shown in Figure 1, we can acquire the types of entities from their mentions, which could help to filter out those impossible relations. Besides, if these entities can be linked to KGs, models can introduce external knowledge from KGs to help RE (Zhang et al., 2019; Peters et al., 2019). Moreover, for pre-trained language models, which are widely adopted for recent RE models, there may be knowledge about entities inherently stored in their parameters after pre-training (Petroni et al., 2019).

In this paper, we carry out extensive experiments to study to what extent RE models rely on the two information sources. We find out that:

(1) Both context and entity mentions are crucial for RE. As shown in our experiments, while context is the main source to support classification, entity mentions also provide critical information, most of which is the type information of entities.

(2) Existing RE benchmarks may leak shallow cues via entity mentions, which contribute to the high performance of existing models. Our experiments show that models still can achieve high performance only given entity mentions as input, suggesting that there exist biased statistical cues from entity mentions in these datasets.

The above observations demonstrate how existing models work on RE datasets, and suggest a way to further improve RE models: we should enhance them via better understanding context and utilizing entity types, while preventing them from simply memorizing entities or exploiting biased cues in mentions. From these points, we investigate an entity-masked contrastive pre-training framework for RE. We use Wikidata to gather sentences that may express the same relations, and let the model learn which sentences are close and which are not in relational semantics by a contrastive objective. In this process, we randomly mask entity mentions to avoid being biased by them. We show its effectiveness across several settings and benchmarks, and suggest that better pre-training technique is a reliable direction towards better RE.

2 Pilot Experiment and Analysis

To study which type of information affects existing neural RE models to make decisions, we first introduce some preliminaries of RE models and settings and then conduct pilot experiments as well as empirical analyses in this section.

2.1 Models and Dataset

There are various NRE models proposed in previous work (refer to Section 5), and we select the following three representative neural models for our pilot experiments and analyses:

CNN We use the convolutional neural networks described in Nguyen and Grishman (2015) and augment the inputs with part-of-speech, named entity recognition and position embeddings following Zhang et al. (2017).

BERT BERT is a pre-trained language model that has been widely used in NLP tasks. We use BERT for RE following Baldini Soares et al. (2019). In short, we highlight entity mentions in sentences by special markers and use the concatenations of entity representations for classification.

Matching the blanks (MTB) MTB (Baldini Soares et al., 2019) is an RE-oriented pre-trained model based on BERT. It is pre-trained by classifying whether two sentences mention the same entity pair with entity mentions randomly masked. It is fine-tuned for RE in the same way as BERT. Since it is not publicly released, we pre-train a BERT$_{\texttt{base}}$ version of MTB and give the details in Appendix A.

There are also a number of public benchmarks for RE, and we select the largest supervised RE dataset **TACRED** (Zhang et al., 2017) in our pilot experiments. TACRED is a supervised RE dataset with $106,264$ instances and 42 relations, which also provides type annotations for each entity.

Note that we use more models and datasets in our main experiments, of which we give detailed descriptions and analyses in Section 4.

2.2 Experimental Settings

We use several input formats for RE, based on which we can observe the effects of context and entity mentions in controllable experiments. The following two formats are adopted by previous literature and are close to the real-world RE scenarios:

Context+Mention (C+M) This is the most widely-used RE setting, where the whole sentence

Model	C+M	C+T	OnlyC	OnlyM	OnlyT
CNN	0.547	0.591	0.441	0.434	0.295
BERT	0.683	0.686	0.570	**0.466**	0.277
MTB	**0.691**	**0.696**	**0.581**	0.433	**0.304**

Table 1: TACRED results (micro F_1) with CNN, BERT and MTB on different settings.

(with both context and highlighted entity mentions) is provided. To let the models know where the entity mentions are, we use position embeddings (Zeng et al., 2014) for the CNN model and special entity markers (Zhang et al., 2019; Baldini Soares et al., 2019) for the pre-trained BERT.

Context+Type (C+T) We replace entity mentions with their types provided in TACRED. We use special tokens to represent them: for example, we use `[person]` and `[date]` to represent an entity with type `person` and `date` respectively. Different from Zhang et al. (2017), we do not repeat the special tokens for entity-length times to avoid leaking entity length information.

Besides the above settings, we also adopt three synthetic settings to study how much information context or mentions contribute to RE respectively:

Only Context (OnlyC) To analyze the contribution of textual context to RE, we replace all entity mentions with the special tokens `[SUBJ]` and `[OBJ]`. In this case, the information source of entity mentions is totally blocked.

Only Mention (OnlyM) In this setting, we only provide entity mentions and discard all the other textual context for the input.

Only Type (OnlyT) This is similar to **OnlyM**, except we only provide entity types in this case.

2.3 Result Analysis

Table 1 shows a detailed comparison across different input formats and models on TACRED. From the results we can see that:

(1) Both textual context and entity mentions provide critical information to support relation classification, and the most useful information in entity mentions is type information. As shown in Table 1, OnlyC, OnlyM and OnlyT suffer a significant performance drop compared to C+M and C+T, indicating that relying on only one source is not enough, and both context and entity mentions are necessary for correct prediction. Besides, we also observe that C+T achieves comparable results on TACRED with C+M for BERT and MTB. This demonstrates that most of the information provided by entity mentions is their type information. We also provide several case studies in Section 2.4, which further verify this conclusion.

C+M
Although her family was from Arkansas, *she* was born in *Washington* state, where ... Label: **`per:state_of_birth`** Prediction: **`per:state_of_residence`**
Dozens of lightly regulated subprime lenders, including New Century Financial Corp., have failed and troubled *Countrywide Financial Corp.* was acquired by *Bank of America Corp.* Label: **`org:parents`** Prediction: **`no_relation`**
C+T
First, *Natalie Hagemo* says, *she* fought the Church of Scientology just to give birth to her daughter. Label: **`no_relation`** Prediction: **`per:children`**
Earlier this week Jakarta hosted the *general assembly* of the *Organisation of Asia-Pacific News Agencies*, ... Label: **`no_relation`** Prediction: **`org:members`**
The boy, identified by the Dutch foreign ministry as *Ruben* but more fully by Dutch media as *Ruben van Assouw*, ... Label: **`per:alternate_names`** Prediction: **`no_relation`**

Table 2: Wrong predictions made only by C+M and only by C+T, where red and blue represent subject and object entities respectively. As the examples suggest, C+M is more easily biased by the entity distribution in the training set and C+T loses some information from mentions that helps to understand the text.

(2) There are superficial cues leaked by mentions in existing RE datasets, which may contribute to the high performance of RE models. We observe high performance on OnlyM with all three models on TACRED, and this phenomenon also exists in other datasets (see Table 5). We also take a deep look into the performance drop of OnlyC compared to C+M in Section 2.4, and find out that in some cases that models cannot well understand the context, they turn to rely on shallow heuristics from mentions. It inspires us to further improve models in extracting relations from context while preventing them from rote memorization of entity mentions.

We notice that CNN results are a little inconsistent with BERT and MTB: CNN on OnlyC is almost the same as OnlyM, and C+M is 5% lower than C+T. We believe that it is mainly due to the limited encoding power of CNN, which cannot fully utilize context and is more easily to overfit the shallow cues of entity mentions in the datasets.

Type	Example
Wrong 42%	..., *Jacinto Suarez*, Nicaraguan deputy to the *Central American Parliament* (PARLACEN) said Monday. **Label**: `org:top_members/employees` **Prediction**: `no_relation`
	US life insurance giant MetLife said on Monday it will acquire *American International Group* unit American Life Insurance company (*ALICO*) in a deal worth 155 billion dollars. **Label**: `org:subsidiaries` **Prediction**: `no_relation`
No pattern 31%	On Monday, the judge questioned the leader of the *Baptist* group, *Laura Silsby*, who ... **Label**: `per:religion` **Prediction**: `no_relation`
Confusing 27%	About a year later, *she* was transferred to Camp Hope, *Iraq*. **Label**: `per:countries_of_residence` **Prediction**: `per:stateorprovinces_of_residence`

Table 3: Case study on unique wrong predictions made by OnlyC (compared to C+M). We sample 10% of the wrong predictions, filter the wrong-labeled instances and manually annotate the wrong types to get the proportions. We use red and blue to highlight the subject and object entities.

2.4 Case Study on TACRED

To further understand how performance varies on different input formats, we carry out a thorough case study on TACRED. We choose to demonstrate the BERT examples here because BERT represents the state-of-the-art class of models and we have observed a similar result on MTB.

First we compare C+M and C+T. We find out that C+M shares 95.7% correct predictions with C+T, and 68.1% wrong predictions of C+M are the same as C+T. It indicates that most information models take advantage of from entity mentions is their type information. We also list some of the unique errors of C+M and C+T in Table 2. C+M may be biased by the entity distributions in the training set. For the two examples in Table 2, "Washington" is only involved in `per:stateorprovince_of_residence` and "Bank of America Corp." is only involved in `no_relation` in the training set, and this bias may cause the error. On the other hand, C+T may have difficulty to correctly understand the text without specific entity mentions. As shown in the example, after replacing mentions with their types, the model is confused by "general assembly" and fails to detect the relation between "Ruben" and "Ruben van Assouw". It suggests that entity mentions provide information other than types to help models understand the text.

We also study why OnlyC suffers such a significant drop compared to C+M. In Table 3, we cluster all the unique wrong predictions made by OnlyC (compared to C+M) into three classes. "Wrong" represents sentences with clear patterns but misunderstood by the model. "No pattern" means that after masking the entity mentions, it is hard to tell what relation it is even for humans. "Confusing" indicates that after masking the entities, the sentence becomes ambiguous (e.g., confusing cities and countries). As shown in Table 3, in almost half (42%) of the unique wrong predictions of OnlyC, the sentence has a clear relational pattern but the model fails to extract it, which suggests that in C+M, the model may rely on shallow heuristics from entity mentions to correctly predict the sentences. In the rest cases, entity mentions indeed provide critical information for classification.

3 Contrastive Pre-training for RE

From the observations in Section 2, we know that both context and entity type information is beneficial for RE models. However, in some cases RE models cannot well understand the relational patterns in context and rely on the shallow cues of entity mentions for classification. In order to enhance the ability to grasp entity types and extract relational facts from context, we propose the entity-masked contrastive pre-training framework for RE. We start with the motivation and process of relational contrastive example generation, and then go through the pre-training objective details.

3.1 Relational Contrastive Example Generation

We expect that by pre-training specifically towards RE, our model can be more effective at encoding relational representations from textual context and modeling entity types from mentions. To do so,

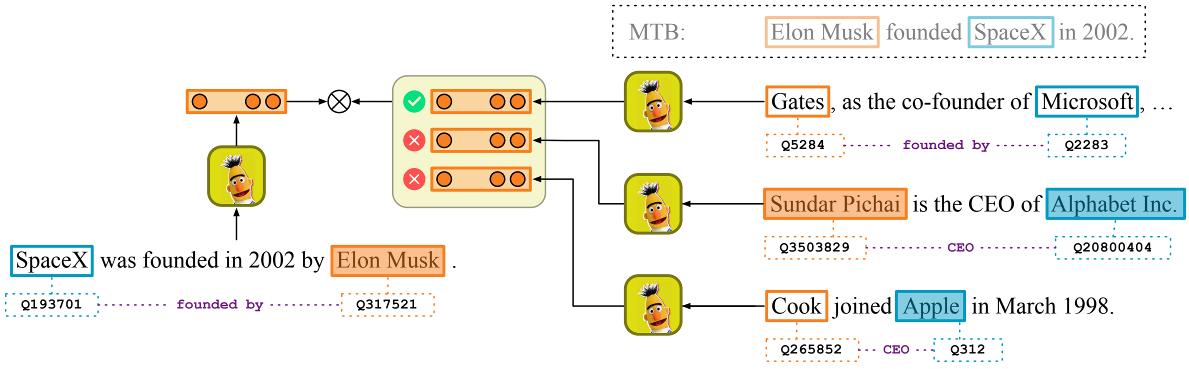

Figure 2: Our contrastive pre-training framework for RE. We assign relations to sentences by linking entity pairs in sentences to Wikidata and checking their relations in the KG. We assume that sentences with the same relation should have similar representations, and those with different relations should be pushed apart. Entity mentions are randomly masked (boxes with colored background) to avoid simple memorization. Compared to MTB (in the dotted box), our method samples data with better diversity, which can not only increase the coverage of entity types and diverse context but also reduce the possibility of memorizing entity names.

we adopt the idea of contrastive learning (Hadsell et al., 2006), which aims to learn representations by pulling "neighbors" together and pushing "non-neighbors" apart. After this, "neighbor" instances will have similar representations. So it is important to define "neighbors" in contrastive learning and we utilize the information from KGs to to that. Inspired by distant supervision (Mintz et al., 2009), we assume that sentences with entity pairs sharing the same relation in KGs are "neighbors".

Formally, denote the KG we use as $\mathcal{K}$, which is composed of relational facts. Denote two random sentences as X_A and X_B, which have entity mentions h_A, t_A and h_B, t_B respectively. We define X_A and X_B as "neighbors" if there is a relation r such that $(h_A, r, t_A) \in \mathcal{K}$ and $(h_B, r, t_B) \in \mathcal{K}$. We take Wikidata as the KG since it can be easily linked to the Wikipedia corpus used for pre-training. When training, we first sample a relation r with respect to its proportion in the KG, and then sample a sentence pair (X_A, X_B) linked to r. To learn contrastively, we randomly sample N sentences $X_B^i, 1 \leq i \leq N$ so they can form N negative pairs with X_A. The model needs to classify which sentence among all the postive and negative samples has the same relation with X_A.

To avoid memorizing entity mentions or extracting shallow features from them during pre-training, we randomly mask entity mentions with the special token `[BLANK]`. We use $P_{\texttt{BLANK}}$ to denote the ratio of replaced entities and set $P_{\texttt{BLANK}} = 0.7$ following Baldini Soares et al. (2019). Note that masking all mentions during pre-training is also not a good option since it will create a gap between pre-training and fine-tuning and also block the pre-trained models from utilizing entity mention information (e.g., learning entity types).

Take an example to understand our data generation process: In Figure 2, there are two sentences "*<u>SpaceX</u> was founded in 2002 by <u>Elon Musk</u>*" and "*As the co-founder of <u>Microsoft</u>, <u>Bill Gates</u> ...*" where both (SpaceX, `founded by`, Elon Musk) and (Microsoft, `founded by`, Bill Gates) exist in the KG. We expect the two sentences to have similar representations reflecting the relation. On the other hand, for the other two sentences in the right part of the figure, since their entity pairs do not have the relation `founded by`, they are regarded as negative samples and are expected to have diverse representations from the left one. During pre-training, each entity mention has a probability of $P_{\texttt{BLANK}}$ to be masked.

The main problem of the generation process is that the sentence may express no relation between the entities at all, or express the relation different from what we expect. For example, a sentence mentioning "SpaceX" and "Elon Musk" may express the relation `founded by`, `CEO` or `CTO`, or simply does not express any relation between them. An example could be "*Elon Musk answers reporters' questions on a SpaceX press conference*", which expresses no clear relation between the two. However, we argue that the noise problem is not critical for our pre-training framework: Our goal is to get relatively better representations towards RE compared to raw pre-trained models like BERT, rather than to directly train an RE model for downstream tasks, so noise in the data is acceptable.

Dataset	# Rel.	# Inst.	% N/A
TACRED	42	106,264	79.5%
SemEval-2010 Task 8	19	10,717	17.4%
Wiki80	80	56,000	-
ChemProt	13	10,065	-
FewRel	100	70,000	-

Table 4: Statistics for RE datasets used in the paper, including numbers of relations, numbers of instances and proportions of `N/A` instances. "-" for the last column means that there is no `N/A` relation in the dataset.

With the help of the generated relational contrastive examples, our model can learn to better grasp type information from mentions and extract relational semantics from textual context: (1) The paired two sentences, which mention different entity pairs but share the same relation, prompt the model to discover the connections between these entity mentions for the relation. Besides, the entity masking strategy can effectively avoid simply memorizing entities. This eventually encourages the model to exploit entity type information. (2) Our generation strategy provides a diverse set of textual context expressing the same relation to the model, which motivates the model to learn to extract the relational patterns from a variety of expressions.

Compared with our model, MTB (Baldini Soares et al., 2019) takes a more strict rule which requires the two sampled sentences to share the same entity pair. While it reduces the noise, the model also samples data with less diversity and loses the chance to learn type information.

3.2 Training Objectives

In our contrastive pre-training, we use the same Transformer architecture (Vaswani et al., 2017) as BERT. Denote the Transformer encoder as $\mathtt{ENC}$ and the output at the position i as $\mathtt{ENC}_i(\cdot)$. For the input format, we use special markers to highlight the entity mentions following Baldini Soares et al. (2019). For example, for the sentence "*SpaceX* *was founded by Elon Musk*.", the input sequence is "`[CLS]` `[E1]` SpaceX `[/E1]` was founded by `[E2]` Elon Musk `[/E2]` `.` `[SEP]`".

During the pre-training, we have two objectives: contrastive pre-training objective and masked language modeling objective.

Contrastive Pre-training Objective As shown in Figure 2, given the positive sentence pair (x_A, x_B), and negative sentence pairs $(x_A, x_B^i), 1 \leq i \leq N$, we first use the Transformer encoder to get relation-aware representation for x in $\{x_A, x_B\} \cup \{x_B^i\}_{i=1}^N$:

$$\mathbf{x} = \mathtt{ENC}_h(x) \oplus \mathtt{ENC}_t(x), \tag{1}$$

where h and t are the positions of special tokens `[E1]` and `[E2]`, and $\oplus$ stands for concatenation. With the sentence representation, we have the following training objective:

$$\mathcal{L}_{CP} = -\log \frac{e^{\mathbf{x}_A^T \mathbf{x}_B}}{e^{\mathbf{x}_A^T \mathbf{x}_B} + \sum_{i=1}^{i \leq N} e^{\mathbf{x}_A^T \mathbf{x}_B^i}}. \tag{2}$$

By optimizing the model with respect to $\mathcal{L}_{CP}$, we expect representations for x_A and x_B to be closer and eventually sentences with similar relations will have similar representations.

Masked Language Modeling Objective To maintain the ability of language understanding inherited from BERT and avoid catastrophic forgetting (McCloskey and Cohen, 1989), we also adopt the masked language modeling (MLM) objective from BERT. MLM randomly masks tokens in the inputs and by letting the model predict the masked tokens, MLM learns contextual representation that contains rich semantic and syntactic knowledge. Denote the MLM loss as $\mathcal{L}_{MLM}$.

Eventually, we have the following training loss:

$$\mathcal{L} = \mathcal{L}_{CP} + \mathcal{L}_{MLM}. \tag{3}$$

4 Experiment

In this section, we explore the effectiveness of our relational contrastive pre-training across two typical RE tasks and several RE datasets.

4.1 RE Tasks

For comprehensive experiments, we evaluate our models on various RE tasks and datasets.

Supervised RE This is the most widely-adopted setting in RE, where there is a pre-defined relation set $\mathcal{R}$ and each sentence x in the dataset expresses one of the relations in $\mathcal{R}$. In some benchmarks, there is a special relation named `N/A` or `no_relation`, indicating that the sentence does not express any relation between the given entities, or their relation is not included in $\mathcal{R}$.

For supervised RE datasets, we use TACRED (Zhang et al., 2017), SemEval-2010 Task 8 (Hendrickx et al., 2009), Wiki80 (Han et al., 2019) and ChemProt (Kringelum et al., 2016). Table 4 shows the comparison between the datasets.

Dataset	Model		1%			10%			100%	
		C+M	OnlyC	OnlyM	C+M	OnlyC	OnlyM	C+M	OnlyC	OnlyM
TACRED	BERT	0.211	0.167	0.220	0.579	0.446	0.433	0.683	0.570	**0.466**

	MTB	**0.362**	0.362	**0.362**	0.682	0.685	0.403	0.796	0.798	0.463
	CP	0.361	**0.362**	0.360	**0.708**	**0.697**	**0.404**	**0.806**	**0.803**	**0.467**

Table 5: Results on supervised RE datasets TACRED (micro F_1), SemEval (micro F_1), Wiki80 (accuracy) and ChemProt (micro F_1). 1% / 10% indicate using 1% / 10% supervised training data respectively.

We also add 1% and 10% settings, meaning using only 1% / 10% data of the training sets. It is to simulate a low-resource scenario and observe how model performance changes across different datasets and settings. Note that ChemProt only has $4,169$ training instances, which leads to the abnormal results on 1% ChemProt in Table 5. We give details about this problem in Appendix B.

Few-Shot RE Few-shot learning is a recently emerged topic to study how to train a model with only a handful of examples for new tasks. A typical setting for few-shot RE is N-way K-shot RE (Han et al., 2018), where for each evaluation episode, N relation types, K examples for each type and several query examples (all belonging to one of the N relations) are sampled, and models are required to classify the queries based on given $N \times K$ samples. We take FewRel (Han et al., 2018; Gao et al., 2019) as the dataset and list its statistics in Table 4.

We use Prototypical Networks as in Snell et al. (2017); Han et al. (2018) and make a little change: (1) We take the representation as described in Section 3.2 instead of using `[CLS]`. (2) We use dot production instead of Euclidean distance to measure the similarities between instances. We find out that this method outperforms original Prototypical Networks in Han et al. (2018) by a large margin.

4.2 RE Models

Besides BERT and MTB we have introduced in Section 2.1, we also evaluate our proposed **c**ontrastive **p**re-training framework for RE (CP). We write the detailed hyper-parameter settings of both the pre-training and fine-tuning process for all the models in Appendix A and B.

Note that since MTB and CP use Wikidata for pre-training, and Wiki80 and FewRel are constructed based on Wikidata, we exclude all entity pairs in test sets of Wiki80 and FewRel from pre-training data to avoid test set leakage.

4.3 Strength of Contrastive Pre-training

Table 5 and 6 show a detailed comparison between BERT, MTB and our proposed contrastive pre-trained models. Both MTB and CP improve model performance across various settings and datasets, demonstrating the power of RE-oriented pre-training. Compared to MTB, CP has achieved even higher results, proving the effectiveness of our proposed contrastive pre-training framework. To be more specific, we observe that:

(1) CP improves model performance on all C+M, OnlyC and OnlyM settings, indicating that our pre-training framework enhances models on both context understanding and type information extraction.

(2) The performance gain on C+M and OnlyC is universal, even for ChemProt and FewRel 2.0, which are from biomedical domain. Our models trained on Wikipedia perform well on biomedical datasets, suggesting that CP learns relational patterns that are effective across different domains.

(3) CP also shows a prominent improvement of OnlyM on TACRED, Wiki80 and FewRel 1.0, which are closely related to Wikipedia. It indicates that our model has a better ability to extract type information from mentions. Both promotions on context and mentions eventually lead to better RE results of CP (better C+M results).

(4) The performance gain made by our contrastive pre-training model is more significant on

Model	5-way 1-shot			5-way 5-shot			10-way 1-shot			10-way 5-shot		
	C+M	OnlyC	OnlyM	C+M	OnlyC	OnlyM	C+M	OnlyC	OnlyM	C+M	OnlyC	OnlyM
FewRel 1.0												
BERT	0.911	0.866	0.701	0.946	0.925	0.804	0.842	0.779	0.575	0.908	0.876	0.715
MTB	0.911	0.879	0.727	0.954	0.939	0.835	0.843	0.779	0.568	0.918	0.892	0.742
CP	**0.951**	**0.926**	**0.743**	**0.971**	**0.956**	**0.840**	**0.912**	**0.867**	**0.620**	**0.947**	**0.924**	**0.763**
FewRel 2.0 Domain Adaptation												
BERT	0.746	0.683	0.316	0.827	0.782	0.406	0.635	0.542	0.210	0.765	0.706	0.292
MTB	0.747	0.692	**0.338**	**0.879**	0.836	0.426	0.625	0.528	**0.216**	**0.811**	**0.744**	**0.298**
CP	**0.797**	**0.745**	0.335	0.849	**0.840**	**0.437**	**0.681**	**0.601**	0.213	0.798	0.738	0.297

Table 6: Accuracy on FewRel dataset. FewRel 1.0 is trained and tested on Wikipedia domain. FewRel 2.0 is trained on Wikipedia domain but tested on biomedical domain.

low-resource and few-shot settings. For C+M, we observe a promotion of 7% on 10-way 1-shot FewRel 1.0, 18% improvement on 1% setting of TACRED, and 24% improvement on 1% setting of Wiki80. There is also a similar trend for OnlyC and OnlyM. In the low resource and few-shot settings, it is harder for models to learn to extract relational patterns from context and easier to overfit to superficial cues of mentions, due to the limited training data. However, with the contrastive pre-training, our model can relatively take better use of textual context while avoiding being biased by entities, and outperform the other baselines by a large margin.

5 Related Work

Development of RE RE of early days has gone through pattern-based methods (Huffman, 1995; Califf and Mooney, 1997), feature-based methods (Kambhatla, 2004; Zhou et al., 2005), kernel-based methods (Culotta and Sorensen, 2004; Bunescu and Mooney, 2005), graphical models (Roth and Yih, 2002, 2004), etc. Since Socher et al. (2012) propose to use recursive neural networks for RE, there have been extensive studies on neural RE (Liu et al., 2013; Zeng et al., 2014; Zhang and Wang, 2015). To solve the data deficiency problem, researchers have developed two paths: **distant supervision** (Mintz et al., 2009; Min et al., 2013; Riedel et al., 2010; Zeng et al., 2015; Lin et al., 2016) to automatically collect data by aligning KGs and text, and **few-shot learning** (Han et al., 2018; Gao et al., 2019) to learn to extract new relations by only a handful of samples.

Pre-training for RE With the recent advance of pre-trained language models (Devlin et al., 2019), applying BERT-like models as the backbone of RE systems (Baldini Soares et al., 2019) has become a standard procedure. Based on BERT, Baldini Soares et al. (2019) propose matching the blanks, an RE-oriented pre-trained model to learn relational patterns from text. A different direction is to inject entity knowledge, in the form of entity embeddings, into BERT (Zhang et al., 2019; Peters et al., 2019; Liu et al., 2020). We do not discuss this line of work here for their promotion comes from relational knowledge of external sources, while we focus on text itself in the paper.

Analysis of RE Han et al. (2020) suggest to study how RE models learn from context and mentions. Alt et al. (2020) also point out that there may exist shallow cues in entity mentions. However, there have not been systematical analyses about the topic and to the best of our knowledge, we are the first one to thoroughly carry out these studies.

6 Conclusion

In this paper, we thoroughly study how textual context and entity mentions affect RE models respectively. Experiments and case studies prove that (i) both context and entity mentions (mainly as type information) provide critical information for relation extraction, and (ii) existing RE datasets may leak superficial cues through entity mentions and models may not have the strong abilities to understand context as we expect. From these points, we propose an entity-masked contrastive pre-training framework for RE to better understand textual context and entity types, and experimental results prove the effectiveness of our method.

In the future, we will continue to explore better RE pre-training techniques, especially with a focus on open relation extraction and relation discovery. These problems require models to encode good relational representation with limited or even zero annotations, and we believe that our pre-trained RE models will make a good impact in the area.

A Pre-training Details

Pre-training Dataset We construct a dataset for pre-training following the method in the paper. We use Wikipedia articles as corpus and Wikidata (Vrandečić and Krötzsch, 2014) as the knowledge graph. Firstly, We use anchors to link entity mentions in Wikipedia corpus with entities in Wikidata. Then, in order to link more unanchored entity mentions, we adopt `spaCy`[1] to find all possible entity mentions, and link them to entities in Wikidata via name matching. Finally, we get a pre-training dataset containing 744 relations and $867,278$ sentences. We release this dataset together with our source code at our GitHub repository[2].

We also use this dataset for MTB, which is slightly different from the original paper (Baldini Soares et al., 2019). The original MTB takes all entity pairs into consideration, even if they do not have a relationship in Wikidata. Using the above dataset means that we filter out these entity pairs. We do this out of training efficiency, for those entity pairs that do not have a relation are likely to express little relational information, and thus contribute little to the pre-training.

Data Sampling Strategy For MTB (Baldini Soares et al., 2019), we follow the same sampling strategy as in the original paper. For pre-training our contrastive model, we regard sentences labeled with the same relation as a "bag". Any sentence pair whose sentences are in the same bag is treated as a positive pair and as a negative pair otherwise. So there will be a large amount of possible positive samples and negative samples. We dynamically sample positive pairs of a relation with respect to the number of sentences in the bag.

Hyperparameters We use Huggingface's `Transformers`[3] to implement models for both pre-training and fine-tuning and use AdamW (Loshchilov and Hutter, 2019) for optimization. For most pre-training hyperparameters, we select the same values as Baldini Soares et al. (2019). We search hyperparameter batch size in $\{256, 2048\}$ and $P_{\texttt{BLANK}}$ in $\{0.3, 0.7\}$. For MTB, batch size N means that a batch contains $2N$ sentences, which form $N/2$ positive pairs and $N/2$ negative pairs. For CP, batch size N means that a batch contains $2N$ sentences, which form N positive pairs. For negative samples, we pair the sentence in each pair with sentences in other pairs.

Parameter	**MTB**	**CP**
Learning Rate	3×10^{-5}	3×10^{-5}
Batch Size	256	2048
Sentence Length	64	64
$P_{\texttt{BLANK}}$	0.7	0.7

Table 7: Hyperparameters for pre-training models. $P_{\texttt{BLANK}}$ corresponds to the probability of replacing entities with `[BLANK]`.

Dataset	**Train**	**Dev**	**Test**
TACRED	68,124	22,631	15,509

FewRel	44,800	11,200	14,000

Table 8: Numbers of instances in train / dev / test splits for different RE datasets.

We set hyperparameters according to results on supervised RE dataset TACRED (micro F_1). Table 7 shows hyperparameters for pre-training MTB and our contrastive model (CP). The batch size of our implemented MTB is different from that in Baldini Soares et al. (2019), because in our experiments, MTB with a batch size of 256 performs better on TACRED than the batch size of 2048.

Pre-training Efficiency MTB and our contrastive model have the same architecture as $\text{BERT}_{\text{BASE}}$ (Devlin et al., 2019), so they both hold 110M parameters approximately. We use four Nvidia 2080Ti GPUs to pre-train models. Pre-training MTB takes $30,000$ training steps and approximately 24 hours. Pre-training our model takes $3,500$ training steps and approximately 12 hours.

B RE Fine-tuning

RE Datasets We download TACRED from `LDC`[4], Wiki80, SemEval from `OpenNRE`[5], ChemProt from `sciBert`[6], and FewRel from `FewRel`[7]. Table 8 shows detailed statistics for each dataset and Table 9 demonstrates the sizes of training data for different supervised RE datasets

Dataset	**1%**	**10%**	**100%**
TACRED	703	6,833	68,124
SemEval	73	660	6,507
Wiki80	400	3,920	3,9200
ChemProt	49	423	4,169

Table 9: Numbers of training instances in supervised RE datasets under different proportion settings.

Parameter	**Supervised RE**	**Few-Shot RE**
Learning Rate	3×10^{-5}	2×10^{-5}
Batch Size	64	4
Epoch	6	10
Sentence Length	100	128
Hidden Size	768	768

Table 10: Hyperparameters for fine-tuning on relation extraction tasks (BERT, MTB and CP).

in 1%, 10% and 100% settings. For 1% and 10% settings, we randomly sample 1% and 10% training data for each relation (so the total training instances for 1% / 10% settings are not exactly 1% / 10% of the total training instances in the original datasets). As shown in the table, the numbers of training instances in SemEval and ChemProt for 1% setting are extremely small, which explains the abnormal performance.

Hyperparameters Table 10 shows hyperparameters when finetuning on different RE tasks for BERT, MTB and CP. For CNN, we train the model by SGD with a learning rate of 0.5, a batch size of 160 and a hidden size of 230. For few-shot RE, we use the recommended hyperparameters in `FewRel`[8].

Multiple Trial Settings For all the results on supervised RE, we run each experiment 5 times using 5 different seeds $(42, 43, 44, 45, 46)$ and select the median of 5 results as the final reported number. For few-shot RE, as the model varies little with different seeds and it is evaluated in a sampling manner, we just run one trial with 10000 evaluation episodes, which is large enough for the result to converge. We report accuracy (proportion of correct instances in all instances) for Wiki80 and FewRel, and micro $\mathtt{F}_1$[9] for all the other datasets.

Abstract

Open relation extraction is the task of extracting open-domain relation facts from natural language sentences. Existing works either utilize heuristics or distant-supervised annotations to train a supervised classifier over pre-defined relations, or adopt unsupervised methods with additional assumptions that have less discriminative power. In this work, we propose a self-supervised framework named `SelfORE`, which exploits weak, self-supervised signals by leveraging large pretrained language model for adaptive clustering on contextualized relational features, and bootstraps the self-supervised signals by improving contextualized features in relation classification. Experimental results on three datasets show the effectiveness and robustness of `SelfORE` on open-domain Relation Extraction when comparing with competitive baselines. Source code is available[1].

1 Introduction

With huge amounts of information people generate, Relation Extraction (RE) aims to extract triplets of the form (subject, relation, object) from sentences, discovering the semantic relation that holds between two entities mentioned in the text. For example, given a sentence *Derek Bell was born in Belfast*, we can extract a relation BORN IN between two entities *Derek Bell* and *Belfast*. The extracted triplets from the sentence are used in various downstream applications like web search, question answering, and natural language understanding.

Existing RE methods work well on pre-defined relations that have already appeared either in human-annotated datasets or knowledge bases. While in practice, human annotation can be labor-intensive to obtain and hard to scale up to a large number of relations. Lots of efforts are made to alleviate the human annotation efforts in Relation Extraction. Distant Supervision (Mintz et al., 2009) is a widely-used method to train a supervised relation extraction model with less annotation as it only requires a small amount of annotated triplets as the supervision. However, distant supervised methods usually make strong assumptions on entity co-occurrence without sufficient contexts, which leads to noises and sparse matching results. More importantly, it works on a set of pre-defined relations, which prevents its applicability on open-domain text corpora.

Open Relation Extraction (OpenRE) aims at inferring and extracting triplets where the target relations cannot be specified in advance. Besides approaches that first identify relational phrases from open-domain corpora using heuristics or external labels via distant supervision and then recognize entity pairs (Yates et al., 2007; Fader et al., 2011), clustering-based unsupervised representation learning models get lots of attentions recently due to their ability to recognize triplets from meaningful semantic features with minimized or even no human annotation. Yao et al. (2011) regards OpenRE as a totally unsupervised task and uses clustering method to extract triplets with new relation types. However, it cannot effectively discard irrelevant information and select meaningful relations. Simon et al. (2019) trains expressive relation extraction models in an unsupervised setting. But it still requires that the exact number of relation types in the open-domain corpus is known in advance.

To further alleviate the human annotation efforts while obtaining high-quality supervision for open relation extraction, in this paper, we propose a self-supervised learning framework which obtains supervision from the data itself and learns to improve the supervision quality by learning better feature presentations in an iterative fashion. The proposed

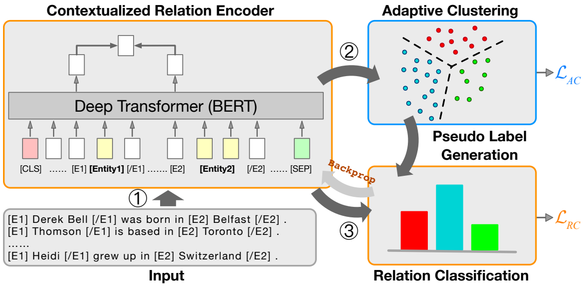

Figure 1: Open Relation Extraction via Self-supervised Learning.

framework has three modules, Contextualized Relation Encoder, Adaptive Clustering, and Relation Classification. As shown in Figure 1, the Contextualized Relation Encoder leverages pretrained BERT model to encode entity pair representations based on the context in which they are mentioned. To recognize and facilitate proximity of relevant entity pairs in the relational semantic space, the Adaptive Clustering module effectively clusters the contextualized entity pair representations generated by Contextualized Relation Encoder and generates pseudo-labels as the self-supervision. The Relation Classification module takes the cluster labels as pseudo-labels to train a relation classification module. The loss of Relation Classification on self-supervised pseudo labels helps improve contextualized entity pairs features in Contextualized Relation Encoder, which further improves the pseudo label quality in Adaptive Clustering in an iterative fashion.

To summarize, the main contributions of this work are as follows:

- We developed a novel self-supervised learning framework `SelfORE` for relation extraction from open-domain corpus where no relational human annotation is available.
- We demonstrated how to leverage pretrained language models to learn and refine contextualized entity pair representations via self-supervised training schema.
- We showed that the self-supervised model outperforms strong baselines, and is robust when no prior information is available on target relations.

2 Proposed Model

The proposed model `SelfORE` consists of three modules: Contextualized Relation Encoder, Adaptive Clustering, and Relation Classification. As illustrated in Figure 1, the Contextualized Relation Encoder takes sentences as the input, where named entities are recognized and marked in the sentence. Contextualized Relation Encoder leverages the pretrained BERT (Devlin et al., 2018) model to output contextualized entity pair representation. The Adaptive Clustering takes the contextualized entity pair representation as the input, aiming to perform clustering that determines the relational cluster an entity pair belongs to. Unlike traditional clustering methods which assign hard cluster labels to each entity pair and are sensitive to the number of clusters, Adaptive Clustering performs soft-assignment which encourages high confidence assignments and is insensitive to the number of clusters. The pseudo labels based on the clustering results are considered as the self-supervised prior knowledge, which further guides the Relation Classification and features learning in Contextualized Relation Encoder.

Before introducing details of each module, we briefly summarize the overall learning schema:

① Obtain contextualized entity pair representations based on entities mentioned in sentences using Contextualized Relation Encoder.

② Apply Adaptive Clustering based on updated entity pair representations in ① to generate pseudo labels for all relational entity pairs.

③ Use pseudo labels as the supervision to train and update both Contextualized Relation Encoder and Relation Classification. Repeat ②.

2.1 Contextualized Relation Encoder

The contextualized relation encoder aims to extract contextualized relational representations between two given entities in a sentence. In this work, we assume named entities in the text have been recognized ahead of time and we only focus on binary relations which involve two entities.

The type of relation between a pair of entities can be reflected by their contexts. Also, the nuances of expression in contexts also contribute to the relational representation of entity pairs. Therefore, we leverage pretrained deep bi-directional transformers networks (Devlin et al., 2018) to effectively encode entity pairs, along with their context information.

For a sentence $X = [x_1, .., x_T]$ where two entities $E1$ and $E2$ are mentioned, we follow the labeling schema adopted in Soares et al. (2019) and augment X with four reserved tokens to mark the beginning and the end of each entity mentioned in the sentence. We introduce the $[E1_{start}]$, $[E1_{end}]$, $[E2_{start}]$, $[E2_{end}]$ and inject them to X:

$$X = [x_1, ..., [E1_{start}], x_i, ..., x_{j-1}, [E1_{end}], ..., [E2_{start}], x_k, ..., x_{l-1}, [E2_{end}], ..., x_T] \tag{1}$$

as the input token sequence for Contextualized Relation Encoder.

The contextualized relation encoder is denoted as $f_\theta(X, E1, E2)$. To get the relation representation of two entities $E1$ and $E2$, instead of using the output of $[CLS]$ token from BERT which summarizes the sentence-level semantics, we use the outputs corresponding to $[E1_{start}]$, $[E2_{start}]$ positions as the contextualized entity representation and concatenate them to derive a fixed-length relation representation $\mathbf{h} \in \mathbb{R}^{2 \cdot h_R}$:

$$\mathbf{h} = [\mathbf{h}_{[E1_{start}]}, \mathbf{h}_{[E2_{start}]}]. \tag{2}$$

2.2 Adaptive Clustering

After we obtained $H = \{\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_N\}$ from N contextualized entity pair representations using Contextualized Relation Encoder, Adaptive Clustering aims to cluster entity pair representations into K semantically-meaningful clusters. Adaptive Clustering gives each entity pair a cluster label, which serves as the pseudo label for later stages.

Comparing with the traditional clustering method which gives hard label assignment for each entity pair (e.g. k-means), the Adaptive Clustering adopts a soft-assignment, adaptive clustering schema. The adaptive clustering encourages high-confidence assignments and is insensitive to the number of clusters. More specifically, Adaptive Clustering consists of two parts: (1) a nonliner mapping g_ϕ to convert the entity pair representation $\mathbf{h} \in \mathbb{R}^{h_R}$ to a latent representation $\mathbf{z} \in \mathbb{R}^{h_{AC}}$, (2) learning a set of K cluster centroids $\{\mu_k \in \mathbb{R}^{h_{AC}}\}_{k=1}^{K}$, and a soft-assignment of all N entity pairs to K cluster centroids.

For the first part, we simply adopt a set of fully connected layers as the non-linear mapping. Instead of initializing parameters randomly and training the mapping from scratch, the initial parameters are adopted from an encoder of an autoencoder model (Vincent et al., 2010). We pretrain an autoencoder model separately, which takes $\mathbf{h}$ as the input and minimizes the reconstruction loss over all N samples:

$$\widetilde{\mathbf{h}} = Dropout(\mathbf{h}) \tag{3}$$

$$\mathbf{z} = \mathrm{g}(\mathbf{W}_\phi \widetilde{\mathbf{h}} + \mathbf{b}_\phi) \tag{4}$$

$$\widetilde{\mathbf{z}} = Dropout(\mathbf{z}) \tag{5}$$

$$\hat{\mathbf{h}} = \mathrm{d}(\mathbf{W}_\sigma \widetilde{\mathbf{z}} + \mathbf{b}_\sigma). \tag{6}$$

For the second part, the module learns to optimize g_ϕ's parameters and assign each sample to a cluster with high confidence. We first perform standard k-means clustering in the feature space $\mathbb{R}^{h_{AC}}$ to obtain K initial centroids $\{\mu_k \in \mathbb{R}^{h_{AC}}\}_{k=1}^{K}$. Inspired by Xie et al. (2016), we use the Student's t-distribution as a kernel to measure the similarity between embedded point $\mathbf{z}_n$ and each centroid μ_k:

$$q_{nk} = \frac{(1 + ||\mathbf{z}_n - \mu_k||^2/\alpha)^{-\frac{\alpha+1}{2}}}{\sum_{k'}(1 + ||\mathbf{z}_n - \mu_{k'}||^2/\alpha)^{-\frac{\alpha+1}{2}}}, \tag{7}$$

where α represents the freedom of the Student's t-distribution and q_{nk} can be regarded as the probability of assigning sample n to cluster k as the soft assignment. We set $\alpha = 1$ for all experiments.

We normalize each cluster by frequency as an auxiliary target distribution in Equation 8 and iteratively refine clusters by learning from high-confidence assignments with the help of an auxiliary distribution:

$$p_{nk} = \frac{q_{nk}^2/f_k}{\sum_{k'} q_{nk'}^2/f_{k'}}, \tag{8}$$

where $f_k = \sum_n q_{nk}$ is the soft cluster frequency.

With the auxiliary distribution, we define KL divergence loss between the soft assignments q_n and the auxiliary distribution p_n as follows to train the Adaptive Clustering module:

$$\mathcal{L}_{AC} = KL(P||Q) = \sum_n \sum_k p_{nk} log \frac{p_{nk}}{q_{nk}}. \tag{9}$$

We use gradient descent based optimizer to minimize $\mathcal{L}_{AC}$. Note that only the parameters for g_ϕ will be updated —parameters in the Contextualized Relation Encoder (f_θ) are not effected when minimizing $\mathcal{L}_{AC}$. We assign the pseudo label s_n for the n-th entity pair by taking the label associated with the largest probability:

$$s_n = \underset{k \in \mathcal{K}}{\mathrm{argmax}}\, p_{nk}. \tag{10}$$

To alleviate the negative impact from choosing unideal initial centroids, Adaptive Clustering reselects a set of K initial centroids randomly if $\mathcal{L}_{AC}$ does not decrease after the first epoch.

In summary, comparing with traditional clustering methods such as k-means, Adaptive Clustering adopts an iterative, soft-assignment learning process which encourages high-confidence assignments and uses high-confidence assignments to improve low-confidence ones. Adaptive Clustering possesses the following advantages: 1) It improves clustering purity and benefits low-confidence assignment for an overall better relational clustering performance. 2) It prevents large relational clusters from distorting the hidden feature space. (3) It neither requires the actual number of target relations in advance (although it is good to have the target relations as the prior knowledge), nor the distribution of relations.

2.3 Relation Classification

Adaptive Clustering generates cluster labels $S = \{s_1, s_2, ..., s_N\}$ for all entity pairs as pseudo labels. With these pseudo labels as self-supervised signals derived from the corpora themselves, Relation Classification module aims to use pseudo labels to guide the relational feature learning in Contextualized Relation Encoder as well as relation classifier learning in Relation Classification.

Similar to supervised classifiers which learn to predict golden labels, the Relation Classification module learns to predict the pseudo labels generated by Adaptive Clustering:

$$\mathbf{l}_n = c_\tau(f_\theta(X_n, E1, E2)), \tag{11}$$

where c_τ denotes the relation classification module parameterized by τ and $\mathbf{l}_n$ is a probability distribution over K pseudo labels for the n-th sample. In order to find the best-performing parameters θ for Contextualized Relation Encoder and τ for Relation Classification, we optimize the following classification loss:

$$\mathcal{L}_{RC} = \min_{\theta,\tau} \frac{1}{N} \sum_{n=1}^{N} loss(\mathbf{l}_n, \text{one\_hot}(s_n)), \tag{12}$$

where $loss$ is the cross entropy loss function and $\text{one\_hot}(s_n)$ returns a one-hot vector indicating the pseudo label assignments.

2.4 The Bootstrapping Self-Supervision Loop

After optimizing $\mathcal{L}_{RC}$, we repeat Adaptive Clustering and Relation Classification in an iterative fashion, shown as ②,③ in Figure 1. Overall, the Adaptive Clustering exploits weak, self-supervised signals from data and Relation Classification bootstraps the discriminative power of the Contextualized Relation Encoder by improving contextualized relational features for Relation Classification. Note that for Adaptive Clustering, although it does not update Contextualized Relation Encoder, it always utilizes the updated θ to get the most up-to-date entity pair feature representations $\mathbf{h}$ for clustering. Hence it generates stronger self-supervision as the loop goes on, by providing pseudo labels with higher quality for the Relation Classification module.

We stop the clustering and classification loop when current pseudo labels have less than 10% difference with the former epoch. To get the surface-form relation name for each cluster, if there is one, we get words between $[E1]$ and $[E2]$ and calculate the most frequent n-gram as the surface form. For quantitative evaluation, we assign the majority ground truth label within each cluster as the predict relation label for each relation cluster.

3 Experiments

We conduct extensive experiments on real-world datasets to show the effectiveness of our self-supervised learning rationale on relation extraction, and give a detailed analysis to show its advantages.

3.1 Datasets

Three datasets are used to evaluate our model: NYT+FB, T-REx SPO, and T-REx DS. NYT+FB dataset aligns sentences from the New York Times corpus (Sandhaus, 2008) with Freebase (Bollacker et al., 2008) triplets. It has been widely used in previous RE works (Yao et al., 2011; Marcheggiani and Titov, 2016; Simon et al., 2019). We follow the setting in Simon et al. (2019) and filter out sentences with non-binary relations. We get 41,000 labeled sentences containing 262 target relations from 2 million sentences. 20% of these sentences will be used as validation datasets for hyperparameter tuning and 80% will be used for model training.

Both T-REx SPO and T-REx DS datasets come from T-REx (Elsahar et al., 2018) which is generated by aligning Wikipedia corpus with Wikidata (Vrandečić, 2012). We filter triplets and keep sentences where both entities appear in the same sentence — a sentence will appear multiple times if it contains multiple binary relations associated with different entity pairs. We built two datasets T-REx SPO and T-REx DS depending on whether the dataset has surface-form relations or not. For example, the relation *give birth to* could be conveyed by surface-forms like *born in*, *date of birth*, etc. T-REx SPO contains 615 relations and 763,000 sentences, where all sentences contain triplets having the surface form relation in the sentence. T-REx DS is generated where the surface-form of relation is not necessarily contained in the sentence. T-REx DS contains 1189 relations and nearly 12 million sentences. The dataset still contains some misalignment, but should nevertheless be easier for models to extract the correct semantic relation. 20% of these sentences will be used as the validation dataset and 80% will be used for model training.

3.2 Baseline and Evaluation metrics

We use standard unsupervised evaluation metrics for comparisons with other three baseline algorithms Yao et al. (2011); Marcheggiani and Titov (2016); Simon et al. (2019) where no human annotation is available for Relation Extraction from the open-domain data. For all models, we assume the number of target relations is known to the model in advance. We set the number of clusters to the number of ground-truth categories and evaluate performance with B^3, V-measure and ARI.

Additionally, we evaluate the performance of our proposed model in a practical, yet more challenging setting: we assume the size of target relations is not known. A much larger cluster size $\hat{K}$ such as 1000 is adopted. When $\hat{K} \gg K$, we use unsupervised approaches such as k-means to further merge $\hat{K}$ clusters into K clusters (the size of ground-truth categories) for a fair evaluation.

For baselines, rel-LDA is a generative model proposed by Yao et al. (2011). We consider two variations of rel-LDA which only differ in the number of features they considered. rel-LDA uses the 3 simplest features and rel-LDA-full is trained with a total number of 8 features listed in Marcheggiani and Titov (2016). UIE (Simon et al., 2019) is the state-of-the-art method that trains a discriminative relation extraction model on unlabeled datasets by forcing the model to predict each relation with confidence and encourage all relations to be predicted on average. Two base model architectures (UIE-March and UIE-PCNN) are considered. To make it fair comparison, we further introduce UIE-BERT, which is trained with losses introduced in Simon et al. (2019) but we replace the PCNN classifier + GloVe embedding with our BERT-based Relation Encoder and Classification module.

To convert pseudo labels indicating the clustering assignment to relation labels for evaluation purposes, we follow the setting in the previous work (Simon et al., 2019) and assign the majority of ground truth relation labels in each cluster to all samples in that cluster as the prediction label. For evaluation metrics, we use B^3 precision and recall to measure the correct rate of putting each sentence in its cluster or clustering all samples into a single class. More specifically, B^3 F_1 is the harmonic mean of precision and recall:

$$\text{B}^3\ \text{Prec.} = \mathop{\mathbb{E}}_{X,Y} P(g(X) = g(Y) | c(X) = c(Y))$$

$$\text{B}^3\ \text{Rec.} = \mathop{\mathbb{E}}_{X,Y} P(c(X) = c(Y) | g(X) = g(Y)).$$

We use V-measures (Rosenberg and Hirschberg, 2007) to calculate homogeneity and completeness, which is analogous to B^3 precision and recall, but with the conditional entropy:

$$\text{Homogeneity} = 1 - H(c(X)|g(X))/H(c(X))$$

$$\text{Completeness} = 1 - H(g(X)|c(X))/H(g(X))$$

where these two metrics penalize small impurities in a relatively "pure" cluster more harshly than in less pure ones. We also report F1, which is the harmonic mean of Homogeneity and Completeness.

Adjusted Rand Index (Hubert and Arabie, 1985) measures the degree of agreement between two data distributions. The range of ARI is [-1,1], the larger the value, the more consistent the clustering result is with the real situation.

3.3 Implementation Details

Following the settings used in Simon et al. (2019), all models are trained with 10 relation classes. Although it is lower than the number of true relations in the dataset, it still reveals important insights as the distribution of target relations is very unbalanced. Also, this allows us to do a fair comparison with baseline results.

For Contextualized Relation Encoder, we use the default tokenizer in BERT to preprocess dataset and set max-length as 128. We use the pretrained `BERT-Base_Cased` model to initialize parameters for Contextualized Relation Encoder and use BertAdam to optimize the loss.

For Adaptive Clustering, we use an autoencoder with fully connected layers with the following dimensions $2h_R$-500-500-200 as the *encoder* and

Dataset	Model	B^3			V-measure			ARI

Table 1: Quantitative performance evaluation on three datasets.

200-500-500-2h_R for the *decoder*. We randomly initialize weights using a Gaussian distribution with zero-mean and a standard deviation of 0.01. The autoencoder is pretrained for 20 epoches with $1e{-}3$ learning rate and $1e{-}5$ weight-decay with Adam Optimizer. To get the initial centroids, we applied k-means and set K as 10.

For Relation Classification, we use a fully connected layer as c_τ and set dropout rate to 10%, learning rate to $1e{-}5$ and warm-up rate to 0.1. We fixed the parameters in f_θ for the first three epochs to allow the classification layer to warm up.

3.4 Results

Table 1 shows the experimental results. UIE-PCNN is considered as the previous state-of-the-art result. We enhance this baseline by replacing PCNN and GloVe embedding with the proposed BERT-based encoder and classifier. The enhanced state-of-the-art model, namely UIE-BERT, achieves the best performance among baselines. The proposed `SelfORE` model outperforms all baseline models consistently on B^3 F1/Precision, V-measure F1/Homogeneity and ARI. `SelfORE` on average achieves 7.0% higher in B^3 F1, 3.4% higher in V-measure F1 and 7.7% higher in ARI among three datasets when comparing with UIE-BERT. Unlike baseline methods which achieve high B^3 Recall but low Precision, or high V-measure Completeness but low Homogeneity, our model obtains a more balanced performance while achieving the highest Precision and Homogeneity, although B^3 Recall and V-measure Completeness are less satisfactory. Having high precision and homogeneity scores can be a quite appealing property for precision-oriented applications in the real-world.

Ablation Study

We conduct ablation study to show the effectiveness of different modules of `SelfORE` to the overall improved performance. `SelfORE` w/o Classification is the proposed model without Relation Classification and only uses the Contextualized Relation Encoder for Adaptive Clustering. `SelfORE` w/o Adaptive Clustering replaces the proposed soft-assignment clustering methods with k-means clustering as a hard-assignment alternative.

A general conclusion from ablation rows in Table 1 is that all modules contribute positively to the improved performance. More specifically, without self-supervised signals for relational feature learn-

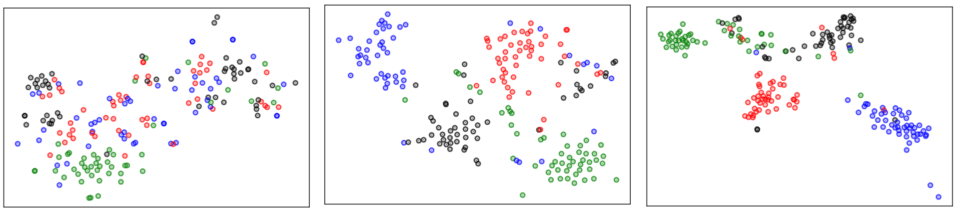

Figure 2: Visualizing contextualized entity pair features after t-SNE dimension reduction for `SelfORE` w/o classification (left), `SelfORE` w/o Adaptive Clustering (middle) and `SelfORE` (right) on NYT+FB dataset.

ing, `SelfORE` w/o Classification gives us 14.4% less performance averaged over all metrics on all datasets. Similarly, Adaptive Clustering gives 6.2% performance boost in average over all metrics when comparing with the hard-assignment alternative (`SelfORE` w/o Adaptive Clustering).

Visualize Contextualized Features
To intuitively show how self-supervised learning helps learn better contextualized relational features on entity pairs, we visualize the contextual representation $\mathbb{R}^{2 \cdot h_R}$ after dimension reduction using t-SNE (Maaten and Hinton, 2008). We randomly choose 4 relations from NYT+FB dataset and sample 50 entity pairs. The visualization results are shown in Figure 2. Features are colored with their ground-truth relation labels.

From Figure 2 we can see that the features obtained through the raw BERT model (left) can already give meaningful semantics to entity pairs having different relations. But these features are not tailored for the relation extraction task. When Adaptive Clustering is not applied (middle) and simply using k-means, which performs hard-assignment on samples, the proposed model without Adaptive Clustering gives decent results but does not provide confident cluster assignments. The proposed model (right) uses soft-assignment and a self-supervised learning schema to improve the relational feature learning —we learn denser clusters and more discriminitaive features.

Sensitivity analysis: when K is unknown

The Adaptive Clustering gives `SelfORE` enough flexibility to model relational features without knowing any prior information on the number of target relations or the relation distribution. This property is appealing when the number of target relations is not available for Relation Extraction on an open-domain corpus.

The proposed model does require an intial cluster size $\hat{K}$ as the scope for pseudo labels. A general guideline for choosing $\hat{K}$ is to choose a value that is larger than the actual number of relations in the corpora as over-specifying the cluster size should not hurt the model performance. We set an initial $\hat{K}$ (for example $\hat{K} = 1000$), and use an unsupervised method, here we use k-means, to merge $\hat{K}$ cluster centroids into K clusters for evaluation.

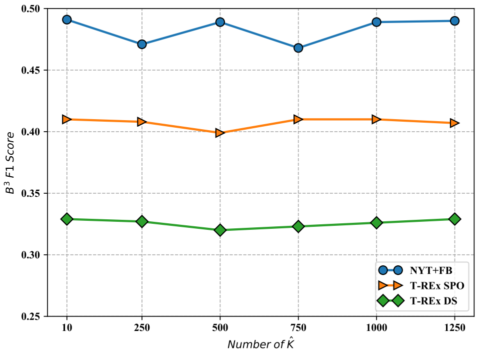

Figure 3: F1 Score with different $\hat{K}$.

We vary $\hat{K}$ from 10 to 1250 and report the B^3 F1 score when comparing the predicted relation type (based on K clusters after merging) with the golden relation type. As shown in Figure 3, the best performance is obtained when $\hat{K} = 10$, indicating that `SelfORE` actually leverages the number of target relations as a useful prior knowledge. Thanks to the self-learning schema and the Adaptive Clustering, when we very $\hat{K}$ from 10 to 1250, the model achieves stable F1 score and is not sensitive to the initial choice of $\hat{K}$ on all three datasets. The results also further indicate the applicability of the proposed model when being applied to an open-domain corpus when the number of target relations is not available in advance. We can assign a larger $\hat{K}$ value than needed and the model is still robust. Note that merging $\hat{K}$ clusters into K clusters is mainly for evaluation purpose: when K is unknown in advance and we simply use a large K directly, it does result in K clusters where clusters tend to be smaller, and multiple clusters may correspond to entity pairs having the same relation.

Table 2: Extracted and golden surface-form relation names on T-REx SPO.

Surface-form Relation Names

We provide a brief case study to show the surface-form relation names we extracted for each cluster (introduced in Section 2.4). We randomly select 5 relations in T-REx SPO and report the extracted surface-form relation names using frequent n-gram in Table 2. The surface-form relation name extraction gives `SelfORE` an extended ability to not only discriminate between entity pairs having different relations, but also derive surface-forms for relation clusters as the final Relation Extraction results. However, evaluating the quality of relation surface-forms is out-of-scope for this work.

4 Related Works

Relation extraction focuses on identifying the relation between two entities in a given sentence. Traditional closed-domain relation extraction methods are supervised models. They need a set of predefined relation labels and require large amounts of annotated triplets, making them less ideal to work on open-domain corpora. Distant supervision (Mintz et al., 2009; Surdeanu et al., 2012) is a widely used method to alleviate human annotation: if multiple sentences contain two entities that have a certain relation in a knowledge base, at least one sentence is believed to convey the related relation. However, entities convey semantic meanings also according to the contexts, distant supervised models do not explicitly consider contexts and the models cannot discover new relations as the supervision is purely adopted from knowledge bases.

Unsupervised relation extraction (Stanovsky et al., 2018; Saha et al., 2018; Yu et al., 2017) gets lots of attention, due to the ability to discover relational knowledge without access to annotations and external resources. Unsupervised models either 1) cluster the relation representation extracted from the sentence; 2) make more assumptions that provide learning signals for classification models. Among clustering models, an important milestone is the OpenIE approach (Banko et al., 2007), assuming the surface form of relations will appear between two entities in its dependency tree. However, these works heavily rely on surface-form relation and have less ideal generalization capabilities. To solve this problem, Roy et al. (2019) proposes a system that learns to supervise unsupervised OpenIE model, which combines the strength and avoids the weakness in each individual OpenIE system. Relation knowledge transfer system (Wu et al., 2019) learns similarity metrics of relations from labeled data, and then transfers the relational knowledge to identify novel relations in unlabeled data.

Marcheggiani and Titov (2016) proposes a variational autoencoder approach (VAE): the encoder part extracts relations from labeled features, and the decoder part predicts one entity when given the other entity and the relation with the function of triplet scoring (Nickel et al., 2011). This scoring function could provide a signal since it is known to predict relation triplets when given their embeddings. However, posterior distribution and prior uniform distribution based on KL divergence is unstable. Simon et al. (2019) proposes a model to solve instability and trains the features on classifiers such as PCNN model (Zeng et al., 2015).

Inspired by the success of self-supervised learning in computer vision (Wiles et al., 2018; Caron et al., 2018), and large pretrained language models that show great potential in encoding meaningful semantics for various downstream tasks (Devlin et al., 2018), we proposed a self-supervised learning schema for open-domain relation extraction. It has the advantages of unsupervised learning to handle the cases where the number of relations is not known in advance, but also keeps the advantage of supervised learning that has strong discriminative power for relational feature learning.

5 Conclusions

We propose a self-supervised learning model `SelfORE` for open-domain relation extraction. Different from conventional distant-supervised models which require labeled instances for Relation Extraction in a closed-world setting, our model does not require annotations and is able to work on open-domain scenarios when target relation number and relation distributions are not known in advance. Comparing with unsupervised models, our model exploits the advantages of supervised models and bootstraps the discriminative power using self-supervised signals via learning improved contextualized relational features. Experiments on three real-world datasets show effectiveness and robustness of `SelfORE` over competitive baselines.

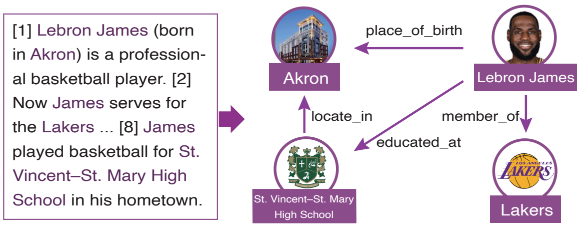
Abstract

Distant supervision (DS) has been widely used to generate auto-labeled data for sentence-level relation extraction (RE), which improves RE performance. However, the existing success of DS cannot be directly transferred to the more challenging document-level relation extraction (DocRE), since the inherent noise in DS may be even multiplied in document level and significantly harm the performance of RE. To address this challenge, we propose a novel pre-trained model for DocRE, which denoises the document-level DS data via multiple pre-training tasks. Experimental results on the large-scale DocRE benchmark show that our model can capture useful information from noisy DS data and achieve promising results. The source code of this paper can be found in `https://github.com/thunlp/DSDocRE`.

1 Introduction

Relation extraction (RE) aims to identify relational facts between entities from texts. Recently, neural relation extraction (NRE) models have been verified in sentence-level RE (Zeng et al., 2014). Distant supervision (DS) (Mintz et al., 2009) provides large-scale distantly-supervised data that multiplies instances and enables sufficient model training.

Sentence-level RE focuses on extracting *intra-sentence* relations between entities in a sentence. However, it is extremely restricted with generality and coverage in practice, since there are plenty of *inter-sentence* relational facts hidden across multiple sentences. Statistics on a large-scale RE dataset constructed from Wikipedia documents show that at least 40.7% relational facts can only be inferred from multiple sentences (Yao et al., 2019). Therefore, *document-level relation extraction (DocRE)* is proposed to jointly extract both inter- and intra- sentence relations (Christopoulou et al., 2019). Fig. 1 gives a brief illustration of DocRE.



[1] Lebron James (born in Akron) is a professional basketball player. [2] Now James serves for the Lakers ... [8] James played basketball for St. Vincent–St. Mary High School in his hometown.

Figure 1: An example of DocRE. Given a document, DocRE models should capture the relational semantics across sentences to extract multiple relational facts.

Most DocRE models heavily rely on high-quality human-annotated training data, which is time-consuming and labor-intensive. However, it is extremely challenging to extend the sentence-level DS to the document level. The challenges of conducting document-level DS mainly come from: (1) Each entity contains multiple mentions, and mentions without relational context bring noise to entity representations; (2) The inherent noise of DS will be even multiplied at the document level. Statistics in Yao et al. (2019) show that 61.8% inter-sentence relation instances generated by document-level DS are actually noise; (3) It is challenging to capture useful relational semantics from long documents, since most contents in the documents may be irrelevant to the given entities and relations. In sentence-level RE, several efforts (Lin et al., 2016; Feng et al., 2018) have been devoted to denoise the DS corpus by jointly considering multiple instances. However, these denoising methods can not be directly adapted to DocRE, since they are specially designed for bag-level RE evaluations.

In this work, we attempt to introduce document-level DS to DocRE after denoising. To alleviate the noise, we propose a pre-trained model with three specially designed tasks to denoise the document-

November 16–20, 2020.

level DS corpus and leverage useful information. The three pre-training tasks include: (1) **Mention-Entity Matching**, which aims to capture useful information from multiple mentions to produce informative representations for entities. It consists of intra-document and inter-document sub-tasks. The intra-document sub-task aims to match masked mentions and entities within a document to grasp the coreference information. The inter-document sub-task aims to match entities between two documents to grasp the entity association across documents. (2) **Relation Detection**, which focuses on denoising "Not-A-Relation (NA)" and incorrectly labeled instances by detecting the entity pairs with relations, i.e., positive instances. It is specially designed as the document-level denoising task. We also conduct a pre-denoising module trained with this task to filter out NA instances before pre-training. (3) **Relational Fact Alignment**, which requires the model to produce similar representations for the same entity pair from diverse expressions. This allows the model to focus more on diverse relational expressions and denoising irrelevant information from the document.

In experiments, we evaluate our model on an open DocRE benchmark and achieve significant improvement over competitive baselines. We also conduct detailed analysis and ablation test, which further highlight the significance of DS data and verify the effectiveness of our pre-trained model for DocRE. To the best of our knowledge, we are the first to denoise document-level DS with pre-trained models. We will release our codes in the future.

2 Related Work

Sentence-level RE. Conventional NRE models focus on sentence-level supervised RE (Zeng et al., 2014; Takanobu et al., 2019), which have achieved superior results on various benchmarks. Other approaches focus on using more data with distant supervision mechanism (Mintz et al., 2009; Min et al., 2013). To denoise distantly supervised corpus, they introduce attention (Lin et al., 2016; Zhou et al., 2018), generative adversarial training (Qin et al., 2018) and reinforcement learning (Feng et al., 2018) to select informative instances. It is hard to directly adopt these models to DocRE, since DocRE should extract multiple relational facts from each document. Soares et al. (2019) propose a pre-trained model for sentence-level RE.

Document-level RE. Document-level RE attempts to extend the scope of knowledge acquisition to the document level, which has attracted great attention recently (Yao et al., 2019). Some works use linguistic features (Xu et al., 2016; Gu et al., 2017) and graph-based models (Christopoulou et al., 2019; Sahu et al., 2019) to extract inter-sentence relations on human-annotated data. Quirk and Poon (2017) and Peng et al. (2017) attempt to extract inter-sentence relations with distantly supervised data. However, they only use entity pairs within three consecutive sentences. Different from these works, we bring in document-level DS to DocRE and conduct pre-training to denoise these DS data.

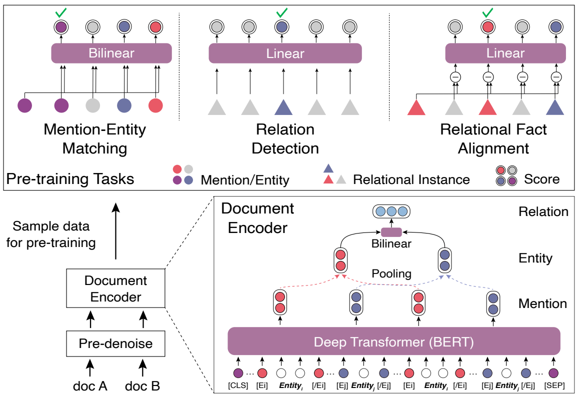

Figure 2: The framework of our proposed model.

3 Methodology

In this section, we present our proposed model in detail. Fig. 2 gives an illustration of our framework. We first apply the pre-denoising module to screen out some NA instances from all documents. Then we pre-train the document encoder with three pre-training tasks on the document-level distantly supervised dataset. Finally, we fine-tune the model on the human-annotated dataset.

3.1 Document Encoder

We adopt BERT (Devlin et al., 2019) as the document encoder to encode documents into representations of entity mentions, entities and relational instances. Let $D = \{\omega_i\}_{i=1}^{n}$ denote the input document which consists of n tokens, and $V = \{e_i\}_{i=1}^{|V|}$ be the set of entities mentioned in the document, where entity $e_i = \{m_i^j\}_{j=1}^{l_i}$ contains l_i mentions in the document. Following Soares et al. (2019), we use entity markers `[Ei]` and `[/Ei]` for each entity e_i. The start marker `[Ei]` is inserted at the begin of all mentions of entity e_i, and the end marker `[/Ei]` is inserted at the end.

We use BERT to encode the token sequence with entity markers into a sequence of hidden state $\{\mathbf{h}_1, ..., \mathbf{h}_{\hat{n}}\}$, where $\hat{n}$ indicates the length of the sequence with entity markers. We define representation $\mathbf{m}_i^j$ of each entity mention as the hidden state of its start marker. Then a max-pooling operation is performed to obtain the aggregated representation of entity e_i from its mentions: $\mathbf{e}_i = \text{MaxPooling}(\{\mathbf{m}_i^j\}_{j=1}^{l_i})$. Next, for each entity pair (e_i, e_k), we use a bilinear layer to compute the relational representation: $\mathbf{r}_{i,k} = \text{Bilinear}_E(\mathbf{e}_i, \mathbf{e}_k)$.

3.2 Pre-training Tasks

We design three pre-training tasks, which help the model to denoise document-level DS data and learn informative representations in both mention/entity-level and relation-level from large-scale DS data.

Mention-Entity Matching. An entity is usually mentioned multiple times in a document, and it is important for expressive entity representations to capture relational information from these mentions. Hence, we propose the mention-entity matching task to help the model to produce expressive representations for mentions and entities, which includes intra-document and inter-document sub-tasks.

The intra-document sub-task requires the model to grasp the coreference information within a document. We randomly mask an entity mention and require the model to predict which entity in the document it belongs to. Formally, given the masked entity mention m^q and k_m entities $\{e_m^i\}_{i=1}^{k_m}$ from the same document, we compute the matching score for e_m^i and m^q with a bilinear layer as follows:

$$s_m(e_m^i, m^q) = \text{Bilinear}_M(\mathbf{e}_m^i, \mathbf{m}^q). \qquad (1)$$

The inter-document sub-task requires the model to link the same entity in two different documents. It aims to develop the model to encode useful information from the contexts into the representations. Given the entities $\{e_A^i\}_{i=1}^{k_e}$ from document d_A where k_e is the size of the entity set, and the entity e_B^q from document d_B which is also mentioned in d_A, we define the matching score for entity e_B^q and e_A^i as:

$$s_m(e_A^i, e_B^q) = \text{Bilinear}_M(\mathbf{e}_A^i, \mathbf{e}_B^q), \qquad (2)$$

where Bilinear_M indicates the same bilinear layer in intra-document sub-task. Then both matching scores are fed into an output softmax function.

Relation Detection. The NA relation is dominating in DocRE. It is necessary for models to denoise NA instances and to identify the true positive instances from NA noise. Therefore, we design this task, which requires the model to distinguish positive entity pairs from NA instances. Formally, given k_n instances $\{r_n^i\}_{i=1}^{k_n}$ from given documents where only one is positive, we have their positive score as:

$$s_n(r_n^i) = \mathbf{w}_n \mathbf{r}_n^i + b_n, \qquad (3)$$

where $\mathbf{w}_n$ and b_n indicate weights and bias. Next, we apply a softmax function to compute the probability of i-th instance to be positive.

Similar to the previous mention/entity-level task, this task can also be divided into intra- and inter-document sub-tasks. For the intra-document sub-task, the instances are all sampled from one single document. For the inter-document sub-task, the instances are sampled from different documents.

Relational Fact Alignment. To grasp useful information from the long documents and denoise irrelevant content, we design the relation-level task, which requires the representations of the same entity pairs in different documents to be similar. Formally, assume d_A and d_B are two documents from the training set, which share several relational facts. Let $\{r_A^i\}_{i=1}^{k_s}$ denote the relational instances in d_A, and r_B^q denote the representation of the relational instance in d_B whose relational fact is contained in d_A. Then the model is required to find the relational instance from $\{r_A^i\}_{i=1}^{k_s}$, which shares the same relational fact with r_B^q. First, we compute the similarity score of two relational instances:

$$s_s(r_A^i, r_B^q) = \mathbf{w}_s |\mathbf{r}_A^i - \mathbf{r}_B^q| + b_s. \qquad (4)$$

$\mathbf{w}_s$ and b_s are weights and bias. Then similarity scores are fed into a softmax over instances in d_A.

Finally, the overall pre-training loss $\mathcal{L}$ is the sum of all cross-entropy losses in three tasks.

$$\mathcal{L} = \mathcal{L}_M + \mathcal{L}_S + \mathcal{L}_N. \qquad (5)$$

Note that the loss can be easily minimized by an entity linking system without any relational knowledge. To avoid this problem, we replace all the mentions of an entity in a document by a special blank symbol `[BLANK]` with probability α following Soares et al. (2019). In such a case, the model can only learn representations from the context. As a result, minimizing the loss $\mathcal{L}$ requires the model to do more than just memorizing named entities.

3.3 Pre-denoising Module

As stated before, the document-level DS will generate more noise. To alleviate the issue, we propose to screen out entity pairs with low relational probability from all documents with a rank model. We train the rank model with the Relation Detection task on the human-annotated training set. Then, the rank model is able to give high scores to positive instances and low scores to NA instances. During the pre-denoising process, we compute positive scores for all entity pairs as stated in Eq. 3. Next, for each document, we rank all its entity pairs according to their positive scores, and keep top k_d entity pairs for pre-training, fine-tuning and evaluation. The framework of the pre-denoising module is the same as the model used for pre-training. Please refer to the previous section for details. With the pre-denoising module, the wrong labeling problem in DS corpus and the label imbalance problem (i.e., most entity pairs belong to NA instances) in the human-annotated corpus can be alleviated.

4 Experiments

4.1 Dataset and Evaluation Metrics

We evaluate our model on DocRED (Yao et al., 2019), which is the largest human-annotated DocRE dataset. DocRED contains $5,053$ human-annotated documents, with $56,354$ relational facts and $63,427$ relation instances. Besides, DocRED also provides large-scale distantly supervised data, which contains $101,873$ documents, with $881,298$ relational facts and $1,508,320$ relation instances labeled automatically by distant supervision (Mintz et al., 2009). Please refer to Yao et al. (2019) for the details about dataset construction.

In experiments, we use the document-level DS data to pre-train our model and then fine-tune and evaluate the model on the human-annotated data. Following Yao et al. (2019), we use F_1 and $IgnF_1$ as evaluation metrics, where $IgnF_1$ denote the F_1 scores excluding relational facts in both training and dev/test sets. Please refer to the appendix for details about DocRED and experimental settings.

4.2 Baseline

We compare our model with the following baselines. (1) CNN/LSTM/BiLSTM (Yao et al., 2019): these models capture relational semantics via various encoder. (2) ContextAware (Sorokin and Gurevych, 2017): it considers the relations' interactions with attention to jointly learn all entity pairs in the contexts. (3) BERT (Devlin et al., 2019): this baseline is implemented as described in Sec. 3.1. (4) BERT-TS (Wang et al., 2019): it predicts whether two entities have relations in the first step and then predicts the specific relation in the second step. (5) HIN-BERT (Tang et al., 2020): it applies a hierarchical inference network to aggregate information from multiple granularity. (6) DS-BiLSTM/ContextAware (Yao et al., 2019): corresponding models trained on DS data.

Model	Dev F_1	Dev $IgnF_1$	Test F_1	Test $IgnF_1$

4.3 Implementation Details

We pre-train our model based on $\text{BERT}_{\text{BASE}}$. All the hyper-parameters are selected with manually tuning. The learning rate is set to 3×10^{-5} for pre-training and 10^{-5} for fine-tuning. The size of relational representations is 256, which is selected from $\{64, 128, 256, 512\}$. The batch size for pre-training is set to 16 and 4 for fine-tuning. We keep $2N_{\text{ent}}$ entity pairs after pre-denoising for each document during fine-tuning, where N_{ent} is the number of entities mentioned in the document. And we keep 20 entity pairs for each document during pre-training. We train our model with GeForce RTX 2080 Ti. All the special tokens including entity markers and the special blank symbol are implemented with unused tokens in the $\text{BERT}_{\text{BASE}}$ vocabulary.

4.4 Main Result

The main results are shown in Tab. 1. Specifically, **D** refers to the pre-denoising module and **P** indicates pre-training tasks. From the results, we can observe that: (1) Our model outperforms all baselines by a significant margin. It is due to the effectiveness of the pre-denoising mechanism

Model	Dev F_1	Dev $IgnF_1$	Test F_1	Test $IgnF_1$
our model	58.65	**57.00**	**58.43**	**56.68**
w/o MM	58.39	56.76	57.60	55.81
w/o RD	57.19	55.61	56.71	54.94
w/o RA	58.48	56.73	58.13	56.30
w/o Inter	**58.68**	56.96	57.72	55.87
w/o Intra	57.78	56.18	57.62	55.89

Table 2: Results of ablation study on DocRED.

and three pre-training tasks. (2) Our model without pre-training (BERT+D) can also outperform all the baseline models, which indicates that our pre-denoising module can deal with the amounts of NA instances. (3) The noise in distantly supervised data harms the performance of RE systems. Our model can filter out noise and capture information from the large-scale distantly supervised data, thus achieving a performance improvement. (4) Pre-training without pre-denoising (BERT+P) cannot converge due to amounts of data labeled incorrect.

4.5 Ablation Study

To explore the contribution of different pre-training tasks, we show the results of the ablation study in Tab. 2. Specifically, we show the scores with different pre-training tasks turned off one at a time. **MM**, **RD**, **RA** indicate three pre-training tasks: Mentions/Entities Matching, Relation Detection, and Relational Facts Alignment. We observe that all three pre-training tasks contribute to the main model, as the performance deteriorates with any of the tasks missing. Note that the removal of the RD pre-training task leads to a large drop in both F_1 and $IgnF_1$ scores, even lower than those of our model without pre-training (BERT+D). This is because without RD, the model is unable to identify positive instances, which is quite important in document-level RE and then the label imbalance problem makes the scores drop.

Moreover, we conduct another ablation study to explore the effectiveness of intra- and inter-document subtasks. The results are shown in Tab. 2, where **w/o Intra** and **w/o Inter** refer to pre-training without intra- and inter-document sub-tasks. We find that both intra-document and inter-document sub-tasks contribute to the main model in general.

5 Conclusion

In this work, we propose to denoise distantly supervised data in DocRE by multiple pre-training tasks. Experiment results verify the effectiveness of our model. In the future, we will explore how to improve the efficiency of our pre-training.

Abstract

Despite efforts to distinguish three different evaluation setups (Bekoulis et al., 2018a,b), numerous end-to-end Relation Extraction (RE) articles present unreliable performance comparison to previous work. In this paper, we first identify several patterns of invalid comparisons in published papers and describe them to avoid their propagation. We then propose a small empirical study to quantify the most common mistake's impact and evaluate it leads to overestimating the final RE performance by around 5% on ACE05. We also seize this opportunity to study the unexplored ablations of two recent developments: the use of language model pretraining (specifically BERT) and span-level NER. This meta-analysis emphasizes the need for rigor in the report of both the evaluation setting and the dataset statistics. We finally call for unifying the evaluation setting in end-to-end RE [1].

1 Introduction

Named Entity Recognition (NER)[2] and Relation Extraction (RE) are key Information Extraction tasks, for example at the heart of Knowledge Graph Construction along with Coreference Resolution and Entity Linking. In the traditional pipeline approach, these tasks are treated with two models trained separately and applied sequentially (Bach and Badaskar, 2007). Nevertheless, combining information from both submodules is beneficial (Roth and Yih, 2002) and end-to-end RE models tackling both tasks jointly have been proposed to better model their interdependency and overcome cascading errors (Li and Ji, 2014).

This end-to-end setting has recently received more attention in the wake of improved language models (LM). However, in this prolific and competitive domain, authors have used several evaluation settings to compare their performance. And despite the attempt to clearly identify three main setups (Bekoulis et al., 2018a,b), this multiplication of settings makes the apprehension of the literature difficult and confusing, but more importantly, it has led to erroneous comparisons and conclusions.

In this paper, we first present a quick literature review of the recent advances in end-to-end RE. Our main contribution is then the identification of invalid comparison patterns in recent publications. We list them with the hope of stopping the propagation of erroneous results and presenting a curated list of published results. To further this contribution, we propose a small empirical study to quantify the impact of switching the two main metrics and estimate it can lead to a relative overestimation of around 5% in the end-to-end RE results on ACE05.

As a second contribution, we take advantage of this quantitative study to perform the omitted ablations of two recent developments in the literature: LM pretraining and Span-level NER. It confirms that recent empirical gains are mainly due to LM pretraining, while there is no evidence for quantitative gains from Span-level NER.

Finally, we argue that the main cause for previously identified mistakes is the lack of reproducibility and, consequently, of previous work reproductions. We call for a more rigorous report of both evaluation settings and dataset statistics in general and particularly in end-to-end RE. And we also suggest unifying our evaluation setting to reduce the chance of future mistakes and enable more meaningful cross-dataset analyses.

2 A Quick Literature Review

In order to have a global view of recent evolutions, we present a quick literature review of end-to-end RE models. We focus on supervised extraction of

intra-sentence binary relations in English corpora. A summary is proposed in Table 1.

Local classifiers The first attempts to model the interdependency between NER and RE combined the predictions of independent local classifiers according to global constraints (e.g. the arguments of the "Live In" relation must be a Person and a Location); either with Probabilistic Graphical Models (Roth and Yih, 2002), Integer Linear Programming (Roth and Yih, 2004) or Card Pyramid Parsing (Kate and Mooney, 2010).

Incremental Joint Training Li and Ji (2014) propose the first joint model using a structured perceptron to parse a sentence with a set of two actions: append a mention to detected entities and possibly link it with a relation to a previous mention. Katiyar and Cardie (2017) adopt the same framing but replace handcrafted features with word embeddings and use a BiLSTM for NER and a Pointer Network for RE. Miwa and Sasaki (2014) simplify this setting by sequentially filling a table containing all entity and relation information. Gupta et al. (2016) take up this Table Filling (TF) approach but use an RNN with a multitask approach. Similarly, (Zhang et al., 2017) use LSTMs but add syntactic features from (Dozat and Manning, 2017)'s Dependency Parser.

Entity Filtering Other models use entity filtering as in the pipeline setting where RE is viewed as classification given a sentence and a pair of arguments. This requires passing each pair of candidate entities through the RE classifier. The only difference is that the NER and RE models share some parameters in end-to-end RE, often in a BiLSTM encoder. Indeed, as in the previous incremental setting, NER is modeled as sequence labeling using BILOU tags (Ratinov and Roth, 2009) and the NER module is often a BiLSTM as in (Huang et al., 2015). The two modules are jointly trained by optimizing for the (weighted) sum of their losses.

Miwa and Bansal (2016) use a sequential BiLSTM for NER and a Tree-LSTM over the shortest dependency path between candidate arguments given by an external parser and Li et al. (2017) apply this model to biomedical data.

Adel and Schütze (2017), Zheng et al. (2017) and Sun et al. (2018) all rely on the Piecewise CNN (PCNN) architecture for RE (Zeng et al., 2015). The sentence is split into three pieces: before the first argument, between the arguments, and after the last argument. The RE classifier is fed with CNN pooled representations of these three pieces and of both arguments. Adel and Schütze (2017) add a CRF to model the argument type / relation type dependencies while Sun et al. (2018) use minimum risk training to incorporate global F1 scores in the loss and make loss functions more interdependent.

Multi-Head Selection To avoid relying explicitly on NER prediction, Bekoulis et al. (2018b,a), propose Multi-Head Selection where RE classification is made for every pair of words. As in Table Filling, relations should only be predicted between the last words of entity mentions to avoid redundancy and inconsistencies. This enables end-to-end RE in a single pass, but contextual information must be implicitly encoded in all word representations since the Linear RE classifier is only fed with representations of both arguments and a label embedding of BILOU NER predictions. Nguyen and Verspoor (2019) replace this linear RE classifier by the bilinear scorer from Dozat and Manning (2017)'s Dependency Parser. A similar architecture is extended with BERT representations in (Giorgi et al., 2019). Finally, Sanh et al. (2019) build on (Bekoulis et al., 2018b) to explore a broader multi-task setting incorporating Coreference Resolution (CR) and another corpus for NER. They use ELMo contextualized embeddings (Peters et al., 2018).

Span-level NER With the same idea of jointly training CR along with joint NER and RE, Luan et al. (2018) replace the traditional sequence labeling framing of NER by span-level classification inspired by end-to-end CR (Lee et al., 2017) and Semantic Role Labeling (SRL) (He et al., 2018). In this setting, all spans (up to a fixed length) are independently classified as entities, which enables detecting overlapping entities, and they use an element-wise biaffine RE classifier to classify all pairs of detected spans. In (Luan et al., 2019), they then propose to iteratively refine predictions with dynamic graph propagation of RE and CR confidence scores. This work is adapted with BERT as an encoder in (Wadden et al., 2019).

Dixit and Al-Onaizan (2019) use a model very similar to Luan et al. (2018)'s but restrict to end-to-end RE. Eberts and Ulges (2020) recently use span-level NER with BERT as an encoder. They add a pooled representation of the middle context for RE, similarly to piecewise models.

Question Answering RE can also be framed as Question Answering (QA) in the zero-shot (Levy et al., 2017) or end-to-end (Li et al., 2019) settings. The latter Multi-Turn QA uses templates of questions to identify entity mentions and their relations.

3 Datasets and Metrics

Datasets Although a variety of datasets have been used, we limit our report to the five we identified as the most frequently studied for brevity.

Following (Roth and Yih, 2002), end-to-end RE has traditionally been explored on English news articles, which is reflected in the domain of its historical benchmarks, CoNLL04 and the ACE datasets. **CoNLL04** (Roth and Yih, 2004) is annotated for four entity types and five relation types and specifically only contains sentences with at least one relation. The **ACE04** dataset (Doddington et al., 2004) defines seven coarse entity types and seven relation types. **ACE05** resumes this setting but merges two relation types leading to six of them.

More recently, Gurulingappa et al. (2012) propose the **ADE** dataset in the biomedical domain, which focuses on one relation, the Adverse Drug Event between a Drug and one of its Adverse Effects. In the scientific domain, Luan et al. (2018) introduce **SciERC** composed of 500 scientific article abstracts annotated with six types of scientific entities, coreference clusters, and seven relations between them.

Metrics The traditional metrics for assessing both NER and RE performance are Precision, Recall and F1 scores. However, there are two points of attention: the use of micro or Macro averaged metrics across types and the criterion used to consider a prediction as true positive.

On this second point, there is no difficulty for NER where the consensus is to both consider detection and typing. However, compared to the pipeline Relation Classification, this end-to-end RE setting adds a source of mistake in the identification of arguments. And while there is an agreement that the relation type must be correctly detected, several evaluation settings have been introduced with different argument detection requirements.

Hence, Bekoulis et al. (2018a) distinguishes three evaluation settings:

Strict: both the boundaries and the entity type of each argument must be correct.

Boundaries: argument type is not considered and boundaries must be correct.

Relaxed: NER is reduced to Entity Classification i.e. predicting a type for each token. A multi-token entity is considered correct if at least one token is correctly typed.

4 Identified Issues in Published Results

This variety of evaluation settings, visible in Table 1, leads to confusion which in turn favors recurring mistakes. By a careful examination of previous work and often only thanks to released source codes and/or sufficiently detailed descriptions, we identified several of them. Because these precious sources of information are sometimes missing, we cannot assert we are exhaustive. However, we will now list them to avoid their propagation and present a curated summary of supposedly comparable results in Table 2.

4.1 Comparing Boundaries to Strict results on ACE datasets

The most common mistake is the comparison of Strict and Boundaries results. Indeed, several works (Zheng et al., 2017; Luan et al., 2019; Wadden et al., 2019) use the Boundaries setting to compare to previous Strict results. However, because the Strict setting is more restrictive, this leads to overestimating the benefit of the proposed model over previous SOTA. We propose a quantification of the resulting improper gain in section 5.4.

4.2 Confusing Settings on CoNLL04

On the CoNLL04 dataset, the two settings that have been used are even more different. Indeed, while Miwa and Sasaki (2014) use the Strict evaluation, Gupta et al. (2016), who build upon the same Table Filling idea, introduce a different setting. They 1) use the Relaxed criterion; 2) discard the "Other" entity type; 3) release another train / test split; 4) use Macro-F1 scores.

This inevitably leads to confusions, first on the train / test splits, e.g. Giorgi et al. (2019) claim to use the splits from (Miwa and Sasaki, 2014) while they link to (Gupta et al., 2016)'s. Second, Nguyen and Verspoor (2019) unconsciously introduce a different *Strict setup* because it ignores the "Other" entity type and considers Macro-F1 instead of micro-F1 scores. This leads to unfair comparisons.

4.3 Altering both Metrics and Data

Sanh et al. (2019) propose a multitask Framework for NER, RE and CR and use ACE05 to evaluate end-to-end RE. However, they combine two mistakes: incorrect metric comparison and dataset alteration. First, they use the typical formulation to describe a Strict setting but, in fact, use a setting looser than Boundaries. Indeed, they do not consider the type of arguments and only their last word must be correctly detected. Second, they truncate the ACE05 dataset to sentences containing at least one relation both in train and test sets, which leads to an even more favorable setting.

What is worrisome is that both these mistakes are almost invisible in their paper and can only be detected in their code. The only hint for incorrect evaluation is that they report a score for a setting where they only supervise RE, which is impossible in any standard setting. For the dataset, the fact that they do not use the standard preprocessing from (Miwa and Bansal, 2016)[1] might be a first clue.

4.4 Are We Even Using the Same Data?

Without going this far into data alteration, a first source of ambiguity resides in the use or not of the validation set as additional training data. While on CoNLL04, because there is no agreement on a dev set, the final model is trained on train+dev by default; the situation is less clear on ACE. And our following experiments show that this point is already critical w.r.t SOTA claims.

Considering data integrity and keeping the ACE datasets example, even when the majority of works refer to the same preprocessing scripts[1] there is no way to check the integrity of the data without a report of complete dataset statistics. This is especially true for these datasets whose license prevents sharing of preprocessed versions.

Yet, we have to go back to (Roth and Yih, 2004) to find the original CoNLL04 statistics and (Li and Ji, 2014) for ACE datasets. To our knowledge, only a few recent works report in-depth datasets statistics (Adel and Schütze, 2017; Sanh et al., 2019; Giorgi et al., 2019). We report them for CoNLL04 and ACE05 in Table 3 along with our own.

Table 2: Summary of recently published results in end-to-end RE on five datasets.
* = partition from (Miwa and Sasaki, 2014). † = explicit use of train+dev. + = experiments on additional datasets. ✗= some results were incorrectly reported as Strict. Models over the dashed lines use LM pretraining.

We observe differences in the number of sentences, entity mentions and relations. Minor differences in the number of annotated mentions likely come from evolutions in datasets versions. Their impact on performance comparison should be limited, although problematic. But we also observe more impactful differences, e.g. with (Giorgi et al., 2019) for both datasets and despite using the same setup and preprocessing.

Table 3: Global datasets statistics in CoNLL04 and ACE05 as reported by different sources. More detailed statistics are available in Appendix.

Such a difference in statistics reminds us that the dataset is an integral part of the evaluation setting. And in the absence of sufficiently detailed reports, we cannot track when and where they have been changed since their original introduction.

5 A Small Empirical Study

Given these previous inconsistencies, we can legitimately wonder what is the impact of different evaluation settings on quantitative performance. However, it is also unrealistic to reimplement and test each and every paper in a same setting to establish a benchmark. Instead, we propose a small empirical study to quantify the impact of using the Boundaries setting instead of the Strict setting on the two main benchmarks: CoNLL04 and ACE05. We discard the Relaxed setting because it cannot evaluate true end-to-end RE without striclty taking argument detection into account. It is also limited to CoNLL04 and we have no example of misuse.

We will consider a limited set of models representative of the main Entity Filtering approach. And we seize this opportunity to perform two ablations that correspond to meaningful recent proposals and are missing in related work.

First, when looking at Table 2, it is difficult to draw general conclusions beyond the now established improvements due to LM pretraining. And in the absence of ablation studies on the matter[1], it is impossible to compare models using LM pretraining and anterior works. For example, in the novel work of Li et al. (2019), we cannot disentangle the quantitative effects of LM pretraining and the proposed MultiTurn QA.

Second, to our knowledge, no article compares the recent use of span-level NER instead of classical sequence tagging in end-to-end RE.

5.1 Dataset preprocessing and statistics

We use the standard preprocessing from (Miwa and Bansal, 2016) to preprocess ACE05[2].

For CoNLL04, we take the preprocessed dataset and train / dev / test split from (Eberts and Ulges, 2020)[3] and check it corresponds to the standard train / test split from (Gupta et al., 2016)[4]. We report global dataset statistics in Table 3.

5.2 Models

We propose to use the model from (Eberts and Ulges, 2020) as a baseline for our ablation study since it combines BERT finetuning and Span-level NER. We then perform two ablations: replacing BERT by a BiLSTM encoder with non-contextual representations and substituting Span-level NER with BILOU sequence tagging.

Encoder : BiLSTM vs BERT We use BERT (Devlin et al., 2019) as LM pretraining baseline, expecting that the effects of ELMo (Peters et al., 2018) would be similar. As in related work, we use cased $\text{BERT}_{\text{BASE}}$ and finetune its weights. A word is represented by max-pooling of the last hidden layer representations of all its subwords.

For our non-contextual baseline, we take the previously ubiquitous BiLSTM encoder and choose a 384 hidden size in each direction so that the encoded representation matches BERT's. We feed this encoder with the concatenation of 300d GloVe 840B word embeddings (Pennington et al., 2014) and a reproduction of the charBiLSTM from (Lample et al., 2016) (100d char embeddings and hidden size 25 in each direction).

NER Decoder : BILOU vs Span In the sequence tagging version, we simply feed the previously encoded word representation $\mathbf{h}_i$ into a linear layer with a softmax to predict BILOU tags.

$$\hat{\mathbf{y}}_i^{seq} = \text{softmax}(W^{seq}.\mathbf{h}_i + \mathbf{b}^{seq}) \tag{1}$$

For span-level NER, we follow (Eberts and Ulges, 2020). We only consider spans up to maximal length 10, which are represented by the max pooling of the representations of their tokens. An additional span width embedding $\mathbf{w}$ of dimension 25 is concatenated to this representation as in (Lee et al., 2017). The only difference with (Eberts and Ulges, 2020) is that they also concatenate the representation of the [CLS] token in all span representations to incorporate sentence-level information. We discard this specificity of BERT-like models. All these span-level representations are classified using a linear layer followed by a softmax to predict entity types (including None). We also use negative sampling by randomly selecting 100 negative spans during training.

$$\begin{aligned} \mathbf{h}(s) &= \text{MaxPool}(\mathbf{h}_i, ...\mathbf{h}_{i+l-1}) && (2)\\ \mathbf{e}(s) &= [\mathbf{h}(s); \mathbf{w}(l)] && (3)\\ \hat{\mathbf{y}}^{span}(s) &= \text{softmax}(W^{span}.\mathbf{e}(s) + \mathbf{b}^{span}) && (4) \end{aligned}$$

The NER loss $\mathcal{L}_{NER}$ is the cross-entropy over either BILOU tags or entity classes.

RE Decoder For the RE Decoder, we strictly follow (Eberts and Ulges, 2020). We first filter candidate entity pairs i.e. all the ordered pairs of entity

Table 4: Double ablation study of BERT and Span-level NER. We report the average of five runs and their standard deviation in subscript. For RE we consider both the Strict and Boundaries settings, RE Strict score is used as the criterion for early stopping.

mentions detected by the NER decoder. Then, for every pair, the input to the relation classifier is the concatenation of each span representation $\mathbf{e}(s_i)$ and a context representation $\mathbf{c}(s_1, s_2)$, the max pooling of all tokens strictly between the two spans[1]. Once again, this pair representation is fed to a linear classifier but with a sigmoid activation so that multiple relations could be predicted for each pair.

$$\mathbf{x}(s_1, s_2) = [\mathbf{e}(s_1); \mathbf{e}(s_2); \mathbf{c}(s_1, s_2)] \tag{5}$$

$$\hat{\mathbf{y}}^{rel}(s_1, s_2) = \sigma(W^{rel}.\mathbf{x}(s_1, s_2) + \mathbf{b}^{rel}) \tag{6}$$

$\mathcal{L}_{RE}$ is computed as the binary cross-entropy over relation classes. During training, we sample up to 100 random negative pairs of detected or ground truth spans, as in (Eberts and Ulges, 2020).

Joint Training As in most related work, we simply optimize for $\mathcal{L} = \mathcal{L}_{NER} + \mathcal{L}_{RE}$.

5.3 Experimental Setting

We implement these models with Pytorch (Paszke et al., 2019) and Huggingface Transformers (Wolf et al., 2019). For all settings, we fix a dropout rate of 0.1 across the entire network, a 0.1 word dropout for Glove embeddings and a batch size of 8. We use Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. A preliminary grid search on CoNLL04 led us to select a learning rate of 10^{-5} when using BERT and 5.10^{-4} with the BiLSTM[2].

We perform early stopping with patience 5 on the dev set Strict RE μ F1 score with a minimum of 10 epochs and a maximum of 100. To compare to related work on CoNLL04, we retrain on train+dev for the optimal number of epochs as determined by early stopping. We report aggregated results from five runs in Table 4.

5.4 Comparing Boundaries and Strict Setups

This humble study first quantifies the impact of using Boundaries instead of Strict evaluation to an overestimation of 2.5 to 3 F1 points on ACE05, which is far from negligible.

But it is also interesting to see that such a mistake has almost no impact on CoNLL04, which highlights an overlooked difference between the two datasets. A simple explanation is the reduced number of entity types (4 against 7) which reduces the chance to wrongly type an entity. But we can also notice the difference in the variety of argument types in each relation. Indeed, in CoNLL04 there is a bijective mapping between a relation type and the ordered types of its arguments; this minimal difference suggests that our models have mostly learned it. On the contrary on ACE05, this mapping is much more complex (e.g. the relation PART-WHOLE fits 9 pairs of types[3]) which explains the larger difference between metrics, whereas the NER F1 scores are comparable.

5.5 Comments on the Ablations

First, we fail to reproduce Eberts and Ulges (2020)'s results on CoNLL04 with our full BERT and Span NER setting. This is most likely due

---

[1] If there are none, $\mathbf{c}(s_1, s_2) = \mathbf{0}$

[2] Search in $\{10^{-6}, 5.10^{-6}, \mathbf{10^{-5}}, 5.10^{-5}, 10^{-4}\}$ with BERT and $\{10^{-4}, \mathbf{5.10^{-4}}, 10^{-3}, 5.10^{-3}, 10^{-2}\}$ otherwise.

[3] see additional details in Appendix

to differences in our hyperparameters and implementation. Furthermore, we generally observe an important variance over runs, especially for RE.

As expected, the empirical gains mainly come from using BERT, which allows the use of simpler decoders for both NER and RE. Indeed, although our non-contextual BILOU model matches (Bekoulis et al., 2018a) on CoNLL04, the results on ACE05 are overtaken by models using external syntactic information or more sophisticated decoders with a similar BiLSTM encoder.

Comparing the Span-level and sequence tagging approaches for NER is also interesting. Although an advantage of Span-level NER is the ability to detect overlapping mentions, its contribution to end-to-end RE has never been quantified to our knowledge. Our experiments suggest that we obtain better results on this task with the more classical sequence tagging approach.

6 How to Prevent Future Mistakes?

The accumulation of mistakes and invalid comparisons should raise questions to both authors and reviewers of end-to-end RE papers. How was it possible to make them in the first place and not to detect them in the second place? How can we reduce their chance to occur in the future?

6.1 Lack of Reproducibility

First, it is no secret that the lack of reproducibility is an issue in science in general and Machine Learning in particular, but we think this is a perfect illustration of its symptoms. Indeed, in the papers we studied, we only found comparisons to reported scores and rarely an attempt to reimplement previous work by different authors. This is perfectly understandable given the complexity of such a reproduction, in particular in the multitask learning setting of end-to-end RE and often without (documented) source code.

However, this boils down to comparing results obtained in different settings. We believe that simply evaluating an implementation of the most similar previous work enables to detect differences in metrics or datasets. But it also allows to properly assess the source of empirical gains (Lipton and Steinhardt, 2018) which could come from different hyperparameter settings (Melis et al., 2018) or in-depth changes in the model.

6.2 Need for More Complete Reports

Although it is often impossible to exactly reproduce previous results even when the source code is provided, we should at least expect that the evaluation setting is always strictly reproduced. This requires a complete explicit formulation of the evaluation metrics associated with a clear and unambiguous terminology, to which end we advocate for using (Bekoulis et al., 2018a)'s. Datasets preprocessing and statistics should also be reported to provide a sanity check. This should include at least the number of sentences, entity and relation mentions as well as the details of train / test partitions.

6.3 Towards a Unified Evaluation Setting

Finally, in order to reduce confusion, we should aim at unifying our evaluation settings. We propose to always at least report RE scores with the Strict criterion, which considers both the boundaries and types of arguments. This view matches the NER metrics and truly assess end-to-end RE performance. It also happens to be the most used in previous work.

The Boundaries setting proposes a complementary measure of performance more centered on the relation. The combination of Strict and Boundaries metrics can thus provide additional insights on the models, as discussed in section 5.4 where we deduce that models can learn the bijective mapping between argument and relation types in CoNLL04. However, we believe this discussion on their specificities often lacks in articles where both metrics are reported mostly in order to compare to previous works. Hence we can only encourage to also report a Boundaries score provided sufficient explanation and exploitation of both metrics.

On the contrary, in our opinion, the Relaxed evaluation, which does not account for argument boundaries, cannot evaluate end-to-end RE since it reduces NER to Entity Classification. Furthermore, some papers report the average of NER and RE metrics (Adel and Schütze, 2017; Giorgi et al., 2019), which we believe is also an incorrect metric since the NER performance is already measured in the RE score.

Using a unified setting would also ease cross-dataset analyses and help to better reflect their often overlooked specificities.

7 Conclusion

The multiplication of settings in the evaluation of end-to-end Relation Extraction makes the comparison to previous work difficult. Indeed, in this confusion, numerous articles present unfair comparisons, often overestimating the performance of their proposed model. Furthermore, this fragmentation of the community complicates the emergence of new proposals. Our critical literature review epitomizes the need for more rigorous reports of evaluation settings, including detailed datasets statistics. And we call for a unified end-to-end RE evaluation setting to prevent future mistakes and enable more meaningful cross-domain comparisons.

A Additional Implementation Details

We used an Nvidia V100 server with 16BG VRAM for our experiments. They can be run with a single Nvidia GTX 1080 with 8GB VRAM with the same hyperparameters as experimented during prototyping. We report the average number of epochs and time for every configuration in Table 5. We report the number of parameters in our models in Table 6.

B Additional Datasets Statistics

We provide more detailed statistics on the two datasets we used for our experimental study in Tables 7 and 8. We believe that reporting the number of sentences, entity mentions and relation mentions per training partition is a minimum to enable sanity checks ensuring data integrity.

	Reference	Train	Dev	Test	Total
Sentences	(R&Y, 04)	-	-	-	1437
	(G, 16)	922	231	288	1441
	Ours	922	231	288	1441

C Additional Comparison of ACE05 and CoNLL04

ACE05 and CoNLL04 have key differences we propose to visualize with global statistics. First, in CoNLL04 every sentence contains at least two entity mentions and one relation while the majority of ACE05 contains no entities nor relations as depicted in Fig. 1.We can also notice that among sentences containing relations, a higher proportion of ACE05 contain several of them. Second, the variety of combinations between relation types and argument types makes RE on ACE05 much more difficult than on CoNLL04 (Fig. 2 and 3).

Exposing Shallow Heuristics of Relation Extraction Models with Challenge Data

Abstract

The process of collecting and annotating training data may introduce distribution artifacts which may limit the ability of models to learn correct generalization behavior. We identify failure modes of SOTA relation extraction (RE) models trained on TACRED, which we attribute to limitations in the data annotation process. We collect and annotate a challenge-set we call Challenging RE (CRE), based on naturally occurring corpus examples, to benchmark this behavior. Our experiments with four state-of-the-art RE models show that they have indeed adopted shallow heuristics that do not generalize to the challenge-set data. Further, we find that alternative question answering modeling performs significantly better than the SOTA models on the challenge-set, despite worse overall TACRED performance. By adding some of the challenge data as training examples, the performance of the model improves. Finally, we provide concrete suggestion on how to improve RE data collection to alleviate this behavior.

1 Introduction

In the relation extraction (RE) task, our goal is, given a set of sentences $s \in S$ to extract tuples (s, e_1, e_2, r) where a relation $r \in R$ holds between e_1 and e_2 (entities that appear in the sentence s, each represented as a span over s). RE is often represented as relation classification (RC): given a triplet of (s, e_1, e_2), determine which relation $r \in R$ holds between e_1 and e_2 in s, or indicate no-relation ($\emptyset$). This can be presented as a set of $|R|$ binary decision problems, $(s, e_1, e_2, r) \mapsto \{0, 1\}$: return 1 for tuples for which the relation holds, and 0 otherwise. The reduction between RE and RC is clear: given a sentence, extract all entity pair candidates (given a NER system), and run the RC problem on each of them.

Indeed, contemporary methods are all RC methods, and the popular TACRED large-scale relation extraction dataset is annotated for RC: each instance in the dataset is a triplet of (s, e_1, e_2) and is associated with a label $r \in R \cup \{\emptyset\}$. Importantly, the annotation is *non exhaustive*: not all e_1, e_2 pairs in the dataset are annotated (only 17.2% of the entity pairs whose type match a TACRED relation are). While this saves a lot of annotation effort, as we show this also leads to sub-optimal behavior of the trained models, and hinders our ability to properly assess their real-world utility.

We show that state of the art models trained on TACRED are often “right for the wrong reasons” (McCoy et al., 2019): instead of learning to perform the intended task, they rely on shallow heuristics which are effective for solving many dataset instances, but which may fail on more challenging examples. In particular, we show two concrete heuristics: classifying based on *entity types*, and classifying based on the *existence of an event without linking the event to its arguments*. We show that while they are not well attested in the dev and test sets, these challenging examples do occur in practice. We introduce CRE (Challenging RE), a challenge set for quantifying and demonstrating the problem, and show that four SOTA RC models significantly fail on the challenge set. We release the challenge set to encourage future research on better models. [1]

While we demonstrate the problem on TACRED, we stress that the model behaviors we expose are directly linked to the dataset construction procedure, and will likely occur in any dataset that is created in a similar fashion. We propose guidelines to help guide better datasets, and in particular better evaluation sets, in the future.

We also show that different modeling techniques

may alleviate this problem: models trained for QA are better at linking events to their arguments. While performing worse on TACRED overall, they perform significantly better on the challenge set.

2 Relation Classification Heuristics

McCoy et al. (2019) discusses the concept of "model heuristics"—decision rules that are used by ML models to score high on a test set, but which are too simplistic to solve the underlying problem—and demonstrated such heuristics used by NLI models. In this work we demonstrate model heuristics used by TACRED-trained RC models. Recall that a relation classification instance is $(s, e_1, e_2, r) \mapsto \{0, 1\}$.

***Event* Heuristic:** Classify based on (s, r). This heuristic ignores the entities altogether, acting as a classification model answering the question "does the sentence attest the relation". This heuristic is of limited applicability, as many sentences attest more than a single related pair of entities.

***Type* Heuristic:** Classify based on $(type(e_1), type(e_2), r)$, where $type(e)$ is the named-entity type of entity e. In a given dataset, a decision can be made based on the type of entities alone. For example of the 41 relations in the TACRED dataset, only the *per:religion* relation is between a *PERSON* and a *RELIGION*. A model may learn to incorrectly rely on the types when making a decision, ignoring the sentence s altogether.[2]

Many type-pairs are compatible with multiple relations in a dataset, weakening the utility of this heuristic. However, for applicable type-pairs, it can be very effective. For example, out of 21,284 Wikipedia sentences containing a PERSON name and a RELIGION name, 8,156 (38%) were classified by a RoBERTA-based RC model as *per:religion*. Manual inspection of a random sample of 100 of these, found that 42% are false-positives.

***Event+Type* Heuristic:** The *event* and *type* heuristics can be combined, by requiring the two decision rules $(s, r) \mapsto \{0, 1\}$ and $(type(e_1), type(e_2), r) \mapsto \{0, 1\}$ to hold. The resulting heuristic verifies that the sentence mentions the relation, and that the entity pairs of interest are type-compatible with the relation; it *does not verify* that the entities are arguments of the relation.

We demonstrate that the event+type heuristic is a particularly strong one for relation-classification datasets, and is widely used by trained state-of-the-art relation classifiers.

3 Challenge Set

Consider the *date_of_birth* relation, that holds between a person$_{e_1}$ and a year$_{e_2}$, and the classification instance:

[$_{e_1}$Steve Jobs] was born in California in [$_{e_2}$1955].

A model making use of the event+type heuristic will correctly classify this relation.[3] The heuristic is challenged by sentences that include multiple entities of an applicable type. For example:

[$_{e_1}$Ed] was born in [$_{e_2}$1561], the son of John, a carpenter, and his wife Mary.

A model relying solely on the event+type heuristic will correctly classify the above, but also incorrectly classify the following instances:

Ed was born in [$_{e_2}$1561], the son of [$_{e_1}$John], a carpenter, and his wife Mary.

---

[2] Another, related, heuristic is "classify based on (e_1, e_2, r)", that is, based on prior knowledge about the entities. For a discussion of related problem see (Shwartz et al., 2020). This is beyond the scope of the current work.

[3] Models that use the event heuristic on its own may predict *birth_location* instead, and models that rely on the type heuristic may predict *date_of_death*.

Ed was born in York in [$_{e_2}$1561], the son of John, a carpenter, and his wife [$_{e_2}$Mary].

While such sentences are frequent in practice, these cases are not represented in the dataset: in only 17.2% of the sentences in TACRED more than a single pair is annotated (and only 3.46% of the sentences have more than one different annotated labels in the sentence) . Additionally, due to the data collection method (Zhang et al., 2017), if a sentence includes a positive pair for a relation $r \in R$, it is significantly more likely that this pair will be chosen for annotation rather than a matching-type pair with a no-relation label. In other words, the data collection process leads to *no-relation* labels between a pair of entities being assigned with very high probability to sentences in which other pairs in the sentence also do not adhere to a relation of interest.

As a result, for models trained on TACRED, the model is incentivized to learn to identify the existence of the relation in the sentence, irrespective of the arguments. There is no signal in the data to incentivize the model to distinguish cases where the relation holds between the given arguments, from cases where the relation holds but between a different pair of arguments. We expect the same to hold for *any* large-scale RC dataset created in a similar manner.[4]

Challenge Set Construction. We seek a benchmark to highlight RC models' susceptibility to the *event+type* heuristic. The benchmark takes the form of a challenge/contrast set; a collection of related examples that specialize in a specific failure case, meant only for evaluation and not training (Kaushik et al., 2020; Gardner et al., 2020). In contrast to the NLI challenge set of McCoy et al. (2019), in which challenge instances are based on synthetic examples, our benchmark is based on naturally occurring examples from real-world corpora.

Methodology. Coming up with a set of real-world sentences that demonstrates a failure mode is not easy. The main challenge is in identifying potential candidate sentences to pass to manual annotation. To identify such cases, we require an effective method for sampling a population that is likely to exhibit the behavior we are interested in.

We propose the following challenge-set creation methodology: (1) use a strong *seed-model* to perform large-scale noisy annotation; (2) identify suspicious cases in the model's output; (3) manually verify (annotate) suspicious cases.

In stage (2), we identify suspicious cases by looking for sentences in which: (a) there are at least two entity-pairs of a NE type which is compatible to a TACRED relation (in most of the cases, the entity-pairs share one of the items, i.e. $(e_1, e_2), (e_1, e_3)$); and (b) these two pairs were assigned by the seed model to the same relation. Note that cases that satisfy condition (b) have, with high probability, at least one incorrect model prediction. On the other hand, given a strong seed model, there is also a high probability that one of the predictions is correct.

For our *seed-model* we use a SOTA relation classification model which is based on fine-tuned SpanBERT (Joshi et al., 2019), which we run over a large corpus of English Wikipedia sentences.[5]

Out of the sentences that passed stage (2), we randomly sampled 100 sentences for each of the 30 relation predicted by the model. All instance entity pairs were manually labeled by two of the authors of this work, while closely adhering to the TACRED annotation guideline. For each instance, the annotators provide a *binary* decision: does the entity pair in question adhere to relation r (as predicted by the model) or not.[6]

The resulting challenge set (CRE) has 3,000 distinct sentences, and 10,844 classification instances. The dataset is arranged into 30 groups of 100 sentences, where each sentence is binary labeled for a given relation. Example sentences from the challenge-set are given in Figure 1. In 57% of the sentences, there are at least two classification instances with conflicting labels, indicating the use of the event+type heuristic. On average there are 3.7 candidate entity-pairs per sentence. In 89.2% of the sentences in the set, the entity-pairs share an argument. Further details are available in the supplementary material.

---

[4] Annotation of entity pairs, if the pairs are chosen at random or all pairs are annotated, carries a significant inefficiency in the number of annotations of related pairs vs. number of annotations of unrelated pairs. For this reason, RE annotation setups such as TACRED (Zhang et al., 2017) implement bias towards labeling pairs that are likely to be related, and thus, a no-relation label implies a higher likelihood of no relation event occurring in the sentence.

[5] Additional details in the supplementary material.

[6] We chose to perform binary annotation, as we find it makes the annotation process faster and more accurate. As demonstrated by Alt et al. (2020), multi-class relation labeling by crowd-workers lead to frequent annotation errors. We observed the same phenomena also with non-crowd workers.

Model	P	R	F_1
RC-SpanBERT	70.8	70.9	70.8
RC-BERT	67.8	67.2	67.5
RC-KnowBERT	71.6	71.4	71.5
RC-RoBERTa	70.17	72.36	71.25

Table 1: Test results on TACRED.

4 Evaluating RE Models

By construction, the CRE dataset includes many instances that fail the seed RC model, which is based on fine-tuned SpanBERT (Joshi et al., 2019). To verify that the behavior is consistent across models, we evaluate also RC models fine-tuned over other state-of-the-art LMs: BERT (Devlin et al., 2019), RoBERTA (Liu et al., 2019b) and KnowBERT (Peters et al., 2019). When evaluated on TACRED test set (Table 1), these models achieve SOTA scores.

We evaluate model's results on the CRE dataset in terms of accuracy. We also report *positive accuracy* (**Acc**$_+$) (the accuracy on instances for which the relation hold; models that make use of the heuristic are expected to score high here) and likewise *negative accuracy* (**Acc**$_-$) (accuracy on instances in which the relation does not hold; models using the heuristic are expected to score low here). The models are consistently more accurate on the positive set then on the negative set showing that models struggle on cases where the heuristic make incorrect predictions.[7]

A direct comparison to the state-of-the-art is difficult with these metrics alone. To facilitate such a comparison, we also report precision, recall and F1 scores on **TACRED+Positive** (Table 3a), in which we add to the TACRED test set all the positive instances from the CRE dataset (easy cases), and on **TACRED+Negative** (Table 3b), in which we add the negative instances (hard cases). All models benefit significantly from the positive setting, and are hurt significantly in the negative setting *primarily in precision*, indicating that they do follow the heuristic on many instances:

the TACRED-trained models often classify based on the type of arguments and the existence of a relation in the text, without verifying that the entities are indeed the arguments of the relation.

Model	Acc	Acc_+	Acc_-
RC-SpanBERT	63.5	89.7	42.5
RC-BERT	67.1	70.0	64.8
RC-KnowBERT	72.4	84.2	62.9
RC-RoBERTa	73.1	82.9	65.3
QA-SpanBERT	75.5	71.5	78.7
QA-BERT	67.4	62.9	70.9
QA-ALBERT	75.3	71.5	78.8

Table 2: CRE accuracy for the RE and QA models. Acc_+ refers to accuracy on positive instances. Acc_- refers to accuracy on negative instances.

Model	P	R	F_1
(a) TACRED + Positive			
RC-SpanBERT	88.2	79.3	83.5
RC-BERT	88.0	67.7	76.5
RC-KnowBERT	87.5	78.3	82.7
RC-RoBERTa	86.6	78.8	82.5
(b) TACRED + Negative			
RC-SpanBERT	43.3	70.9	53.8
RC-BERT	42.0	64.0	50.7
RC-KnowBERT	43.9	71.6	54.4
RC-RoBERTa	43.6	72.7	54.5

Table 3: P/R/F_1 scores on TACRED test set + all positive instances from the CRE dataset (a), and + all negative instances (b).

5 QA Models Perform Better

The CRE dataset results indicate that RE-trained models systematically fail to link the provided relation arguments to the relation mention. We demonstrate that QA-trained models perform better in this respect. The QA models differ in both in their training data (SQuAD 2.0, (Rajpurkar et al., 2018)) and in their training objective (span-prediction, rather than classification). Inspired by Levy et al. (2017) we reduce RC instances into QA instances. We follow the reduction from Cohen et al. (2020) between QA and binary relation classification which works by forming two questions for each relation instance, one for each argument. For example, for the relation instance pair *(Mark, FB, founded)* we ask "Who founded FB?" and "what did Mark found?".[8]

---

[7] CRE is binary labeled and relatively balanced between positive and negative examples, making accuracy a valid and natural metric. We chose to report **Acc**$_+$ and **Acc**$_-$ instead of the popular precision and recall because precision and recall emphasize the positive class, and do not tell the full story of the negative class (indeed, prec/rec do not involve the true-negative case), which is of interest to us. Using the **Acc**$_{+/-}$ metric allows us to focus on both the positive and negative classes.

[8] The question templates for each relation are defined manually. The full set, and additional details on the reduction method, are given in Appendix D.

If the QA model answers either one of the questions with the correct span, we return 1 (relation holds), otherwise we return 0 (relation does not hold). We use three pre-trained SOTA models, fine-tuned on SQuAD 2.0: QA-SpanBERT, QA-BERT, and QA-AlBERT (Lan et al., 2020).

Results. While the scores on the TACRED test set are unsurprisingly substantially worse (with F$_1$ of 59.1%, 52.0% and 61.4%) than the TACRED trained models, they also perform better on the CRE dataset (Table 2).

QA-trained models pay more attention to the relation between an event and its arguments than RC-trained models.

6 Augmenting the Training Data with Challenge Set Examples

We test the extent by which we can "inoculate" (Liu et al., 2019a) the relation extraction models by enhancing their training data with some examples from the challenge-set. We re-train each model on the TACRED dataset, which we augment with half of the challenge-set (5504 examples, 8% of the size of the original TACRED training set). The other half of the challenge-set is used for evaluation.

Results. We begin by evaluating the inoculated models on the original TACRED evaluation set, establishing that this result in roughly the same scores, with small increases for most models (RC-SpanBERT: 71.0 F$_1$ (original: 70.8), RC-BERT: 69.9 F$_1$ (original:67.5), RC-KnowBERT: 72.1 F$_1$ (original:71.5), RC-RoBERTa: 70.8 F$_1$ (original:71.25)).

When evaluating on the CRE dataset examples, we see a large increase in performance for the inoculated dataset, as can be seen in Table 4. Compared to TACRED-only scores, While we see a small and expected drop for **Acc**$_+$, it is accompanied by a very large improvement on **Acc**$_-$. However, while accuracies improve, there is still a wide gap from perfect accuracy.

7 Discussion and Conclusion

We created a challenge dataset demonstrating the tendency of TACRED-trained models to classify using an event+type heuristic that fails to connect the relation and its arguments. QA-trained models are less susceptible to this behavior. Continuing Gardner et al. (2020), we conclude that challenge sets are an effective tool of benchmarking against shallow heuristics, not only of models and systems, but also of data collection methodologies.

Model	Acc	Acc_+	Acc_-
(a) Trained on TACRED			
RC-SpanBERT	62.8	89.5	41.6
RC-BERT	65.8	68.4	63.7

Table 4: Acc/Acc_+/Acc_- scores on half of the CRE dataset, models trained on TACRED training set (a), models trained on TACRED training set with examples from the second half of the CRE dataset (b).

We suggest the following **recommendation for future RE data collection**: *evaluation sets* should be exhaustive, and contain *all* relevant entity pairs. Ideally, the same should apply also to *training sets*. If impractical, the data should at least attempt to exhaustively annotate *confusion-sets*: if a certain entity-pair is annotated in a sentence, all other pairs of the same entity-types in the sentence should also be annotated.

A Challenge Set

We use SpanBERT as a seed model, SpanBert is a recent state-of-the-art model uses pre-trained language model fine-tuned to the RC task which uses a bidirectional LM pre-trained on SpanBERT We run the seed model over a large corpus of English Wikipedia sentences in which contains more than 10 million sentences. Table 8 contain all the relations in the challenge set with number of positive and negative instances per relation. The challenge set is relatively balanced in terms of positive examples (44%) and negative examples (56%), and the classification is binary, so it is possible to use accuracy as evaluation method. The average length of a sentence is 28.7 tokens. Crucially, there are no sentences with less than two pair of entities.

B Experiment Details

RC models We evaluate four RC models fine-tuned on TACRED: **SpanBERT** (Joshi et al., 2019) extends BERT model by pre-trained on a span-level; **KnowBERT** (Peters et al., 2019) which integrates knowledge bases into BERT, we use KnowBERT-W+W, where the knowledge comes from joint entity linking and language modelling on Wikipedia and WordNet; **RoBERTa** (Liu et al., 2019b), we use the same baseline from (Wang et al., 2020); **BERT** (Devlin et al., 2019) we use the same model from (Joshi et al., 2019) for BERT base. Table 1 contain the performance of the four models on TACRED.

QA models We use three pre-trained SOTA models, fine-tuned on SQuAD 2.0: **QA-SpanBERT**: SpanBERT (Joshi et al., 2019) we use a pre-trained model (Joshi et al., 2019) fine-tuned on SQuAD 2.0 for QA (F_1: 88.7). **QA-BERT**: BERT (Devlin et al., 2019), we use a pre-trained model (Joshi et al., 2019) fine-tuned on SQuAD 2.0 for QA. (F_1: 83.3) **QA-ALBERT**: ALBERT xxlarge (Lan et al., 2020), we use a pre-trained model (El-Geish, 2020) fine-tuned on SQuAD 2.0 for QA. (F_1: 88.9)

C How we evaluate TACRED + pos/neg

In order to evaluate TACRED + Positive and TACRED+Negative we presented them as binary decision problem as explained in section 1. We simulate ACRED + pos/neg in which for each relation $r \in R$ we create a set that contain all the examples $(s, e_1, e_2, r) \mapsto \{0, 1\}$, which the arguments types e_1 and e_2 match the relation r. We evaluate each set of relation r separately, and we report the results as micro-averaged F1 scores.

D Detailed QA reduction

Table 7 contain the templates for the questions, each relation have two questions, a question for the head entity and a question for the tail entity, we use this templates to reduce the relation classification task.

E Detailed Results

Table 5, 6 shows the full results of all the models on the challenge set, and table 6 shows the full results of all the models on **TACRED+Positive** and **TACRED+Negative**, Δ denotes the difference in performance between them, All models preformed a big difference in precision between the positive and negative examples.

Abstract

Relation extraction (RE) aims to identify the semantic relations between named entities in text. Recent years have witnessed it raised to the document level, which requires complex reasoning with entities and mentions throughout an entire document. In this paper, we propose a novel model to document-level RE, by encoding the document information in terms of entity global and local representations as well as context relation representations. Entity global representations model the semantic information of all entities in the document, entity local representations aggregate the contextual information of multiple mentions of specific entities, and context relation representations encode the topic information of other relations. Experimental results demonstrate that our model achieves superior performance on two public datasets for document-level RE. It is particularly effective in extracting relations between entities of long distance and having multiple mentions.

1 Introduction

Relation extraction (RE) aims to identify the semantic relations between named entities in text. While previous work (Zeng et al., 2014; Zhang et al., 2015, 2018) focuses on extracting relations within a sentence, a.k.a. *sentence*-level RE, recent studies (Verga et al., 2018; Christopoulou et al., 2019; Sahu et al., 2019; Yao et al., 2019) have escalated it to the *document* level, since a large amount of relations between entities usually span across multiple sentences in the real world. According to an analysis on Wikipedia corpus (Yao et al., 2019), at least 40.7% of relations can only be extracted on the document level.

Compared with sentence-level RE, document-level RE requires more complex reasoning, such as logical reasoning, coreference reasoning and common-sense reasoning. A document often contains many entities, and some entities have multiple mentions under the same phrase of alias. To identify the relations between entities appearing in different sentences, document-level RE models must be capable of modeling the complex interactions between multiple entities and synthesizing the context information of multiple mentions.

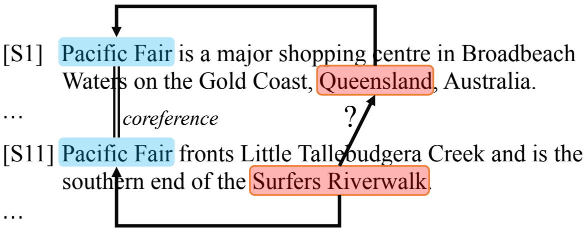

Figure 1: An example of document-level RE excerpted from the DocRED dataset (Yao et al., 2019). Arrows denote intra/inter-sentential relations.

Figure 1 shows an example of document-level RE. Assume that one wants to extract the relation between *"Surfers Riverwalk"* in S11 and *"Queensland"* in S1. One has to find that *"Surfers Riverwalk"* contains *"Pacific Fair"* (from S11), and *"Pacific Fair"* (coreference) is located in *"Queensland"* (from S1). This chain of interactions helps infer the inter-sentential relation *"located in"* between *"Surfers Riverwalk"* and *"Queensland"*.

State-of-the-art. Early studies (Peng et al., 2017; Quirk and Poon, 2017) confined document-level RE to short text spans (e.g., within three sentences). Some other studies (Nguyen and Verspoor, 2018; Gupta et al., 2019) were restricted to handle two entity mentions in a document. We argue that they are incapable of dealing with the example in Figure 1, which needs to consider multiple mentions of entities integrally. To encode the semantic interactions of multiple entities in long distance, recent

work defined document-level graphs and proposed graph-based neural network models. For example, Sahu et al. (2019); Gupta et al. (2019) interpreted words as nodes and constructed edges according to syntactic dependencies and sequential information. However, there is yet a big gap between word representations and relation prediction. Christopoulou et al. (2019) introduced the notion of document graphs with three types of nodes (mentions, entities and sentences), and proposed an edge-oriented graph neural model for RE. However, it indiscriminately integrated various information throughout the whole document, thus irrelevant information would be involved as noise and damages the prediction accuracy.

Our approach and contributions. To cope with the above limitations, we propose a novel graph-based neural network model for document-level RE. Our key idea is to make full use of document semantics and predict relations by learning the representations of involved entities from both coarse-grained and fine-grained perspectives as well as other context relations. Towards this goal, we address three challenges below:

First, *how to model the complex semantics of a document?* We use the pre-trained language model BERT (Devlin et al., 2019) to capture semantic features and common-sense knowledge, and build a heterogeneous graph with heuristic rules to model the complex interactions between all mentions, entities and sentences in the document.

Second, *how to learn entity representations effectively?* We design a global-to-local neural network to encode coarse-grained and fine-grained semantic information of entities. Specifically, we learn entity global representations by employing R-GCN (Schlichtkrull et al., 2018) on the created heterogeneous graph, and entity local representations by aggregating multiple mentions of specific entities with multi-head attention (Vaswani et al., 2017).

Third, *how to leverage the influence from other relations?* In addition to target relation representations, other relations imply the topic information of a document. We learn context relation representations with self-attention (Sorokin and Gurevych, 2017) to make final relation prediction.

In summary, our main contribution is twofold:

- We propose a novel model, called *GLRE*, for document-level RE. To predict relations between entities, GLRE synthesizes entity global representations, entity local representations and context relation representations integrally. For details, please see Section 3.
- We conducted extensive experiments on two public document-level RE datasets. Our results demonstrated the superiority of GLRE compared with many state-of-the-art competitors. Our detailed analysis further showed its advantage in extracting relations between entities of long distance and having multiple mentions. For details, please see Section 4.

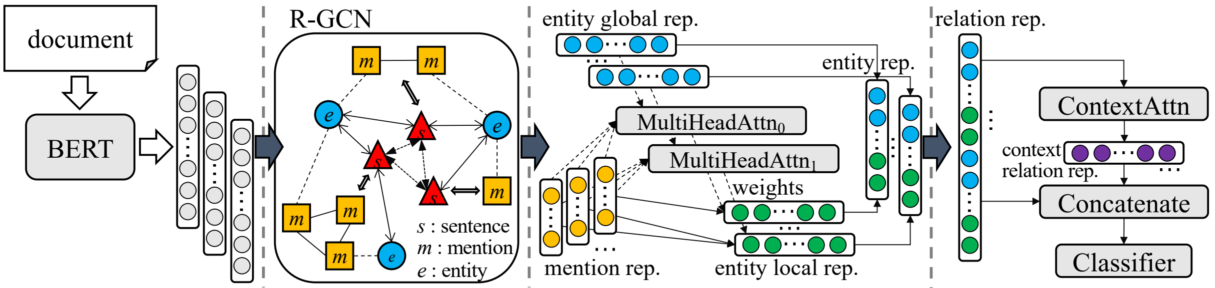
2 Related Work

RE has been intensively studied in a long history. In this section, we review closely-related work.

Sentence-level RE. Conventional work addressed sentence-level RE by using carefully-designed patterns (Soderland et al., 1995), features (Kambhatla, 2004) and kernels (Culotta and Sorensen, 2004). Recently, deep learning-based work has advanced the state-of-the-art without heavy feature engineering. Various neural networks have been exploited, e.g., CNN (Zeng et al., 2014), RNN (Zhang et al., 2015; Cai et al., 2016) and GNN (Zhang et al., 2018). Furthermore, to cope with the wrong labeling problem caused by distant supervision, Zeng et al. (2015) adopted Piecewise CNN (PCNN), Lin et al. (2016); Zhang et al. (2017) employed attention mechanisms, and Zhang et al. (2019); Qu et al. (2019) leveraged knowledge graphs as external resources. All these models are limited to extracting intra-sentential relations. They also ignore the interactions of entities outside a target entity pair.

Document-level RE. As documents often provide richer information than sentences, there has been an increasing interest in document-level RE. Gu et al. (2017); Nguyen and Verspoor (2018); Gupta et al. (2019); Wang et al. (2019) extended the sentence-level RE models to the document level. Ye et al. (2020) explicitly incorporated coreference information into language representation models (e.g., BERT). Zheng et al. (2018); Tang et al. (2020) proposed hierarchical networks to aggregate information from the word, sentence and document levels.

Quirk and Poon (2017) proposed the notion of document-level graphs, where nodes denote words and edges incorporate both syntactic dependencies and discourse relations. Following this, Peng et al. (2017) first splitted a document-level graph into two directed acyclic graphs (DAGs), then used a graph LSTM for each DAG to learn the contextual representation of each word, which was concate-



(a) Encoding layer (b) Global rep. layer (c) Local rep. layer (d) Classifier layer

Figure 2: Architecture of the proposed model.

nated and finally fed to the relation classifier. Differently, Song et al. (2018) kept the original graph structure and directly modeled the whole document-level graph using graph-state LSTM. These models only predict the relation of a single mention pair in a document at a time, and ignore multiple mentions of a target entity pair as well as other entities.

Several models predict the relation of a target entity pair by aggregating the scores of all mention pairs with multi-instance learning. Verga et al. (2018) proposed a Transformer-based model. Later, Sahu et al. (2019) switched Transformer to GCN. The two models only consider one target entity pair per document, and construct the document-level graphs relying on external syntactic analysis tools. Christopoulou et al. (2019) built a document graph with heterogeneous types of nodes and edges, and proposed an edge-oriented model to obtain global representations for relation classification. Our model differs in further learning entity local representations to reduce the influence of irrelevant information and considering other relations in the document to refine the prediction. Recently, Nan et al. (2020) defined a document graph as a latent variable and induced it based on the structured attention. Unlike our work, it improves the performance of document-level RE models by optimizing the structure of the document graph.

Besides, a few models (Levy et al., 2017; Qiu et al., 2018) borrowed the reading comprehension techniques to document-level RE. However, they require domain knowledge to design question templates, and may perform poorly in zero-answer and multi-answers scenarios (Liu et al., 2019), which are very common for RE.

3 Proposed Model

We model document-level RE as a *classification* problem. Given a document annotated with entities and their corresponding textual mentions, the objective of document-level RE is to identify the relations of all entity pairs in the document.

Figure 2 depicts the architecture of our model, named GLRE. It receives an entire document with annotations as input. First, in (a) *encoding layer*, it uses a pre-trained language model such as BERT (Devlin et al., 2019) to encode the document. Then, in (b) *global representation layer*, it constructs a global heterogeneous graph with different types of nodes and edges, and encodes the graph using a stacked R-GCN (Schlichtkrull et al., 2018) to capture entity global representations. Next, in (c) *local representation layer*, it aggregates multiple mentions of specific entities using multi-head attention (Vaswani et al., 2017) to obtain entity local representations. Finally, in (d) *classifier layer*, it combines the context relation representations obtained with self-attention (Sorokin and Gurevych, 2017) to make final relation prediction. Please see the rest of this section for technical details.

3.1 Encoding Layer

Let $\mathcal{D} = [w_1, w_2, \dots, w_k]$ be an input document, where w_j ($1 \leq j \leq k$) is the j^{th} word in it. We use BERT to encode $\mathcal{D}$ as follows:

$$\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_k] = \text{BERT}([w_1, w_2, \dots, w_k]), \quad (1)$$

where $\mathbf{h}_j \in \mathbb{R}^{d_w}$ is a sequence of hidden states at the output of the last layer of BERT. Limited by the input length of BERT, we encode a long document sequentially in form of short paragraphs.

3.2 Global Representation Layer

Based on $\mathbf{H}$, we construct a *global heterogeneous graph*, with different types of nodes and edges to capture different dependencies (e.g., co-occurrence dependencies, coreference dependencies and order dependencies), inspired by Christopoulou et al. (2019). Specifically, there are three types of nodes:

- *Mention nodes,* which model different mentions of entities in $\mathcal{D}$. The representation of a mention node m_i is defined by averaging the representations of contained words. To distinguish node types, we concatenate a node type representation $\mathbf{t}_m \in \mathbb{R}^{d_t}$. Thus, the representation of m_i is $\mathbf{n}_{m_i} = [\text{avg}_{w_j \in m_i}(\mathbf{h}_j); \mathbf{t}_m]$, where $[\,;]$ is the concatenation operator.
- *Entity nodes,* which represent entities in $\mathcal{D}$. The representation of an entity node e_i is defined by averaging the representations of the mention nodes to which they refer, together with a node type representation $\mathbf{t}_e \in \mathbb{R}^{d_t}$. Therefore, the representation of e_i is $\mathbf{n}_{e_i} = [\text{avg}_{m_j \in e_i}(\mathbf{n}_{m_j}); \mathbf{t}_e]$.
- *Sentence nodes,* which encode sentences in $\mathcal{D}$. Similar to mention nodes, the representation of a sentence node s_i is formalized as $\mathbf{n}_{s_i} = [\text{avg}_{w_j \in s_i}(\mathbf{h}_j); \mathbf{t}_s]$, where $\mathbf{t}_s \in \mathbb{R}^{d_t}$.

Then, we define five types of edges to model the interactions between the nodes:

- *Mention-mention edges.* We add an edge for any two mention nodes in the same sentence.
- *Mention-entity edges.* We add an edge between a mention node and an entity node if the mention refers to the entity.
- *Mention-sentence edges.* We add an edge between a mention node and a sentence node if the mention appears in the sentence.
- *Entity-sentence edges.* We create an edge between an entity node and a sentence node if at least one mention of the entity appears in the sentence.
- *Sentence-sentence edges.* We connect all sentence nodes to model the non-sequential information (i.e., break the sentence order).

Note that there are no entity-entity edges, because they form the relations to be predicted.

Finally, we employ an L-layer stacked R-GCN (Schlichtkrull et al., 2018) to convolute the global heterogeneous graph. Different from GCN, R-GCN considers various types of edges and can better model multi-relational graphs. Specifically, its node forward-pass update for the $(l+1)^{\text{th}}$ layer is defined as follows:

$$\mathbf{n}_i^{l+1} = \sigma\Big(\sum_{x \in \mathcal{X}} \sum_{j \in \mathcal{N}_i^x} \frac{1}{|\mathcal{N}_i^x|} \mathbf{W}_x^l \mathbf{n}_j^l + \mathbf{W}_0^l \mathbf{n}_i^l\Big), \quad (2)$$

where $\sigma(\cdot)$ is the activation function. $\mathcal{N}_i^x$ denotes the set of neighbors of node i linked with edge x, and $\mathcal{X}$ denotes the set of edge types. $\mathbf{W}_x^l, \mathbf{W}_0^l \in \mathbb{R}^{d_n \times d_n}$ are trainable parameter matrices (d_n is the dimension of node representations).

We refer to the representations of entity nodes after graph convolution as *entity global representations*, which encode the semantic information of entities throughout the whole document. We denote an entity global representation by $\mathbf{e}_i^{\text{glo}}$.

3.3 Local Representation Layer

We learn *entity local representations* for specific entity pairs by aggregating the associated mention representations with multi-head attention (Vaswani et al., 2017). The "local" can be understood from two angles: (i) It aggregates the original mention information from the encoding layer. (ii) For different entity pairs, each entity would have multiple different local representations w.r.t. the counterpart entity. However, there is only one entity global representation.

Multi-head attention enables a RE model to jointly attend to the information of an entity composed of multiple mentions from different representation subspaces. Its calculation involves the sets of queries $\mathcal{Q}$ and key-value pairs $(\mathcal{K}, \mathcal{V})$:

$$\text{MHead}(\mathcal{Q}, \mathcal{K}, \mathcal{V}) = [\text{head}_1; \dots; \text{head}_z]\mathbf{W}^{\text{out}}, \quad (3)$$

$$\text{head}_i = \text{softmax}\Big(\frac{\mathcal{Q}\mathbf{W}_i^{\mathcal{Q}}(\mathcal{K}\mathbf{W}_i^{\mathcal{K}})'}{\sqrt{d_v}}\Big)\mathcal{V}\mathbf{W}_i^{\mathcal{V}}, \quad (4)$$

where $\mathbf{W}^{\text{out}} \in \mathbb{R}^{d_n \times d_n}$ and $\mathbf{W}_i^{\mathcal{Q}}, \mathbf{W}_i^{\mathcal{K}}, \mathbf{W}_i^{\mathcal{V}} \in \mathbb{R}^{d_n \times d_v}$ are trainable parameter matrices. z is the number of heads satisfying that $z \times d_v = d_n$.

In this paper, $\mathcal{Q}$ is related to the entity global representations, $\mathcal{K}$ is related to the initial sentence node representations before graph convolution (i.e., the input features of sentence nodes in R-GCN), and $\mathcal{V}$ is related to the initial mention node representations. Specifically, given an entity pair (e_a, e_b), we define their local representations as follows:

$$\begin{aligned}
\mathbf{e}_a^{\text{loc}} &= \text{LN}\big(\text{MHead}_0(\mathbf{e}_b^{\text{glo}}, \{\mathbf{n}_{s_i}\}_{s_i \in \mathcal{S}_a}, \{\mathbf{n}_{m_j}\}_{m_j \in \mathcal{M}_a})\big),\\
\mathbf{e}_b^{\text{loc}} &= \text{LN}\big(\text{MHead}_1(\mathbf{e}_a^{\text{glo}}, \{\mathbf{n}_{s_i}\}_{s_i \in \mathcal{S}_b}, \{\mathbf{n}_{m_j}\}_{m_j \in \mathcal{M}_b})\big),
\end{aligned} \quad (5)$$

where $\text{LN}(\cdot)$ denotes layer normalization (Ba et al., 2016). $\mathcal{M}_a$ is the corresponding mention node set of e_a, and $\mathcal{S}_a$ is the corresponding sentence node set in which each mention node in $\mathcal{M}_a$ is located. $\mathcal{M}_b$ and $\mathcal{S}_b$ are similarly defined for e_b. Note that MHead_0 and MHead_1 learn independent model parameters for entity local representations.

Intuitively, if a sentence contains two mentions m_a, m_b corresponding to e_a, e_b, respectively, then the mention node representations $\mathbf{n}_{m_a}, \mathbf{n}_{m_b}$ should contribute more to predicting the relation of (e_a, e_b) and the attention weights should be greater in getting $\mathbf{e}_a^{\text{loc}}, \mathbf{e}_b^{\text{loc}}$. More generally, a higher semantic similarity between the node representation of a sentence containing m_a and $\mathbf{e}_b^{\text{glo}}$ indicates that this sentence and m_b are more semantically related, and $\mathbf{n}_{m_a}$ should get a higher attention weight to $\mathbf{e}_a^{\text{loc}}$.

3.4 Classifier Layer

To classify the target relation r for an entity pair (e_a, e_b), we firstly concatenate entity global representations, entity local representations and relative distance representations to generate entity final representations:

$$\begin{aligned}\hat{\mathbf{e}}_a &= [\mathbf{e}_a^{\text{glo}}; \mathbf{e}_a^{\text{loc}}; \mathbf{\Delta}(\delta_{ab})],\\ \hat{\mathbf{e}}_b &= [\mathbf{e}_b^{\text{glo}}; \mathbf{e}_b^{\text{loc}}; \mathbf{\Delta}(\delta_{ba})],\end{aligned} \tag{6}$$

where δ_{ab} denotes the relative distance from the first mention of e_a to that of e_b in the document. δ_{ba} is similarly defined. The relative distance is first divided into several bins $\{1, 2, \dots, 2^b\}$. Then, each bin is associated with a trainable distance embedding. $\mathbf{\Delta}(\cdot)$ associates each δ to a bin.

Then, we concatenate the final representations of e_a, e_b to form the *target relation representation* $\mathbf{o}_r = [\hat{\mathbf{e}}_a; \hat{\mathbf{e}}_b]$.

Furthermore, all relations in a document implicitly indicate the topic information of the document, such as *"director"* and *"character"* often appear in movies. In turn, the topic information implies possible relations. Some relations under similar topics are likely to co-occur, while others under different topics are not. Thus, we use self-attention (Sorokin and Gurevych, 2017) to capture *context relation representations*, which reveal the topic information of the document:

$$\mathbf{o}_c = \sum_{i=0}^{p} \theta_i \mathbf{o}_i = \sum_{i=0}^{p} \frac{\exp(\mathbf{o}_i \mathbf{W} \mathbf{o}_r')}{\sum_{j=0}^{p} \exp(\mathbf{o}_j \mathbf{W} \mathbf{o}_r')} \mathbf{o}_i, \tag{7}$$

where $\mathbf{W} \in \mathbb{R}^{d_r \times d_r}$ is a trainable parameter matrix. d_r is the dimension of target relation representations. $\mathbf{o}_i$ ($\mathbf{o}_j$) is the relation representation of the i^{th} (j^{th}) entity pair. θ_i is the attention weight for $\mathbf{o}_i$. p is the number of entity pairs.

Finally, we use a feed-forward neural network (FFNN) over the target relation representation $\mathbf{o}_r$ and the context relation representation $\mathbf{o}_c$ to make the prediction. Besides, considering that an entity pair may hold several relations, we transform the multi-classification problem into multiple binary classification problems. The predicted probability distribution of r over the set $\mathcal{R}$ of all relations is defined as follows:

Datasets		#Doc.	#Rel.	#Inst.	#N/A Inst.
CDR	Train	500	1	1,038	4,280
	Dev.	500	1	1,012	4,136
	Test	500	1	1,066	4,270
DocRED	Train	3,053	96	38,269	1,163,035
	Dev.	1,000	96	12,332	385,263
	Test	1,000	96	12,842	379,316

Table 1: Dataset statistics (Inst.: relation instances excluding N/A relation; N/A Inst.: negative examples).

$$\mathbf{y}_r = \text{sigmoid}(\text{FFNN}([\mathbf{o}_r; \mathbf{o}_c])), \tag{8}$$

where $\mathbf{y}_r \in \mathbb{R}^{|\mathcal{R}|}$.

We define the loss function as follows:

$$\mathcal{L} = -\sum_{r \in \mathcal{R}} \Big(y_r^* \log(y_r) + (1 - y_r^*) \log(1 - y_r) \Big), \tag{9}$$

where $y_r^* \in \{0, 1\}$ denotes the true label of r. We employ Adam optimizer (Kingma and Ba, 2015) to optimize this loss function.

4 Experiments and Results

We implemented our GLRE with PyTorch 1.5. The source code and datasets are available online.[1] In this section, we report our experimental results.

4.1 Datasets

We evaluated GLRE on two public document-level RE datasets. Table 1 lists their statistical data:

- The Chemical-Disease Relations (*CDR*) data set (Li et al., 2016) was built for the BioCreative V challenge and annotated with one relation *"chemical-induced disease"* manually.
- The *DocRED* dataset (Yao et al., 2019) was built from Wikipedia and Wikidata, covering various relations related to science, art, personal life, etc. Both manually-annotated and distantly-supervised data are offered. We only used the manually-annotated data.

4.2 Comparative Models

First, we compared GLRE with five sentence-level RE models adapted to the document level:

- Zhang et al. (2018) employed GCN over pruned dependency trees.

---

[1] `https://github.com/nju-websoft/GLRE`

- Yao et al. (2019) proposed four baseline models. The first three ones are based on CNN, LSTM and BiLSTM, respectively. The fourth context-aware model incorporates the attention mechanism into LSTM.

We also compared GLRE with nine document-level RE models:

- Zhou et al. (2016) combined feature-, tree kernel- and neural network-based models.
- Gu et al. (2017) leveraged CNN and maximum entropy.
- Nguyen and Verspoor (2018) integrated character-based word representations in CNN.
- Panyam et al. (2018) exploited graph kernels.
- Verga et al. (2018) proposed a bi-affine network with Transformer.
- Zheng et al. (2018) designed a hierarchical network using multiple BiLSTMs.
- Christopoulou et al. (2019) put forward an edge-oriented graph neural model with multi-instance learning.
- Wang et al. (2019) applied BERT to encode documents, and used a bilinear layer to predict entity relations. It improved performance by two phases. First, it predicted whether a relation exists between two entities. Then, it predicted the type of the relation.
- Tang et al. (2020) is a sequence-based model. It also leveraged BERT and designed a hierarchical inference network to aggregate inference information from entity level to sentence level, then to document level.

4.3 Experiment Setup

Due to the small size of CDR, some work (Zhou et al., 2016; Verga et al., 2018; Zheng et al., 2018; Christopoulou et al., 2019) created a new split by unionizing the training and development sets, denoted by *"train + dev"*. Under this setting, a model was trained on the train + dev set, while the best epoch was found on the development set. To make a comprehensive comparison, we also measured the corresponding precision, recall and F1 scores.

For consistency, we used the same experiment setting on DocRED. Additionally, the gold standard of the test set of DocRED is unknown, and only F1 scores can be obtained via an online interface. Besides, it was noted that some relation instances are present in both training and development/test sets (Yao et al., 2019). We also measured F1 scores ignoring those duplicates, denoted by *Ign F1*.

Models	**Train**			**Train + Dev**		
	P	R	F1	P	R	F1
Zhang et al.¶	52.3	72.0	60.6	58.1	**74.6**	65.3

Tang et al.	53.7	55.6	-	-
GLRE (ours)	**55.4**	**57.4**	**56.7**	**58.9**

Table 3: Result comparison on DocRED.

For GLRE and Wang et al. (2019), we used different BERT models in the experiments. For CDR, we chose BioBERT-Base v1.1 (Lee et al., 2019), which re-trained the BERT-Base-cased model on biomedical corpora. For DocRED, we picked up the BERT-Base-uncased model. For the comparative models without using BERT, we selected the PubMed pre-trained word embeddings (Chiu et al., 2016) for CDR and GloVe (Pennington et al., 2014) for DocRED. For the models with source code, we used our best efforts to tune the hyperparameters. Limited by the space, we refer interested readers to the appendix for more details.

4.4 Main Results

Tables 2 and 3 list the results of the comparative models and GLRE on CDR and DocRED, respectively. We have four findings below:

(1) The sentence-level RE models (Zhang et al., 2018; Yao et al., 2019) obtained medium performance. They still fell behind a few document-level models, indicating the difficulty of directly applying them to the document level.

(2) The graph-based RE models (Panyam et al., 2018; Verga et al., 2018; Christopoulou et al., 2019) and the non-graph models (Zhou et al., 2016; Gu et al., 2017; Nguyen and Verspoor,

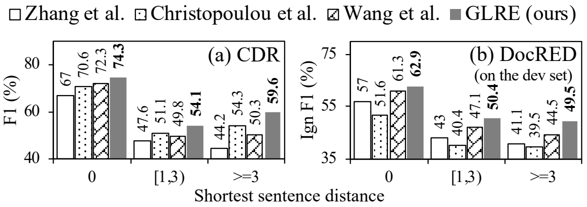

Figure 3: Results w.r.t. entity distance.

2018; Zheng et al., 2018) achieved comparable results, while the best graph-based model (Christopoulou et al., 2019) outperformed the best non-graph (Nguyen and Verspoor, 2018). We attribute it to the document graph on the entity level, which can better model the semantic information in a document.

(3) From the results of Wang et al. (2019); Tang et al. (2020), the BERT-based models showed stronger prediction power for document-level RE. They outperformed the other comparative models on both CDR and DocRED.

(4) GLRE achieved the best results among all the models. We owe it to entity global and local representations. Furthermore, BERT and context relation representations also boosted the performance. See our analysis below.

4.5 Detailed Analysis

Entity distance. We examined the performance of the open-source models in terms of entity distance, which is defined as the shortest sentence distance between all mentions of two entities. Figure 3 depicts the comparison results on CDR and DocRED using the training set only. We observe that:

(1) GLRE achieved significant improvement in extracting the relations between entities of long distance, especially when distance ≥ 3. This is because the global heterogeneous graph can effectively model the interactions of semantic information of different nodes (i.e., mentions, entities and sentences) in a document. Furthermore, entity local representations can reduce the influence of noisy context of multiple mentions of entities in long distance.

(2) According to the results on CDR, the graph-based model (Christopoulou et al., 2019) performed better than the sentence-level model (Zhang et al., 2018) and the BERT-based model (Wang et al., 2019) in extracting inter-sentential relations. The main reason is that it leveraged heuristic rules to construct the document graph at the entity level, which can better model the semantic information across sentences and avoid error accumulation involved by NLP tools, e.g., the dependency parser used in Zhang et al. (2018).

(3) On DocRED, the models (Wang et al., 2019; Zhang et al., 2018) outperformed the model (Christopoulou et al., 2019), due to the power of BERT and the increasing accuracy of dependency parsing in the general domain.

Number of entity mentions. To assess the effectiveness of GLRE in aggregating the information of multiple entity mentions, we measured the performance in terms of the average number of mentions for each entity pair. Similar to the previous analysis, Figure 4 shows the results on CDR and DocRED using the training set only. We see that:

(1) GLRE achieved great improvement in extracting the relations with average number of mentions ≥ 2, especially ≥ 4. The major reason is that entity local representations aggregate the contextual information of multiple mentions selectively. As an exception, when the average number of mentions was in $[1, 2)$, the performance of GLRE was slightly lower than Christopoulou et al. (2019) on CDR. This is because both GLRE and Christopoulou et al. (2019) relied on modeling the interactions between entities in the document, which made them indistinguishable under this case. In fact, the performance of all the models decreased when the average number of mentions was small, because less relevant information was provided in the document, which made relations harder to be predicted. We will consider external knowledge in our future work.

(2) As compared with Zhang et al. (2018) and Christopoulou et al. (2019), the BERT-based model (Wang et al., 2019) performed better in general, except for one interval. When the average number of mentions was in $[1, 2)$ on CDR, its performance was significantly lower than other models. The reason is twofold. On one hand, it is more difficult to capture the latent knowledge in the biomedical field. On the other hand, the model (Wang et al., 2019) only relied on the semantic information of the mentions of target entity pairs to predict the relations. When the average number was small, the prediction became more difficult. Furthermore, when the average number was large, its performance increase was not significant. The

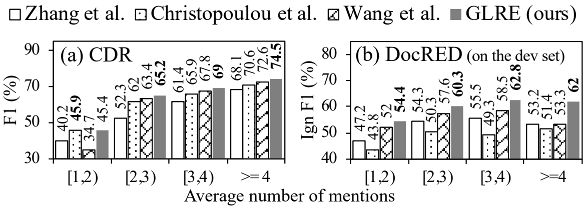

Figure 4: Results w.r.t. number of entity mentions.

Models	**CDR**			**DocRED**	
	P	R	F1	Ign F1	F1
GLRE	65.1	72.2	**68.5**	**55.4**	**57.4**
w/o BERT	**69.6**	66.5	68.0	51.6	53.6
w/o Entity global rep.	67.0	65.4	66.2	54.7	56.6
w/o Entity local rep.	60.9	68.5	64.5	54.6	56.4
w/o Context rel. rep.	60.5	**75.1**	67.1	54.6	56.8

Table 4: Results of ablation study.

main reason is that, although BERT brought rich knowledge, the model (Wang et al., 2019) indiscriminately aggregated the information of multiple mentions and introduced much noisy context, which limited its performance.

Ablation study. To investigate the effectiveness of each layer in GLRE, we conducted an ablation study using the training set only. Table 4 shows the comparison results. We find that: (1) BERT had a greater influence on DocRED than CDR. This is mainly because BERT introduced valuable linguistic knowledge and common-sense knowledge to RE, but it was hard to capture latent knowledge in the biomedical field. (2) F1 scores dropped when we removed entity global representations, entity local representations or context relation representations, which verified their usefulness in document-level RE. (3) Particularly, when we removed entity local representations, F1 scores dropped more dramatically. We found that more than 54% and 19% of entities on CDR and DocRED, respectively, have multiple mentions in different sentences. The local representation layer, which uses multi-head attention to selectively aggregate multiple mentions, can reduce much noisy context.

Pre-trained language models. To analyze the impacts of pre-trained language models on GLRE and also its performance upper bound, we replaced BERT-Base with BERT-Large, XLNet-Large (Yang et al., 2019) or ALBERT-xxLarge (Lan et al., 2020). Table 5 shows the comparison results using the training set only, from which we observe that larger models boosted the performance of GLRE to some extent. When the "train + dev" setting was used on DocRED, the Ign F1 and F1 scores of XLNet-Large even reached to 58.5 and 60.5, respectively. However, due to the lack of biomedical versions, XLNet-Large and ALBERT-xxLarge did not bring improvement on CDR. We argue that selecting the best pre-trained models is not our primary goal.

GLRE	**CDR**			**DocRED**	
	P	R	F1	Ign F1	F1
BERT-Base	65.1	72.2	68.5	55.4	57.4
BERT-Large	65.3	72.3	**68.6**	**56.8**	58.9
XLNet-Large	**66.1**	70.5	68.2	**56.8**	**59.0**
ALBERT-xxLarge	57.5	**80.6**	67.1	56.3	58.3

Table 5: Results w.r.t. different pre-training models.

Case study. To help understanding, we list a few examples from the CDR test set in Table 6. See Appendix for more cases from DocRED.

(1) From Case 1, we find that logical reasoning is necessary. Predicting the relation between *"rofecoxib"* and *"GI bleeding"* depends on the bridge entity *"non-users of aspirin"*. GLRE used R-GCN to model the document information based on the global heterogeneous graph, thus it dealt with complex inter-sentential reasoning better.

(2) From Case 2, we observe that, when a sentence contained multiple entities connected by conjunctions (such as *"and"*), the model (Wang et al., 2019) might miss some associations between them. GLRE solved this issue by building the global heterogeneous graph and considering the context relation information, which broke the word sequence.

(3) Prior knowledge is required in Case 3. One must know that *"fatigue"* belongs to *"adverse effects"* ahead of time. Then, the relation between *"bepridil"* and *"dizziness"* can be identified correctly. Unfortunately, both GLRE and Wang et al. (2019) lacked the knowledge, and we leave it as our future work.

We analyzed all 132 inter-sentential relation instances in the CDR test set that were incorrectly predicted by GLRE. Four major error types are as follows: (1) Logical reasoning errors, which occurred when GLRE could not correctly identify the relations established indirectly by the bridge entities, account for 40.9%. (2) Component missing errors, which happened when some component of a sentence (e.g., subject) was missing, account for 28.8%. In this case, GLRE needed the whole document information to infer the lost component and

... [S8] Among **non-users of aspirin**, the adjusted hazard ratios were: **rofecoxib** 1.27, naproxen 1.59, diclofenac 1.17 and ibuprofen 1.05. ... [S10] CONCLUSION: Among **non-users of aspirin**, naproxen seemed to carry the highest risk for AMI / **GI bleeding**. ...

Case 1 Label: CID GLRE: CID Wang et al.: N/A

... [S2] **S-53482** and **S-23121** are N-phenylimide herbicides and produced **embryolethality**, teratogenicity. ...

Case 2 Label: CID GLRE: CID Wang et al.: N/A

[S1] Clinical evaluation of **adverse effects** during **bepridil** administration for atrial fibrillation and flutter. ... [S8] There was marked QT prolongation greater than 0.55 s in 13 patients ... and general **fatigue** in 1 patient each. ...

Case 3 Label: CID GLRE: N/A Wang et al.: N/A

Table 6: Case study on the CDR test set. CID is short for the *"chemical-induced disease"* relation. Target entities and related entities are colored accordingly.

predict the relation, which was not always accurate. (3) Prior knowledge missing errors account for 13.6%. (4) Coreference reasoning errors, which were caused by pronouns that could not be understood correctly, account for 12.9%.

5 Conclusion

In this paper, we proposed GLRE, a global-to-local neural network for document-level RE. Entity global representations model the semantic information of an entire document with R-GCN, and entity local representations aggregate the contextual information of mentions selectively using multi-head attention. Moreover, context relation representations encode the topic information of other relations using self-attention. Our experiments demonstrated the superiority of GLRE over many comparative models, especially the big leads in extracting relations between entities of long distance and with multiple mentions. In future work, we plan to integrate knowledge graphs and explore other document graph modeling ways (e.g., hierarchical graphs) to improve the performance.

Abstract

The idea of using multi-task learning approaches to address the joint extraction of entity and relation is motivated by the relatedness between the entity recognition task and the relation classification task. Existing methods using multi-task learning techniques to address the problem learn interactions among the two tasks through a shared network, where the shared information is passed into the task-specific networks for prediction. However, such an approach hinders the model from learning explicit interactions between the two tasks to improve the performance on the individual tasks. As a solution, we design a multi-task learning model which we refer to as recurrent interaction network which allows the learning of interactions dynamically, to effectively model task-specific features for classification. Empirical studies on two real-world datasets confirm the superiority of the proposed model.

1 Introduction

The extraction of entities and relations from textual data comprises of two sub-tasks: entity recognition (ER) and relation classification (RC). The ER task aims at extracting all entities in a given text. The RC task aims at classifying the relation between any pair of entities in the text. In practice, both tasks are required to be solved jointly, and have been observed to contribute significantly in extracting structured knowledge from unstructured text for several applications, including knowledge base construction (Komninos and Manandhar, 2017; Deng et al., 2019; Nathani et al., 2019). For instance, consider the sentence *John was born in Sheffield, a city in the north of England*. The goal of a joint entity and relation extraction task is to identify all the factual relational triples (or relational facts) `(Sheffield, birth_place_of, John)` and `(England, contains, Sheffield)`.

(a) Flat Structure (b) Graph Structure

Figure 1: Two topological structures for multi-task learning. Here, A and B are related tasks, and S is the shared information of the two tasks. The directed edges define the information flow.

The simplest approach to solve this joint task is to utilize a pipeline-based approach by firstly extracting all entities in the sentence and then classifying the relation between all entity pairs (Zelenko et al., 2003; Zhou et al., 2005; Chan and Roth, 2011). However, pipeline-based approaches disregard the correlation between ER and RC tasks, leading to error propagation in these methods.

Recently, researchers have exploited multi-task learning (MTL) (Collobert and Weston, 2008) techniques to capture the correlation between the ER and RC tasks, and have successfully improved the performance of the individual tasks (Miwa and Bansal, 2016; Fu et al., 2019; Zeng et al., 2019a). These methods have a flat structure (Liu et al., 2019a). Figure 1(a) shows a flat structure for multi-task learning. Methods using a flat structure learn interactions between tasks through a shared network, and extract a shared common representation which is exploited by task-specific networks independently. We refer to MTL methods utilizing a flat structure as conventional MTL methods. A conventional MTL method is effective to an extent because they help to improve generalization performance on all the tasks. However, it is based on the strong assumption that the shared network is sufficient to capture the correlations between the tasks.

Even so, identifying the relational facts in sentences is a difficult problem. Reason being that several relational facts may overlap in a sentence (Zhang et al., 2018). Although a conventional MTL method may learn task-specific features and has been successfully applied in a wide variety of scenarios (Zhang and Wang, 2016; Wu et al., 2016; Goo et al., 2018; Han et al., 2019; Li et al., 2019; Nishino et al., 2019; Liu et al., 2019b; Hu et al., 2019), its flat structure restricts the model to effectively learn the correlations between tasks. For example in Figure 1(a), the model cannot explicitly learn correlations between the two tasks. Without modeling explicit interactions, as shown in a sequence learning task (Liu et al., 2019a), the existing MTL-based methods (Miwa and Bansal, 2016; Fu et al., 2019; Zeng et al., 2019a) cannot effectively capture the correlation between the ER and the RC tasks.

In this paper, we overcome the aforementioned limitation of previous MTL-based methods by proposing a recurrent interaction network (RIN) to effectively capture the correlations between the ER and RC tasks. RIN has a multi-task learning architecture which allows interactions between the ER and RC tasks to be learned explicitly, with the aim to improve the performance on the individual tasks. More specifically, RIN has a recurrent structure comprising of multiple interaction layers, allowing the model to progressively learn complex interactions while refining predictions for ER and RC. The RIN structure is an example of a multi-task learning network with a graph structure (Liu et al., 2019a). We show the graph structure in Figure 1(b). As shown by our experiment, the proposed model progressively provides discriminating features which is an essential requirement of the individual task for classification. Empirical studies on NYT and WebNLG datasets achieve new state-of-the-art performances and confirm the effectiveness of the proposed RIN model.

2 Related Work

Previous neural methods proposed for jointly extracting entities and relations can generally be categorized into three classes. The first class models the joint extraction task as a sequence labeling problem (Zheng et al., 2017; Dai et al., 2019; Takanobu et al., 2019; Yu et al., 2019). Among the proposed works, (Zheng et al., 2017) was the first to introduce a tagging strategy to address the problem, transferring the joint extraction task to a sequence labelling problem. However, this method has the fundamental weakness of addressing the overlapping problem of relational facts in the text. To meet it, (Dai et al., 2019) proposed a position-attentive tagging scheme to solve the overlapping problem. Meanwhile, (Takanobu et al., 2019; Yu et al., 2019) approach the problem by decomposing the joint extraction task into two sequence labeling sub-tasks, to address the joint entity and relation extraction problem.

The second class of works use a sequence-to-sequence (seq2seq) approach to address the problem (Zeng et al., 2018, 2019b). (Zeng et al., 2018) employs a seq2seq model to directly extract relational facts from the sentence by decoding the first entity, second entity, and relation in that order. But, their approach is limited to extracting a predefined number of relational facts from the text. In extracting relational triples, the order of extraction is key to identify the relational facts. As such, (Zeng et al., 2019b) proposed a seq2seq approach which utilizes a reinforcement learning model to learn the order of extracting the relational triples. Although effective, the proposed seq2seq models (Zeng et al., 2018, 2019b) only decode a single word for an entity.

The third class design a multi-task learning model to extract relational facts (Miwa and Sasaki, 2014; Miwa and Bansal, 2016; Adel and Schütze, 2017; Fu et al., 2019; Zeng et al., 2019a). Among these works, (Miwa and Bansal, 2016) consider the dependency structure of the sentence to model the common features between the ER and RC tasks, while (Adel and Schütze, 2017) employ convolutional neural networks (CNN) to encode the common features. (Zeng et al., 2019a) proposed an MTL model which comprises of an ER model to extract entities with multi-tokens, and a seq2seq model to extract relational facts. Their approach solves the entity extraction problem faced by models which are solely seq2seq based. (Fu et al., 2019) exploits a bidirectional recurrent neural network and graph convolutional network to extract the common features. Despite the substantial efforts and great successes in the design of these MTL-based methods, these methods follow the conventional MTL approach (Collobert and Weston, 2008). Thus, they only capture implicit interactions by means of the shared network of the ER and RC tasks.

Modelling explicit interactions between multiple tasks in an MTL architecture has been explored to improve predictions in several domains (He et al., 2019; Zhao et al., 2019; Dankers et al., 2019; Lan et al., 2017; Liu et al., 2019a, 2016). Modeling explicit interactions have also been explored for the joint extraction task (Gupta et al., 2016). However, (Gupta et al., 2016) models the interaction in a successive way by using the output of one task to benefit the prediction of the other task. The method we propose considers the output of the tasks simultaneously, and model their interaction in a dynamic way with a recurrent structure, allowing the tasks to gradually refine their predictions and benefit from each other. To the best of our knowledge, this is the first work to model explicit interactions in a multi-task learning architecture for the joint extraction of entities and relations in text.

3 Problem Statement

In this section, we formally describe the joint entity and relation extraction problem. For a set $T = \{t_1, \cdots, t_l\}$ of pre-defined l relation types, and a given sentence $s = \{w_1, w_2, \cdots, w_n\}$ of n words, the problem is to extract all relational facts for the given sentence. In this paper, a single relational triple is of the form $\langle w_i, t, w_j \rangle$, where $w_i, w_j \in s$ are entity words or heads of multi-token entities, and $w_i \neq w_j$, and the relation $t \in T$. The goal of the relation classification task is to predict the probability $y^t_{(i,j)}$ that the relational triple $\langle w_i, t, w_j \rangle$ is factual given the word pair (w_i, w_j). Moreover, the entity recognition task takes each word $w_i \in s$ and predicts a probability y_i over BIOES labels (Fu et al., 2019). When no confusion will arise, we will remove the subscript i from the prediction y_i for clarity and brevity. Clearly, the ER task can help identify the head or tail words of multi-token entities for the joint extraction task.

4 Model

In this section, we describe the recurrent interaction network (RIN) for extracting relational facts in text. The RIN model is composed of an entity recognition (ER) module and a relation classification (RC) module. We start by presenting an overview of the RIN model, showing the interaction between the ER and RC tasks. Next, we elaborate the ER and RC modules and define the training objective. The framework of RIN is shown in Figure 2.

4.1 Recurrent Interaction Network

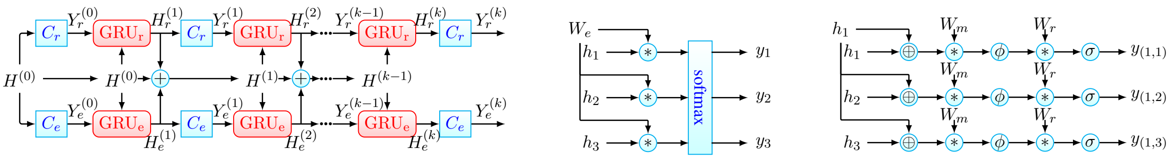
The RIN model we propose uses a bidirectional LSTM network to learn correlations between the ER and the RC tasks, and derives shared features for the two tasks. We denote H as the output of shared features, where $H = \{h_1, h_2, \ldots, h_n\}$ corresponds to the representations of words in sentence s. A straightforward strategy for the joint ER and RC task is to pass H into independent ER or RC modules for predictions. Denote C_e as the ER module to identify and extract entities in the text, and C_r as the RC module to classify relational triples in the text. Formally, Y_e and Y_r, the set of predictions of the entities and relational triples are formulated as:

$$\begin{aligned} Y_r &= C_r(H) \\ Y_e &= C_e(H) \end{aligned} \tag{1}$$

where $Y_e =: \{y_i | h_i \in H\}$, $Y_r =: \{y_{(i,j)} | h_i, h_j \in H\}$, y_i is a probability distribution over BIOES labels (Fu et al., 2019), and $y_{(i,j)}$ is a probability distribution over the relation types $t \in T$. This structure is basically a conventional MTL method, where interactions are learned implicitly, impeding dynamic learning of intrinsic correlations between the two tasks.

To enhance the interaction between the two tasks, we dynamically learn the explicit interactions between the ER and RC tasks. Each layer of the RIN model is an interaction layer comprising of two separate gated recurrent units (GRUs), accounting for the ER task and the RC task. The GRU networks are designed to model task-specific features at the k-th layer, taking into account the previous shared features $H^{(k-1)}$ and the previous predictions Y_e^{k-1} and Y_r^{k-1}. Meanwhile, the shared features $H^{(k)}$ generated at the k-th layer is a sum of the previous task-specific features and the previous shared features $H^{(k-1)}$. Such a mechanism ensures that we retain the learned correlations as learning progresses along the network.

Let GRU$_r$ and GRU$_e$ denote the GRU networks for the relation classification and entity recognition modules in the interaction layer. Denote H_r^k and H_e^k the task-specific features modeled by the respective GRU$_r$ and GRU$_e$ networks at the k-th layer. Formally, the outputs H_r^k and H_e^k and shared features H^k at the k-th interaction layer is com-



(a) Framework of RIN. (b) The ER module (C_e). (c) The RC module (C_r).

Figure 2: (a) The framework of RIN. (b) The entitiy recognition module. (c) The relation classification module. In (b) and (c), we use a toy example of shared features $H = \{h_1, h_2, h_3\}$ to demonstrate the entity prediction for word w_i and relation prediction for all pairs $(w_1, w_1), (w_1, w_2), (w_1, w_3)$. $+$, $\oplus$, $*$, ϕ, and σ denote a summation operator, a concatenation operator, a matrix multiplication, relu activation function and sigmoid function respectively.

puted as follows:

$$\begin{aligned} H_r^k &= \mathrm{GRU}_r\left(Y_r^{k-1}, H^{k-1} | \theta_{\mathrm{GRU}_r}\right) \\ H_e^k &= \mathrm{GRU}_e\left(Y_e^{k-1}, H^{k-1} | \theta_{\mathrm{GRU}_e}\right) \\ H^k &= H_r^k + H_e^k + H^{k-1} \end{aligned} \tag{2}$$

where θ_{GRU_r} and θ_{GRU_e} are parameters for the GRU_r and GRU_e networks respectively. To take advantage of the previous learned explicit interactions in this network, we allow the network to have a minimum of two layers, i.e, $k = 2, 3 \ldots K$. Hence, for the ER task and RC tasks, the outputs at the k-th layer is formulated as:

$$\begin{aligned} Y_r^k &= C_r(H_r^k) \\ Y_e^k &= C_e(H_e^k) \end{aligned} \tag{3}$$

4.1.1 The GRU network

In the RIN model, we proposed the GRU_r and GRU_e networks for the relation classification and entity recognition modules. Formally, for a single word w, the GRU_e network takes the output $y \in Y_e$ and the shared word representation $h \in H$ as inputs and computes the ER task feature vector $h_e \in H_e$. Formally, this can be formulated as:

$$\begin{aligned} z &= \sigma\left(W_{\mathrm{z}}(h \oplus y)\right) \\ u &= \sigma\left(W_{\mathrm{u}}(h \oplus y)\right) \\ \check{h} &= \tanh\left(W_{\mathrm{o}}((u * h) \oplus y)\right) \\ h_e &= (1 - z) * h + z * \check{h} \end{aligned} \tag{4}$$

where $\oplus$ is a concatenation operator, W_z, W_u, W_o are learnable parameters of the GRU network. GRU_r follows the same architecture as GRU_e to compute the RC task feature vector $h_r \in H_r$ for word w. However, for a given word w_i, it considers $h_i \in H$ and the vector y_i^r, where y_i^r is modeled from the set of relation predictions for all word pairs containing w_i. We can define this set as $Y_r(w_i) =: \{y_{(i,j)} \in Y_r | w_j \in s\}$.

$$y_i^r = \mathrm{maxpool}\left(Y_r(w_i)\right), \tag{5}$$

where the function $\mathrm{maxpool}(\cdot)$ is a maxpool operation along the dimension.

4.2 Entity Recognition (ER)

The ER module C_e attempts to recognize all entities in the text based on the features H_e. As an entity may consist of multiple words, we formalize the ER task as tagging each word with an entity label, taking values from *(Begin, Inside, End, Single, Out)* using the BIOES tagging scheme (Fu et al., 2019). Specifically, the ER module classifies each word to one of the five label clusters. The probability distribution y of word w over these five clusters is calculated based on the ER task feature vector h_e as follows:

$$y = \mathrm{softmax}(W_{\mathrm{e}} h_e + b_{\mathrm{e}}), \tag{6}$$

where $\theta_{\mathrm{ER}} = \{W_{\mathrm{e}}, b_{\mathrm{e}}\}$ are learnable model parameters.

4.3 Relation Classification (RC)

The RC module C_r makes an attempt to identify and extract relational facts from the sentence. Following (Fu et al., 2019), we classify all relations between pairs of words in the sentence based on the features H_r. Thus, the relation classification task is interpreted as a binary classification problem, where we identify the truth value of a relational triple $\langle w_i, t, w_j \rangle$ by classifying the word pair (w_i, w_j). The task can be regarded as learning the probability distribution $y_{(i,j)}$ for each word pair (w_i, w_j). The value $y_{(i,j)}$ is a probability distribution over the relation types $t \in T$. Thus, $y_{(i,j)}$ is a vector with size l, where each dimension is a probability $y_{(i,j)}^t$ of the relational triple $\langle w_i, t, w_j \rangle$

to be factual. We compute $y_{(i,j)}$ for each word pair (w_i, w_j) by performing the following steps:

$$\begin{aligned} m &= \phi\left(W_{\mathrm{m}}(h_i \oplus h_j)\right) \\ y_{(i,j)} &= \sigma\left(W_{\mathrm{r}} m + b_r\right) \end{aligned} \tag{7}$$

where $h_i, h_j \in H_r$ are the RC task feature vectors for $w_i, w_j \in s$, $\oplus$ is a concatenation operation, $\phi(\cdot)$ is the ReLU activation function, $\sigma(\cdot)$ is the sigmoid activation function. $\theta_{\mathrm{RC}} = \{W_{\mathrm{m}}, W_{\mathrm{r}}, b_r\}$ are learnable model parameters. Instead of using a softmax function for classification, as used in (Fu et al., 2019), we find that the sigmoid function offers a natural way of identifying multiple relations that may exist between word pairs, solving the overlapping problem more efficiently.

4.4 Training Objective

The RIN model ultimately outputs task-specific representations, which are fed into their corresponding ER module and the RC module for predictions. As such, the training objective of RIN is comprised of two parts: the loss function for RC L_{r} and the loss function for ER L_{e}. The losses L_{e} and L_{r} are defined as

$$\begin{aligned} L_{\mathrm{e}}(w) &= \mathrm{CrossEntropy}\left(\bar{y}, y\right) \\ L_{\mathrm{r}}(\langle w_i, t, w_j \rangle) &= \mathrm{CrossEntropy}\left(\bar{y}^t_{(i,j)}, y^t_{(i,j)}\right) \end{aligned} \tag{8}$$

where $\bar{y}$ and $\bar{y}^t_{(i,j)}$ are the respective ground truth values of word w and relational triple $\langle w_i, t, w_j \rangle$, and y and $y^t_{(i,j)}$ are the predictions from the ER module (C_e) and the RC module (C_r) at the K-th layer (i.e. the last layer) of RIN.

The total loss L over all words and relational triples for all sentences is then calculated as follows.

$$L = \sum_{s} \left(\sum_{w \in s} L_{\mathrm{e}}(w) + \sum_{w_i, w_j \in s, t \in T} L_{\mathrm{r}}(\langle w_i, t, w_j \rangle) \right) \tag{9}$$

With gradient based algorithm, we seek to minimize the total loss L over all model parameters $\Theta = \{\theta_{\mathrm{GRU}_r}, \theta_{\mathrm{GRU}_e}, \theta_{\mathrm{RC}}, \theta_{\mathrm{ER}}, \theta_{\mathrm{H}}\}$ (θ_{H} is the parameters for the BiLSTM network) to achieve good performance for both the ER and RC tasks.

5 Experiment

We conduct experiments to evaluate RIN on two public datasets NYT (Riedel et al., 2010) and WebNLG (Gardent et al., 2017). The NYT dataset consists of 1.18M sentences with 24 predefined relation types. The WebNLG dataset was created by Natural Language Generation (NLG) tasks, and adapted by (Zeng et al., 2018) for a relational triple extraction task. We directly use the preprocessed datasets released by (Zeng et al., 2018).[1] It is worth mentioning that only the tail word of an entity is marked in the preprocessed dataset released by (Zeng et al., 2018). To properly distinguish entities, we take a further step of tagging entities with the conventional BIOES tagging scheme as the one used in (Fu et al., 2019). We report Precision (Prec), Recall (Rec) and micro-F1 (F1) scores on our model and other recent models (Zeng et al., 2018, 2019b; Zheng et al., 2017; Fu et al., 2019; Zeng et al., 2019a) for the *Partial Match* task and the *Exact Match* task. For our proposed method, we report the mean results over five runs using different random seeds, along with its standard deviation to show the stability of our results. The statistics of datasets are summarized in Table 2. Additional experiments on older datasets NYT10 (Riedel et al., 2010) and NYT11 (Hoffmann et al., 2011) are also performed, and the results are available in the supplementary file. Our results on these datasets show satisfactory performance, generally outperforming previous models on the NYT10 and NYT11.

5.1 Partial Match and Exact Match

Both NYT and WebLG datasets support evaluation for the *Partial Match* task and the *Exact Match* task. The Partial Match task only requires the relation and the heads of both subject and object entities of the extracted relational triple to be correct. For the Exact Match as recently adopted by (Zheng et al., 2017; Fu et al., 2019; Zeng et al., 2019a), the extracted relational triple is considered to be correct if the relation and the heads and tails of the subject and object entities are all correct. Thus, the extracted relational triple completely matches the gold relational triple.

5.2 Implementation Details

For a fair comparison with previous recent works (Zeng et al., 2018), we use the 100-dimensional Glove embedding (Pennington et al., 2014) to represent the word embeddings.[2] Part-of-speech (POS) tags are assigned to words using Stanford POS tagger.[3] We map each POS tag to

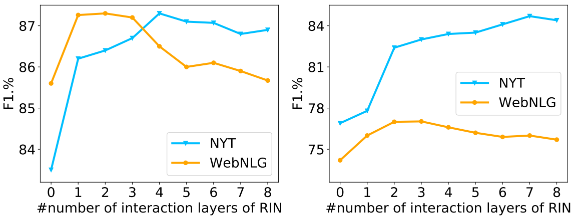
a randomly initialized 10-dimensional POS embedding. We concatenate both word and POS embeddings as the input embeddings. For any given sentence, the input embeddings for words are fed to a BiLSTM network to learn a 100-dimensional embedding for each word. We improve learning by using dropout regularization in the input embeddings. The BiLSTM embeddings represent the shared features H in the RIN model. Our model is trained using an Adam optimizer (Kingma and Ba, 2014). The hyper-parameters are set empirically and manually tuned on the development set to select the best model. We implement our model using PyTorch on a Linux machine with a GPU device NVIDIA V100 NVLINK 32GB. Table 3 lists the hyper-parameters of RIN on the datasets. For the relation classification task, we threshold the probabilities of the prediction and return only the relations with probability values ≥ 0.5. The code for our model is available at [4].

5.3 Performance Comparison

We compare our model with several recent models based on the Partial Match and the Exact Match evaluation tasks. We also include a baseline model $\text{RIN}_{\text{w/o interaction}}$ which excludes the interaction network used in RIN. In $\text{RIN}_{\text{w/o interaction}}$, the shared features H modeled by BiLSTM network is directly passed into C_e and C_r for task-specific predictions. We also compare with several recent models, including the NovelTagging (Zheng et al., 2017), sequence-to-sequence (seq2seq) models such as OneDecoder (Zeng et al., 2018), MultiDecoder (Zeng et al., 2018), and OrderRL (Zeng et al., 2019b), and MTL-based methods CopyMLT (Zeng et al., 2019a), and GraphRel (Fu et al., 2019).



(A) Partial Match (B) Exact Match

Figure 3: Curves of F1 performance on different number of interaction layers K.

Partial Match Table 1 shows the performance of different models on the datasets. For the Partial Match evaluation task, it can first be noted that the small standard deviation for our model RIN and its ablated model $\text{RIN}_{\text{w/o interaction}}$ shows that our results are stable to an extent on the datasets.

---

[4] `https://github.com/BDBC-KG-NLP/Recurrent_Interaction_Network_EMNLP2020`

Even with the simple structure of $\text{RIN}_{\text{w/o interaction}}$, its results outperform the compared methods. In extracting relational facts, our model treats the Partial Match task as a relation classification problem. Whereas the compared methods take a seq2seq based approach to directly extract relational facts in the sentence. The results suggest that our approach may be more effective in identifying the relational facts for this task. It is more interesting to see the performance achieved by RIN. First of all, it can be noted that the model shows a level of stability due to its small standard deviation. Moreover, RIN shows a significant performance boost to the $\text{RIN}_{\text{w/o interaction}}$ model, suggesting the importance of dynamically learning the explicit interactions between the ER task and the RC task.

Exact Match For the Exact Match task, we do not consider the methods (Zeng et al., 2018, 2019b), since these methods consider a seq2seq approach in extracting relational triples. Seq2seq methods are able to only decode a single word for an entity. Hence, they will inevitably fail to identify entities with multiple words.

In Table 1, we find that our ablated model $\text{RIN}_{\text{w/o interaction}}$ consistently outperforms previous models on the two datasets. In a more detailed analysis, we can note that the variants of the GraphRel model (Fu et al., 2019) consider the Exact Match task as a relation classification problem which classifies all word pairs in the sentence. In its relation classification module, it exploits a softmax function for the final classification. Hence, the model is not able to address cases where multiple relations exist between a pair of entities. We believe this explains why its results underperforms when compared to $\text{RIN}_{\text{w/o interaction}}$. Although CopyMLT and its variants (Zeng et al., 2019a) consider a seq2seq based approach to directly extract relational triples, its ER model can identify entities with multiple words and hence can address the Exact Match task. Nonetheless, it fails to outperform our model due to the fact that it uses a seq2seq based approach which we believe to be a more complex method for identifying relational triples. Besides, our main model RIN significantly outperforms $\text{RIN}_{\text{w/o interaction}}$ on the two datasets, further proving the importance of the explicit interactions learned between the ER and RC tasks.

5.4 Impact of K on the results

The hyper-parameter K is the number of interaction layers of the RIN model. Thus, K controls the number of times the RIN model attempts to learn explicit interactions between the ER and RC task. We conduct experiments to study the impact of K on the performance of RIN. We expect that the performance of the model increases as we learn more explicit interactions between the ER task and the RC task. Figure 3 shows the F1 curves of RIN on the datasets for increasing values of K. Here, at $K = 0$ the RIN model is reduced to $\text{RIN}_{\text{w/o interaction}}$.

We observe that as K increases the performance of RIN increases to an extent up to a point where it overfits. Taking a closer look at the performance on the Partial Match task, we find that $\text{RIN}_{\text{w/o interaction}}$ poorly models the interaction between the ER and RC task. By learning explicit interactions using the RIN model, we observe a sharp rise in performance at $K = 1$. On the Exact Match task we observe an interesting behaviour of RIN on the NYT and WebNLG dataset. Note that the 60% of entities on the WebNLG are multi-tokens, while 30% of the entities in the NYT dataset are multi-tokens. This means that the Exact Match task is more difficult on the WebNLG dataset, compared to the NYT dataset. As a consequence, RIN finds it difficult to learn explicit interactions on the WebNLG, while it learns much more easily on the NYT as K rises. We observe a sharp rise in performance from the first layer to the second layer on the NYT dataset. The second layer of RIN takes advantage of the original shared features H and the task-specific features of the first interaction layer. Thus, effective learning of the interaction between the two tasks takes place from the second layer. This explains the sharp rise in performance on the NYT dataset for the Exact Match task.

5.5 Ablation Experiment

To examine the contributions of our main model components, we conduct ablation experiments on the NYT and WebNLG datasets. We use the default hyper-parameter settings for the ablated models (see Table 3). The ablated models are: (1) $\text{RIN}_{\text{w/o ER}}$: A RIN model which excludes the task-specific features H_e in the update of the shared features H, restricting the RC module from learning from the ER module. (2) $\text{RIN}_{\text{w/o RC}}$: A RIN model which excludes the task-specific features H_r

Case1: A cult of victimology arose and was happily exploited by clever radicals among Europe's Muslims, especially certain religious leaders like Imam Ahmad Abu Laban in Denmark and Mullah Krekar in Norway.	**Golden**:*Europe, Denmark, Norway* *(Europe, /location/location/contains, Denmark)* *(Europe, /location/location/contains, Norway)* **$\text{RIN}_{\text{w/o interaction}}$**: *Europe, Denmark, Norway* *(Europe, /location/location/contains, Denmark)* **RIN**: *Europe, Denmark, Norway* *(Europe, /location/location/contains, Denmark)* ***(Europe, /location/location/contains, Norway)***
Case2: Scott (No rating , 75 minutes) Engulfed by nightmares, blackouts and the anxieties of the age, a Texas woman flees homeland insecurity for a New York vision quest in this acute, resourceful and bracingly ambitious debut film.	**Golden**: *Scott, New York* *(York, /location/location/contains, Scott)* **$\text{RIN}_{\text{w/o interaction}}$**: ***Texas***, *New York* *(York, /location/location/contains, Scott)* **RIN**: *Scott, New York* *(York, /location/location/contains, Scott)*

Table 4: Case study for RIN and $\text{RIN}_{\text{w/o interaction}}$. Entities and relational triples are in blue and orange texts respectively. We mark a wrong prediction with a red text.

in the update of the shared features H, restricting the ER module from learning from the RC module. (3) $\text{RIN}_{\text{w/o POS}}$: A RIN which only uses the Glove word embeddings as the input embeddings. We also include the ablated model $\text{RIN}_{\text{w/o interaction}}$. Table 5 shows the results for the experiment.

Model	NYT	WebNLG
RIN	84.7	77.0
$\text{RIN}_{\text{w/o ER}}$	83.9	76.4
$\text{RIN}_{\text{w/o RC}}$	77.3	76.0
$\text{RIN}_{\text{w/o interaction}}$	76.9	74.2
$\text{RIN}_{\text{w/o POS}}$	84.1	76.6

Table 5: F1 performance of different ablation models on the datasets. The Exact Match evaluation is used.

We find that the performance of RIN deteriorates as we remove critical components. Among the ablated models designed, $\text{RIN}_{\text{w/o interaction}}$ performs very poorly on the two datasets, suggesting the importance of learning explicit interactions dynamically between the ER and RC tasks. We also find that $\text{RIN}_{\text{w/o ER}}$ marginally underperforms the RIN model, and also showing a better performance when compared to $\text{RIN}_{\text{w/o RC}}$. The results suggest that the performance of RIN is heavily dependent on the ER module exploiting information from the RC module. Lastly, the results for $\text{RIN}_{\text{w/o POS}}$ suggest that the POS tags does not significantly boost the performance of RIN.

5.6 Case Study

We present two case examples from NYT dataset as illustrations to observe the behaviour of the RIN and $\text{RIN}_{\text{w/o interaction}}$ models. Table 4 shows the results of the study. In the first case example, both RIN and $\text{RIN}_{\text{w/o interaction}}$ correctly extracts all the gold entities in the sentence. But, $\text{RIN}_{\text{w/o interaction}}$ captures only the gold relational triple `(Europe, /location/location/contains, Denmark)`, and misses the gold triple `(Europe, /location/location/contains, Norway)`. Given the fact that `(Europe, /location/location/contains, Norway)` overlaps a relational fact, it is important to dynamically learn to capture the complex interaction between the ER and RC tasks. The RIN model takes advantage of its interaction network to identify both gold triples.

In the second case, we observe that both RIN and $\text{RIN}_{\text{w/o interaction}}$ correctly extract the relational triple `(York, /location/location/contains, Scott)`. However, $\text{RIN}_{\text{w/o interaction}}$ identifies `Texas` as an entity by error while RIN correctly extracts the entity `Scott` and `New York`. The results suggest that RIN is able to leverage information from the RC module to correctly identify entities in the ER module. It is worth noting that we can easily complete the entity `York` in the extracted relational triple by aligning it to the extracted entity `New York`.

6 Conclusion

In this paper, we tackle the weakness of existing MTL-based methods proposed for the joint extraction of entities and relation in unstructured text. Specifically, these methods assume that a shared network is sufficient to capture the correlations between the entity recognition task and the relation classification task, and that the shared features derived from this network can be passed into models for the task-specific tasks to make predictions independently. Instead, we show that dynamically learning the interactions between the tasks may capture complex correlations which improves the task-specific feature for classification. We proposed multi-task learning model which allows explicit interactions to be dynamically learned among the subtasks. Our experiments on benchmark datasets validates clear advantage over the existing proposed methods. We note that our model can be adapted for other NLP tasks, including aspect level sentiment classification and slot filling. As future work, we intend to explore its application in those fields.

Abstract

Research on temporal knowledge bases, which associate a relational fact (s, r, o) with a validity time period (or time instant), is in its early days. Our work considers predicting missing entities (link prediction) and missing time intervals (time prediction) as joint Temporal Knowledge Base Completion (TKBC) tasks, and presents TIMEPLEX, a novel TKBC method, in which entities, relations and, time are all embedded in a uniform, compatible space. TIMEPLEX exploits the recurrent nature of some facts/events and temporal interactions between pairs of relations, yielding state-of-the-art results on both prediction tasks.

We also find that existing TKBC models heavily overestimate link prediction performance due to imperfect evaluation mechanisms. In response, we propose improved TKBC evaluation protocols for both link and time prediction tasks, dealing with subtle issues that arise from the partial overlap of time intervals in gold instances and system predictions.

1 Introduction

A knowledge base (KB) is a collection of triples (s, r, o), with a subject s, a relation type r and an object o. KBs are usually incomplete, necessitating completion (KBC), i.e., inferring facts not provided in the KB. A KBC model is often evaluated via link prediction: supplying missing arguments to queries of the form $(s, r, ?)$ and $(?, r, o)$.

Many relations are transient or impermanent. Temporal KBs annotate each fact (event) with the time period (instant) in which it holds (occurs) (Hoffart et al., 2013). A person is born in a city in an instant, a politician can be a country's president for several years, and a marriage may last between years and decades. Temporal KBs represent these by (s, r, o, T) tuples, where T is a span of time. Temporal KBC (TKBC) performs completion of temporal KBs. It is also primarily evaluated by link prediction queries $(s, r, ?, T)$ and $(?, r, o, T)$. Recently, time prediction $(s, r, o, ?)$ has also been considered for predicting time instants, but not time intervals (Lacroix et al., 2020).

While KBC has been intensely researched, TKBC is only beginning to be explored. TKBC presents novel challenges in task definition and modeling. For instance, little is known about how best to predict intervals for $(s, r, o, ?)$ queries, or how to evaluate a system response interval. Moreover, we show that even for link prediction queries, evaluation faces subtle complications owing to the inclusion of T in $(s, r, ?, T)$ queries and requires careful rethinking of evaluation protocols. In this paper, we propose improved evaluation protocols for both link and time prediction tasks in a TKBC.

TKBC also brings unique modeling opportunities. A TKBC system can learn typical durations of relation validity, or distributions over time gaps between events, from training data. E.g., a person must be born before becoming president, which must precede death. A nation rarely has two presidents at the same time. Such constraints can better inform both link and time predictions.

In response, we present TIMEPLEX, a novel TKBC model, which obtains state-of-the-art results on benchmark datasets for both link and time prediction. At a high level, TIMEPLEX performs tensor factorization of a temporal KB, using complex-valued embeddings for relations, entities and time points. It enables these embeddings to capture implicit temporal relationships across facts and relations, by providing temporal differences as explicit features. Our contributions are summarized as:

- We propose evaluation protocols for link and time interval prediction queries for TKBC. For link prediction, we highlight that existing evaluations seriously over/under-estimate system

performance, and offer a time-aware filtering method for more reliable evaluation. For time interval prediction, we propose an evaluation metric that rewards a model for predicting an interval with partial overlap with gold interval, as well as for nearness to gold in case of no overlap.
- We present TIMEPLEX, a TKBC model that factorizes a temporal KB using entity, relation and time embeddings. It can learn and exploit soft ordering and span constraints between potentially all relation pairs (including that of a relation with itself). It beats recent and competitive models on several recent standard TKBC data sets.

We will release an open-source implementation[1] of all models and experiments discussed here.

2 Preliminaries and Prior Work

2.1 Time-Agnostic KBC

Time-agnostic KBC has been intensely researched (Bordes et al., 2013; Yang et al., 2015; Nickel et al., 2016; Jain et al., 2018a; Lacroix et al., 2018; Jain et al., 2018b). A common approach is to score an (s, r, o) triple as a function over jointly learned entity and relation embeddings. The models are trained using loss functions imposing - scores for known triples should be higher than (randomly sampled) negative triples.

Our work is based on ComplEx (Trouillon et al., 2016), abbreviated as CX. It embeds s, r, o to vectors of complex space $\boldsymbol{s}, \boldsymbol{r}, \boldsymbol{o} \in \mathbb{C}^D$. CX defines the score ϕ of a fact (s, r, o) as $\mathrm{Re}(\langle \boldsymbol{s}, \boldsymbol{r}, \boldsymbol{o}^\star \rangle)$ where

$$\langle \boldsymbol{s}, \boldsymbol{r}, \boldsymbol{o}^\star \rangle = \textstyle\sum_{d=1}^{D} s[d]\; r[d]\; o^\star[d] \qquad (1)$$

is a 3-way inner product, $\boldsymbol{o}^\star$ is the complex conjugate of $\boldsymbol{o}$, and $\mathrm{Re}(c)$ is real part of $c \in \mathbb{C}$. If real embeddings are used instead, the above formula reduces to DistMult (Yang et al., 2015). We choose CX as our base model, because it is competitive with recent KBC models (Ruffinelli et al., 2020).

2.2 Temporal KBC Problem Setup

A temporal KB associates the validity of a triple (s, r, o) with one or more time intervals $T \subseteq \mathfrak{T}$, where $\mathfrak{T}$ is the domain of "all time". Each interval T is represented as $[t_b, t_e]$, with begin and end time instants. Some event-style facts (e.g., born in) may have $t_b = t_e$. For simplicity, we assume that $\mathfrak{T}$ is discretized to a suitable granularity and is represented by a set of integers. Temporal KB facts have the form (s, r, o, T), and are partitioned into train, dev and eval (test) folds, abbreviated as $\mathrm{tr}, \mathrm{de}, \mathrm{ev}$. System predictions are abbreviated as pr.

Given the train and dev folds, our goal is to learn a model that scores any unseen fact. A system is evaluated via link prediction queries $(?, r, o, T)$ and $(s, r, ?, T)$, and time interval prediction queries $(s, r, o, ?)$. In our setting, KB incompleteness exists at all times — the eval fold may include instances from any interval in time, arbitrarily overlapping train and dev fold instances.[2]

2.3 Recent TKBC Systems

Recent work adopts a common style for extending $\phi(s, r, o)$ to temporal score $\phi(s, r, o, t)$. Lacroix et al. (2020) embed each time instant t to vector $\boldsymbol{t}$ and use the form $\langle \boldsymbol{s}, \boldsymbol{r}, \boldsymbol{o}^\star, \boldsymbol{t} \rangle$ (called TNT-ComplEx). This can be interpreted as any *one* of $\boldsymbol{s}, \boldsymbol{r}, \boldsymbol{o}^\star$ becoming $\boldsymbol{t}$-dependent. Goel et al. (2020) make *both* subject and object embeddings time-dependent; the 'diachronic' embedding $\boldsymbol{e} \in \mathbb{R}^D$ of entity e is characterized by $\boldsymbol{e}_t[d] = a_e[d] \sin(w_e[d]\, t + b_e[d])$, where $d \in D$ and the sinusoidal nonlinearity affords the capacity to switch "entity features" on and off with time t. HyTE (Dasgupta et al., 2018) models $\boldsymbol{t} \in \mathbb{R}^D, \|\boldsymbol{t}\|_2 = 1$ and project *all* of $\boldsymbol{s}, \boldsymbol{r}, \boldsymbol{o}$ on to $\boldsymbol{t}$: $\boldsymbol{x} \downarrow \boldsymbol{t} = \boldsymbol{x} - (\boldsymbol{x} \cdot \boldsymbol{t})\boldsymbol{t}$, where $\boldsymbol{x} \in \{\boldsymbol{s}, \boldsymbol{r}, \boldsymbol{o}\}$. In all cases, time-dependent entity embeddings are plugged into standard scoring functions like DistMult, CX, or SimplE (Kazemi and Poole, 2018). A very different approach (García-Durán et al., 2018) encodes the string representation of relation and time with an LSTM, which is used in TransE (TA-TransE) or DistMult (TA-DM).

These formulations do not directly model recurrences of a relation or interactions (e.g., mutual exclusion) between relations. There is some prior work on explicitly providing ordering constraints between relations (e.g., born, married, died) (Jiang et al., 2016). In contrast, TIMEPLEX assumes no such additional engineered inputs; it has explicit components to enable learning of temporal (soft) constraints, as model weights, jointly with embeddings of entities, relations, and time instants. Such constraint based reasoning has also been exploited (in a limited way) for a different task, namely, temporal question answering (Jia et al., 2018).

---

[2] A different TKBC task studies only future fact predictions (Trivedi et al., 2017; Jin et al., 2019).

2.4 Standard Evaluation Schemes

Link Prediction: Link prediction queries in KBC are of the form $(s, r, ?)$ with a gold response o^{ev}. Similarly, for TKBC they are of the form $(s, r, ?, T)$. The cases of $(?, r, o)$ and $(?, r, o, T)$ are symmetric and receive analogous treatment. Link prediction performance is evaluated by finding the rank of o^{ev} in the list of all entities ordered by decreasing score ϕ assigned by the model, and computing MRR. Other measures include the fraction of queries where o^{ev} is recalled within the top 1 or top 10 ranked predictions (HITS@1 and HITS@10).

A query may have multiple correct answers. A model must not be penalized for ranking a different *correct* entity over o^{ev}. In KBC this is achieved by filtering out all correct entities above o^{ev} in ranked list before computing the metrics. In TKBC, filtering requires additional care, as depicted in Table 1. We develop time-aware filtering in Section 3.2.

Time Prediction: Time prediction queries of the form $(s, r, o, ?)$ will require comparing a gold time interval $T^{\text{ev}} = [t_b^{\text{ev}}, t_e^{\text{ev}}]$ with a predicted interval $T^{\text{pr}} = [t_b^{\text{pr}}, t_e^{\text{pr}}]$. Since this is an understudied task, evaluation metrics have not yet been standardized. One might adapt the TAC metric popular in Temporal Slot Filling (Ji et al., 2011; Surdeanu, 2013). Adapted to TKBC, TAC[3] will compute a score as $\frac{1}{2}\left[\frac{1}{1+|t_b^{\text{ev}}-t_b^{\text{pr}}|} + \frac{1}{1+|t_e^{\text{ev}}-t_e^{\text{pr}}|}\right]$. Unfortunately, TAC score is not entirely satisfactory for this task. For instance, TAC will assign the same merit score when gold interval [10,20] is compared with predicted interval [5,15], versus when gold [100,200] is compared with prediction [95,195]. However, a human would judge the latter more favorably, because a 5-minute delay in a 10-minute trip would usually be considered more serious than in a 100-minute journey. In response, we investigate alternative evaluation metrics inspired by bounding box evaluation protocols from Computer Vision, in Section 3.1.

3 Evaluation Metrics and Filtering

The preceding discussion motivates why we need clearly-thought-out filtering and evaluation schemes, not only for time interval prediction queries, but also because time affects link prediction evaluation in subtle but fundamental ways. This section addresses both issues.

3.1 Time Interval Prediction

One possible way to evaluate time prediction is to adapt measures to compare bounding boxes in computer vision, e.g., Intersection Over Union (IOU): $\text{IOU}(T^{\text{ev}}, T^{\text{pr}}) = \frac{\text{vol}(T^{\text{ev}} \cap T^{\text{pr}})}{\text{vol}(T^{\text{ev}} \cup T^{\text{pr}})} \in [0, 1]$, where vol for our case simply refers to the size of the interval. Unfortunately, IOU loses discrimination once $T^{\text{ev}} \cap T^{\text{pr}} = \varnothing$; e.g., $\text{IOU}([1, 2], [3, 4]) = \text{IOU}([1, 2], [30, 40]) = 0$. This has been noticed recently in computer vision also, and a metric called gIOU been introduced (Rezatofighi et al., 2019):

$$\text{gIOU}(T^{\text{ev}}, T^{\text{pr}}) = \text{IOU}(T^{\text{ev}}, T^{\text{pr}}) - \frac{\text{vol}((T^{\text{ev}} \Cup T^{\text{pr}}) \setminus (T^{\text{ev}} \cup T^{\text{pr}}))}{\text{vol}(T^{\text{ev}} \Cup T^{\text{pr}})} \in (-1, 1]. \quad (2)$$

$T^{\text{ev}} \Cup T^{\text{pr}}$ is the smallest single contiguous interval (**hull**) containing all of T^{ev} and T^{pr}. E.g., $[1, 2] \Cup [30, 40] = [1, 40]$.

gIOU can be negative, which is not ideal for a performance metric that is aggregated over instances. A simple fix (gIOU′) is to scale it to [0,1] via $(\text{gIOU} + 1)/2$, but we notice that the tiniest overlap between T^{ev} and T^{pr} yields gIOU′ to be at least half, regardless of $\text{vol}(T^{\text{ev}})$ or $\text{vol}(T^{\text{pr}})$. In response, we propose a novel *affinity enhanced IOU*:

$$\text{aeIOU}(T^{\text{ev}}, T^{\text{pr}}) = \frac{\max\{1, \text{vol}(T^{\text{ev}} \cap T^{\text{pr}})\}}{\text{vol}(T^{\text{ev}} \Cup T^{\text{pr}})} \quad (3)$$

When $T^{\text{ev}} \cap T^{\text{pr}} = \varnothing$, the denominator includes “wasted time”, reducing aeIOU. The ‘1’ in the numerator represents the smallest granularity of time in the data (see Section 2.2).

Comparison of Evaluation Metrics: A good time interval prediction metric (M) must satisfy the property (P) that: if two predicted intervals have intersections of the same size (possibly zero) with the gold interval, then the prediction that has a smaller hull with the gold interval should be scored higher by M. Formally, let T^{pr_1} and T^{pr_2} be two predictions made for T^{ev}.

Property P: Let $\text{vol}(T^{\text{ev}} \cap T^{\text{pr}_1}) = \text{vol}(T^{\text{ev}} \cap T^{\text{pr}_2})$. Then, $M(T^{\text{ev}}, T^{\text{pr}_1}) > M(T^{\text{ev}}, T^{\text{pr}_2})$ if and only if $\text{vol}(T^{\text{ev}} \Cup T^{\text{pr}_1}) < \text{vol}(T^{\text{ev}} \Cup T^{\text{pr}_2})$.

Theorem: IOU and gIOU′ do not satisfy property P, whereas aeIOU satisfies it.

The proof for the theorem is in Appendix B. This suggests that aeIOU is a more defensible metric for our task, compared to other alternatives.

---

[3] TAC’s original score compares gold and predicted *bounds* on begin and end of an interval. This formula is its adaptation, where begin and end are each a specific time point.

Eval query: (s = French National Assembly, r = has member, o =?, T^{ev} = $[2000, 2003]$)							
Candidates o, system ordered	Known duration of o (any fold)	**Method 1** Unfiltered	**Method 2** Time-insensitive	**Method 3** Time-sensitive			
				2000	2001	2002	2003
Pierre	$[2002, 2003]$	1	0	1	1	0	0
Paul	$[2003, 2008]$	1	0	1	1	1	0
Alain	$[2008, 2009]$	1	0	1	1	1	1
Claude	$[2000, 2003]$	1	0	0	0	0	0
Jean	-	-	-	-	-	-	-
Time-sensitive rank of *Jean*		1+4=5	1+0=1	1+3=4	1+3=4	1+2=3	1+1=2

Table 1: *Jean* is the gold answer (o^{ev}). Rows are ranked system predictions, which may be seen with same s and r for different intervals (Column 2). Columns 3–4 show the filtering of existing methods (1:unfiltered, 0:filtered). Columns 5–8 (Method 3, our proposal) show the filtering for each time instant. The bottom row shows ranks of *Jean* as computed by different methods. Existing methods over- or under-estimate performance. Method 3 assigns *Jean* a rank of 3.25, which is the average of the filtered ranks $\{4, 4, 3, 2\}$ for each time instant in $[2000, 2003]$.

3.2 Link Prediction

We first illustrate the unique challenges offered by TKBC link prediction queries through an example in Table 1. The query asks for the name of a person who was a member of the French National Assembly in interval $[2000, 2003]$. Let the gold answer (object) o^{ev} be Jean, which is ranked at the fifth position by the model. All four entities above Jean are seen with the same subject and relation in the data, but for different time intervals. E.g., Pierre is also a member of the assembly, but during $[2002, 2003]$. The key question is: how should the four entities above Jean be filtered to compute its final rank?

We argue (Table 1) that existing filtering approaches are unsatisfactory. Dasgupta et al. (2018) underrate model performance by not performing any filtering (Method 1). In this example, the model is penalized for Claude, even though the time-interval for Claude exactly matches the query. On the other hand, García-Durán et al. (2018) and Jin et al. (2019) ignore time information altogether and filter out *all* entities seen with gold (s, r). This can greatly overestimate system quality (Method 2). For instance, the model is not penalized for predicting Alain, even though its membership interval has no overlap with the query interval.

Ideally, filtering must account for the overlap between the query time interval and the time intervals associated with system-proposed entities. We propose such a filtering strategy (Method 3). We split the query interval into time instants, and compute a filtered rank for each time point independently. Entities that have full time overlap (or no overlap) will always (respectively, never) get filtered for a time instant. Partially overlapping entities will get filtered in only overlapping instants (e.g., 2 out of 4 for Pierre). After computing filtered ranks for each time instant, we output the final rank as an average of all such filtered ranks. In this example, this approach will compute the average of $\{4, 4, 3, 2\}$, which is 3.25. This average rank is used when computing standard metrics like MRR and HITS@10.

Note that the run-time complexity of the proposed evaluation protocol is linear in the size of interval, because we compute a filtered rank for each time point separately.

4 The Proposed TimePlex Framework

Similar to TNT-Complex, TimePlex learns complex-valued entity, relation, and time instant embeddings. However, it has several differences from TNT-Complex. (1) Its base scoring function $\phi^{TX}(s, r, o, t)$ adds several products of three embeddings, instead of a single four-way product (Section 4.1). (2) It has a fully automatic mechanism to introduce additional features to capture recurrent nature of a relation, as well as temporal interactions between pairs of relations (Section 4.2). (3) It uses a two-phase training (Section 4.3) curriculum that estimates first the embeddings and then novel additional parameters. (4) Its testing protocol can output a missing time-interval T for time-interval prediction queries (Section 4.4).

4.1 TimePlex Base Model

Just as a joint distribution is often approximated using lower-order marginals in graphical models (Koller and Friedman, 2009), TimePlex constructs a base score (ϕ^{TX}) by augmenting CX score with three time-dependent terms:

$$\begin{aligned}\phi^{TX}&(s, r, o, t)\\ &= \langle \boldsymbol{s}, \boldsymbol{r}^{\text{SO}}, \boldsymbol{o}^{\star} \rangle + \alpha \, \langle \boldsymbol{s}, \boldsymbol{r}^{\text{ST}}, \boldsymbol{t}^{\star} \rangle \\ &\qquad + \beta \, \langle \boldsymbol{o}, \boldsymbol{r}^{\text{OT}}, \boldsymbol{t}^{\star} \rangle + \gamma \, \langle \boldsymbol{s}, \boldsymbol{o}, \boldsymbol{t}^{\star} \rangle. \end{aligned} \tag{4}$$

Here, $\boldsymbol{s}, \boldsymbol{o}, \boldsymbol{t} \in \mathbb{C}^D$, whereas each r is represented as a collection of three such vectors $(\boldsymbol{r}^{\text{SO}}, \boldsymbol{r}^{\text{ST}}, \boldsymbol{r}^{\text{OT}})$, and hence requires three times the parameters. $\boldsymbol{r}^{\text{ST}}$ represents a relation which is true for entity s at time t (similarly for $\boldsymbol{r}^{\text{SO}}$ and $\boldsymbol{r}^{\text{OT}}$). α, β and γ are hyperparameters.

Jiang et al. (2016) observed that several relations attach to a subject or object only at specific time points. E.g., subject Barack Obama was president in 2009, regardless of the object United States. In such cases, the formulation above is fully expressive. To extend from single time instants t to an interval T, we propose

$$\phi^{TX}(s, r, o, T) = \textstyle\sum_{t \in T} \phi^{TX}(s, r, o, t). \quad (5)$$

4.2 Relation Recurrence and Pair Scores

We extend TIMEPLEX's base model via additional (soft) temporal constraints that can help in better assessing the validity of a tuple. We aim to capture three types of temporal constraints:

Relation Recurrence: Many relations do not recur for a given entity (e.g., a person is born only once). Some relations recur with fixed periodicity (e.g., Olympic games recur every four years). Recurrences of other relations may be distributed around a mean time period.

Ordering Between Relations: A relation precedes another, for a given entity. E.g., *personBornYear* should precede *personDiedYear* for a given subject entity (person).

Time Gaps Between Relations: The difference in time instants of two relations (wrt to an entity) is distributed around a mean, e.g., *personDiedYear* minus *personBornYear* has a mean of about 70 with some observed variance.

The first constraint concerns a single relation, whereas the latter two concern pairs of relations. Jiang et al. (2016) attempted to capture relation ordering constraints as model regularization, but their approach does not take into account time differences. Nor does it model relation recurrence.

Basic TIMEPLEX may not be able to learn these constraints from data either, since each time instant is modeled as a separate embedding with *independent* parameters — it has no explicit understanding of the difference between two time instants. In response, we augment TIMEPLEX with additional features that capture how soon an event recurs, or how soon after the occurrence of one relation, another relation is likely to follow. We define two scoring functions ϕ^{Rec} and ϕ^{Pair} for these two cases, to be aggregated with ϕ^{TX} (eqn. 4).

Inspired by García-Durán and Niepert (2018), we model time gaps as drawn from Gaussian distributions. We use $\mathcal{N}(x|\mu, \sigma)$ to denote the probability density of a Gaussian distribution with mean μ and std deviation σ at the time (difference) value x (See Figure 1 (a)). We denote as KB^{tr} all tuples in the train fold.

Recurrence Score: We say that (s, r, o) *recurs* if there are at least two distinct intervals T such that $(s, r, o, T) \in \text{KB}^{\text{tr}}$. If there are at least K^{Rec} distinct pairs (s, o) such that (s, r, o) recurs, then r is considered *recurrent*. K^{Rec} is a hyperparameter.

For each recurrent relation r, our model learns three new parameters: μ_r, σ_r, and b_r. Intuitively, $\mathcal{N}(\cdot|\mu_r, \sigma_r)$ represents a distribution of typical durations between two recurring instances of a relation (with a specific subject and object entity) and b_r is the bias term. For non-recurrent relations, only the bias b_r is learnt. While computing recurrence features, all training tuples of the form (s, r, o, T) are reduced to (s, r, o, t), i.e., with a singleton time interval, where $t = t_b$, the start time of T. TIMEPLEX sets a fact recurrence score, ϕ^{Rec}, as follows:

1. If $(s, r, o, \star) \notin \text{KB}^{\text{tr}}$, set $\phi^{\text{Rec}} = 0$.
2. Else, if r is not recurrent, set $\phi^{\text{Rec}} = b_r$. This allows the model to learn to penalize repetition of relations that do not recur.
3. Find time gap (δ) to its closest recurrence:
$$\delta = \min_{\{(s,r,o,t') \in \text{KB}^{\text{tr}} :\, t' \neq t\}} |t - t'|. \quad (6)$$
Then, set
$$\phi^{\text{Rec}}(s, r, o, T = [t_b, t_e]) =$$
$$\phi^{\text{Rec}}(s, r, o, t_b) = w_r \mathcal{N}\big(\delta|\mu_r, \sigma_r\big) + b_r. \quad (7)$$

The intuition is that ϕ^{Rec} should penalize the proposed (s, r, o, T) if δ is not close to the mean gap μ_r. For example, (Presidential election, held in, USA, 2017) should be penalized, if (Presidential election, held in, USA, 2016) is known, and the event reoccurs every 4 years ($\mu_r = 4, \sigma_r \approx 0$).

Relation Pairs Score: TIMEPLEX also learns soft time constraints between pairs of relations. We describe this mechanism for subjects; objects are handled analogously. For each relation pair (r, r'), we maintain four parameters, $\mu_{rr'}$, $\sigma_{rr'}$, $b_{rr'}$ and $w_{rr'}$, whose purpose we will describe presently. As with recurrence scores, all training tuples (s, r, o, T) are reduced to (s, r, o, t), where $t = t_b$, the start time of T. Given the candidate tuple

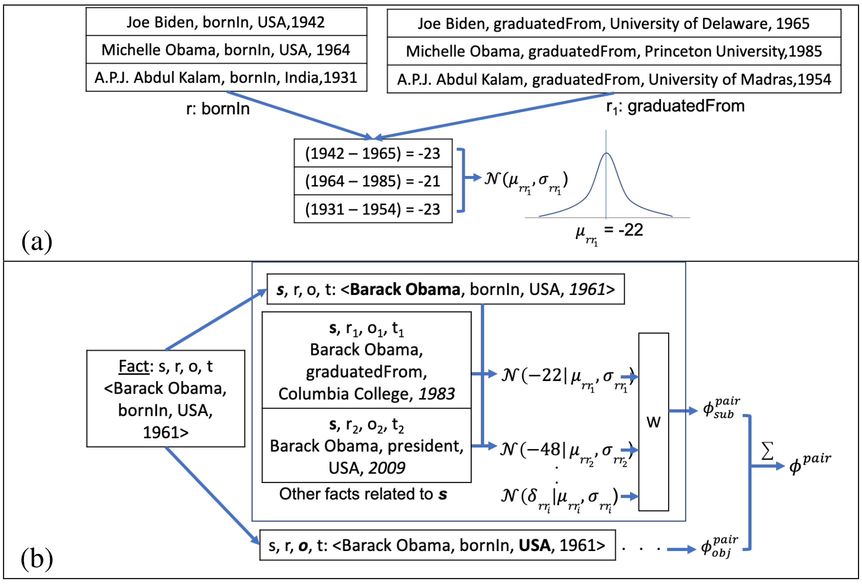

Figure 1: (a) *Pre-training Data Statistics Collection Strategy* for relation pair (bornIn, graduatedFrom). Such statistics are computed for all relation pairs, and (b) *Relation Pair Score Computation* of a fact using the statistics collected in part (a). Here, $\delta_{rr_i} = (t - t_i)$.

(s, r, o, t) to score, we collect fact tuples

$$\{f_i = (s, r_i, o_i, t_i) \in \text{KB}^{\text{tr}}, r_i \neq r\}, \tag{8}$$

$sc(f_i) = \mathcal{N}(t - t_i|\mu_{rr_i}, \sigma_{rr_i}) + b_{rr_i}$ having the same subject but a different relation, into the set called $\text{KB}^{\text{Pair}}(s)$. The i^{th} tuple in $\text{KB}^{\text{Pair}}(s)$ is scored as $sc(f_i) = \mathcal{N}(t - t_i|\mu_{rr_i}, \sigma_{rr_i}) + b_{rr_i}$. This represents the contribution of f_i in the validity of candidate tuple, based on their (signed) time difference, and typical time differences observed between these two relations. $\phi^{\text{Pair}}_{\text{sub}}$ needs to aggregate these over f_i. The (trained) parameter $w_{rr'}$ measures how much the times associated with r' influence our belief in (s, r, o, t). Using these, we define the weighted average

$$\phi^{\text{Pair}}_{\text{sub}}(s, r, o, t) = \sum_{f_i \in \text{KB}^{\text{Pair}}(s)} sc(f_i) \frac{\exp(w_{rr_i})}{\sum_{f_j} \exp(w_{rr_j})}.$$

A similar $\phi^{\text{Pair}}_{\text{obj}}$ score is computed for the object entity, and overall $\phi^{\text{Pair}} = \phi^{\text{Pair}}_{\text{sub}} + \phi^{\text{Pair}}_{\text{obj}}$ (See Figure 1 (b)). The **final scoring function** of TIMEPLEX is

$$\phi(s, r, o, T) = \phi^{TX}(s, r, o, T) + \kappa\phi^{\text{Pair}}(s, r, o, T) + \lambda\phi^{\text{Rec}}(s, r, o, T), \tag{9}$$

where κ and λ are model hyperparameters.

4.3 Training

We train TIMEPLEX in a curriculum of two phases. In the first phase, we optimize embeddings for all entities, relations and time-instants by minimizing the log-likelihood loss using only the base model TX. We compute the probability of predicting a response o for a query $(s, r, ?, T)$ as:

$$\Pr(o|s, r, T) = \frac{\exp(\phi^{TX}(s, r, o, T))}{\sum_{o'} \exp(\phi^{TX}(s, r, o', T))} \tag{10}$$

We can similarly compute $\Pr(s|r, o, T)$ and similar terms for time instant queries, e.g., $\Pr(o|s, r, t)$ and $\Pr(t|s, r, o)$. We then convert every $(s, r, o, T = [t_b, t_e]) \in \text{KB}^{\text{tr}}$ in time-instant format by enumerating all (s, r, o, t), for $t \in [t_b, t_e]$. Training of embeddings minimizes the **log-likelihood loss**:

$$-\sum_{\langle s,r,o,t\rangle \in KB^{\text{tr}}} \Big(\log \Pr(o|s, r, t; \theta) + \log \Pr(s|o, r, t; \theta) + \log \Pr(t|s, r, o; \theta)\Big) \tag{11}$$

In the second phase, we freeze all embeddings and train the parameters of the recurrence and pairs models. Here, too, we use the log-likelihood loss, except that ϕ^{TX} is replaced by the overall ϕ function. Parameters $\mu_{rr'}$ and $\sigma_{rr'}$ of the relation-pairs model component are not trained via backpropagation. Instead, they are fitted separately, using the difference distributions for the pair of relations in the training KB. This improves the overall stability of training.

4.4 Inference

At test time, for a link prediction query, TIMEPLEX ranks all entities in decreasing order of $\Pr(o|s, r, T)$ or $\Pr(s|r, o, T)$ scores. For time prediction, its goal is to output a predicted time duration T^{pr}. We first compute a probability distribution over time instants $\Pr(t|s,r,o) = \frac{\exp(\phi(s,r,o,t))}{\sum_{t'\in\mathfrak{T}}\exp(\phi(s,r,o,t'))}$. We then greedily coalesce time instants to output the best duration. For greedy coalescing, we tune a threshold parameter θ_r for each relation r using the dev fold (such that shorter θ_r prefers short duration and vice versa). We then initialize the predicted interval T^{pr} as $\text{argmax}_t \Pr(t|s,r,o)$. Then, as long as total probability of the interval, i.e., $\sum_{t\in T^{\text{pr}}} \Pr(t|s,r,o)$ is less than θ_r, we extend T^{pr} with the instant to its left or right, whichever has a higher probability.

5 Experiments

We investigate the following research questions. (1) Does TimePlex convincingly outperform the best time-agnostic and time-aware KBC systems on link prediction and time interval prediction tasks? (2) Are recurrent and pairwise features helpful in the final performance? (3) Are TimePlex's time embeddings meaningful, i.e., do they capture the passage of time in an interpretable manner? (4) Do TimePlex predictions honor temporal constraints between relations?

5.1 Datasets & Experimental Setup

Datasets: We report on experiments with four standard TKBC datasets. WIKIDATA12k and YAGO11k (Dasgupta et al., 2018) are two knowledge graphs with a time interval associated with each triple. These contain relational facts like (David Beckham, plays for, Manchester United; [1992, 2003]). ICEWS14 and ICEWS05-15 (García-Durán et al., 2018) are two event-based temporal knowledge graphs, with facts from Integrated Crisis Early Warning System repository. These primarily include political events with timestamps (no nontrivial intervals). We consider the time granularity for interval datasets as 1 year, and for ICEWS datasets as 1 day. See Table 5 in Appendix A for salient statistics of these datasets. By experimenting across the spectrum, from 'point' events to facts with duration, we wish to ensure the robustness of our observations.

García-Durán et al. (2018) also report performance on the Yago15k dataset. However, for this dataset, only 17% of the facts have associated temporal information. In contrast, all the datasets we used had at least 99% of facts with temporal information. Hence, we believe a temporal model will not substantially improve the performance of a time-agnostic model on this dataset. Note that TNT-Complex (Lacroix et al., 2020) also obtained only a slight improvement over a time-agnostic model on Yago15k, supporting our hypothesis. A contemporaneous work by (Ahrabian et al., 2020) proposed new multi-relational temporal Knowledge Graph based on the daily interactions between artifacts in GitHub. We leave exploration of this dataset for future work.

Algorithms compared: We compare against our reimplementations of CX, HyTE, TA-family, and TNT-Complex. In all cases we verify that our implementations give comparable or better scores as reported in literature. We combine HyTE and TA, with scoring functions from TransE, DistMult and CX and present the best results. We also compare against reported results in DE-SimplE.

Experimental Details: For all models, we optimize parameters with AdaGrad running for 500 epochs for all losses, with early stopping on dev fold. We control for an approximately comparable number of parameters and set dimensionality of 200 for all complex embeddings and 400 for all real embeddings. We follow other best practices in the literature, such as L2 regularization only on embeddings used in the current batch (Trouillon et al., 2016), adding inverted facts (o, r^{-1}, s, T) , using 1vsAll negative sampling (Dettmers et al., 2018) whenever applicable, and using temporal smoothing for ICEWS datasets (Lacroix et al., 2020).

Some instances in interval datasets have t_b or t_e missing. Following Dasgupta et al. (2018), we replace missing values by $-\infty$ or $+\infty$, respectively. For time prediction queries, we remove such instances from test sets. For ICEWS datasets we set $t_b = t_e$. For time interval prediction, all models use our greedy coalescing inference from Section 4.4.

For TimePlex, we perform a grid search for all hyperparameters, and pick the best values based on MRR scores on valiations set. Hyperparameters for all datasets are described in Appendix G.

5.2 Results and Observations

Table 2 compares all algorithms for link prediction. We find that the best performing baseline among existing TKBC systems is the recently proposed TNT-Complex model. TimePlex outperforms TNT-Complex by over 3 MRR points in ICEWS datasets. Its gains (3.25 and 5.6 pts) are even more pronounced in interval datasets. All differences are statistically significant using paired t-test with

TIMEPLEX	**20.03**	**26.36**

Table 3: Time prediction performance.

$p < 0.01$. These scores establish a new state of the art for link prediction on all four datasets.

A contemporaneous work, ATiSE (Nayyeri et al., 2020) models KB entities and relations using time dependent Gaussian embedding, but show weaker performance (see Table 2 and Table 11).

We are the first to look at the task of predicting *time intervals*, and we report performance using our novel aeIOU metric (Table 3). We see that TIMEPLEX outperforms TNT-Complex on both datasets, with a huge 11+ pt jump on the Yago11K dataset. It is also noteworthy that even the base model of TIMEPLEX is consistently better than TNT-Complex across all experiments.

On Pair/recurrent features: We find that recurrent features are very helpful in both interval datasets, and significantly improve link prediction performance. Relation pair features particularly help in YAGO11k — over 5 pt aeIOU boost in time prediction, but on WIKIDATA12k they make only a marginal difference. On inspecting the datasets, we find that 78% of entities in WIKIDATA12k are seen with a single, recurring relation (such as *award received*, or *member of sports team*); therefore, relation pair features cannot help.

ICEWS datasets are scraped from news events. On inspecting the datasets, we find that the events do not follow any temporal ordering and are fairly non-regular in event recurrence as well. Hence, TIMEPLEX's improvements over the base model are limited. We further investigate the differing performance on datasets and the value of pair features in the next section.

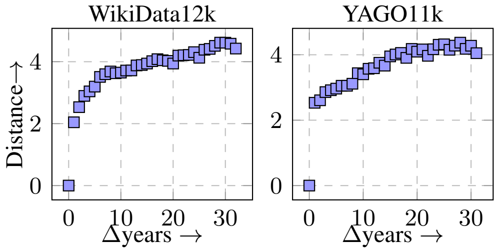

Figure 2: L_2 distances (y-axis) between TIMEPLEX time embeddings increase with time gap (x-axis).

5.3 Diagnostics

Time gap vs. embedding distances: Longevity of relations, or gaps between events, are often determined by physical phenomena that are smooth and continuous in nature. Therefore, we expect the embedding of the year 1904 to be closer to that of 1905 compared to the embedding of, say, 1950.

To validate this hypothesis, we compute mean L2 distance between embeddings of time instants which are apart by a given time gap. To filter noise, we drop instant pairs with extreme gaps that have low support (less than 30). For WIKIDATA12k we used embeddings of years $[1984, 2020]$ and for YAGO11k we use embeddings of years $[1958, 2017]$.

Figure 2 shows that L_2 distance between pairs of time embeddings increases with the actual year gap between them. Since we enumerate all time points in the given fact time-interval, years that are closer share a lot of facts (triples), and are hence closer in the embedding space. This has a smoothing effect on time embeddings. Hence they correlate well with actual time-gaps. This strongly suggests that the time embeddings learnt by TIMEPLEX naturally represent physical time.

Temporal ordering of relation pairs: Both YAGO11k and WIKIDATA12k contain relations with temporal dependencies, e.g., *bornInPlace* should always precede *diedInPlace* for the same

	YAGO11k	WIKIDATA12k
CX	10.04	0.7
HyTE	7.2	0.4
TNT-Complex	8.82	0.3
TIMEPLEX (Base)	6.6	0.3
TIMEPLEX	**1.9**	**0.2**

Table 4: Ordering constraint violations among top predictions of various models (% of facts in test set).

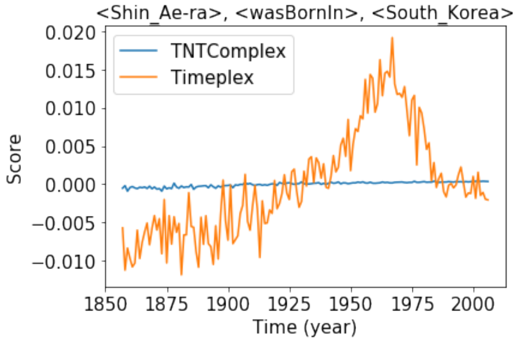

Figure 3: Time prediction comparison for two systems.

person. We now study whether TIMEPLEX models are able to learn these natural constraints from data.

We first exhaustively extract all relation pairs (r_1, r_2), where the existence of both $(s, r_1, \star, t_1)$ and $(s, r_2, \star, t_2)$ is accompanied by $t_1 < t_2$ at least 99% of the time, with a minimum support of 100 entities s.[4] We now verify whether TIMEPLEX honors r_1 before r_2 when making predictions.

For each query $(?, r, o, t)$ in the test set, we check whether the top model prediction violates any known temporal ordering constraint in this list. For example, for a query *(?, **hasWonPrize**, Nobel Prize, **1925**)*, if the model predicted *Barack Obama* and the KB already had Barack Obama born in Hawaii in 1961, then this will be considered as an ordering violation. Table 4 reports the number such violations as fraction of test set size. TIMEPLEX significantly reduces such errors for YAGO11k; this is also reflected in its superior time prediction performance. For WIKIDATA12k, the errors for TIMEPLEX (base) are already low, hence pair features are not found to be particularly helpful.

As an illustrative example, we consider the time prediction query *(Shinae-ra, wasBornIn, South Korea, ?)*, with the gold answer 1969. The only other fact seen for *Shinae-ra* in the train KB is *(Shinae-ra, isMarriedTo, ChaIn-Pyo, (1995, -))*. TIMEPLEX predicts 1967 for this query (earning an aeIOU credit of 33.33). However, TNTComplex predicts 2013 (earning almost no credit) – this also highlights that it does not capture commonsense that a person can marry only after they are born.

To understand further, we plot the normalized scores for this query in time range $[1850, 2010]$ in Figure 3. The peak around 1967 for the TIMEPLEX plot can be attributed to the fact that mean difference for *isMarriedTo* and *wasBornIn* relations is around 30 in the dataset. Standard tensor factorization models like TNT-Complex are unable to exploit this, but our Pair features provide a way to the model to make very reasonable predictions. Other similar plots can be found in the Appendix.

6 Discussion

TIMEPLEX cannot exploit the influence that an entity can have on time difference distributions. For example, the life expectancy of a person (mean difference between *diedIn* and *bornIn* events) would be around 85 in Japan, but 54 in Lesotho. Extending our model to learn separate parameters for each ⟨rel, entity⟩ pair may be difficult due to sparsity. Also, recurrent facts may admit exceptions: Winter Olympics are held every 4 years except for 1992 and 1994. However, we do not expect even humans to do well in such cases. Exceptions like these are sparse and difficult to learn, except by rote.

7 Conclusion

We presented TIMEPLEX, a new TKBC framework, which combines representations of time with representations of entities and relations. It also learns soft temporal consistency constraints, which allow knowledge of one temporal fact to influence belief in another fact. TIMEPLEX exceeds the performance of existing TKBC systems. Time embeddings are temporally meaningful, and TIMEPLEX makes fewer temporal consistency and ordering mistakes. We also argue that current evaluation schemes for both link and time prediction have limitations, and propose more meaningful schemes.

Temporal Knowledge Base Completion:
New Algorithms and Evaluation Protocols
(Appendix)

A Dataset statistics

See Table 5 for some salient statistics of the datasets we used for experiments. Yago11k and Wikidata12k are interval based datasets. ICEWS14 and ICEWS05-15 are instant based datasets.

B Discussion on time evaluation metrics

We re-state the desired property P for a time evaluation metric-
Let $\text{vol}(T^{\text{ev}} \cap T^{\text{pr}_1}) = \text{vol}(T^{\text{ev}} \cap T^{\text{pr}_2})$ $M(T^{\text{ev}}, T^{\text{pr}_1}) > M(T^{\text{ev}}, T^{\text{pr}_2})$ if and only if $\text{vol}(T^{\text{ev}} \Cup T^{\text{pr}_1}) < \text{vol}(T^{\text{ev}} \Cup T^{\text{pr}_2})$.

aeIOU satisfies P:
For a fixed $\text{vol}(T^{\text{ev}} \cap T^{\text{pr}})$, we have $\text{aeIOU}(T^{\text{ev}}, T^{\text{pr}}) \propto 1/\text{vol}(T^{\text{ev}} \Cup T^{\text{pr}})$ (see Eqn 3). Hence, aeIOU satisfies property P.

IoU and gIOU do not satisfy P:
IoU: This metric gives 0 score to a model, if model's predicted interval does not intersect with the gold, irrespective of the hull. Hence IoU do not satisfy property P.
gIoU: Let us look at the following example. Suppose gold interval is [2002,2005], and consider 2 predictions- [1999,2001] and [1900,2001]. For both predictions, $\text{vol}((T^{\text{ev}} \Cup T^{\text{pr}}) \setminus (T^{\text{ev}} \cup T^{\text{pr}}))$ is zero, so the hull for the two predictions will be ignored (see Eqn 2), resulting in same scores for both predictions. Hence gIoU does not satisfy property P.

Model Performance with respect to various time evaluation metrics:
Table 6 reports the TAC, gIOU, and IOU scores of various temporal methods discussed in the paper.

C Temporal Constraints: Relation Ordering

Table 7 and 8 lists automatically extracted high confidence relation orderings seen in Yago11k and Wikidata12k datasets respectively. These orderings are used to guide TimePlex at the time of training.

D Time prediction performance across relation classes

Instant relations include *wasBornIn, diedIn, hasWonPrize*, which are events that don't span an interval.
Short relations include *graduatedFrom, playsFor* whose duration averages less than 5 years.
Long relations include *isMarriedTo, isAffiliatedTo* whose duration averages more than 5 years.

E Comparison of filtering methods

In Table 11, we report the performance of most competitive baseline and TimePlex, the reported performance use a filtering strategy that does not enumerate time points in an interval and filters out entities on exact matching time-interval. Note that our model consistently outperforms TNT-Complex, even with a stricter filtering.

F Ablation Study

In this study, we remove each component of TimePlex (see equation 9) by making either κ=0 or λ=0, to understand the importance of each component (see Table 12).

G Details of Hyperparameters and Model training

All models are trained on a single NVIDIA Tesla K40 GPU. Our final model TimePlex consist of a base model and two time-based gadgets.
TimePlex*(base)* takes less than 10 minutes to train on all datasets except for ICEWS05-15, where it takes 80 minutes. Table 10 lists best hyperparameters of TimePlex(base) on respective dataset.
Both gadgets are trained independently in less than 10 minutes. The parameter λ=5.0 gave best results for interval datasets, while λ=1.0 gave best results on event datasets. On Yago11k κ=3.0, while for rest κ=0.0. The gadget weights are L2 regularized, with a regularization penalty of 0.002. The model use 100 negative samples per correct fact for training.

H Model parameters

The number of parameters for the TimePlexand baseline models are compared in Table 13.

I Training details of TimePlex, HyTE

Each dataset spans along a *time range*, with a certain *time granularity*, which can be year, month or day. TimePlex learns a time embedding for every point in this time range, discretized on the basis of the dataset's granularity (years for the interval datasets WIKIDATA12k and YAGO11k, and days for ICEWS datasets). At training time, TimePlex looks at a single time point at a time - for this, we sample a time point uniformly at random from the query interval $[t_b, t_e]$ associated with the fact. In contrast, HyTE maps each time point to bin (heuristically determined), making the data granularity coarser, and learns representation of these bins. HyTE looks at time points in an interval as well, but enumerates each interval fact to produce a separate fact for each time point beforehand.

Our method of sampling is efficient as the data size is unchanged. It also ensures each fact is sampled uniformly, not hurting link prediction performance by oversampling of long duration facts.

HyTE time prediction: HyTE can only predict a bin for the test fact. To convert predicted bins to years (or days), we take a mean of all years seen with the predicted bin and then do greedy coalescing to output time interval in years.

J More diagnostics

We plot the normalized scores of TimePlex, TimePlex(base), and TNTComplex for different time queries in time range $[1850, 2010]$ in Table 14. Figure (a) highlights how TNTComplex model fails to learn that one cannot marry before birth. Figure (b) shows how with the limited background knowledge on the subject in question, TimePlex can predict the gold time-interval.

	Learning Rate	**Reg wt**	**Batch size**	**Temporal smoothing**	α	β	γ

Table 10: Hyperparameters for training TIMEPLEX(base) model embeddings on various datasets, tuned on MRR for validation set. Temporal smoothing was found to help on ICEWS datasets, however it gave no improvement for interval datasets. We tuned the parameters in a staged manner - first we tune learning rate (lr), regularization weight (r), batch size(b), and temporal smoothing weight (ts). We performed a random search in the following ranges: $lr \in [0.0001, 1.0]$, $r \in [0.0001, 1.0]$, $b \in [100, 5000]$, and $ts \in [0.0001, 10.0]$. The models were most sensitive to regularization weight and learning rate. After finding best values for these parameters, we tuned α, β and γ weights for each dataset, doing a grid search over the set {0.0, 2.0, 5.0, 7.0, 10.0}

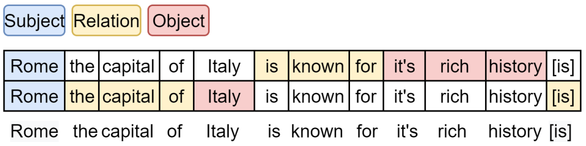
Abstract

A recent state-of-the-art neural open information extraction (OpenIE) system generates extractions iteratively, requiring repeated encoding of partial outputs. This comes at a significant computational cost. On the other hand, sequence labeling approaches for OpenIE are much faster, but worse in extraction quality. In this paper, we bridge this trade-off by presenting an iterative labeling-based system that establishes a new state of the art for OpenIE, while extracting 10× faster. This is achieved through a novel Iterative Grid Labeling (IGL) architecture, which treats OpenIE as a 2-D grid labeling task. We improve its performance further by applying coverage (soft) constraints on the grid at training time.

Moreover, on observing that the best OpenIE systems falter at handling coordination structures, our OpenIE system also incorporates a new coordination analyzer built with the same IGL architecture. This IGL based coordination analyzer helps our OpenIE system handle complicated coordination structures, while also establishing a new state of the art on the task of coordination analysis, with a 12.3 pts improvement in F1 over previous analyzers. Our OpenIE system, **OpenIE6**[1], beats the previous systems by as much as 4 pts in F1, while being much faster.

1 Introduction

Open Information Extraction (OpenIE) is an ontology-free information extraction paradigm that generates extractions of the form *(subject; relation; object)*. Built on the principles of domain-independence and scalability (Mausam, 2016), OpenIE systems extract open relations and arguments from the sentence, which allow them to be used for a wide variety of downstream tasks like Question Answering (Yan et al., 2018; Khot et al., 2017), Event Schema Induction (Balasubramanian et al., 2013) and Fact Salience (Ponza et al., 2018).



Rome	the	capital	of	Italy	is	known	for	it's	rich	history	[is]
Rome	the	capital	of	Italy	is	known	for	it's	rich	history	[is]
Rome	the	capital	of	Italy	is	known	for	it's	rich	history	[is]

Figure 1: The extractions *(Rome; [is] the capital of; Italy)* and *(Rome; is known for; it's rich history)* can be seen as the output of grid labeling. We additionally introduce a token *[is]* to the input.

End-to-end neural systems for OpenIE have been found to be more accurate compared to their non-neural counterparts, which were built on manually defined rules over linguistic pipelines. The two most popular neural OpenIE paradigms are *generation* (Cui et al., 2018; Kolluru et al., 2020) and *labeling* (Stanovsky et al., 2018; Roy et al., 2019).

Generation systems generate extractions one word at a time. IMoJIE (Kolluru et al., 2020) is a state-of-the-art OpenIE system that re-encodes the partial set of extractions output thus far when generating the next extraction. This captures dependencies among extractions, reducing the overall redundancy of the output set. However, this repeated re-encoding causes a significant reduction in speed, which limits use at Web scale.

On the other hand, *labeling*-based systems like RnnOIE (Stanovsky et al., 2015) are much faster (150 sentences per second, compared to 3 sentences of IMoJIE) but relatively less accurate. They label each word in the sentence as either *S* (Subject), *R* (Relation), *O* (Object) or *N* (None) for each extraction. However, as the extractions are predicted independently, this does not model the inherent dependencies among the extractions.

We bridge this trade-off though our proposed

Table 1: For the given sentence, IGL based OpenIE extractor produces an incomplete extraction. Constraints improve the recall by covering the remaining words. Coordination Analyzer handles hierarchical conjunctions.

OpenIE system that is both fast and accurate. It consists of an OpenIE extractor based on a novel iterative labeling-based architecture — **I**terative **G**rid **L**abeling (**IGL**). Using this architecture, OpenIE is modeled as a 2-D grid labeling problem of size (M, N) where M is a pre-defined maximum number of extractions and N is the sentence length, as shown in Figure 1. Each extraction corresponds to one row in the grid. Iterative assignment of labels in the grid helps IGL capture dependencies among extractions without the need for re-encoding, thus making it much faster than generation-based approaches.

While IGL gives high precision, we can further improve recall by incorporating (soft) global coverage constraints on this 2-D grid. We use constrained training (Mehta et al., 2018) by adding a penalty term for all constraint violations. This encourages the model to satisfy these constraints during inference as well, leading to improved extraction quality, without affecting running time.

Furthermore, we observe that existing neural OpenIE models struggle in handling coordination structures, and do not split conjunctive extractions properly. In response, we first design a new coordination analyzer (Ficler and Goldberg, 2016b). It is built with the same IGL architecture, by interpreting each row in the 2-D grid as a coordination structure. This leads to a new state of the art on this task, with a 12.3 pts improvement in F1 over previous best reported result (Teranishi et al., 2019), and a 1.8 pts gain in F1 over a strong BERT baseline.

We then combine the output of our coordination analyzer with our OpenIE extractor, resulting in a further increase in performance (Table 1). Our final OpenIE system — OpenIE6 — consists of IGL-based OpenIE extractor (trained with constraints) and IGL-based coordination analyzer. We evaluate OpenIE6 on four metrics from the literature and find that it exceeds in three of them by at least 4.0 pts in F1. We undertake manual evaluation to reaffirm the gains. In summary, this paper describes OpenIE6, which

- is based on our novel IGL architecture,
- is trained with constraints to improve recall,
- handles conjunctive sentences with our new state-of-art coordination analyzer, which is 12.3 pts better in F1, and
- is 10× faster compared to current state of the art and improves F1 score by as much as 4.0 pts.

2 Related Work

Banko et al. (2007) introduced the Open Information Extraction paradigm (OpenIE) and proposed TextRunner, the first model for the task. Following this, many statistical and rule-based systems have been developed (Fader et al., 2011; Etzioni et al., 2011; Christensen et al., 2011; Mausam et al., 2012; Del Corro and Gemulla, 2013; Angeli et al., 2015; Pal and Mausam, 2016; Stanovsky et al., 2016; Saha et al., 2017; Gashteovski et al., 2017; Saha and Mausam, 2018; Niklaus et al., 2018).

Recently, supervised neural models have been proposed, which are either trained on extractions bootstrapped from earlier non-neural systems (Cui et al., 2018), or on SRL annotations adapted for OpenIE (Stanovsky and Dagan, 2016). These systems are primarily of three types, as follows.

Labeling-based systems like RnnOIE (Stanovsky et al., 2018), and SenseOIE (Roy et al., 2019) identify words that can be syntactic heads of relations, and, for each head word, perform a single labeling to get the extractions. Jiang et al. (2020) extend these to better calibrate confidences across sentences. *Generation-based* systems (Cui et al., 2018; Sun et al., 2018) generate extractions sequentially using seq2seq models. IMoJIE (Kolluru et al., 2020), the current state of art in OpenIE, uses a BERT-based encoder and an iterative decoder that re-encodes the extractions generated so far. This re-encoding captures dependencies between extractions, increasing overall performance, but also makes it 50x slower than RnnOIE. Recently, *span-based* models (Jiang et al., 2020) have been proposed, e.g., SpanOIE (Zhan and Zhao, 2020), which uses a predicate module to first choose potential candidate relation spans, and for each relation span, classifies all possible spans of the sentence as subject or object.

Concurrent to our work (Ro et al., 2020) proposed Multi^{2}OIE, a sequence-labeling model for OpenIE, which first predicts all the relation arguments using BERT, and then predicts subject and object arguments associated with each relation using multi-head attention blocks. Their model cannot handle nominal relations and conjunctions in arguments, which can be extracted in our iterative labeling scheme.

OpenIE Evaluation: Several datasets have been proposed to automatically evaluate OpenIE systems. OIE2016 (Stanovsky and Dagan, 2016) introduced an automatically generated reference set of extractions, but it was found to be too noisy with significant missing extractions. Re-OIE2016 (Zhan and Zhao, 2020) manually re-annotated the corpus, but did not handle conjunctive sentences adequately. Wire57 (Léchelle et al., 2018) contributed high-quality expert annotations, but for a small corpus of 57 sentences. We use the CaRB dataset (Bhardwaj et al., 2019), which re-annotated OIE2016 corpus via crowd-sourcing.

The benchmarks also differ in their scoring functions along two dimensions: (1) computing similarity for each (gold, system) extraction pair, (2) defining a mapping between system and gold extractions using this similarity. OIE16 computes similarity by serializing the arguments into a sentence and finding the number of matching words. It maps each system extraction to one gold (one-to-one mapping) to compute both precision and recall. Wire57 uses the same one-to-one mapping but computes similarity at an argument level. CaRB uses one-to-one mapping for precision but maps multiple gold to the same system extraction (many-to-one mapping) for recall. Like Wire57, CaRB computes similarity at an argument level.

OpenIE for Conjunctive Sentences: Performance of OpenIE systems can be further improved by identifying coordinating structures governed by conjunctions (e.g., ‘and’), and splitting conjunctive extractions (see Table 1). We follow CalmIE (Saha and Mausam, 2018), which is part of OpenIE5 system – it splits a conjunctive sentence into smaller sentences based on detected coordination boundaries, and runs OpenIE on these split sentences to increase overall recall.

For detecting coordination boundaries, Ficler and Goldberg (2016a) re-annotate the Penn Tree Bank corpus with coordination-specific tags. Neural parsers trained on this data use similarity and replacability of conjuncts as features (Ficler and Goldberg, 2016b; Teranishi et al., 2017). The current state-of-the-art system (Teranishi et al., 2019) independently detects coordinator, begin, and end of conjuncts, and does joint inference using Cocke–Younger–Kasami (CYK) parsing over context-free grammar (CFG) rules. Our end-to-end model obtains better accuracy than this approach.

	w_1	w_2	w_3	w_4	w_5	w_6	w_7	w_8	st_1	st_2	st_3

Figure 2: 2-D grid for OpenIE with extraction as rows and words as columns. The values represent the labels (S)ubject, (R)elation, (O)bject. The empty cells represent (N)one. Constraints are applied across rows (**HVE**) and columns (**POSC**).

Constrained Training: Constraining outputs of the model is a way to inject prior knowledge into deep neural networks (Hu et al., 2016; Xu et al., 2018; Nandwani et al., 2019). These constraints can be applied either during training or inference or both. We follow Mehta et al. (2018), which models an output constraint as a differentiable penalty term defined over output probabilities given by the network. This penalty is combined with the original loss function for better training.

Bhutani et al. (2019) propose an OpenIE system to get extractions from question-answer pairs. Their decoder enforces vocabulary and structural constraints on the output both during training and inference. In contrast, our system uses constraints only during training.

3 Iterative Grid Labeling for OpenIE

Given a sentence with word tokens $\{w_1, w_2, \ldots, w_N\}$ the task of OpenIE is to output a set of extractions, say $\{E_1, E_2, \ldots, E_M\}$,

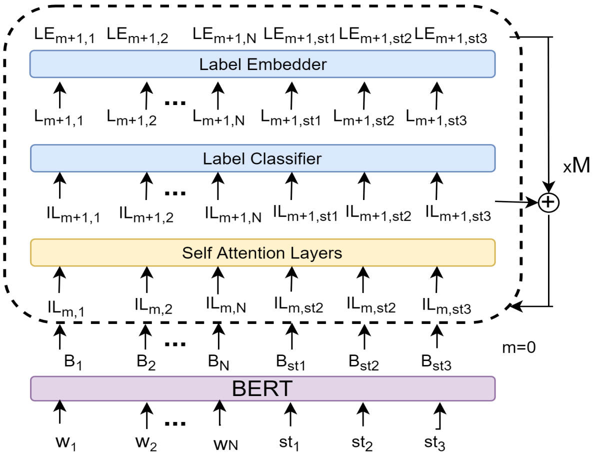

Figure 3: Model architecture for IGL. BERT-embeddings of the words are iteratively passed through self-attention layers. st_1, st_2, st_3 refer to the appended tokens *[is]*, *[of]*, *[from]*, respectively. At every iteration, we get an extraction by labeling the words using a fully-connected layer. Embeddings of the generated labels are added to the iterative layer embeddings before passing them to the next iteration.

where each extraction is of the form *(subject; relation; object)*. For a labeling-based system, each word is labeled as *S* (Subject), *R* (Relation), *O* (Object), or *N* (None) for every extraction. We model this as a 2-D grid labeling problem of size (M, N), where the words represent the columns and the extractions represent the rows (Figure 2). The output at position (m, n) in the grid $(L_{m,n})$ represents the label assigned to the n^{th} word in the m^{th} extraction.

We propose a novel **I**terative **G**rid **L**abeling (IGL) approach to label this grid, filling up one row after another iteratively. We refer to the OpenIE extractor trained using this approach as IGL-OIE.

IGL-OIE is based on a BERT encoder, which computes contextualized embeddings for each word. The input to the BERT encoder is $\{w_1, w_2, \ldots, w_N,$ *[is]*, *[of]*, *[from]*$\}$. The last three tokens (referred as st_i in Figure 3) are appended because, sometimes, OpenIE is required to predict tokens that are not present in the input sentence.[2] E.g., "*US president Donald Trump gave a speech on Wednesday.*" will have one of the extractions as *(Donald Trump; [is] president [of]; US)*. The appended tokens make such extractions possible in a labeling framework.

The contextualized embeddings for each word or appended token are iteratively passed through a 2-layer transformer to get their *IL embeddings* at different levels, until a maximum level M, i.e. a word w_n has a different contextual embedding $IL_{m,n}$ for every row (level) m. At every level m, each $IL_{m,n}$ is passed though a fully-connected labeling layer to get the labels for words at that level (Figure 3). Embeddings of the predicted labels are added to the *IL embeddings* before passing them to the next iteration. This, in principle, maintains the information of the extractions output so far, and hence can capture dependencies among labels of different extractions. For words that were broken into word-pieces by BERT, only the embedding of the first word-piece is retained for label prediction. We sum the cross-entropy loss between the predicted labels and the gold labels at every level to get the final loss, denoted by J_{CE}.

OpenIE systems typically assign a confidence value to an extraction. In IGL, at every level, the respective extraction is assigned a confidence value by adding the log probabilities of the predicted labels (*S*, *R*, and *O*), and normalizing this by the extraction length.

We believe that IGL architecture has value beyond OpenIE, and can be helpful in tasks where a set of labelings for a sentence is desired, especially when labelings have dependencies amongst them.[3] We showcase another application of IGL for the task of coordination analysis in Section 5.

4 Grid Constraints

Our preliminary experiments revealed that IGL-OIE has good precision, but misses out important extractions. In particular, we observed that the set of output extractions did not capture all the information from the sentence (Table 1). We formulate constraints over the 2-D grid of extractions (as shown in Figure 2) which act as an additional form of supervision to improve the coverage. We implement these as soft constraints, by imposing additional violation penalties in the loss function. This biases the model to learn to satisfy the constraints, without explicitly enforcing them at inference time.

To describe the constraints, we first define the notion of a *head verb* as all verbs except light verbs (do, be, is, has, etc.). We run a POS tagger on the input sentence, and find all head verbs in the sentence by removing all light verbs.[4] For example,

---

[2] 'is', 'of' and 'from' are the most frequent such tokens.

[3] IGL is a generalization of Ju et al. (2018). Their model can only label spans which are subsets of one another.

[4] We used the light verbs listed by Jain and Mausam (2016).

L2:	Jeff	founded	Amazon	and	Blue	Origin	and	invested	in	Google	,	Grail	and	ZocDoc

Figure 4: The final OpenIE system. IGL-CA identifies conjunct boundaries by labeling a 2-D grid. This generates simple sentences and CIGL-OIE emits the final extractions.

for the sentence, *"Obama gained popularity after Oprah endorsed him for the presidency"*, the head verbs are *gained* and *endorsed*. In order to cover all valid extractions like *(Obama; gained; popularity)* and *(Oprah; endorsed him for; the presidency)*, we design the following coverage constraints:

- *POS Coverage* (**POSC**): All words with POS tags as nouns (N), verbs (V), adjectives (JJ), and adverbs (RB) should be part of at least one extraction. E.g. the words *Obama*, *gained*, *popularity*, *Oprah*, *endorsed*, *presidency* must be covered in the set of extractions.
- *Head Verb Coverage* (**HVC**): Each head verb should be present in the relation span of some (but not too many) extractions. E.g. *(Obama; gained; popularity)*, *(Obama; gained; presidency)* is not a comprehensive set of extractions.
- *Head Verb Exclusivity* (**HVE**): The relation span of one extraction can contain at most one head verb. E.g. *gained popularity after Oprah endorsed* is not a good relation as it contains two head verbs.
- *Extraction Count* (**EC**): The total number of extractions with head verbs in the relation span must be no fewer than the number of head verbs in the sentence. In the example, there must be at least two extractions containing head verbs, as the sentence itself has two head verbs.

Notation: We now describe the penalty terms for these constraints. Let p_n be the POS tag of w_n. We define an indicator $x_n^{imp} = 1$ if $p_n \in \{\text{N, V, JJ, RB}\}$, and 0 otherwise. Similarly, let $x_n^{hv} = 1$ denote that w_n is a head verb. At each extraction level m, the model computes $Y_{mn}(k)$, the probability of assigning the n^{th} word the label $k \in \{\text{S, R, O, N}\}$. We formulate the penalties associated with our constraints as follows:

- **POSC** - To ensure that the n^{th} word is covered, we compute its maximum probability ($posc_n$) of belonging to any extraction. We introduce a penalty if this value is low. This penalty is aggregated over words with important POS tags, $J_{posc} = \sum_{n=1}^{N} x_n^{imp} \cdot posc_n$, where
$$posc_n = 1 - \max_{m\in[1,M]} \left(\max_{k\in\{\text{S,R,O}\}} Y_{mn}(k) \right)$$
- **HVC** - A penalty is imposed for the n^{th} word, if it is not present in relation of any extraction or if it is present in relation of many extractions. This penalty is aggregated over head verbs, $J_{hvc} = \sum_{n=1}^{N} x_n^{hv} \cdot hvc_n$, where $hvc_n = \left|1 - \sum_{m=1}^{M} Y_{mn}(R)\right|$.
- **HVE** - A penalty is imposed if the relation span of an extraction contains more than one head verb. This penalty is summed over all extractions. I.e., $J_{hve} = \sum_{m=1}^{M} hve_m$, where
$$hve_m = \max\left(0, \left(\sum_{n=1}^{N} x_n^{hv} \cdot Y_{mn}(R)\right) - 1\right)$$
- **EC** - ec_m denotes the score $\in [0, 1]$ of the m^{th} extraction containing a head verb, i.e. $ec_m = \max_{n\in[1,N]} \left(x_n^{hv} \cdot Y_{mn}(R)\right)$. A penalty is imposed if the sum of these scores is less than the actual number of head verbs in the sentence.
$$J_{ec} = \max\left(0, \sum_{n=1}^{N} x_n^{hv} - \sum_{m=1}^{M} ec_m\right)$$

Ideally, no constraint violations of **HVC** and **HVE** would imply that **EC** would also never gets violated. However, as these are soft constraints, this scenario is never materialized in practice. We find that our model performs better and results in fewer constraint violations when trained with **POSC**, **HVC**, **HVE** and **EC** combined. The full loss function is $J = J_{CE} + \lambda_{posc} J_{posc} + \lambda_{hvc} J_{hvc} + \lambda_{hve} J_{hve} + \lambda_{ec} J_{ec}$, where $\lambda_{\star}$ are hyperparameters. We refer to the OpenIE extractor trained using this constrained loss as Constrained Iterative Grid Labeling OpenIE Extractor (CIGL-OIE).

The model is initially trained without constraints for a fixed *warmup* number of iterations, followed by constrained training till convergence.

5 Coordination Boundary Detection

Coordinated conjunctions (CC) are conjunctions such as *"and"*, *"or"* that connect, or coordinate words, phrases, or clauses (they are called the conjuncts). The goal of coordination analysis is to detect coordination structures — the coordinating conjunctions along with their constituent conjuncts. In this section we build a novel coordination analyzer and use its output downstream for OpenIE.

Sentences can have hierarchical coordinations, i.e., some coordination structures nested within the conjunct span of others (Saha and Mausam, 2018). Therefore, we pose coordination analysis as a hierarchical labeling problem, as illustrated in Figure 4. We formulate a 2-D grid labeling problem, where all coordination structures at the same hierarchical level are predicted in the same row.

Specifically, we define a grid of size (M, N), where M is the maximum depth of hierarchy and N is the number of words in the sentence. The value at $(m, n)^{th}$ position in the grid represents the label assigned to the n^{th} word in the m^{th} hierarchical level, which can be *CC* (coordinated conjunction), *CONJ* (belonging to a conjunct span), or *N* (None). Using IGL architecture for this grid gives an end-to-end Coordination Analyzer that can detect multiple coordination structures, with two or more conjuncts. We refer to this Coordination Analyzer as IGL-CA.

Coordination Analyzer in OpenIE: Conjuncts in a coordinate structure exhibit *replaceability* – a sentence is still coherent and consistent, if we replace a coordination structure with any of its conjuncts (Ficler and Goldberg, 2016b). Following CalmIE's approach, we generate simple (non-conjunctive) sentences using IGL-CA. We then run CIGL-OIE on these simple sentences to generate extractions. These extractions are de-duplicated and merged to yield the final extraction set (Figure 4). This pipelined approach describes our final OpenIE system — **OpenIE6**.

For a conjunctive sentence, CIGL-OIE's confidence values for extractions will be with respect to multiple simple sentences, and may not be calibrated across them. We use a separate confidence estimator, consisting of a BERT encoder and an LSTM decoder trained on (sentence, extraction) pairs. It computes a log-likelihood for every extraction w.r.t. the original sentence — this serves as a better confidence measure for OpenIE6.

6 Experimental Setup

We train OpenIE6 using the OpenIE4 training dataset used to train IMoJIE[5]. It has 190,661 extractions from 92,774 Wikipedia sentences. We convert each extraction to a sequence of labels over the sentence. This is done by looking for an exact string match of the words in the extraction with the sentence. In case there are multiple string matches for one of the arguments of the extraction, we choose the string match closest to the other arguments. This simple heuristic covers almost 95% of the training data. We ignore the remaining extractions that have multiple string matches for more than one argument.

We implement our models using Pytorch Lightning (Falcon, 2019). We use pre-trained weights of "BERT-base-cased"[6] for OpenIE extractor and "BERT-large-cased"[6] for coordination analysis. We do not use BERT-large for OpenIE extractor as we observe almost same performance with a significant increase in computational costs. We set the maximum number of iterations, M=5 for OpenIE and M=3 for Coordination Analysis. We use the SpaCy POS tagger[7] for enforcing constraints. The various hyper-parameters used are mentioned in Appendix B.

Comparison Systems: We compare OpenIE6 against several recent neural and non-neural systems. These include generation (IMoJIE and Cui et al. (2018)[8]), labeling (RnnOIE, SenseOIE) and span-based (SpanOIE) systems. We also compare against non-neural baselines of MinIE (Gashteovski et al., 2017), ClausIE (Del Corro and Gemulla, 2013), OpenIE4 (Christensen et al., 2011)[9] and OpenIE5 (Saha et al., 2017; Saha and Mausam, 2018).[10] We use open-source implementations for all systems except SenseOIE, for which the code is not available and we use the system output provided by the authors.

Evaluation Dataset and Metrics: We evaluate all systems against CaRB's reference extractions, as they have higher coverage and quality compared to other datasets. Apart from CaRB's scoring function, we also use scoring functions of OIE16 and

OpenIE4	51.6	29.5	40.5	20.1	54.3	37.1	34.4	20.1
OpenIE5	48.0	25.0	42.7	20.6	59.9	39.9	35.4	3.1
SenseOIE	28.2	-	23.9	-	31.1	-	10.7	-
SpanOIE	48.5	-	37.9	-	54.0	-	31.9	19.4
RnnOIE	49.0	26.0	39.5	18.3	56.0	32.0	26.4	**149.2**
(Cui et al., 2018)	51.6	32.8	38.7	19.8	53.5	37.0	33.3	11.5
IMoJIE	53.5	33.3	41.4	22.2	56.8	39.6	36.0	2.6
IGL-OIE	52.4	33.7	41.1	22.9	55.0	36.0	34.9	142.0
CIGL-OIE	**54.0**	**35.7**	42.8	24.6	59.2	40.0	36.8	142.0
CIGL-OIE + IGL-CA (OpenIE6)	52.7	33.7	**46.4**	**26.8**	**65.6**	**48.4**	**40.0**	31.7

Table 2: Evaluation of OpenIE. Using constrained learning, CIGL-OIE gives better scores on all metrics compared to IMoJIE. Adding a coordination analyzer, CIGL-OIE + IGL-CA (OpenIE6) gives the best scores in 3 of the 4 metrics. MinIE, SenseOIE, SpanOIE do not output confidences. Code of SenseOIE is not available to compute speed.

System	Precision	Yield	Total Extrs
CIGL-OIE	77.9	131	174
OpenIE6	**78.8**	**222**	**291**

Table 3: Manual comparison of Precision and Yield on 100 random conjunctive sentences from CaRB Gold.

Wire57 benchmarks on the CaRB reference set, which we refer to as *OIE16-C* and *Wire57-C*. Additionally we use *CaRB(1-1)*, a variant of CaRB that retains CaRB's similarity computation, but uses a one-to-one mapping for both precision and recall (similar to OIE16-C, Wire57-C).

For each system, we report a final F1 score using precision and recall computed by these scoring functions. OpenIE systems typically associate a confidence value with each extraction, which can be varied to generate a precision-recall (P-R) curve. We also report the area under P-R curve (AUC) for all scoring functions except Wire57-C, as its matching algorithm is not naturally compatible with P-R curves. We discuss details of these four metrics in Appendix A.

For determining the speed of a system, we analyze the number of sentences it can process per second. We run all the systems on a common set of 3,200 sentences (Stanovsky et al., 2018), using a V100 GPU and 4 cores of Intel Xeon CPU (the non-neural systems use only the CPU).

7 Experiments and Results

7.1 Speed and Performance

How does OpenIE6 compare in speed and performance?

Table 2 reports the speed and performance comparisons across all metrics for OpenIE. We find that the base OpenIE extractor — IGL-OIE — achieves a 60× speed-up compared to IMoJIE, while being lower in performance by 1.1 F1, and better in AUC by 0.4 pts, when using CaRB scoring function.

We find that training IGL-OIE along with constraints (CIGL-OIE), helps to improve the performance without affecting inference time. This system is better than all previous systems over all the considered metrics. It beats IMoJIE by (0.5, 2.4) in CaRB (F1, AUC) and 0.8 F1 in Wire57-C.

Further, adding the coordination analyzer module (IGL-CA) gives us OpenIE6, which is 10× faster than IMoJIE (32 sentences/sec) and achieves significant improvements in performance in 3 of the 4 metrics considered. It improves upon IMoJIE in F1 by 5.0, 8.8, 4.0 pts in CaRB(1-1), OIE16-C and Wire57-C, respectively. However, in the CaRB metric, adding this module leads to a decrease of (1.5, 0.9) pts in (F1, AUC).

On closer analysis, we notice that the current scoring functions for OpenIE evaluation do not handle conjunctions properly. CaRB over-penalizes OpenIE systems for incorrect coordination splits whereas other scoring functions under-penalize them. This is also evidenced in the lower CaRB scores of for both OpenIE-5[11] (vs. OpenIE4) and

---

[11] OpenIE5 uses CalmIE for conjunctive sentences.

System	Wire57-C	CaRB		Constraint Violations					Num. of Extrs
	F1	F1	AUC	POSC	HVC	HVE	EC	HVC+HVE+EC	
IMoJIE	36.0	53.5	33.3	687	521	105	330	957	1354
IGL-OIE	34.9	52.4	33.7	1494	375	**128**	284	787	1401
IGL-OIE (POSC)	36.7	49.6	33.4	**396**	303	200	**243**	746	**1577**
IGL-OIE (HVC,HVE,EC)	35.8	53.2	32.7	1170	295	144	246	**655**	1509
CIGL-OIE	**36.8**	**54.0**	**35.7**	766	**274**	157	237	668	1531
Gold	100	100	100	371	324	272	224	820	2714

Table 4: Performance and number of constraint violations for training with different sets of constraints. CIGL-OIE represents training IGL architecture based OpenIE extractor with all the constraints - POSC, HVC, HVE and EC

OpenIE6 (vs. CIGL-OIE) — the two systems that focus on conjunctive sentences. We trace this issue to the difference in mapping used for recall computation (one-to-one vs many-to-one). We refer the reader to Appendix A.3 for a detailed analysis of this issue.

To resolve this variation in different scoring functions, we undertake a manual evaluation. Two annotators (authors of the paper), blind to the underlying systems (CIGL-OIE and OpenIE6), independently label each extraction as correct or incorrect for a subset of 100 conjunctive sentences. Their inter-annotator agreement is 93.46% (See Appendix C for details of manual annotation setup). After resolving the extractions where they differ, we report the precision and yield in Table 3. Here, yield is the number of correct extractions generated by a system. It is a surrogate for recall, since its denominator, number of all correct extractions, is hard to annotate for OpenIE.

We find that OpenIE6 significantly increases the yield (1.7×) compared to CIGL-OIE along with a marginal increase in precision. This result underscores the importance of splitting coordination structures for OpenIE.

7.2 Constraints Ablation

How are constraint violations related to model performance?

We divide the constraints into two groups: one which is dependent on head verb(s): {HVC, HVE and EC}, and the other which is not – POSC. We separately train IGL architecture based OpenIE extractor with these two groups of constraints, and compare them with no constraints (IGL-OIE), all constraints (CIGL-OIE) and IMoJIE. In Table 4, we report the performance on Wire57-C and CaRB, and also report the number of constraint violations in each scenario.

Training IGL architecture based OpenIE extractor with POSC constraint (IGL-OIE (POSC)), leads to a reduction in POSC violations. However, the number of violations of (HVC+HVE+EC) remains high. On the other hand, training only with head verb constraints (HVC,HVE,EC) reduces their violations but the POSC violations remains high. Hence, we find that training with all the constraints achieves the best performance. Compared to IGL-OIE, it reduces the POSC violation from 1494 to 766 and (HVC+HVE+EC) violations from 787 to 668. The higher violations of Gold may be attributed to an overall larger number of extractions in the reference set.

7.3 Coordination Analysis

How does our coordination analyzer compare against other analyzers? How much does the coordination analyzer benefit OpenIE systems?

Following previous works (Teranishi et al., 2017, 2019), we evaluate two variants of our IGL architecture based coordination analyzer (IGL-CA) – using BERT-Base and BERT-Large, on coordination-annotated Penn Tree Bank (Ficler and Goldberg, 2016a). We compute the Precision, Recall and F1 of the predicted conjunct spans. In Table 5, we find that both BERT-Base and BERT-Large variants outperform the previous state-of-art (Teranishi et al., 2019) by 9.4 and 12.3 F1 points respectively. For fair comparison, we train a stronger variant of Teranishi et al. (2019), replacing the LSTM encoder with BERT-Base and BERT-Large. Even in these settings, IGL-CA performs better by 1.8 and 1.3 F1 points respectively, highlighting the significance of our IGL architecture. Overall, IGL-CA establishes a new state of the art for this task.

To affirm that the gains of better coordination analysis help the downstream OpenIE task, we experiment with using different coordination analyzers with CIGL-OIE and IMoJIE. From Table 6, we see a considerable improvement in the downstream

System	Precision	Recall	F1
(Teranishi et al., 2017)	71.5	70.7	71.0
(Teranishi et al., 2019)	75.3	75.6	75.5
BERT-Base:			
(Teranishi et al., 2019)	83.1	83.2	83.1
IGL-CA	86.3	83.6	84.9
BERT-Large:			
(Teranishi et al., 2019)	86.4	86.6	86.5
IGL-CA	**88.1**	**87.4**	**87.8**

Table 5: P, R, F1 of the system evaluated on Penn Tree Bank for different systems. We use both BERT-Base and BERT-Large as the encoder

Coordination Analyzer	IMoJIE	CIGL-OIE
None	36.0	36.8
CalmIE	37.7	38.0
(Teranishi et al., 2019)	36.1	36.5
IGL-CA	**39.5**	**40.0**

Table 6: Wire57 F1 scores of IMoJIE and CIGL-OIE with addition of different coordination analyzers. IGL-CA improves both of the OpenIE extractors.

OpenIE task using IGL-CA for both IMoJIE and CIGL-OIE, which we attribute to better conjunct-boundary detection capabilities of the model. For CIGL-OIE, this gives a 2 pts increase in Wire57-C F1, compared to CalmIE's coordination analyzer (CalmIE-CA).

8 Error Analysis

We examine extractions from a random sample of 50 sentences from CaRB validation set, as output by OpenIE6. We identify three major sources of errors in these sentences:

Grammatical errors: (24%) We find that the sentence formed by serializing the extraction is not grammatically correct. We believe that combining our extractor with a pre-trained language model might help reduce such errors.

Noun-based relations: (16%) These involve introducing additional words in the relation span. Although our model can introduce *[is], [of], [from]* in relations (Section 3), it may miss some words for which it was not trained. E.g. *[in]* in *(First Security; based [in]; Salt Lake City)* for the phrase *Salt Lake City-based First Security*.

Lack of Context: (10%) Neural models for OpenIE including ours, do not output extraction context (Mausam et al., 2012). E.g. for "*She believes aliens will destroy the Earth*", the extraction *(Context(She believes); aliens; will destroy; the Earth)* can be misinterpreted without the context.

We also observe incorrect boundary identification for relation argument (13%), cases in which coordination structure in conjunctive sentences are incorrectly split (11%), lack of coverage (4%) and other miscellaneous errors (18%).

9 Conclusion

We propose a new OpenIE system – OpenIE6, based on the novel Iterative Grid Labeling architecture, which models sequence labeling tasks with overlapping spans as a 2-D grid labeling problem. OpenIE6 is 10x faster, handles conjunctive sentences and establishes a new state of art for OpenIE. We highlight the role of constraints in training for OpenIE. Using the same architecture, we achieve a new state of the art for coordination parsing, with a 12.3 pts improvement in F1 over previous analyzers. We plan to explore the utility of this architecture in other NLP problems. OpenIE6 is available at `https://github.com/dair-iitd/openie6` for further research.

A Metrics

A.1 Introduction

Designing an evaluation benchmark for an underspecified and subjective task like OpenIE has gathered much attention. Several benchmarks, consisting of gold labels and scoring functions have been contributed. While coverage and quality of gold labels of these benchmarks have been extensively studied, differences in their scoring functions is largely unexplored. We evaluate all our systems on the CaRB reference set, which has 641 sentences and corresponding human annotated extractions in both dev and test set. As the underlying gold labels, is the same, system performances differ only due to difference in design choices of these scoring functions, which we explore in detail here.

A.2 Scoring Functions of Benchmarks

OIE2016[12] creates a one-to-one mapping between (gold, system) pairs by serializing the extractions and comparing the number of common words within them. Hence the system is not penalized for misidentifying parts of an one argument in another. Precision and recall for the system are computed using the one-to-one mapping obtained, i.e. precision is (no. of system extractions mapped to gold extractions)/ (total no. of system extractions) and recall is (no. of gold extractions mapped to system extractions)/(total no. of gold extractions). These design choices have several implications (Léchelle et al., 2018; Bhardwaj et al., 2019). Overlong system extractions which are mapped, are not penalized, and extractions with partial coverage of gold extractions, which are not mapped, are not rewarded at all.

Wire57[13] attempts to tackle the shortcomings of OIE2016. For each gold extraction, a set of candidate system extractions are chosen on the basis of whether they share at least one word for each of the arguments[14] of the extraction, with the gold. It then creates a one-to-one mapping by greedily matching gold with one of the candidate system extraction on the basis of token-level F1 score. Token level precision and recall of the matches are then aggregated to get the score for the system. Computing scores at token level helps in penalizing overly long extractions.

Wire57 ignores the confidence of extraction and reports just the F1 score (F1 at zero confidence). One way to generate AUC for Wire57 is by obtaining precision and recall scores at various confidence levels by passing a subset of extractions to the scorer. However, due to Wire57's criteria of matching extractions on the basis of F1 score, the recall of the system does not decrease monotonically with increasing confidence, which is a requirement for calculating AUC.

OIE2016 and Wire57 both use one-to-one mapping strategy, due to which a system extraction, that contains information from multiple gold extractions, is unfairly penalized.

CaRB[15] also computes similarity at a token level, but it is slightly more lenient than Wire57 — it considers number of common words in (gold,system) pair for each argument of the extraction. However, it uses one-to-one mapping for precision and many-to-one mapping for computing recall. While this solves the issue of penalizing extractions with information from multiple gold extractions, it inadvertently creates another one — unsatisfactorily evaluating systems which split on conjunctive sentences. We explore this in detail in the next section.

A.3 CaRB on Conjunctive Sentences

Coordinate structure in conjunctive sentences are of two types:

- *Combinatory*, where splitting the sentence by replacing the coordinate structure with one of the conjuncts can lead to incoherent extractions. E.g. splitting "*Talks resumed between USA and China*" will give *(Talks; resumed; between USA)*.
- *Segregatory*, where splitting on coordinate structure can lead to shorter and coherent extractions. E.g. splitting "*I ate an apple and orange.*" gives *(I; ate; an apple)* and *(I; ate; an orange)*.

Combinatory coordinate structures are hard to detect (in some cases even for humans). Some systems (ClausIE, CalmIE and ours) use some heuristics such as not splitting if coordinate structure is preceded by "*between*". In all other cases, coordinate structure is treated as segregatory, and is split.

The human-annotated gold labels of CaRB dataset correctly handle conjunctive sentences in most of the cases. However, we find that compared to scoring function of OIE2016 and Wire57,

[14] We refer to *subject*, *relation* and *object* as *arguments* of the extraction.

[15] `https://github.com/dair-iitd/CaRB`

	System 1 (P, R, F1)	System 2 (P, R, F1)
Talks resumed between USA and China Gold: (Talks; resumed; between USA and China)	(Talks; resumed; between USA) (Talks; resumed; between China) CaRB: (50.0, 66.7, 57.1) CaRB (1-1): (50.0, 66.7, 57.1)	(Talks; resumed; between USA and China) CaRB: (100, 100, 100) CaRB (1-1): (100, 100, 100)
I ate an apple and orange Gold: (I; ate; an apple) (I; ate; an orange)	(I; ate; an apple) (I; ate; an orange) CaRB: (100, 100, 100) CaRB (1-1): (100, 100, 100)	(I; ate; an apple and an orange) CaRB: (57.1, 100, **72.7**) CaRB (1-1): (53.5, 50.0, **57.1**)

Table 7: Evaluation of CaRB and CaRB (1-1) on two sentences.

CaRB over-penalizes systems for incorrectly splitting combinatory coordinate structures.

We trace this issue to the difference in mapping used for recall computation (one-to-one vs many-to-one).

Consider two systems – System 1, which splits on all conjunctive sentences (without any heuristics), and System 2, which does not. For the sentence “*I ate an apple and orange*”, the set of gold extractions are $\{$*(I; ate; an apple)*, *(I; ate; orange)*$\}$. System 2, which (incorrectly) doe not split on the coordinate structure, gets a perfect recall score of 1.0, similar to System 1, which correctly splits the extractions (Table 7). On the other hand, when System 2 incorrectly splits extractions for the sentence “*Talks resumed between USA and China*”, it is penalized on both precision and recall by CaRB, giving it a much lower score than System 2.

Due to this phenomena, we find that the gains obtained by our system on splitting the segregatory coordinate structures correctly is overshadowed by penalties of incorrectly splitting the coordinate structures. To re-affirm this, we evaluate all the systems on **CaRB(1-1)**, a variant of CaRB which retains all the properties of CaRB, except that it uses one-to-one mapping for computing recall.

We notice that our CIGL-OIE+IGL-CA shows improvements in CaRB(1-1) and other metrics which use one-to-one mapping (OIE16, Wire57) (Table 2). But it shows a decrease in CaRB score. This demonstrates that the primary reason for the decrease in performance is the many-to-one mapping in CaRB.

However, we also observe that this is not the best strategy for evaluation as it assigns equal score to both the cases — splitting a combinatory coordinate structure, and not splitting a segregatory coordinate structure (Table 7). This is also not desirable as a long extraction which is not split is better than two incorrectly split extractions. Hence, we consider that one-to-one mapping for computing recall under-penalizes splitting a combinatory coordinate structure.

Determining the right penalty in this case is an open-ended problem. We leave it to further research to design an optimal metric for evaluating conjunctive sentences for OpenIE.

B Reproducibility

Compute Infrastructure: We train all of our models using a Tesla V100 GPU (32 GB).

Hyper-parameter search: The final hyper-parameters used during train our model are listed in Table 8. We also list the search-space, which was manually tuned. We select the model based on the best CaRB (F1) score on validation set.

Validation Scores: We report the best validation scores in Table 9.

Number of parameters: The CIGL-OIE model contains 110 million parameters and IGL-CA contains 335 million parameters. The difference is because they use BERT-base and BERT-large models, respectively.

C Manual Comparison

The set of extractions from both the systems, CIGL-OIE and OpenIE6 were considered for a random 100 conjunctive sentences from the validation set. We identify a conjunctive sentence, based on the predicted conjuncts of coordination analyzer. The annotators are instructed to check if the extraction has well formed arguments and is implied by the sentence.

A screenshot of the process is shown in Figure 5.

Abstract

Detecting public sentiment drift is a challenging task due to sentiment change over time. Existing methods first build a classification model using historical data and subsequently detect drift if the model performs much worse on new data. In this paper, we focus on distribution learning by proposing a novel Hierarchical Variational Auto-Encoder (HVAE) model to learn better distribution representation, and design a new drift measure to directly evaluate distribution changes between historical data and new data. Our experimental results demonstrate that our proposed model achieves better results than three existing state-of-the-art methods.

1 Introduction

Public sentiments, whose information hidden in a temporal sequence of documents, become increasingly valuable for real-world applications. Especially, *identifying when public drifts occur* is of great importance to different stakeholders, such as government agencies, companies and news agencies, where they can take proactive actions to avoid damages and pay close attentions to new topics/sentiments etc (Hu et al., 2017). However, the dynamic nature of drifts/changes makes it a challenging problem, although concept drift analysis can be applied to focus on detecting *variation of data distributions* over time. Given historical data and new incoming data, how to *accurately detect drift based on distributional change* is a critical issue.

While existing methods are proposed for sentiment analysis Wu et al. (2019); Fu et al. (2019); Kong et al. (2019); Hoang et al. (2019); Li et al. (2019), etc., many of them are not designed for sentiment *drift* detection task. Xia et al. (2016) focuses on polarity shift detection, but it is at document-level instead of multi-document (or public) level. Recently, some research have been conducted for stream sentiment classification Iosifidis et al. (2017). In particular, statistic processing control (SPC) Ross et al. (2012); Raza et al. (2015) built a detection mechanism which accumulates statistic information of drift indications, and Zhou et al. (2018) applied the mechanism in sentiment drift detection. In addition, Bifet and Gavalda (2007) proposed ADWIN method, which used the upper bound of Hoeffding's inequality to mark drifts. Additionally, Nguyen et al. (2018) combined ADWIN with variational inference and built an online classification system. Wang et al. (2013) proposed an opinion drift detection method which is threshold-based, restricting its applications. A novel framework, proposed by Liu et al. (2016), contains an opinion shift detector based on KL-divergence, while its detection performance is affected by its labeling results. Tsytsarau and Palpanas (2016) defined a novel concept of opinion contradictions and used it in a sentiment change detection experiment. However, the pair-wise method does not involve much history information.

We observe most of the above methods *indirectly* detect drifts instead of *directly evaluate distribution difference*, leading to less effective results. The Variational Auto-Encoder (VAE) model, proposed by Kingma and Welling (2014), is capable to learn latent distributions of inputs, and has better generalization performance (Zhao et al., 2018). As such, we propose a novel *Hierarchical* Variational Auto-Encoder (**HVAE**) model to tackle sentiment drift problem. In particular, we take sentiment distribution changes as the drifts. Practically, sentiments are represented into a 2D vector, whose dimensions and values correspond to polarities (positive or negative) and corresponding intensities respectively. Our main contributions can be summarized as

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3762–3767,
November 16–20, 2020.

follows:

1. We propose a HVAE model, which designs 3-level meta-distributions to extend VAE over *hierarchical* structure, enabling effective learning latent distribution representations of input sentiments.
2. We propose a new drift detection measure to compare historical and new data distributions learned by the proposed HVAE.
3. Extensive experimental results on real-world data demonstrate our proposed model is significantly better than state-of-the-arts for sentiment drift detection.

2 Methodology

We now introduce our proposed methodology, including HVAE model and drift measure.

2.1 HVAE Model

Fig. 1 shows a novel three-level hierarchical structure, where W is a length *N* moving window, each time period *i* in W contains a set of historical documents $s^{(i)}_{1:L_i}$, and $s_{1:L_{new}}$ contains a set of newly incoming documents. More detailed annotations are described in Tab. 1.

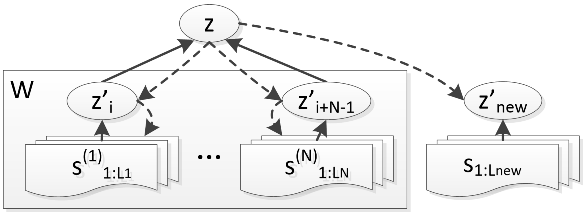

Figure 1: The illustration of HVAE model.

In the *bottom* level of Fig. 1, each document s is viewed as a sample from the *middle* level distribution of z'; On the same principle, each z' distribution is sampled from its corresponding *top* level meta-distribution z.

The HVAE is composed of an encoder and a decoder, where the encoder infers latent distributions from inputs. In Eq. 1 and 2, the meta-distribution among input sentiments $s^{(i)}_{1:L_i}$ from i'th time period are learned by $EncodeModel$. Similarly, the meta-distribution among all period distributions are achieved as 3 and 4 show.

On the other hand, the decoder module is applied to generate inputs by making use of the learned latent variables. In Eq. 5 and 7, z and z'_i are sampled from (μ_Φ, σ_ϕ) and $(\mu'_{\phi_i}, \sigma'_{\phi_i})$, respectively. Both $EncodeModel$ and $DecodeModel$ are neural networks. During the model training, two modules keep interacting and all parameters are updated through gradient descent, until inputs are well fitted and latent distributions are finally obtained.

Table 1: Annotations of our method

W	N length slide window.
s	A sentiment document, with its superscript indicating its time period.
L_i	Data quantity in *i*'th period.
z', z	Latent meta-distributions of period and window, respectively.
θ, ϕ	Parameters of decoder and encoder.
dash/solid line	Decode/Encode process.

$$(\mu'_{\phi_i}, \sigma'_{\phi_i}) = \text{EncoderModel}_\phi(s^{(i)}_{1:L_i}) \quad (1)$$

$$z'|s^{(i)}_{1:L_i} \sim N(\mu'_{\Phi_i}, \sigma'^2_{\Phi_i}) \quad (2)$$

$$(\mu_\Phi, \sigma_\phi) = \text{EncoderModel}_\phi(z'_{1:N}) \quad (3)$$

$$z|z'_{1:N} \sim N(\mu_\phi, \sigma^2_\phi) \quad (4)$$

The object function is shown in Eq. 9, where $S = \{s^{(1)}_{1:L_1}, s^{(2)}_{1:L_2}, \dots, s^{(N)}_{1:L_N}\}$ are historical data in window, and $\log p(S)$ is the log-likelihood for fitting inputs. The Evidence Lower Bound (ELBO) of the log-likelihood is increased through training, and latent meta-distribution are learned at the same time.

$$(\mu_\theta, \sigma_\theta) = \text{DecoderModel}_\theta(z) \quad (5)$$

$$z'_i|z \sim N(\mu_\theta, \sigma^2_\theta) \quad (6)$$

$$(\mu'_{\theta_i}, \sigma'_{\theta_i}) = \text{DecoderModel}_\theta(z'_i) \quad (7)$$

$$s^{(i)}_j|z'_i \sim N(\mu'_{\theta_i}, \sigma'^2_{\theta_i}) \quad (8)$$

Note at the bottom level of HVAE, input information of each time period are compressed to a less noisy condensed representation in middle level distribution form. In the same spirit, information from middle level time periods of a window are also compressed into a concise meta-distribution. Through training, the representativeness of all meta-distributions are increased. As such, the follow-

$$\log p(S) \geq E_{q_\phi(z'_{1:N}, z|S)} \left[\overbrace{\begin{array}{l} \log p(z) + \log p_\theta(z'_{1:N}|z) + \log p_\theta(S|z'_{1:N}) \\ -\log q_\phi(z|z'_{1:N}) - \log q_\phi(z'_{1:N}|S) \end{array}}^{Decode} \right] \tag{9}$$

$$\underbrace{-\log q_\phi(z|z'_{1:N}) - \log q_\phi(z'_{1:N}|S)}_{Encode}$$

up drift comparison step can benefit significantly from the *better learned distribution representations*, where certain level of data chaotic issue that frequently occurs in sentiment drift will be more tolerated than existing methods.

2.2 Drift Measure

The drift measure evaluates the *distributional difference* between historical and newly arrived data. Note this is different from existing methods which are typically based on classifier performance degradation; here we directly compare data distribution and thus more effective. In particular, we choose two distributions, namely $z'|z$ and $z'_{new}|S_{new}$, for drift measuring. Difference between two distributions are illustrated as shading area in Fig. 2. Obviously, the bigger the size of shading area, the smaller the similarity between the new and history data distribution, which has become a part of built-in drift detection algorithm of HVAE model. Mathematically, the irregular shading area can be computed as the integration of distribution difference. Correspondingly, we propose a new measure, namely, *Accumulation of Distribution Differences* (ADD) as Eq. 10. The parameters of latent distribution over newly arrived z'_{new} are $(\mu'_{\phi_{new}}, \sigma'_{\phi_{new}})$, and the parameters of latent distribution within latest historical data window $z'|z$ are $(\mu_\theta, \sigma_\theta)$. The p is the drift indicator, whose value is larger when the drift is more significant and vice versa.

$$p = \int \left| N(x; \mu'_{\phi_{new}}, \sigma'^2_{\phi_{new}}) - N(x; \mu_\theta, \sigma^2_\theta) \right| dx \tag{10}$$

More specifically, we compute the *intersections* of the two distribution curves, which are named as x_1 and x_2 ($x_1 = x_2$ when there is only one intersection, i.e. both distributions are same, and make $x_1 \leq x_2$ valid). The intersections split the curves into segments whose probability difference accumulations are normalized to [0,1] as our final drift score.

$$p = \left\{ \begin{array}{l} |\mathrm{F}_1(x_1) - \mathrm{F}_2(x_1)| + \\ |\mathrm{F}_1(x_2) - \mathrm{F}_1(x_1) - [\mathrm{F}_2(x_2) - \mathrm{F}_2(x_1)]| \\ + |\mathrm{F}_1(x_2) - \mathrm{F}_2(x_2)| \end{array} \right\} \Big/ 2 \tag{11}$$

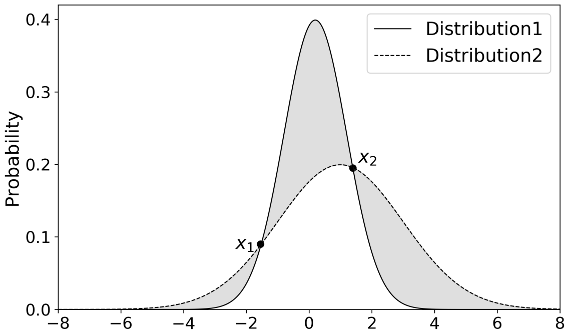

Figure 2: The difference between two gaussian distributions, which is represented as the shading area, the x_1 and x_2 are intersections of distributions. The reason of gaussian distribution assumption is that mean sentiment of across multiple documents is more likely to perform as gaussian according to the Central Limit Theorem.

Under the condition of processing extremely unstable inputs (big drifts), many of the values will be very close to 1, which decreases system performance. Hence, for increasing sparsity, the score can be squared to be the final drift score, i.e., p^2 from Eq. 11, named as ADD_2.

Through the ADD, all sentiment drifts of each time period is collected to current window W. Whether to update the HVAE with new data in the window can be viewed as a Bernoulli experiment, which applies the parameter $\bar{p_i} = \text{mean}(p_1, p_2, \cdots, p_N)$ and deviation $\sigma_i = \sqrt{\bar{p_i}(1 - \bar{p_i})/i}$. The parameters are inputted to SPC method (Bouchachia, 2011) for drift detection, and retrain/update model with next window once it alarms for drift occurring. If SPC does not incur alarm, the window moves one time period and meanwhile obtains new parameters as new data arrives.

3 Experiments

We have conducted extensive experiments to evaluate our proposed HVAE model.

3.1 Datasets & Baselines

We employ two datasets for our experiments, including Twitter data and CIRCLES data. Twitter

Sentiment[1], containing 1.6m tweets created from 2009-04-06 to 2009-06-25. The dataset is split by hours (time periods), and we delete those periods with empty categories, resulting in 432 periods. Note inputs of tweets are sentiment labels whose format is one-hot.

The second dataset is CIRCLES, which is taken from Gama et al. (2004) and sampled from a uniform distribution in which $x \in [0, 1.2], y \in [0, 1]$. It contains 40 data blocks, each of them contains 10 time periods which apply one of four kind category boundaries (in Tab. 2). Each time period contains 100 2-dimensions numeric vectors. The CIRCLES data is noise-free and used for simulating gradual drift scenario. Both datasets are used to validate model performance, representing both noise-free (ideal) and real-world scenario.

Table 2: The four circles category boundaries

Center	[0.2,0.5]	[0.4,0.5]	[0.6,0.5]	[0.8,0.5]
Radius	0.15	0.2	0.25	0.3

We compared with three state-of-the-art systems, including: 1) Nguyen et al. (2018), the VAE cooperated with a built-in drift detection method, 2) Zhou et al. (2018), an improved EWMA algorithm (Raza et al., 2015) based on statistic chart, 3) Iosifidis et al. (2017), stream sentiment classification based method.

3.2 Experimental Settings

Given a sequence of tweets, we will detect sentiment drifts across different time periods (cutting points). As such, drift detection is treated as sequence segmentation task, and the better segmentations, the higher the overall accuracy. Therefore, experiment results of our model and all baselines are compared with the same metric, i.e., overall accuracy. For running Nguyen et al. (2018) and Zhou et al. (2018) on the two datasets, their drift detection components are implemented and tested. Our experimental settings are the same with existing methods Iosifidis et al. (2017). Accumulative multinomial Naive Bayes (Accumulative MNB) is employed as the sentiment classifier. Data is processed from a new time period according to the principle of prequential evaluation, and drift adaption is done in an *rebuild* way. Specifically, if drift does not occur when a new period arrives, labels of data are predicted and then appended to the training set to retrain the classifier. Otherwise, the current training set is abandoned, and the classifier is updated with a new window. In the case of the CIRCLES, each detected drift is viewed as a category boundary switch and data before the drift are evaluated by the previous boundary.

For ablation experiment, several variations of HVAE models are generated: No_D does not apply decoder module, while No_E does not apply encoder module. Finally $Plain$ has only one level meta-distribution.

3.3 Experimental Results & Analysis

Table 3 shows HVAE with ADD_2 setting achieves the best accuracy, i.e. 0.55% better than HVAE with ADD. In addition, HVAE is 3.97%, 4.33%, 8.75% better than Nguyen et al. (2018), Zhou et al. (2018) and Iosifidis et al. (2017) respectively, indicating it is extremely effective for sentiment drift detection.

Table 3: Accuracy comparison on Twitter data.

Mea. Mod.		ADD	ADD_2
HVAE		0.827	**0.833**
Nguyen et al. (2018)		0.793	
Zhou et al. (2018)		0.789	
Iosifidis et al. (2017)		0.745	
HVAE Ablation	Plain	0.798	0.769
	No_D	0.8011	0.800
	No_E	0.826	0.829

Table 4 shows HVAE with ADD_2 once again achieves best result and is 10.5% and 13.5% better than two existing methods. Note we did not compare with Iosifidis et al. (2017), as it cannot be applied to numeric data. For ablation study, we can clearly see the importance of our proposed 3-level hierarchical structure for meta-distribution learning, encoder and decode modules respectively.

Table 4: Accuracy comparison on CIRCLES data.

Mea. Mod.		ADD	ADD_2
HVAE		0.315	**0.350**
Nguyen et al. (2018)		0.245	
Zhou et al. (2018)		0.215	
HVAE Ablation	Plain	0.265	0.310
	No_D	0.262	0.270
	No_E	0.207	0.235

According to results, HVAE achieves better performance than all baselines and ablation models,

---

[1] http://help.sentiment140.com/

which validate the effectiveness of several novelties in our proposed model. It is obvious that all models have much better results on tweets than CIRCLES, as gradual drift detection is more difficult. Generally, the resutls of ADD_2 measure algorithm is superior than the ADD, except for results which apply Plain model with the Twitter dataset. Since the sentiment fluctuation of tweets are stable in most of time periods, the disadvantage of ADD may not be so obvious. Moreover, the Plain manner without latent meta-distributions is lack of generalization capability, which performs much worse than the superior ADD_2. In the ablation experiment on CIRCLES, different from results with Twitter data, No_E performance worst and Plain is best. This is because the CIRCLES data are sampled from uniform distribution, but the No_E model is based on Gaussian distribution assumption and it lacks of Encoder part for input fitting. The Plain suffers less performance loss from distribution assumption since it has no meta-distribution structure. The results indicate the importance of HVAE's all innovative components where we need to extract latent distributions from inputs (encoder) as well as fit them with the distributions (decoder).

4 Conclusions

To tackle challenges in sentiment drift detection, we have proposed a novel HVAE model, which is 3-level meta-distributions to extend VAE over *hierarchical* structure, leading to effective learning latent distribution representations of input sentiments. In addition, a new drift measure is designed to effectively measure distribution difference between historical and newly arrived data. Different from existing classifier and threshold based models, the proposed method *directly measures the distribution differences* and thus is more effective. Finally, extensive experimental results demonstrate that HVAE performs significantly better than three state-of-the-art techniques across two benchmark datasets, indicating that it can be effectively used for real-world public sentiment drift analysis.

Abstract

Solving algebraic word problems has recently emerged as an important natural language processing task. To solve algebraic word problems, recent studies suggested neural models that generate solution equations by using 'Op (operator/operand)' tokens as a unit of input/output. However, such a neural model suffered two issues: expression fragmentation and operand-context separation. To address each of these two issues, we propose a pure neural model, Expression-Pointer Transformer (EPT), which uses (1) 'Expression' token and (2) operand-context pointers when generating solution equations. The performance of the EPT model is tested on three datasets: ALG514, DRAW-1K, and MAWPS. Compared to the state-of-the-art (SoTA) models, the EPT model achieved a comparable performance accuracy in each of the three datasets; 81.3% on ALG514, 59.5% on DRAW-1K, and 84.5% on MAWPS. The contribution of this paper is two-fold; (1) We propose a pure neural model, EPT, which can address the expression fragmentation and the operand-context separation. (2) The fully automatic EPT model, which does not use hand-crafted features, yields comparable performance to existing models using hand-crafted features, and achieves better performance than existing pure neural models by at most 40%.

1 Introduction

Problem	**One** number is **eight** more than **twice** another and their sum is **20**. What are their numbers?
Numbers	1('one'), 8('eight'), 2('twice'), 20.
Equations	$x_0 - 2x_1 = 8$, $x_0 + x_1 = 20$
Answers	$(16, 4)$

Table 1: A sample algebraic word problem

Solving algebraic word problems has recently become an important research task in that automatically generating solution equations requires understanding natural language. Table 1 shows a sample algebraic word problem, along with corresponding solution equations that are used to generate answers for the problem. To solve such problems with deep learning technology, researchers recently suggested neural models that generate solution equations automatically (Huang et al., 2018; Amini et al., 2019; Chiang and Chen, 2019; Wang et al., 2019). However, suggested neural models showed a fairly large performance gap compared to existing state-of-the-art models based on hand-crafted features in popular algebraic word problem datasets, such as ALG514 (44.5% for pure neural model vs. 83.0% for using hand-crafted features) (Huang et al., 2018; Upadhyay and Chang, 2016). To address the large performance gap in this study, we propose a larger unit of input/output (I/O) token called "*Expressions*" for a pure neural model. Figure 1 illustrates conventionally used "Op (operator/operands)" versus our newly proposed "Expression" token.

To improve the performance of pure neural models that can solve algebraic word problems, we identified two issues that can be addressed using Expression tokens, which are shown in Figure 1: (1) *expression fragmentation* and (2) *operand-context separation*. First, the expression fragmentation issue is a segmentation of an expression tree, which represents a computational structure of equations that are used to generate a solution. This issue arises when Op, rather than the whole expression tree, is used as an input/output unit of a problem-solving model. For example, as shown in Figure 1 (a), using Op tokens as an input to a problem-solving model disassembles a tree structure into operators ("×") and operands ("x_1" and "2"). Meanwhile, we propose using the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3768–3779,
November 16–20, 2020.

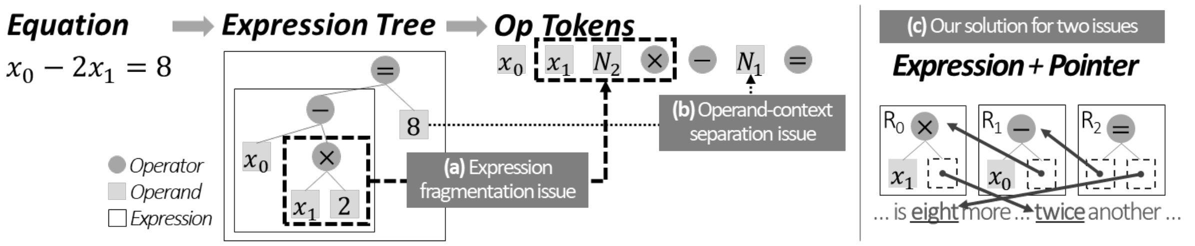

Figure 1: Illustration using the word problem in Table 1 for the (a) expression fragmentation issue, (b) operand-context separation issue, and (c) our solution for these two issues.

"Expression" $(\times(x_1, 2))$ token, which can explicitly capture a tree structure as a whole, as shown in Figure 1 (c).

The second issue of operand-context separation is the disconnection between an operand and a number that is associated with the operand. This issue arises when a problem-solving model substitutes a number stated in an algebraic word problem into an abstract symbol for generalization. As shown in Figure 1 (b), when using an Op token, the number 8 is changed into an abstract symbol 'N_1'. Meanwhile, when using an Expression token, the number 8 is not transformed into a symbol. Rather a pointer is made to the location where the number 8 occurred in an algebraic word problem. Therefore, using such an "operand-context pointer" enables a model to access contextual information about the number directly, as shown in Figure 1 (c); thus, the operand-context separation issue can be addressed.

In this paper, we propose a pure neural model called Expression-Pointer Transformer (EPT) to address the two issues above. The contribution of this paper is two-fold;

1. We propose a pure neural model, Expression-Pointer Transformer (EPT), which can address the expression fragmentation and operand-context separation issues.

2. The EPT model is the first pure neural model that showed comparable accuracy to the existing state-of-the-art models, which used hand-crafted features. Compared to the state-of-the-art pure neural models, the EPT achieves better performance by about 40%.

In the rest of the paper, we introduce existing approaches to solve algebraic word problems in Section 2. Next, Section 3 introduces our proposed model, EPT, and Section 4 reports the experimental settings. Then in Section 5, results of two studies are presented. Section 5.1 presents a performance comparison between EPT and existing SoTA models. Section 5.2 presents an ablation study examining the effects of Expression tokens and applying operand-context pointers. Finally, in Section 6, a conclusion is presented with possible future directions for our work.

2 Related work

Our goal is to design a pure neural model that generates equations using 'Expression' tokens to solve algebraic word problems. Early attempts for solving algebraic word problems noted the importance of Expressions in building models with hand-crafted features (Kushman et al., 2014; Roy et al., 2015; Roy and Roth, 2015; Zhou et al., 2015; Upadhyay et al., 2016). However, recent neural models have only utilized 'Op (operator/operand)' tokens (Wang et al., 2017; Amini et al., 2019; Chiang and Chen, 2019; Huang et al., 2018; Wang et al., 2019), resulting in two issues: (1) the expression fragmentation issue and (2) the operand-context separation issue. In the remaining section, we present existing methods for tackling each of these two issues.

To address the expression fragmentation issue, researchers tried to reflect relational information between operators and operands either by using a two-step procedure or a single step with sequence-to-sequence models. Earlier attempts predicted operators and their operands by using a two-step procedure. Such early models selected operators first by classifying a predefined template (Kushman et al., 2014; Zhou et al., 2015; Upadhyay et al., 2016), then in the second step, operands were applied to the template selected in the first step. Other models selected operands first before constructing expression trees with operators in the second step (Roy et al., 2015; Roy and Roth, 2015). However, such two-step procedures in these early attempts

Input position	Output index	Expression token Operator (f_i)	 Operand 0 (a_{i0})	 Operand 1 (a_{i1})	Meaning
0	-	`BEGIN`			(Start an equation)
1	R_0	`VAR`			(Generate variable x_0)
2	R_1	`VAR`			(Generate variable x_1)
3	R_2	$\times$	2	R_1	$2x_1$
4	R_3	$-$	R_0	R_2	$x_0 - 2x_1$
5	R_4	$=$	R_3	8	$x_0 - 2x_1 = 8$
6	R_5	$+$	R_0	R_1	$x_0 + x_1$
7	R_6	$=$	R_5	20	$x_0 + x_1 = 20$
-	R_7	`END`			(Gather all equations)

Table 2: The Expression token sequence for $x_0 - 2x_1 = 8$ and $x_0 + x_1 = 20$

can be performed via a single-step procedure with neural models. Specifically, recent attempts have utilized sequence-to-sequence (seq2seq) models as a single-step procedure to learn the implicit relationship between operators and operands (Amini et al., 2019; Chiang and Chen, 2019; Wang et al., 2019). For example, to capture the operator-operand relationship, Chiang and Chen (2019) constructed a seq2seq model that used push/pop actions on a stack for generating operator/operand tokens. Similarly, Amini et al. (2019) built a seq2seq model to generate an operator token right after producing required operand tokens. However, although these seq2seq approaches consider relational information of operands when generating operators, the approach still does not address the problem of lacking relation information of operators when generating operands. On the other hand, by using Expression token, our model can consider relational information when generating both operator and operands.

Secondly, there were efforts to address the operand-context separation issue. To utilize contextual information of an operand token, researchers built hand-crafted features that capture the semantic content of a word, such as the unit of a given number (Roy and Roth, 2015; Koncel-Kedziorski et al., 2015; Zhou et al., 2015; Upadhyay et al., 2016; Roy and Roth, 2017) or dependency relationship between numbers (Kushman et al., 2014; Zhou et al., 2015; Upadhyay et al., 2016). However, devising hand-crafted input features was time-consuming and required domain expertise. Therefore, recent approaches have employed distributed representations and neural models to learn numeric context of operands automatically (Wang et al., 2017; Huang et al., 2018; Chiang and Chen, 2019; Amini et al., 2019). For example, Huang et al. (2018) used a pointer-generator network that can point to the context of a number in a given math problem. Although Huang's model can address the operand-context separation issue using pointers, their pure neural model did not yield a comparable performance to the state-of-the-art model using hand-crafted features (44.5% vs. 83.0%). In this paper, we propose that by including additional pointers that utilize the contextual information of operands and neighboring Expression tokens, performance of pure neural models can improve.

3 EPT: Expression-Pointer Transformer

Figure 2 shows the proposed Expression-Pointer Transformer (EPT)[1] model, which adopts the encoder-decoder architecture of a Transformer model (Vaswani et al., 2017). The EPT utilizes the ALBERT model (Lan et al., 2019), a pretrained language model, as the encoder. The encoder input is tokenized words of the given word problem, and encoder output is the encoder's hidden-state vectors that denote numeric contexts of the given problem.

After obtaining the encoder's hidden-state vectors from the ALBERT encoder, the transformer decoder generates 'Expression' tokens. The two decoder inputs are Expression tokens and the ALBERT encoder's hidden-state vectors, which are used as memories. For the given example problem, the input is a list of 8 Expression tokens shown in Table 2. We included three special commands in the list: `VAR` (generate a variable), `BEGIN` (start an equation), and `END` (gather all equations). Following the order specified in the list of Table 2, the EPT receives one input Expression

---

[1] The code is available on `https://github.com/snucclab/ept`.

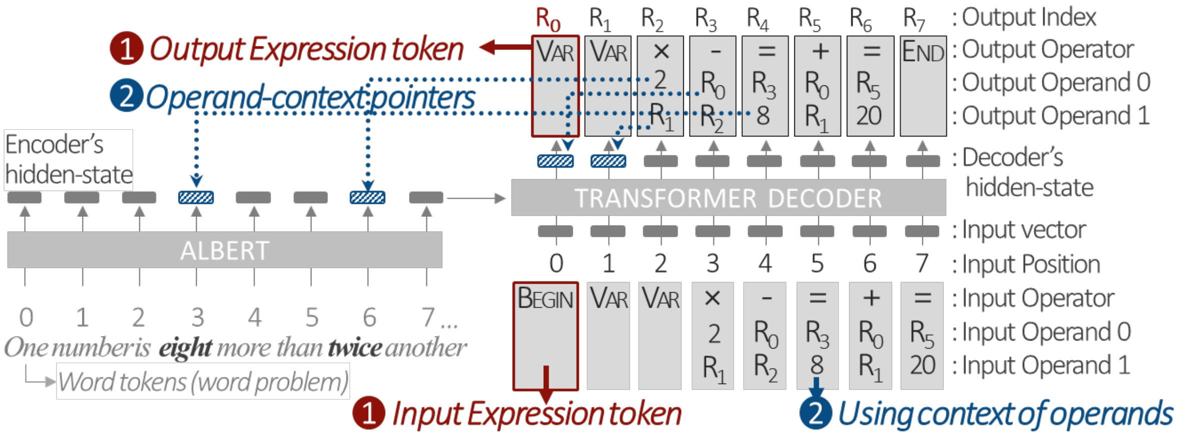

Figure 2: The architecture of Expression-Pointer Transformer (EPT) where two ideas applied: (1) Expression token and (2) operand-context pointer.

at a time. For the ith Expression input, the model computes an input vector $\mathbf{v}_i$. The EPT's decoder then transforms this input vector to a decoder's hidden-state vector $\mathbf{d}_i$. Finally, the EPT predicts the next Expression token by generating the next operator and operands simultaneously.

To produce 'Expression' tokens, two components are modified from the vanilla Transformer: input vector and output layer. In the following subsections, we explain the two components.

3.1 Input vector of EPT's decoder

The input vector $\mathbf{v}_i$ of ith Expression token is obtained by combining operator embedding $\mathbf{f}_i$ and operand embedding $\mathbf{a}_{ij}$ as follows:

$$\mathbf{v}_i = \mathrm{FF}_{\mathrm{in}}\left(\mathrm{Concat}\left(\mathbf{f}_i, \mathbf{a}_{i1}, \mathbf{a}_{i2}, \cdots, \mathbf{a}_{ip}\right)\right), \quad (1)$$

where FF_* indicates a feed-forward linear layer, and $\mathrm{Concat}(\cdot)$ means concatenation of all vectors inside the parentheses. All the vectors, including $\mathbf{v}_i$, $\mathbf{f}_i$, and $\mathbf{a}_{ij}$, have the same dimension D. Formulae for computing the two types of embedding vectors, $\mathbf{f}_i$ and $\mathbf{a}_{ij}$ are stated in the next paragraph.

For the operator token f_i of ith Expression, the EPT computes the operator embedding vector $\mathbf{f}_i$ as in Vaswani et al. (2017)'s setting:

$$\mathbf{f}_i = \mathrm{LN}_{\mathrm{f}}\left(c_{\mathrm{f}}\mathrm{E}_{\mathrm{f}}(f_i) + \mathrm{PE}(i)\right), \quad (2)$$

where $\mathrm{E}_*(\cdot)$ indicates a look-up table for embedding vectors, c_* denotes a scalar parameter, and $\mathrm{LN}_*(\cdot)$ and $\mathrm{PE}(\cdot)$ represent layer normalization (Ba et al., 2016) and positional encoding (Vaswani et al., 2017), respectively.

The embedding vector $\mathbf{a}_{ij}$, which represents the jth operand of ith Expression, is calculated differently according to the operand a_{ij}'s source. To reflect contextual information of operands, three possible sources are utilized: problem-dependent numbers, problem-independent constants, and the result of prior Expression tokens. First, problem-dependent numbers are numbers provided in an algebraic problem (e.g., '20' in Table 1). To compute $\mathbf{a}_{ij}$ of a number, we reuse the encoder's hidden-state vectors corresponding to such number tokens as follows:

$$\mathbf{a}_{ij} = \mathrm{LN}_{\mathrm{a}}\left(c_{\mathrm{a}}\mathbf{u}_{\mathrm{num}} + \mathbf{e}_{a_{ij}}\right), \quad (3)$$

where $\mathbf{u}_*$ denotes a vector representing the source, and $\mathbf{e}_{a_{ij}}$ is the encoder's hidden-state vector corresponding to the number a_{ij}.[2] Second, problem-independent constants are predefined numbers that are not stated in the problem (e.g., 100 is often used for percentiles). To compute $\mathbf{a}_{ij}$ of a constant, we use a look-up table E_{c} as follows:

$$\mathbf{a}_{ij} = \mathrm{LN}_{\mathrm{a}}\left(c_{\mathrm{a}}\mathbf{u}_{\mathrm{const}} + \mathrm{E}_{\mathrm{c}}(a_{ij})\right). \quad (4)$$

Note that LN_{a}, c_{a} are shared across different sources. Third, the result of the prior Expression token is an Expression generated before the ith Expression (e.g., R_0). To compute $\mathbf{a}_{ij}$ of a result, we utilize the positional encoding as follows[3]:

$$\mathbf{a}_{ij} = \mathrm{LN}_{\mathrm{a}}\left(c_{\mathrm{a}}\mathbf{u}_{\mathrm{expr}} + \mathrm{PE}(k)\right), \quad (5)$$

---

[2] When two or more tokens form a number in the problem, we averaged all related hidden-state vectors.

[3] Since we want to sustain simultaneous decoding, which is one of the strengths in the Transformer, we use $\mathrm{PE}(k)$ for the kth prior Expression, although it is possible to use decoder hidden state $\mathbf{d}_k$.

where k is the index where the prior Expression a_{ij} generated.

3.2 Output layer of EPT's decoder

The output layer of the EPT's decoder predicts the next operator f_{i+1} and operands $a_{i+1,j}$ simultaneously when the ith Expression token is provided. First, the next operator, f_{i+1}, is predicted as follows:

$$f_{i+1} = \arg\max_{f} \sigma(f|\mathrm{FF}_{\mathrm{out}}(\mathbf{d}_i)), \tag{6}$$

where $\sigma(k|\mathbf{x})$ is the probability of selecting an item k under a distribution following the output of softmax function, $\sigma(\mathbf{x})$.

Second, to utilize the context of operands when predicting an operand, the output layer applies 'operand-context pointers,' inspired by the pointer networks (Vinyals et al., 2015). In the pointer networks, the output layer predicts the next token using attention over candidate vectors. The EPT collects candidate vectors for the next $(i+1)$th Expression in three different ways depending on the source of operands:

$$\begin{array}{ll} \mathbf{e}_k & \text{for the } k\text{th number in the problem,} \\ \mathbf{d}_k & \text{for the } k\text{th Expression output,} \\ \mathrm{E}_{\mathrm{c}}(x) & \text{for a constant } x \end{array} \tag{7}$$

Then the EPT predicts the next jth operand $a_{i+1,j}$, as follows. Let $\mathbf{A}_{ij}$ be a matrix whose row vectors are such candidates. Then, the EPT predicts $a_{i+1,j}$ by computing attention of a query vector Q_{ij} on a key matrix K_{ij}, as follows.

$$Q_{ij} = \mathrm{FF}_{\mathrm{query},j}(\mathbf{d}_i), \tag{8}$$

$$K_{ij} = \mathrm{FF}_{\mathrm{key},j}(\mathbf{A}_{ij}), \tag{9}$$

$$a_{i+1,j} = \arg\max_{a} \sigma\left(a \,\middle|\, \frac{Q_{ij}K_{ij}^{\top}}{\sqrt{D}}\right). \tag{10}$$

As the output layer is modified to predict an operator and its operands simultaneously, we also modified the loss function. We compute the loss of an Expression by summing up the loss of an operator and the loss of required arguments. All loss functions are computed using cross-entropy with the label smoothing approach (Szegedy et al., 2016).

4 Experimental Setup

4.1 Metric and Datasets

The metric for measuring the EPT model's performance is answer accuracy, which is the proportion of correctly answered problems over the entire set of problems. We regard a problem is correctly answered if a solution to the generated equations matches the correct answer without considering the order of answer-tuple, as in Kushman et al. (2014). To obtain a solution to the generated equations, we use `SymPy` (Meurer et al., 2017) at the end of the training phase.

	ALG514	DRAW-1K	MAWPS
Dataset size			
Problems	514	1,000	2,373
Splits	5-fold	Train 600 Dev., Test 200	5-fold
Complexity of generating equations (per problem)			
Unknown	1.82	1.75	1.00
Op tokens	13.08	14.16	6.20
Complexity of selecting an operand (per problem)			
Numbers	4.26	3.88	2.72
Expressions	7.45	7.95	3.60

Table 3: Characteristics of datasets used in the experiment

For the datasets, we use three publicly available English algebraic word problem datasets[4]: ALG514 (Kushman et al., 2014)[5], DRAW-1K (Upadhyay and Chang, 2016)[6], and MAWPS (Koncel-Kedziorski et al., 2016)[7]. The three datasets differ in terms of size and complexity, as shown in Table 3. The high-complexity datasets, ALG514 and DRAW-1K, require more expressions and unknowns when solving the algebraic problems than the low-complexity dataset, MAWPS. For DRAW-1K, we report the accuracy of a model on the development and test set since training and development sets are provided. For the other two datasets — MAWPS and ALG514, — we report the average accuracy and standard error using 5-fold cross-validation.

4.2 Baseline and ablated models

We examine the performance of EPT against five existing state-of-the-art (SoTA) models. The five models are categorized into three types; model using hand-crafted features, pure neural models,

---

[4] We provide a preprocessed version of these datasets on `https://github.com/snucclab/ept/tree/master/dataset`.

[5] `http://groups.csail.mit.edu/rbg/code/wordprobs/`

[6] `https://www.microsoft.com/en-us/download/details.aspx?id=52628`

[7] `http://lang.ee.washington.edu/MAWPS`

and a hybrid of these two types.

- Models using hand-crafted features use expert-defined input features without using a neural model: MixedSP (Upadhyay et al., 2016). Upadhyay et al. (2016) designed a model using a set of hand-crafted features similar to those used by Zhou et al. (2015). Using a data augmentation technique, they achieved the SoTA on ALG514 (83.0%) and DRAW-1K (59.5%).

- Pure neural models take algebraic word problems as the raw input to a neural model and do not require the use of a rule-based model: CASS-RL (Huang et al., 2018) and T-MTDNN (Lee and Gweon, 2020). The CASS-RL, which applied pointer-generator networks to generate Op tokens, achieved the best-performing neural model on ALG514 (44.5%). The T-MTDNN is the SoTA model on MAWPS (78.88%) dataset. T-MTDNN utilized multi-task learning for training a template classification model and a number aligning model.

- Hybrid models are models that are neither purely hand-crafted nor pure neural models: CASS-hybrid (Huang et al., 2018) and DNS (Wang et al., 2019). The CASS-hybrid is the best-performing hybrid model of the CASS-RL and Huang et al. (2017)'s model using hand-crafted features. The DNS is a hybrid model of a sequence-to-sequence model and a model using hand-crafted features. We copied the accuracy of DNS on DRAW-1K from Zhang et al. (2019).

After examining the EPT model performance, we conducted an ablation study to analyze the effect of using two main components of EPT; Expression tokens and operand-context pointers. We compared three types of models to test each of the components: (1) the vanilla Transformer model, (2) the Transformer with Expression token model, which investigates the effect of using Expression tokens, and (3) the EPT, which investigates the effect of using pointers in addition to Expression tokens. Additional details on the input/output of the vanilla Transformer and the Transformer with Expression token models are provided in Appendix A.

4.3 Implementation details

The implementation details of EPT and its ablated models are as follows. To build encoder-decoder models, we used `PyTorch` 1.5 (Paszke et al., 2019). For the encoder, three different sizes of ALBERT models in the `transformers` library (Wolf et al., 2019) are used: `albert-base-v2`, `albert-large-v2`, and `albert-xlarge-v2`. We fixed the encoder's embedding matrix during the training since such fixation preserves the world knowledge embedded in the matrix and stabilizes the entire learning process. For the decoder, we stacked six decoder layers and shared the parameters across different layers to reduce memory usage. We set the dimension of input vector D as the same dimension of encoder hidden-state vectors. To train and evaluate the entire model, we used teacher forcing in the training phase and beam search with 3 beams in the evaluation phase.

For the hyperparameters of the EPT, parameters follow the ALBERT model's parameters except for training epoch, batch size, warm-up epoch, and learning rate. First, for the training epoch T, a model is trained in 500, 500, and 100 epochs on ALG514, DRAW-1K, and MAWPS, respectively. For batch sizes, we used 2,048 (`albert-base-v2` and `albert-large-v2`) and 1,024 (`albert-xlarge-v2`) in terms of Op or Expression tokens. To acquire a similar effect of using 4,096 tokens as a batch, we also employed gradient accumulation technique on two types of consecutive mini-batches; two (`base` and `large`) and four (`xlarge`). Then, for the warm-up epoch and learning rate, we conduct the grid-search algorithm for each pair of a dataset and the size of the ALBERT model. For the grid search, we set the sampling space as follows: $\{0.00125, 0.00176, 0.0025\}$ for the learning rates and $\{0, 0.005T, 0.01T, 0.015T, 0.02T, 0.025T\}$ for the warm-up. The resulting parameters are listed in Appendix B. During each grid search, we only use the following training/validation sets and keep other sets unseen: the fold-0 training/test split for ALG514 and MAWPS and the training/development set for DRAW-1K. For the unstated hyperparameters, the parameters follow those of the ALBERT. These parameters include the optimizer and warm-up scheduler; we used LAMB (You et al., 2019) optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 10^{-12}$; and we

employed linear decay with warm-up scheduling. All the experiment, including hyperparameter search, was conducted on a local computer with 64GB RAM and two GTX1080 Ti GPUs.

5 Result and Discussion

In section 5.1, we first present a comparison study, which examines the EPT's performance. Next, in section 5.2, we present an ablation study, which analyzes the two main components of EPT; Expression tokens and operand-context pointers.

5.1 Comparison study

As shown in Table 4, the performance of EPT is comparable or better in terms of performance accuracy compared to existing state-of-the-art (SoTA) models when tested on the three datasets of ALG514, DRAW-1K, and MAWPS. The fully automatic EPT model, which does not use hand-crafted features, yields comparable performance to existing models using hand-crafted features. Specifically, on the ALG514 dataset, the EPT outperforms the best-performing pure neural model by about 40% and shows comparable performance accuracy to the SoTA model that uses hand-crafted features. On the DRAW-1K dataset, which is harder than ALG514 dataset, a similar performance trend to ALG514 is found. The EPT model outperforms the hybrid model by about 30% and achieved comparable accuracy to the SoTA model that uses hand-crafted features. On the MAWPS dataset, which is only tested on pure neural models in existing studies, the EPT achieves SoTA accuracy.

+ Expression	42.03	32.0	32.5	80.46
(Std. Err)	(1.97)			(1.09)
+ Pointer (EPT)	75.46	55.5	51.5	83.41
(Std. Err)	(2.23)			(0.32)

Table 5: Accuracy(%) of the EPT and its ablated models `(albert-base-v2)`.

One possible explanation for EPT's outstanding performance over the existing pure neural model is the use of operand's contextual information. Existing neural models solve algebraic word problems by using symbols to provide an abstraction of problem-dependent numbers or unknowns. For example, Figure 1 shows that existing methods used Op tokens, such as x_0 and N_1. However, treating operands as symbols only reflects 2 out of 4 means in which symbols are used in humans' mathematical problem-solving procedures (Usiskin, 1999). The 4 means of symbol usage are; (1) generalizing common patterns, (2) representing unknowns in an equation, (3) indicating an argument of a function, and (4) replacing arbitrary marks. By applying template classification or machine learning techniques, (1) and (2) were successfully utilized in existing neural models. However, the existing neural models could not consider (3) and (4). Therefore, in our suggested EPT model, we dealt with (3) by using Expression tokens and (4) by using operand-context pointers. We suspect that the EPT's performance, which is comparable to existing models using hand-crafted features, comes from dealing with (3) and (4) explicitly when solving algebraic word problems.

5.2 Ablation study

From the ablation study, our data showed that the two components of generating 'Expression' token and applying operand-context pointer, each improved the accuracy of the EPT model in different ways. Specifically, as seen in Table 5, adding Expression token to the vanilla Transformer improved the performance accuracy by about 15% in ALG514 and DRAW-1K and about 1% in MAWPS. In addition, applying operand-context pointer to the Transformer with Expression token

Case 1. Effect of using Expression tokens	Problem	The sum of two numbers is 90. Three times the smaller is 10 more than the larger. Find the larger number.		
	Expected	$3x_0 - x_1 = 10,$	$x_0 + x_1 = 90$	
	Vanilla Transformer	$x_0 + x_1 = 3,$	$x_0 - x_1 = 10$	(**Incorrect**)
	+ Expression	$3x_0 - x_1 = 10,$	$x_0 + x_1 = 90$	(Correct)
	+ Pointer (EPT)	$3x_0 - x_1 = 10,$	$x_0 + x_1 = 90$	(Correct)
Case 2. Effect of using pointers	Problem	A minor league baseball team plays 130 games in a season. If the team won 14 more than three times as many games as they lost, how many wins and losses did the team have?		
	Expected	$x_0 - 3x_1 = 14,$	$x_0 + x_1 = 130$	
	Vanilla Transformer	$14x_0 - 3x_1 = 0,$	$x_0 + x_1 = 130$	(**Incorrect**)
	+ Expression	$x_0 - 3x_1 = 14,$	$130x_0 - x_1 = 0$	(**Incorrect**)
	+ Pointer (EPT)	$x_0 - 3x_1 = 14,$	$x_0 + x_1 = 130$	(Correct)
Case 3. Comparative error	Problem	One number is 6 more than another. If the sum of the smaller number and 3 times the larger number is 34, find the two numbers.		
	Expected	$x_0 + 3x_1 = 34,$	$x_1 - x_0 = 6$	
	Vanilla Transformer	$x_0 + 3x_1 = 34,$	$x_1 - x_0 = 6$	(Correct)
	+ Expression	$3x_0 + 34x_1 = 2,$	$x_1 - x_0 = 6$	(**Incorrect**)
	+ Pointer (EPT)	$3x_0 + x_1 = 34,$	$x_1 - x_0 = 6$	(**Incorrect**)
Case 4. Temporal order error	Problem	The denominator of a fraction exceeds the numerator by 7. if the numerator is increased by three and the denominator increased by 5, the resulting fraction is equal to half. Find the original fraction.		
	Expected	$x_0 - \frac{1}{2}x_1 = \frac{1}{2} \cdot 5 - 3,$	$x_0 - x_1 = 7$	
	Vanilla Transformer	$3x_0 + 5x_1 = \frac{1}{2}N_4,$		(**Incorrect**)
	+ Expression	$3x_0 - 5x_1 = 0,$	$x_0 + x_1 = 7$	(**Incorrect**)
	+ Pointer (EPT)	$5x_0 - 3x_1 = \frac{1}{2},$	$x_1 - x_0 = 7$	(**Incorrect**)

Table 6: Sample incorrect problems (`albert-base-v2`) from the DRAW-1K development dataset.

model enhanced the performance by about 30% in ALG514 and DRAW-1K and about 3% in MAWPS.

Table 6 shows the result of an error analysis. The cases 1 and 2 show how the EPT model's two components contributed to performance improvement. In case 1, the vanilla Transformer yields an incorrect solution equation by incorrectly associating $x_0 + x_1$ and 3. However, using an Expression token, the explicit relationship between operator and operands is maintained, enabling the distinction between $x_0 + x_1$ and $3x_0 - x_1$. The case 2 example shows how adding an operand-context pointer can help distinguish between different expressions, in our example, x_0, $130x_0$, and $14x_0$. As the operand-context pointer directly points to the contextual information of an operand, the EPT could utilize the relationship between unknown (x_0) and its multiples ($130x_0$ or $14x_0$) without confusion.

We observed that the existing pure neural model's performance on low-complexity dataset of MAWPS was relatively high at 78.9%, compared to that of high-complexity dataset of ALG514 (44.5%). Therefore, using Expression tokens and operand-context pointers contributed to higher performance when applied to high-complexity datasets of ALG514 and DRAW-1K, as shown in Table 5. We suspect two possible explanations for such a performance enhancement.

First, using Expression tokens in high-complexity datasets address the expression fragmentation issue when generating solution equations, which is more complex in ALG514 and DRAW-1K than MAWPS. Specifically, Table 3 shows that on average the number of unknowns in ALG514 and DRAW-1K is almost twice (1.82 and 1.75, respectively) than MAWPS (1.0). Similarly, the number of Op tokens is also twice in ALG514 and DRAW-1K (13.08 and 14.16, respectively) than that of MAWPS (6.20). As the expression fragmentation issue can arise for each token, probability of fragmentation issues' occurrence increases exponentially as the number of unknowns/Op tokens in a problem increases.

Therefore, the vanilla Transformer model, which could not handle the fragmentation issue, yields low accuracy on high-complexity datasets.

Second, using operand-context pointers in high-complexity datasets addresses the operand-context separation issue when selecting an operand, which is more complex in ALG514 and DRAW-1K than MAWPS. Specifically, Table 3 shows that on average the amount of Expression tokens is also twice in ALG514 and DRAW-1K (7.45 and 7.95, respectively) than that of MAWPS (3.60). As numbers and Expression tokens are candidates for selecting an operand, probability of separation issues' occurrence increases linearly as the amount of numbers/Expressions in an equation increases. Since a Transformer with Expression token could not handle the separation issue, the model showed lower accuracy on high-complexity datasets.

In addition to the correctly solved problem examples, Table 6 also shows cases 3 and 4, which were incorrectly answered by the EPT model. The erroneous examples can be categorized into two groups; 'Comparative' error and 'Temporal order' error. 'Comparative' occurs when an algebraic problem contains comparative phrases, such as '6 more than,' as in case 3. 49.3% of incorrectly solved problems contained comparatives. When generating solution equations for the comparative phrases, the order of arguments is a matter for an equation that contains non-commutative operators, such as subtractions or divisions. Therefore, errors occurred when the order of arguments for comparative phrases with non-commutative operators was mixed up. Another group of error is 'Temporal order' error that occurs when a problem contains phrases with temporal orders, such as 'the numerator is increased by three,' as in case 4. 44.5% of incorrectly solved problems contained temporal orders. We suspect that these problems occur when co-referencing is not handled correctly. In a word problem with temporal ordering, a same entity may have two or more numeric values that change over time. For example, in case 4, the denominator has two different values of x_1 and $x_1 + 7$. The EPT model failed to assign a same variable for the denominators. The model assigned x_0 in the former expression and x_1 in the latter.

6 Conclusion

In this study, we proposed a neural algebraic word problem solver, Expression-Pointer Transformer (EPT), and examined its characteristics. We designed EPT to address two issues: expression fragmentation and operand-context separation. The EPT resolves the expression fragmentation issue by generating 'Expression' tokens, which simultaneously generate an operator and required operands. In addition, the EPT resolves the operand-context separation issue by applying operand-context pointers. Our work is meaningful in that we demonstrated a possibility for alleviating the costly procedure of devising hand-crafted features in the domain of solving algebraic word problems. As future work, we plan to generalize the EPT to other datasets, including non-English word problems or non-algebraic domains in math, to extend our model.

A Input/output of ablation models

In this section, we describe how we compute the input and output of the two ablation models: (1) a vanilla Transformer and (2) a vanilla Transformer with 'Expression' tokens. Figure 3 shows the two models.

The first ablation model is a vanilla Transformer. The model generates an 'Op' token sequence and does not use operand-context pointers. The model manages an 'Op' token vocabulary that contains operators, constants, variables, and number placeholders (e.g., N_0). So the input of this model's decoder only utilizes a look-up table for embedding vectors. For the decoder's output, the vanilla Transformer uses a feed-forward softmax layer to output the probability of selecting an Op token. In summary, the input vector $\mathbf{v}_i$ of a token t_i and the output t_{i+1} can be computed as follows.

$$\mathbf{v}_i = \mathrm{LN}_{\mathrm{in}}\left(c_{\mathrm{in}}\mathrm{E}_{\mathrm{in}}(t_i) + \mathrm{PE}(i)\right), \quad (11)$$

$$t_{i+1} = \arg\max_t \sigma\left(\mathrm{FF}_{\mathrm{out}}(\mathbf{d}_i)\right)_t. \quad (12)$$

The second ablation model is a vanilla Transformer model that uses 'Expression' tokens as a unit of input/output. This model generates an 'Expression' token sequence but does not apply operand-context pointers. Instead of using operand-context pointers, this model uses an operand vocabulary that contains constants, placeholders for numbers, and placeholders of previous Expression token results (e.g., R_0). The input of this model's decoder is similar to that of EPT's decoder, but we replaced the equations 3 and 5 with the following formulae.

$$\mathbf{a}_{ij} = \mathrm{LN}_{\mathrm{a}}\left(c_{\mathrm{a}}\mathbf{u}_{\mathrm{num}} + \mathrm{E}_{\mathrm{c}}(a_{ij})\right), \quad (13)$$

$$\mathbf{a}_{ij} = \mathrm{LN}_{\mathrm{a}}\left(c_{\mathrm{a}}\mathbf{u}_{\mathrm{expr}} + \mathrm{E}_{\mathrm{c}}(a_{ij})\right). \quad (14)$$

For the output of this model's decoder, we used a feed-forward softmax layer to output the probability of selecting an operand. Since the softmax output can select the unavailable operand, we set the probability of such unavailable tokens as zeros to mask them. So, we replace equation 10 with the following formula.

$$a_{i+1,j} = \arg\max_a \sigma\left(a\left|\mathrm{M}\left(\mathrm{FF}_{\mathrm{j}}(\mathbf{d}_i)\right)\right.\right), \quad (15)$$

where M is a masking function to set zero probability on unavailable tokens when generating ith Op token. The other unstated equations 1, 2, 4, and 6 remain the same.

B Hyperparameters used for this study

Table 7 shows the best parameters and performances on the development set, which are found using grid search.

Abstract

A practical automatic textual math word problems (MWPs) solver should be able to solve various textual MWPs while most existing works only focused on one-unknown linear MWPs. Herein, we propose a simple but efficient method called Universal Expression Tree (UET) to make the first attempt to represent the equations of various MWPs uniformly. Then a semantically-aligned universal tree-structured solver (SAU-Solver) based on an encoder-decoder framework is proposed to resolve multiple types of MWPs in a unified model, benefiting from our UET representation. Our SAU-Solver generates a universal expression tree explicitly by deciding which symbol to generate according to the generated symbols' semantic meanings like human solving MWPs. Besides, our SAU-Solver also includes a novel subtree-level semantically-aligned regularization to further enforce the semantic constraints and rationality of the generated expression tree by aligning with the contextual information. Finally, to validate the universality of our solver and extend the research boundary of MWPs, we introduce a new challenging **H**ybrid **M**ath **W**ord **P**roblems dataset (HMWP), consisting of three types of MWPs. Experimental results on several MWPs datasets show that our model can solve universal types of MWPs and outperforms several state-of-the-art models[1].

1 Introduction

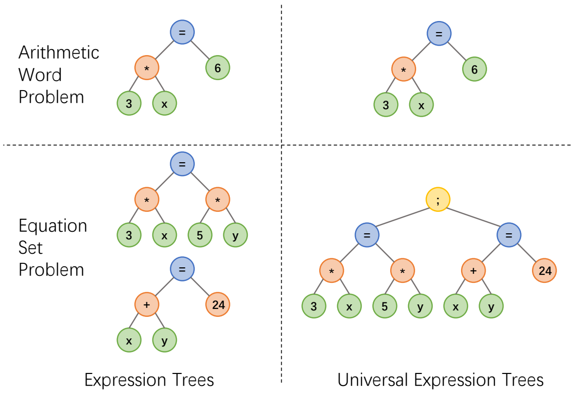

Figure 1: Universal Expression Trees (UET). In our UET representation, multiple expression trees underlying a MWP will be integrated as an universal expression tree (UET) via symbol extension. UET can enable a solver to handle multiple types of MWPs in an unified manner like a single expression tree of an equation.

Math word problems (MWPs) solving aims to automatically answer a math word problem by understanding the textual description of the problem and reasoning out the underlying answer. A typical MWP is a short story that describes a partial state of the world and poses a question about an unknown quantity or multiple unknown quantities. Thus, a machine should have the ability of natural language understanding and reasoning. To solve an MWP, the relevant quantities need to be identified from the text, and the correct operators and their computation order among these quantities need to be determined.

Many traditional methods (Yuhui et al., 2010; Kushman et al., 2014; Shi et al., 2015) have been proposed to address this problem, but they relied on tedious hand-crafted features and template annotation, which required extensive human efforts and knowledge. Recently, deep learning has opened a new direction towards automatic MWPs solving (Wang et al., 2017; Huang et al., 2018; Wang et al., 2018b, 2019; Xie and Sun, 2019; Chiang and Chen, 2019). Most of deep learning-based methods try to train an end-to-end neural network to automatically learn the mapping function between problems and their corresponding equations. However, there are some limitations hindering them from

being applied in real-world applications. First, although seq2seq model (Wang et al., 2017) can be applied to solve various MWPs, it suffers from fake numbers generation and mispositioned numbers generation due to all data share the same target vocabulary without problem-specific constraints. Second, some advanced methods (Wang et al., 2018b, 2019; Xie and Sun, 2019) only target at arithmetic word problems without any unknown or with one unknown that do not need to model the unknowns underlying in MWPs, which prevent them from generalizing to various MWPs, such as equation set problems. Thus, their methods can only handle arithmetic problems with no more than one unknown. Besides, they also lack an efficient equation representation mechanism to handle those MWPs with multiple unknowns and multiple equations, such as equation set problems. Finally, though some methods (Wang et al., 2017; Huang et al., 2018; Chiang and Chen, 2019) can handle multiple types of MWPs, they neither generate next symbol by taking full advantage of the generated symbols like a human nor consider the semantic transformation between equations in a problem, resulting in poor performance on the multiple-unknown MWPs, such as the MWPs involving equation set.

To address the above issues, we propose a simple yet efficient method called Universal Expression Tree (UET) to make the first attempt to represent the equations of various MWPs uniformly like the expression tree of one-unknown linear word problems with considering unknowns. Specifically, as shown in Fig. 1, UET integrates all expression trees underlying in an MWP into an ensemble expression tree via math operator symbol extension so that the grounded equations of various MWPs can be handled in a unified manner as handling one-unknown linear MWPs. Thus, it can significantly reduce the difficulty of modeling equations of various MWPs.

Then, we propose a semantically-aligned universal tree-structured solver (SAU-Solver), which is based on our UET representation and an Encoder-Decoder framework, to solve multiple types of MWPs in a unified manner with a single model. In our SAU-Solver, the encoder is designed to understand the semantics of MWPs and extract number semantic representation while the tree-structured decoder is designed to generate the next symbol based on the problem-specific target vocabulary in a semantically-aligned manner by taking full advantage of the semantic meanings of the generated expression tree like a human uses problem's contextual information and all tokens written to reason next token for solving MWPs. The problem-specific target vocabulary can help our solver to mitigate the problem of fake numbers generation as much as possible.

Besides, to further enforce the semantic constraints and rationality of the generated expression tree, we also propose a subtree-level semantically-aligned regularization to further improve subtree-level semantic representation by aligning with the contextual information of a problem, which can improve answer accuracy effectively.

Finally, to validate the universality of our solver and push the research boundary of MWPs to math real-word applications better, we introduce a new challenging **H**ybrid **M**ath **W**ord **P**roblems dataset (HMWP), consisting of one-unknown linear word problems, one-unknown non-linear word problems, and equation set problems with two unknowns. Experimental results on HWMP, ALG514, Math23K, and Dolphin18K-Manual show the universality and superiority of our approach compared with several state-of-the-art methods.

2 Related Works

Numerous methods have been proposed to attack the MWPs task, ranging from rule-based methods (Bakman, 2007; Yuhui et al., 2010), statistical machine learning methods (Kushman et al., 2014; Zhou et al., 2015; Mitra and Baral, 2016; Huang et al., 2016; Roy and Roth, 2018),semantic parsing methods (Shi et al., 2015; Koncelkedziorski et al., 2015; Huang et al., 2017), and deep learning methods (Ling et al., 2017; Wang et al., 2017, 2018b; Huang et al., 2018; Wang et al., 2018a; Xie and Sun, 2019; Wang et al., 2019). Due to space limitations, we only review some recent advances on deep leaning-based methods. (Wang et al., 2017) made the first attempt to generate expression templates using Seq2Seq model. Seq2seq method has achieved promising results, but it suffers from generating spurious numbers, predicting numbers at wrong positions, or equation duplication problem (Huang et al., 2018; Wang et al., 2018a). To address them, (Huang et al., 2018) proposed to add a copy-and-alignment mechanism to the standard Seq2Seq model. (Wang et al., 2018a) proposed equation normalization to normalize the duplicated equations by considering the uniqueness of an expression tree.

Different from seq2seq-based works, (Xie and Sun, 2019) proposed a tree-structured decoder to generate an expression tree inspired by the goal-driven problem-solving mechanism. (Wang et al., 2019) proposed a two-stage template-based solution based on a recursive neural network for math expression construction. However, they do not model the unknowns underlying in MWPs, resulting in only handling one-unknown linear word problems. Besides, they also lack an efficient mechanism to handle those MWPs with multiple unknowns and multiple equations, such as equation set problems. Therefore, their solution can not solve other types of MWPs that are more challenging due to larger search space, such as equation set problems, non-linear equation problems, etc. (Chiang and Chen, 2019) is a general equation generator that generates expression via the stack, but they did not consider the semantic transformation between equations in a problem, resulting in poor performance on the multiple-unknown MWPs, such as equation set problems.

3 The design of SAU-Solver

3.1 Universal Expression Tree (UET)

The primary type of textual MWPs can be divided into two groups: arithmetic word problems and equation set problems. For a universal MWPs solver, it is highly demanded to represent various equations of various MWPs in a unified manner so that the solver can generate equations efficiently. Although most of the existing works can handle one-unknown linear word problems well, it is more challenging and harder for current methods to handle the equation set MWPs with multiple unknowns well since they not only do not model the unknowns in the MWPs but also lack of an efficient equations representation mechanism to make their decoder generate required equations efficiently. To handle the above issue, an intuitive way is treating the equation set as a forest of expression trees and all trees are processed iteratively in a certain order. Although this is an effective way to handle equations set problems, it increases the difficulty of equation generation since the model needs to reason out the number of equations before starting equation generation and the prediction error will influence equation generation greatly. Besides, it is also challenging to take full advantage of the context information from the problem and the generated trees. Another way is that we can deploy Seq2Seq-based architecture to handle various equations in infix order like in previous works (Wang et al., 2017; Huang et al., 2018), but there are some limitations, such as generating invalid expression, generating spurious numbers, and generating numbers at wrong positions.

To overcome the above issues and maintain simplicity, we propose a new equation representation called Universal Expression Tree (UET) to make the first attempt to represent the equations of various MWPs uniformly. Specially, we extend the math operator symbol table by introducing a new operator ; as the lowest priority operator to integrate one or more expression trees into a universal expression tree, as shown in Fig. 1. With UET, a solver can handle the underlying equations of various textual MWPs easier in a unified manner like the way on arithmetic word problems. Although our UET is simple, it provides an efficient, concise, and uniform way to utilize the context information from the problem and treat the semantic transformation between equations as simple as treating the semantic transformation between subtrees in an equation.

3.2 SAU-Solver

Based on our proposed UET representation, we design a universal tree-structured solver to generate a universal expression tree explicitly according to the problem context and explicitly model the relationships among unknown variables, quantities, math operations, and constants in a tree-structured way, as shown in Fig. 2. Our solver consists of a Bi-GRU-based problem encoder and an explicit tree-structured equation decoder. When a problem is entered, our model first encodes each word of the problem to generate the problem's contextual representation $\mathbf{g}_0$ by our problem encoder. Then, the $\mathbf{g}_0$ will be used as the initial hidden state by our tree-structured equation decoder to guide the equation generation in prefix order with two intertwined processes: top-down tree-structured decoding and bottom-up subtree semantic transformation. With the help of top-down tree-structured decoding and bottom-up subtree semantic transformation, SAU-Solver can generate the next symbol by taking full advantage of generated symbols in a semantically-aligned manner like human solving MWPs. Finally, we apply infix traversal and inverse number mapping to generate the corresponding human-readable

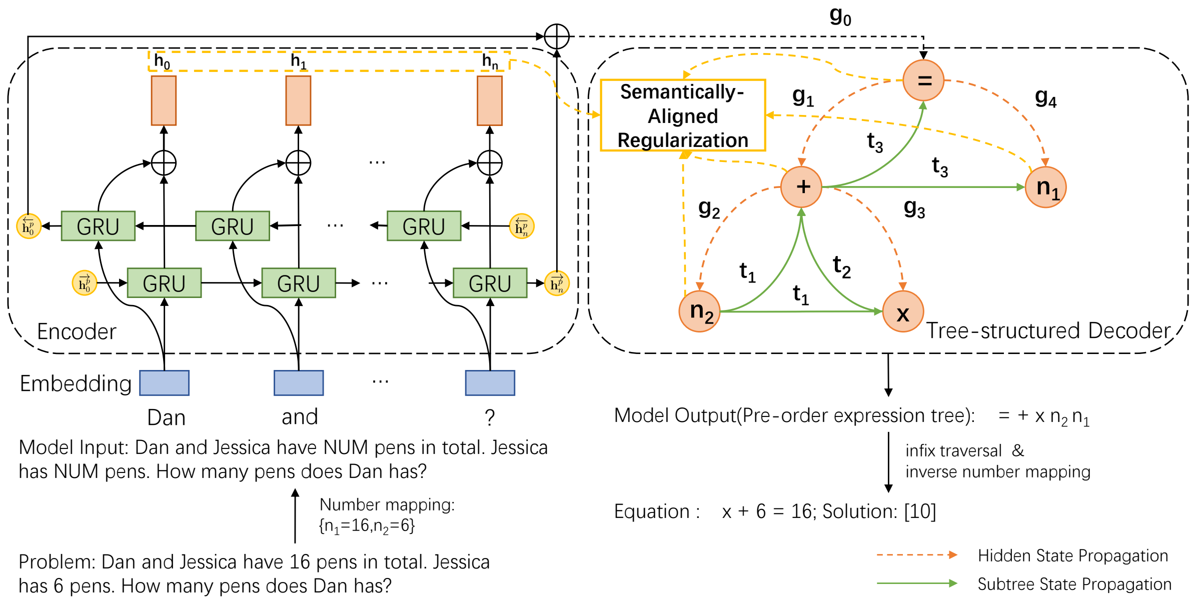

Figure 2: An overview of our SAU-Solver. When a problem preprocessed by number mapping and replacement is entered, our problem encoder encodes the problem text as context representation. Then our equation decoder generates an expression tree explicitly in pre-order traversal for the problem according to the context representation. Finally, infix traversal and inverse number mapping are applied to generate the corresponding equation.

equation that can be computed by SymPy[2], which is a python library for symbolic mathematics.

3.2.1 Problem Encoder

Bidirectional Gated Recurrent Unit (BiGRU) (Cho et al., 2014) is an efficient method to encode sequential information. Formally, given an input math word problem sentence $P = \{x_t\}_{t=1}^{n}$, we first embed each word into a vector $\mathbf{x}_t$. Then these embeddings are fed into a two-layer BiGRU from beginning to end and from end to beginning to model the problem sequence:

$$\begin{aligned} \overrightarrow{\mathbf{h}_t^p} &= GRU(\overrightarrow{\mathbf{h}_{t-1}^p}, \mathbf{x}_t) \\ \overleftarrow{\mathbf{h}_t^p} &= GRU(\overleftarrow{\mathbf{h}_{t+1}^p}, \mathbf{x}_t) \\ \mathbf{h}_t^p &= \overrightarrow{\mathbf{h}_t^p} + \overleftarrow{\mathbf{h}_t^p} \end{aligned} \tag{1}$$

where $GRU(\cdot,\cdot)$ represents the function of a two-layer GRU. $\mathbf{h}_t^p$ is the sum of the hidden states $\overrightarrow{\mathbf{h}_t^p}$ and $\overleftarrow{\mathbf{h}_t^p}$, which are from both forward and backward GRUs. These representation vectors are then fed into our tree-structured equation decoder for ensemble expression tree generation. Besides, we also construct the hidden state $\mathbf{g}_0$ as the initial hidden state of our equation decoder:

$$\mathbf{g}_0^p = \overrightarrow{\mathbf{h}_n^p} + \overleftarrow{\mathbf{h}_0^p} \tag{2}$$

where $\overrightarrow{\mathbf{h}_n^p}$ and $\overleftarrow{\mathbf{h}_0^p}$ are the hidden states of forward sequence and backward sequence respectively.

3.2.2 Equation Decoder

For decoding, inspired by previous works (Xie and Sun, 2019; Chiang and Chen, 2019), we build a semantically-aligned tree decoder to decide which symbol to generate by taking full advantage of the semantic meanings of the generated symbols with two intertwined processes: top-down tree-structured decoding and bottom-up subtree semantic transformation. Our decoder takes tree-based information $\mathbf{g}_{parent}$ (left node) or $(\mathbf{g}_{parent}, \mathbf{t}_l)$ (right node) as the input and maintains two auxiliary stacks G and T to enforce semantically-aligned decoding procedure. The stack G maintains the hidden states generated from the parent node while the stack T helps the model decide which symbol to generate by maintaining subtree semantic information of generated symbols. Benefiting from UET, our decoder can automatically end the decoding procedure without any special token. If the predicted token y_t is an operator, then we generate two children hidden states $\mathbf{g}_l$ and $\mathbf{g}_r$ according to the current node embedding $\mathbf{n}$ of y_t, and push them into the stack G to maintain the state transition among nodes and be used to predict token and its node embedding. Besides, we also push the token embedding $\mathbf{e}(y_t|P)$ of y_t into the stack T so that

---

[2] https://www.sympy.org/

we can maintain subtree semantic information of generated symbols after right child node generation. If the predicted token y_t is not an operator, we check the size of the stack T to judge whether the current node is a right node. If the current node is a right node, we transform the embedding of parent node op, left sibling node l and current node $\mathbf{e}(y_t|P)$ to a subtree semantic representation $\mathbf{t}$, which represents the semantic meanings of generated symbols for current subtree and is used to help the right node generation of the upper subtree. In this way, our equation decoder can decode out an equation as a human writes out an equation according to the problem description.

Token Embedding. For a problem P, its target vocabulary V^{tar} consists of 4 parts: math operators V_{op}, unknowns V_u, constants V_{con} that are those common-sense numerical values occurred in the target expression but not in the problem text (e.g. a chick has 2 legs.), and the numbers n_p occurred in P. For each token y in V^{tar}, its token embedding $\mathbf{e}(y|P)$ is defined as:

$$\mathbf{e}(y|P) = \begin{cases} \mathbf{M}_{op}(y) & \text{if } y \in V_{op} \\ \mathbf{M}_{u}(y) & \text{if } y \in V_{u} \\ \mathbf{M}_{con}(y) & \text{if } y \in V_{con} \\ \mathbf{h}^p_{loc}(y,P) & \text{if } y \in n_P \end{cases} \tag{3}$$

where $\mathbf{M}_{op}$, $\mathbf{M}_u$, and $\mathbf{M}_{con}$ are three trainable word embedding matrices independent of the specific problem. However, for a numeric value in n_P, we take the corresponding hidden state $\mathbf{h}^p_{loc}$ from encoder as its token embedding, where $loc(y,P)$ is the index position of numeric value y in P.

Gating Mechanism and Attention Mechanism. To better flow important information and ignore useless information, we apply a gating mechanism to generate node state $\mathbf{n}$ which will be used for predicting the output and generating child hidden states $\mathbf{g}_l$ and $\mathbf{g}_r$ for descendant nodes if the output of the current node is a math operator:

$$\begin{aligned} q &= \sigma\left(\mathbf{W}_q I\right) \\ Q &= \tanh\left(\mathbf{W}_Q I\right) \\ O &= q \odot Q \end{aligned} \tag{4}$$

where O can be a left node state $\mathbf{n}_l$, a right node state, a left child hidden state $\mathbf{g}_l$, or a right child hidden state $\mathbf{g}_r$. For $\mathbf{n}_l$, I is $\mathbf{g}_l$ generated by the parent node. For $\mathbf{n}_r$, I is $[\mathbf{g}_r, \mathbf{t}_l]$ which is the concatenation of the hidden state $\mathbf{g}_r$ generated by the parent node and the subtree semantic embedding $\mathbf{t}_l$ of left sibling. For $\mathbf{g}_l$ and $\mathbf{g}_r$, I is $[\mathbf{n}, \mathbf{c}, \mathbf{e}(y_t|P)]$ which is the concatenation of the current node state $\mathbf{n}$, the contextual vector $\mathbf{c}$ aggregating relevant information of the problem as a weighted representation of the input tokens by attention mechanism, and the token embedding $\mathbf{e}(y_t|P)$ of the predicted token y_t.

For better predicting a token y_t by utilizing contextual information, we deploy an attention mechanism to aggregate relevant information from the input vectors. Formally, given current node state $\mathbf{n}$ and the encoder outputs $\{\mathbf{h}^p_t\}^n_{t=1}$, we calculate the contextual vector $\mathbf{c}$ as follows:

$$\mathbf{c} = \sum_s \frac{\exp\left(\mathbf{V}_a \tanh\left(\mathbf{W}_a\left[\mathbf{n}, \mathbf{h}^p_s\right]\right)\right)}{\sum_i \exp\left(\mathbf{V}_a \tanh\left(\mathbf{W}_a\left[\mathbf{n}, \mathbf{h}^p_i\right]\right)\right)} \mathbf{h}^p_s \tag{5}$$

Based on the contextual vector $\mathbf{c}$ and current node state $\mathbf{n}$, we can predict the token y_t as follows:

$$y = \arg\max \frac{\exp(\mathbf{s}(y|\mathbf{n}, \mathbf{c}, P))}{\sum_i \exp\left(\mathbf{s}\left(y_i|\mathbf{n}, \mathbf{c}, P\right)\right)} \tag{6}$$

where

$$\mathbf{s}(y|\mathbf{n}, \mathbf{c}, P) = \mathbf{V}_n \tanh\left(\mathbf{W}_s[\mathbf{n}, \mathbf{c}, \mathbf{e}(y|P)]\right) \tag{7}$$

Subtree Semantic Transformation. Although our decoder decodes a universal expression tree in the prefix, to help our model to generate the next symbol in a semantically-aligned manner by taking full advantage of the semantic meanings of the generated expression tree, we design a recursive neural network to transform the semantic representations of the current node and its two child subtrees $\mathbf{t}_l$ and $\mathbf{t}_r$ into a high-level embedding $\mathbf{t}$ in a bottom-up manner. Formally, let t be a subtree, and y denotes the predicted token of the root node of the subtree. If y is a math operator, which means that the current subtree t must have two child subtrees $\mathbf{t}_l$ and $\mathbf{t}_r$, the high-level embedding $\mathbf{t}$ should fuse the semantic information from the operator token y, the left child subtree $\mathbf{t}_l$ and the right child subtree $\mathbf{t}_r$ as follows:

$$\begin{aligned} g_t &= \sigma\left(\mathbf{W}_{gt}\left[\mathbf{t}_l, \mathbf{t}_r, \mathbf{e}(\hat{y}|P)\right]\right) \\ C_t &= \tanh\left(\mathbf{W}_{ct}\left[\mathbf{t}_l, \mathbf{t}_r, \mathbf{e}(\hat{y}|P)\right]\right) \\ \mathbf{t} &= g_t \odot C_t \end{aligned} \tag{8}$$

Otherwise, $\mathbf{t}$ is the embedding $\mathbf{e}(y|P)$ of the predicted token y because y is a numeric value, an unknown variable, or a constant quantity and the recursion stops.

3.2.3 Semantically-Aligned Regularization

When a subtree t is produced by our model, this means that we have a computable unit. The semantics of this computable unit should be consistent with the problem text P. To achieve this goal, we propose a subtree-level semantically-aligned regularization to help train a better model with higher performance. For each subtree embedding $\mathbf{t}$ and encoder outputs $\{\mathbf{h}_1^P, \mathbf{h}_1^P, \cdots, \mathbf{h}_n^P\}$, we first apply an attention function to compute a semantically-aligned vector $\mathbf{a}$ as Equation(5), then we use a two-layer feed-forward neural network with tanh activation to transform $\mathbf{t}$ and $\mathbf{a}$ into same semantic space respectively. The procedure can be formulated as:

$$\begin{aligned} \mathbf{e}_{sa} &= \mathbf{W}_{e2} \tanh(\mathbf{W}_{e1}\mathbf{a}) \\ \mathbf{d}_{sa} &= \mathbf{W}_{d2} \tanh(\mathbf{W}_{d1}\mathbf{t}) \end{aligned} \tag{9}$$

where $\mathbf{W}_{e1}$, $\mathbf{W}_{e2}$, $\mathbf{W}_{d1}$, and $\mathbf{W}_{d2}$ are trainable parameter matrices. With the vectors $\mathbf{e}_{sa}$ and $\mathbf{d}_{sa}$ Let m be the number of subtrees in a universal expression tree, we can regularize our model by minimizing the following loss:

$$\mathcal{L}_{sa}(T|P) = \frac{1}{m}\sum_{i=1}^{m} \|\mathbf{d}_{sa} - \mathbf{e}_{sa}\|_2 \tag{10}$$

3.2.4 Training Objective

Given the training dataset $\mathbf{D}$=$\{(P^i, T^1)$, (P^2, T^2), $\cdots$,(P^N, T^N) $\}$, where T^i is the universal expression tree of problem P^i, we minimize the following loss function:

$$\mathcal{L}(T|P) = \sum_{(P,T)\in\mathbf{D}} [-\log p(T|P) + \lambda * \mathcal{L}_{sa}(T|P)] \tag{11}$$

where

$$p(T|P) = \prod_{t=1}^{m} \text{prob}(y_t|\mathbf{g}_t, \mathbf{c}_t, P) \tag{12}$$

where m denotes the size of T, and $\mathbf{g}_t$ and $\mathbf{c}_t$ are the hidden state vector and its contextual vector at the t-th node. We set λ as 0.01 empirically.

3.3 Discussion

The methods most relevant to our method are GTS (Xie and Sun, 2019) and StackDecoder (Chiang and Chen, 2019). However, compared with them, our method is different from them as follows. First, our method applies a universal expression tree to represent the diverse equations underlying different MWPs uniformly, which match real-word MWPs better than GTS and StackDecoder which either can only handle single-var linear MWPs without considering unknowns or can handle equations set problem iteratively. Second, we introduce subtree-level semantically-aligned regularization for better enforcing the semantic constraints and rationality of generated expression tree during training, leading to higher answer accuracy, as illustrated in Table 2.

4 Hybrid Math Word Problem Dataset

Most public datasets for automatic MWPs solving either are quite small such as Alg514 (Kushman et al., 2014), DRAW-1K (Upadhyay and Chang, 2017), MaWPS (Koncel-Kedziorski et al., 2016) or exist some incorrect labels such as Dolphin18K (Huang et al., 2016). An exception is the Math23K dataset which contains 23161 problems labeled well with structured equations and answers. However, it only contains one-unknown linear MWPs, which is not sufficient to validate the ability of a math solver about solving multiple types of MWPs. Therefore, we introduce a new high-quality MWPs dataset, called HMWP, in which each sample is extracted from a Chinese K12 math word problem bank, to validate the universality of math word problem solvers and push the research boundary of MWPs to match real-world scenes better. Our dataset contains three types of MWPs: arithmetic word problems, equations set problems, and non-linear equation problems. There are 5491 MWPs, including 2955 one-unknown-variable linear MWPs, 1636 two-unknown-variable linear MWPs, and 900 one-unknown-variable non-linear MWPs. It should be noticed that our dataset is sufficient for validating the universality of math word problem solvers since these problems can cover most cases about MWPs. We labeled our data with structured equations and answers as Math23K (Wang et al., 2017). The data statistics of our dataset and several publicly available datasets are shown in Table 1. From the statistics, we can see that the #AVG EL (average equation length), #Avg PN (average number of quantities occurred in problems and their corresponding equations), and #Avg Ops (average numbers of operators in equations) are the largest among the serval publicly available datasets. (Xie and Sun, 2019) showed the higher these values, the more difficult it is. Therefore, our dataset is more challenging for MWPs solvers.

Dataset	# Problems	# Templates	# Sentences	# Words	# Avg EL	# Avg SNI	# Avg Constants	# Avg Ops	Problem types
Alg514	514	28	1.62k	19.3k	9.67	3.54	0.44	5.69	algebra, linear
Dolphin1878	1,878	1,183	3.30k	41.4k	8.18	2.58	0.63	4.97	linear + nonlinear
DRAW-1K	1,000	230	6.23k	81.5k	9.985	3.386	0.747	5.852	algebra, linear
MaWPS	2373	-	2373	73.3k	4.55	2.31	0.26	1.78	algebra, linear
Math23K	23,161	2,187	70.1k	822k	5.55	3.0	0.28	2.28	algebra, linear
Dolphin18k	18,460	5,871	49.9k	604k	9.19	3.15	1.09	4.96	linear + nonlinear
HMWP	5470	2779	9.56k	342k	**10.73**	3.42	**1.35**	**5.96**	linear + nonlinear

Table 1: Statistics of our dataset and several publicly available datasets. Avg EL, Avg SNI, Avg Constants, and Avg Ops represent average equation length, average number of quantities occurred in problems and their corresponding equations, average numbers of constants only occurred in equations, and average numbers of operators in equations, respectively. The higher these values, the more difficult it is. This has been shown in (Xie and Sun, 2019).

5 Experiments

5.1 Experimental Setup and Training Details

Datasets, Baselines, and Evaluation metric. We conduct experiments on four datasets, such as HMWP, Alg514 (Kushman et al., 2014), Math23K (Wang et al., 2017) and Dolphin18K-Manual (Huang et al., 2016). The data statistics of four datasets are shown in Table 1. The main state-of-the-art learning-based methods to be compared are as follows: **Seq2Seq-attn w/ SNI** (Wang et al., 2017) is a universal solver based on the seq2seq model with significant number identification(SNI). **GTS** (Xie and Sun, 2019) is a goal-driven tree-structured MWP solver only for one-unknown-variable non-linear MWPs. **StackDecoder** (Chiang and Chen, 2019) is a semantically-aligned MWPs solver. **SAU-Solver w/o SSAR** and **SAU-Solver** are two universal tree-structured solvers proposed in this paper without and with subtree semantically-aligned regularization. Following our baselines, we use *answer accuracy* as the evaluation metric: if the calculated value of the predicted expression tree equals to the true answer, it is thought of correct since the predicted expression is equivalent to the target expression.

Model	HMWP	ALG514	Math23K	Dolphin18K Manual
Seq2Seq-attn w/ SNI	23.2%	16.1%	58.1%	5.9%
GTS	-	-	73.9%	-
StackDecoder	27.4%	28.86%	66.0%	9.8%
SAU-Solver w/o SSAR (ours)	44.40%	55.44%	74.53%	11.02%
SAU-Solver (ours)	**44.83%**	**57.39%**	**74.84%**	**11.41%**

Table 2: Model comparison on answer accuracy via 5-fold cross-validation. “-” means either the code is not released or the model is not suitable on those datasets.

Implementation Details. We use PyTorch[3] to implement our model on Linux with NVIDIA RTX 2080Ti. All the words with less than five occurrences are converted into a special token UNK. We set the dimensionality of word embedding and the size of all hidden states for other layers as 128 and 512, respectively. But for HMWP and Dolphin18K-Manual, we set the size of all hidden states for other layers as 384 since the memory consumption exceeds the capacity of NVIDIA RTX 2080Ti. Our model is trained by ADAM optimizor (Kingma and Ba, 2015) with β_1 = 0.9, β_2 =0.999, and ϵ = 10^{-8}. The mini-batch size is set to 32. The initial learning rate is set to 10^{-3} and then decreases to half every 20 epochs. To prevent overfitting, we set the dropout probability as 0.5 and weight decay as $1e^{-5}$. Finally, we set beam size as 5 in beam search to generate expression trees.

	linear (One-VAR)	linear (Two-VAR)	non-linear (One-VAR)	All
# Num	1944	1614	1912	5470
# Avg EL	10.50	12.10	9.83	10.73
# Avg SNI	3.59	3.59	3.12	3.42
# Avg Constants	1.21	1.41	1.45	1.35
# Avg Ops	5.70	7.10	5.26	5.96
Correct number (Retrieval-Jaccard)	222	348	618	1188
Accuracy (Retrieval-Jaccard)	11.42%	21.56%	32.32%	21.72%
Correct number (Seq2Seq-attn w/SNI)	244	312	711	1267
Accuracy (Seq2Seq-attn w/SNI)	12.55%	19.33%	37.19%	23.2%
Correct number (SAU-Solver (ours))	**593**	**673**	**1186**	**2452**
Accuracy (SAU-Solver (ours))	**30.50%**	**41.70%**	**62.03%**	**44.83%**

5.2 Results and Analyses

Answer Accuracy. We conduct 5-fold cross-validation to evaluate the performances of baselines and our models on all four datasets. The results are shown in Table 2. Several observations can be made from the results in Table 2 as follows:

First, our SAU-Solver has achieved significantly better than the baselines on four datasets. It proves that our model is feasible for solving multiple types

Table 4: Typical cases. Note that the results are represented as infix traversal of expression trees which is more readable than prefix traversal.

of MWPs. It also proves that our model is more general and more effective than other state-of-the-art models on the real-word scenario that need to solve multiple types of MWPs with a unified solver.

Second, with our subtree-level semantically-aligned regularization on training procedure, our SAU-Solver has gained additional absolute 0.43% accuracy on HMWP, absolute 1.95% accuracy on ALG514, absolute 0.31% accuracy on Math23k, and absolute 0.39% accuracy on Dolphin18k-Manual. This shows that subtree-level semantically-aligned regularization is helpful for improving subtree semantic embedding, resulting in improving expression tree generation, especially for the generation of the right child node. Although StackDecoder can be a universal math word problem solver via simple operator extension, the performances on HMWP, ALG514, and Dolphin18k-Manual are very poor, since it generates expression trees independently and only considers the semantic-aligned transformation in an expression tree. Different from it, our SAU-Solver generates multiple expression trees as a universal expression tree and conducts subtree-level semantic-aligned transformation for subsequent tree node generation in our universal expression tree. In this way, we can deliver the semantic information of the previous expression tree to help the generation of the current expression tree. Therefore we can achieve better performance than StackDecoder.

Overall, our model is more general and effective than other state-of-the-art models on multiple MWPs and outperforms the compared state-of-the-art models by a large margin on answer accuracy.

Performance on different types of MWPs. We drill down to analyse the performance of **Retrieval-Jaccard**, **Seq2seq-attn w/SNI**, and **SAU-Solver** on different types of MWPs in HMWP. The data statistics and performance results are shown in Table 3. We can observe that our model outperforms the other two models by a large margin on all subsets. Intuitively, the longer the expression length is, the more complex the mathematical relationship of the problem is, and the more difficult it is. And the average expression length of our dataset is much longer than Math23K according to the data statistics of Table 3 and Table 1. Therefore, we can observe that the accuracy of our model on linear (One-VAR) is lower than Math23K in Table 2.

Expression Tree Sizes	Math23K			HMWP		
	Correct	Error	Acc(%)	Correct	Error	Acc(%)
3-	729	168	81.27%	0	0	0%
5	1872	435	81.14%	3	1	75.00%
7	620	291	68.06%	32	25	56.14%
9	147	143	50.69%	159	69	69.74%
11	66	74	47.14%	102	111	47.89%
13+	20	66	23.26%	197	395	33.28%

Table 5: Accuracy of different expression tree size.

5.3 Error Analysis

In Table 5, we show the results of how the accuracy changes as the expression tree size becomes larger. We can observe that as the expression tree size becomes larger, our model's performance becomes lower. This shows that although our model can handle various equations in a unified manner, it still has limitations at predicting long equations since longer equations often match with more complex MWPs which are more difficult to solve. Thus, our model still has room for improvement in reasoning, inference, and semantic understanding. Besides, compared with performances on Math23K which has only a few examples with complex templates, our model achieves significant improvement on the subset of HMWP with expression tree size 13+. This shows that constructing datasets with abundant complex examples can improve the model's ability to handle complex problems.

5.4 Case Study

Further, we conduct a case analysis and provide four cases in Table 4, which shows the effectiveness of our approach. Our analyses are summarized as follows. From **Case 1**, Seq2Seq generates a spurious number n_2 not in problem text while both SAU-Solver w/o SSAR and SAU-Solver predict correctly owning to the problem-specific target vocabulary. Besides, although both SAU-Solver w/o SSAR and SAU-Solver can generate correct an equation, the equation generated by our SAU-Solver is more semantically-aligned with a human than the equation generated by SAU-Solver. From **Case 2**, we can see that Seq2Seq generates an invalid expression containing consecutive operators while our models can guarantee the validity of expressions since they generate expression trees directly. From **Case 3**, we find it interesting that tree-based models can avoid generating redundant operations, such as "n_1*". From **Case 4**, we can see that SAU-Solver can prevent generating the similar subtree as its left sibling when the parent node is "*".

6 Conclusion

We propose an SAU-Solver, which is able to solve multiple types of MWPs, to generate the universal express tree explicitly in a semantically-aligned manner. Besides, we also propose a subtree-level semantically-aligned regularization to improve subtree semantic representation. Finally, we introduce a new MWPs datasets, called HMWP, to validate our solver's universality and push the research boundary of MWPs to math real-world applications better. Experimental results show the superiority of our approach.

Abstract

Graph Neural Networks (GNNs) that capture the relationships between graph nodes via message passing have been a hot research direction in the natural language processing community. In this paper, we propose Graph Topic Model (GTM), a GNN based neural topic model that represents a corpus as a document relationship graph. Documents and words in the corpus become nodes in the graph and are connected based on document-word co-occurrences. By introducing the graph structure, the relationships between documents are established through their shared words and thus the topical representation of a document is enriched by aggregating information from its neighboring nodes using graph convolution. Extensive experiments on three datasets were conducted and the results demonstrate the effectiveness of the proposed approach.

1 Introduction

Probabilistic topic models (Blei, 2012) are tools for discovering main themes from large corpora. The popular Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and its variants (Lin and He, 2009; Zhao et al., 2010; Zhou et al., 2014) are effective in extracting coherent topics in an interpretable manner, but usually at the cost of designing sophisticated and model-specific learning algorithm. Recently, neural topic modeling that utilizes neural-network-based black-box inference has been the main research direction in this field. Notably, NVDM (Miao et al., 2016) employs variational autoencoder (VAE) (Kingma and Welling, 2013) to model topic inference and document generation. Specifically, NVDM consists of an encoder inferring topics from documents and a decoder generating documents from topics, where the latent topics are constrained by a Gaussian prior. Srivastava and Sutton (2017) argued that Dirichlet distribution is a more appropriate prior for topic modeling than Gaussian in NVDM and proposed ProdLDA that approximates the Dirichlet prior with logistic normal. There are also attempts that directly enforced a Dirichlet prior on the document topics. W-LDA (Nan et al., 2019) models topics in the Wasserstein autoencoders (Tolstikhin et al., 2017) framework and achieves distribution matching by minimizing their Maximum Mean Discrepancy (MMD) (Gretton et al., 2012), while adversarial topic model (Wang et al., 2019a,b, 2020) directly generates documents from the Dirichlet prior and such a process is adversarially trained with a discriminator under the framework of Generative Adversarial Network (GAN) (Goodfellow et al., 2014).

Recently, due to the effectiveness of Graph Neural Networks (GNNs) (Li et al., 2015; Kipf and Welling, 2016; Zhou et al., 2018) in embedding graph structures, there is a surge of interests of applying GNN to natural language processing tasks (Yasunaga et al., 2017; Song et al., 2018; Yao et al., 2019). For example, GraphBTM (Zhu et al., 2018) is a neural topic model that incorporates the graph representation of a document to capture biterm co-occurrences in the document. To construct the graph, a sliding window over the document is employed and all word pairs in the window are connected.

A limitation of GraphBTM is that only word relationships are considered while ignoring document relationships. Since a topic is possessed by a subset of documents in the corpus, we believe that the topical neighborhood of a document, i.e., documents with similar topics, would help determine the topics of a document. To this end, we propose Graph Topic Model (GTM), a neural topic model that a corpus is represented as a document relationship graph where documents and words in the corpus are nodes and they are connected based on

November 16–20, 2020.

document-word co-occurrences. In GTM, the topical representation of a document node is aggregated from its multi-hop neighborhood, including both document and word nodes, using Graph Convolutional Network (GCN) (Kipf and Welling, 2016). As GCN is able to capture high-order neighborhood relationships, GTM is essentially capable of modeling both word-word and doc-doc relationships. In specific, the relationships between relevant documents are established by their shared words, which is desirable for topic modeling as documents belonging to one topic typically have similar word distributions.

The main contributions of the paper are:

- We propose GTM, a novel topic model that incorporates document relationship graph to enrich document and word representations.
- We extensively experimented on three datasets and the results demonstrate the effectiveness of the proposed approach.

2 Graph Topic Model

2.1 Graph Representation of the Corpus

We represent the whole corpus $\mathcal{D}$ with an undirected graph $\mathcal{G} = (\mathcal{N}, \mathcal{E})$, where $\mathcal{N}$ and $\mathcal{E}$ are nodes and edges in the graph respectively. To model both words and documents, each of them is represented as a node $n_i \in \mathcal{N}$, which gives rise to $N = V + D$ nodes in total, where V is the size of vocabulary $\mathcal{V}$ and D is the number of documents in corpus $\mathcal{D}$. An edge (n_i, n_j) indicates the relevance of node n_i and n_j, whose weight is determined by

$$A_{i,j} = \begin{cases} \text{TF-IDF}_{ij}, & i \in \mathcal{D} \text{ and } j \in \mathcal{V} \\ \text{TF-IDF}_{ji}, & i \in \mathcal{V} \text{ and } j \in \mathcal{D} \\ 1, & i = j \\ 0, & \text{otherwise} \end{cases} \tag{1}$$

where $\boldsymbol{A}$ is the adjacency matrix of $\mathcal{G}$ and TF-IDF$_{ij}$ denotes the max-normalized TF-IDF (Term Frequency–Inverse Document Frequency) weight of word j in document i. Besides self-connections, we only apply positive weights to edges between documents and words, while rely on the model to capture higher-order relationships, e.g. doc-doc and word-word relationships, by applying graph convolutions on graph $\mathcal{G}$.

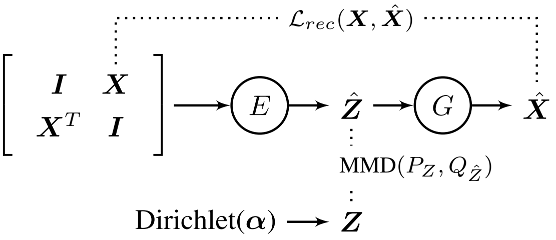

Figure 1: The framework of GTM. Circles denote neural networks. $\boldsymbol{X}$, $\boldsymbol{I}$, $\hat{\boldsymbol{Z}}$, $\hat{\boldsymbol{X}}$, $\boldsymbol{Z}$ are the TF-IDF matrix of the corpus, an identity matrix, latent topics of all documents, reconstructed word weights and topic distributions drawn from the Dirichlet prior respectively. $\mathcal{L}_{rec}(\boldsymbol{X}, \hat{\boldsymbol{X}})$ and MMD(P_Z, Q_Z) are training objectives.

2.2 Model Architecture

The proposed GTM consists of an encoder E and a decoder G. The framework is shown in Figure 1, and we detail the architecture in the following.

The encoder network E maps nodes in $\mathcal{G}$ to their topic distributions by iteratively applying graph convolution to the node features. Following (Kipf and Welling, 2016), the layer-wise propagation rule of the graph convolution at layer $l + 1 \in [1, L]$ is defined as

$$\boldsymbol{H}^{(l+1)} = \sigma(\boldsymbol{D}^{-\frac{1}{2}} \boldsymbol{A} \boldsymbol{D}^{-\frac{1}{2}} \boldsymbol{H}^{(l)} \boldsymbol{W}^{(l)}) \tag{2}$$

where $\boldsymbol{A} \in \mathbb{R}^{N \times N}$ is the adjacency matrix of $\mathcal{G}$, $D_{ii} = \sum_j A_{ij}$, $\boldsymbol{W}^{(l)} \in \mathbb{R}^{d^{(l)} \times d^{(l+1)}}$ is a layer-specific weight matrix where $d^{(l)}$ is the output size of layer l, and σ denotes an activation function that is LeakyReLU (Maas et al., 2013) in this paper. $\boldsymbol{H}^{(l)} \in \mathbb{R}^{N \times d^{(l)}}$ is the activations of all nodes at layer l and $\boldsymbol{H}_i^{(0)}$ is the embedding of node i.

At each encoder layer, what the graph convolution does is aggregating node features from a node's first-order neighborhood, which consequently enlarges the receptive field of the central node and enables the information propagation between relevant nodes. After successively applying L graph convolution layers, the encoding of a node essentially involves its L^{th}-order neighborhood. With $L \geq 2$, doc-doc and word-word relationships are naturally captured in the topic inference process.

We also add a batch normalization (Ioffe and Szegedy, 2015) after each graph convolution. After the graph encoding, a softmax is further applied to the node features of a document to produce a multinomial topic distribution $\hat{\boldsymbol{z}} \in \mathbb{R}^K$, where K is the topic number.

Based on the inferred topic distribution $\hat{\boldsymbol{z}}$, the decoder network G tries to restore the original document representations. To achieve this goal, we employ a 2-layer MLP with LeakyReLU activation and batch normalization in the first layer. The output of the MLP decoder is then softmax-normalized to generate a word distribution $\hat{\boldsymbol{x}} \in \mathbb{R}^V$.

The decoder is also used to interpret topics. In this case, we feed to the decoder an identity matrix $\boldsymbol{I} \in \mathbb{R}^{K\times K}$, and the decoder output $G(\boldsymbol{I})_i$ is the word distribution of the i-th topic.

2.3 Training Objective

Based on the Wasserstein Autoencoder (Tolstikhin et al., 2017) framework, the training objective of GTM is to minimize the document reconstruction loss when the latent topic space is constrained by a prior distribution. The reconstruction loss is defined as

$$\mathcal{L}_{rec}(\boldsymbol{X}, \hat{\boldsymbol{X}}) = -\mathbb{E}(\boldsymbol{x} \log \hat{\boldsymbol{x}}), \tag{3}$$

where $\boldsymbol{x}$ denotes the TF-IDF of a document and $\hat{\boldsymbol{x}}$ is the reconstructed word distribution corresponding to $\boldsymbol{x}$. we use TF-IDF as the reconstruction target since TF-IDF basically preserves the relative importance of words and reduces some background noise that may hurt topic modeling, e.g., stop words.

We impose a Dirichlet prior, the conjugate prior of the multinomial distribution, to the latent topic distributions. Following W-LDA (Nan et al., 2019), we achieve this goal by minimizing the Maximum Mean Discrepancy (MMD) (Gretton et al., 2012) between the distribution $Q_{\hat{Z}}$ of inferred topic distributions $\hat{\boldsymbol{z}}$ and the Dirichlet prior P_Z from which we draw multinomial noises $\boldsymbol{z}$:

$$\text{MMD}(P_Z, Q_{\hat{Z}}) = \frac{1}{m(m-1)} \sum_{i\neq j} k(\boldsymbol{z}^{(i)}, \boldsymbol{z}^{(j)}) + \frac{1}{n(n-1)} \sum_{i\neq j} k(\hat{\boldsymbol{z}}^{(i)}, \hat{\boldsymbol{z}}^{(j)}) - \frac{2}{mn} \sum_{i,j} k(\boldsymbol{z}^{(i)}, \hat{\boldsymbol{z}}^{(j)}), \tag{4}$$

where m and n are the number of samples from Z and $\hat{Z}$ respectively (m and n are batch sizes and they are equal in our experiments), and $k\colon Z \times Z \to \mathbb{R}$ is the kernel function. We use the information diffusion kernel (Lebanon and Lafferty, 2003) as in W-LDA:

$$k(\boldsymbol{z}, \boldsymbol{z}') = \exp(-\arccos^2(\sum_{i=1}^{K} \sqrt{z_i z_i'})), \tag{5}$$

which is sensitive to points near the simplex boundary and thus more suitable for the sparse topic distributions.

3 Experiments

We evaluate our model on three datasets: 20Newsgroups consisting of 11,259 documents, Grolier consisting of 29,762 documents, and NYTimes consisting of 99,992 documents. We use the preprocessed 20Newsgroups of (Srivastava and Sutton, 2017), and preprocessed Grolier and NYTimes of (Wang et al., 2019a). We compare the performance of our model with LDA (Blei et al., 2003), NVDM (Miao et al., 2016), ProdLDA (Srivastava and Sutton, 2017), GraphBTM (Zhu et al., 2018), ATM (Wang et al., 2019a) and W-LDA (Nan et al., 2019) using topic coherence measures (Röder et al., 2015). To quantify the understandability of the extracted topics, a topic coherence measure aggregates the relatedness scores of the topic words (top-weighted words) of each topic, where the word relatedness scores are estimated based on word co-occurrence statistics on a large external corpus. For example, the NPMI coherence measure (Aletras and Stevenson, 2013) applies a sliding window of size 10 over the Wikipedia corpus to calculate NPMI (Bouma, 2009) for word pairs. We use three topic coherence measures in our experiments: C_A (Aletras and Stevenson, 2013), C_P (Röder et al., 2015), and NPMI. The topic coherence scores are calculated using Palmetto (Röder et al., 2015) [1].

---

[1] `https://github.com/AKSW/Palmetto`

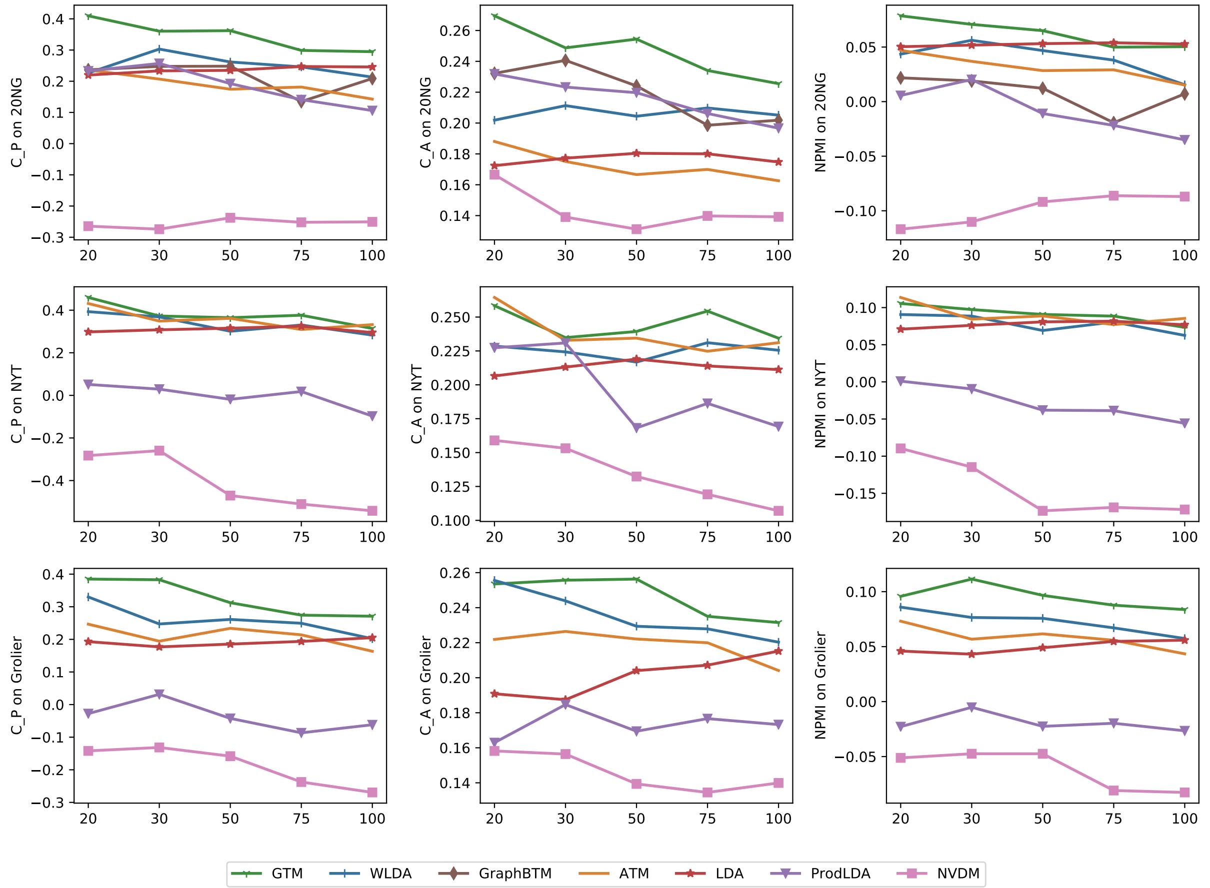

Figure 2: Topic coherence scores (C_P, C_A, NPMI) w.r.t. topic numbers on 20Newsgroups (20NG), NYTimes (NYT), and Grolier.

We use 2 graph convolution layers with output dimensions of 100 and K respectively in the encoder. The hidden size of the decoder is also set to 100. We use the RMSProp (Hinton et al., 2012) optimizer with a learning rate of 0.01 to train the model for 100 epochs. Since the training datasets scale up to 100K documents, i.e., 100K document nodes in the graph, it is hard to do batch training on a single GPU given the large memory requirements. We solve this issue by mini-batching the datasets and feeding to the model a subgraph consisting of 1000 document nodes and all word nodes at a training step, which results in efficient training (The training time increases almost linearly with the number of documents) and makes it possible to apply our model to even bigger datasets.

The topic coherence results on the three datasets are shown in Table 1, where each value is the average of 5 topic number settings: 20, 30, 50, 75, 100. From Table 1, we can observe that our proposed GTM is the best-performing model under all dataset/metric settings. W-LDA, ATM, LDA, and GraphBTM alternately achieve the second-best but they are always under-performed compared to our model. As described in section 2, GTM is an extension to W-LDA with the main difference that GTM models topics in a larger context and incorporates more global information with the graph encoder. Therefore the improvements of GTM over W-LDA indicate the effectiveness of such information for topic modeling. We only experimented GraphBTM on 20Newsgroups because only 20Newsgroups preserves the sequential information that is necessary for GraphBTM to build graphs. GraphBTM performs well on the C_A metric, which is reasonable since C_A is a coherence measure based on a small sliding window of size 5 and consequently prefers models concentrating on a smaller context like GraphBTM. However, GraphBTM fails to achieve a high C_P or NPMI score, which uses a bigger window (70 and 10 respectively).

To explore how topic coherence results vary w.r.t. different topic numbers, we present in Figure 2 the topic coherence scores under different topic

Table 2: Discovered topics that are most similar to 4 ground-truth categories (sci.med, sci.space, rec.autos, misc.forsale) on 20Newsgroups with topic number 50. Italics are manually labeled off-topic words.

numbers settings. It can be observed in Figure 2 that GTM enjoys the best overall performance, achieving the highest scores in most settings. LDA has a slightly higher NPMI score on 20Newsgroups dataset with 75 and 100 topics, nevertheless, GTM outperforms all baseline models with a relatively large margin on other settings of 20Newsgroups. NVDM is apparently the worst-performing model, while performances of models other than GTM and NVDM are not so consistent. Notably, W-LDA, GraphBTM, and LDA obtain the second-best overall C_P, C_A, and NPMI scores respectively. Another observation from Figure 2 is that GTM performs better on smaller topics, probably due to the fact that topics become more discriminative against each other when the topic number is small.

To gain an intuitive impression on the discovered topics, we present in Table 2 4 topics corresponding to 4 out of 20 ground-truth categories of 20Newsgroups. It can be observed that the topics discovered by GTM are more coherent and interpretable, containing few off-topic words. As a comparison, GraphBTM's rec.autos topic mixes up automobiles and criminals, W-LDA's misc.forsale topic is difficult to identify with too many off-topic words, while LDA can not distinguish between rec.autos and misc.forsale well thus recognizes them as the same topic. It can be observed that GTM learns more discriminative topics by examining topic words from overlapping topics, e.g. rec.autos and misc.forsale.

4 Conclusion

We have introduced Graph Topic Model, a neural topic model that incorporates corpus-level neighboring context using graph convolutions to enrich document representations and facilitate the topic inference. Both quantitative and qualitative results are presented in the experiments to demonstrate the effectiveness of the proposed approach. In the future, we would like to extend GTM to corpora with explicit doc-doc interactions, e.g., scientific documents with citations or social media posts with user relationships. Replacing GCN in GTM with more advanced graph neural networks is another promising research direction.

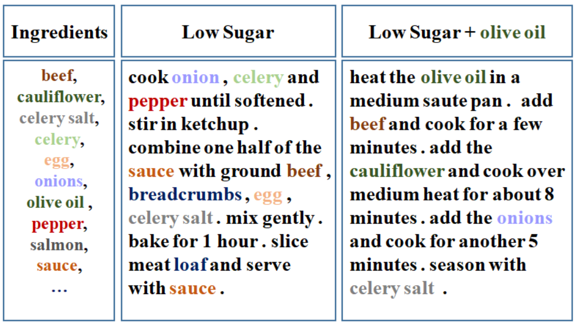
Abstract

One of the most challenging part of recipe generation is to deal with the complex restrictions among the input ingredients. Previous researches simplify the problem by treating the inputs independently and generating recipes containing as much information as possible. In this work, we propose a routing method to dive into the content selection under the internal restrictions. The routing enforced generative model (RGM) can generate appropriate recipes according to the given ingredients and user preferences. Our model yields new state-of-the-art results on the recipe generation task with significant improvements on BLEU, F1 and human evaluation.

1 Introduction

Food is a critical contributor to physical well being, a major source of pleasure, worry and stress, a major occupant of waking time, and across the world, the single greatest category of expenditures for human beings (Rozin et al., 1999). Recipes are a specific genre of instructional language to teach people how to prepare delicious food. They have been gaining interests in recent researches as recipes contain immensely rich information about the real world (Yagcioglu et al., 2018).

Among previous efforts towards computational recipe studies, there are two lines in obtaining cooking recipes for users: recipe retrieval and recipe generation. Recipe retrieval (Chen and Ngo, 2016; Min et al., 2017) matches the entities from the given dish pictures or text inputs to find the corresponding recipes. Provided with ingredients (Yang et al., 2017), recipe titles (Kiddon et al., 2016), or dish photos (Salvador et al., 2019), recipe generation models introduce additional mechanisms to assure the generated recipes containing as much given ingredients as possible. In previous studies, the target recipes are exactly composed of the given ingredients. However, in practice, people usually have a number of ingredients at hand and do not know what to cook. They have difficulty in choosing appropriate set of ingredients. And it can be hard for them to input an accurate recipe title for the models (Kiddon et al., 2016; Majumder et al., 2019). What's more, users may have preferences on some ingredients (e.g. "olive oil") or categories (e.g. "Low Sugar"). As Figure 1 shows, given the same ingredient list, there can be different sets of ingredients contributing to recipes with different user demands. Previous researches have not discussed this common scene of life. There is a clear need in finding suitable cooking recipes that match user demands. As increasing the variety and creativity of daily dishes can promote our happiness, in this work, we manage to obtain the desired recipes in a generation manner.



Ingredients	Low Sugar	Low Sugar + olive oil
beef, cauliflower, celery salt, celery, egg, onions, olive oil , pepper, salmon, sauce, ...	cook onion , celery and pepper until softened . stir in ketchup . combine one half of the sauce with ground beef , breadcrumbs , egg , celery salt . mix gently . bake for 1 hour . slice meat loaf and serve with sauce .	heat the olive oil in a medium saute pan . add beef and cook for a few minutes . add the cauliflower and cook over medium heat for about 8 minutes . add the onions and cook for another 5 minutes . season with celery salt .

Figure 1: Recipe Examples

Our task is generally defined as follows:

> *Given the input of objective background information I and subjective semantic constraints C, our model is to help the machine automatically grounding the inputs to the text output $\boldsymbol{Y}$.*

Such application contexts is common for many specific tasks. For recipe generation, we define I as

---

heat the olive oil in a medium saute pan . add beef and cook for a few minutes . add the cauliflower and cook over medium heat for 8 minutes . add the onions and cook for 5 minutes . season with celery salt.

heat oven to 400 f . place salmon into prepared pan . sprinkle with lemon zest , celery salt . divide tomatoes evenly on top of salmon . pour lemon juice over top . bake , uncovered , about 12-15 minutes .

Figure 2: Routing Enforced Generative Model (RGM). LSTM encoder calculates representations of the input ingredients. Routing module computes the routing weights. Attention decoder generates the recipes allowing for routing weights and user demands.

a set of ingredients (e.g. "beef", "olive oil") the user has. And $C = \{CI, CD\}$ denotes user preferences on some ingredients ($CI \subseteq I$) and category demands ($CD \subseteq D$, D represents the set of dish categories. e.g. "Low Fat", "Low Sugar"). The generated $\boldsymbol{Y}$ is the text of the recipe which satisfies the user preferences with the given ingredients. There are two significant challenges: how to select appropriate set of ingredients to satisfy user demands; and how to generate recipes accordingly. We propose a novel approach to solve these problems.

Inspired by (Sabour et al., 2017), we propose a selective routing algorithm to cluster the given ingredients into five categories (*Low Sugar*, *High Fiber*, *Low Fat*, *Grilling* and *Frying*) and get the category vectors. Length of the category vector represents the probability of generated $\boldsymbol{Y}$ belonging to a specific category. We augment attention mechanism to capture ingredient information according to the routing weights between ingredients and categories. Then decoder generates words in sequence. We introduce both manual ways and automatic metrics to evaluate the generated recipes. Experimental results demonstrate the efficacy of our approach. To summarize, the contributions of our work are as follows[1]:

- To our knowledge, our work is the first endeavor to take ingredient selection into consideration in recipe generation process. We propose a novel algorithm to calculate the ingredient collocation weights to enforce recipe generation model.
- Given ingredients with noises, our model can satisfy personalized user demands by taking ingredients and category constraints into consideration.
- Our approach yields significant improvements on both automatic and human evaluation.

2 Related Work

Recipes have been gaining interest in recent researches, including recipe processing (Mori et al., 2012, 2014; Bosselut et al., 2017), recipe parsing (Malmaud et al., 2014; Jermsurawong and Habash, 2015), recipe retrieval (Chen and Ngo, 2016; Min et al., 2017), regional cuisine style transformation (Kazama et al., 2018), recipe QA (Yagcioglu et al., 2018) and recipe generation (Kiddon et al., 2016; Yang et al., 2017). Among previous efforts towards recipes researches, our study is closer to recipe generation. Kiddon et al. (2016) define the task as given a goal (recipe title) and an agenda (ingredient list) to generate a complete recipe. They present the neural checklist model to improve the semantic coverage of the agenda in the generated texts. Yang et al. (2017) develop a language model that treats reference as an explicit stochastic latent variable and create mentions of entities together with their

---

[1] https://github.com/ArleneYuZhiwei/RGM-for-Recipe-Generation

attributes by accessing external databases. Majumder et al. (2019) take the historical user preference records into consideration. They generate personalized recipes from incomplete input specifications (name and incomplete ingredient details).

Different from the existing methods on recipe generation which focus on covering all of the given ingredients, we extend the previous generation task with a selection of given items. Selective generation is a task to produce the natural language description for a salient subset of a rich records (Mei et al., 2016). A lot of attention has been paid to individual content selection and selective realization sub-problems (Barzilay and Lee, 2004; Barzilay and Lapata, 2005; Liang et al., 2009). Recent works (Chen and Mooney, 2008; Chen et al., 2010; Mei et al., 2016) explore full selective generation and learn alignments between generated texts and input data using a translation model.

We find appropriate set of ingredients by selective routing algorithm. And our model can generate texts according to the user constraints on both ingredients and categories. The core inspiration for our routing module comes from following works. Hinton et al. (2011) propose transformation matrices that learn to encode the intrinsic spatial relationship between a part and a whole constitute viewpoint. Later, Sabour et al. (2017) propose an iterative routing-by-agreement mechanism to learn the intrinsic relationship between two layers. Hinton et al. (2018) propose a new iterative routing procedure based on the EM algorithm. Inspired by the previous work, Yang et al. (2018) firstly investigate the performance of dynamic routing on text classification. They propose three strategies (orphan category, leaky-softmax, coefficient amendment) to stabilize the dynamic routing process and alleviate the disturbance of some noises.

3 Our Approach

The basic structure of our model is shown in Figure 2. Generally speaking, we take two steps to achieve the recipe generation:

Select with Routing: In this part, our task is to select an appropriate set (soft selection as weight distribution) of ingredients to support a dish for each category with the given constraints. The procedure can be defined as

$$\boldsymbol{O} = f_S(I, D, C), \tag{1}$$

where ingredients I and constraints $C = \{CI \subseteq I, CD \subseteq D\}$ are inputs. We propose a selective routing algorithm to cluster the ingredients I into different dish categories D. Assuming that I and D contains n and m items independently, the output $\boldsymbol{O} \in \mathbb{R}^{n \times m}$. We define $\boldsymbol{O}$ as the routing weights, where $o_{i,j}$ stands for the importance of the ingredient i in the category j.

Generate with Attention: After the content selection, we choose a proper category d and use the routing weights $\boldsymbol{o_{*,d}}$ [2] to help with the attention-based generation process. And we get the recipe Y by

$$Y = f_G(I, \boldsymbol{o_{*,d}}), \tag{2}$$

The generative module is an improved encoder-decoder framework with hierarchical attention mechanism.

In the following sections, we will give more details about the model design and training objective.

3.1 Routing Module (RM)

The routing module is designed to find routing weights that contribute to the generation process. The process is shown in Algorithm 1. We first apply an LSTM network as the encoder to obtain the representation of the i-th ingredient $\boldsymbol{h^{(i)}} \in \mathbb{R}^z$ (z is the size of hidden vectors). $\boldsymbol{h^{(i)}}$ is the average of the encoder hidden states $\boldsymbol{H^{(i)}} \in \mathbb{R}^{n_i \times z}$ (n_i is the number of words in the i-th ingredient). We then obtain the corresponding routing vectors $\boldsymbol{U} \in \mathbb{R}^{n \times z}$ from the ingredient representation, where $\boldsymbol{u_{i,*}} = \boldsymbol{h^{(i)}} \boldsymbol{M}$ and $\boldsymbol{M} \in \mathbb{R}^{z \times z}$ is a mapping matrix to map the ingredient semantic information to the routing space. Given routing vectors $\boldsymbol{U = \{u_{1,*}, u_{2,*}, ...u_{n,*}\}}$ and the routing iteration number r, we use selective routing algorithm f_R to obtain the routing weights $\boldsymbol{O} \in \mathbb{R}^{n \times m}$ and category vectors $\boldsymbol{V} \in \mathbb{R}^{m \times z}$.

We define coupling coefficients as $\boldsymbol{B} \in \mathbb{R}^{n \times m}$. The initial values $b_{i,j}$ are the log prior probabilities that ingredient i should be coupled to category j. And then we calculate the routing weights $o_{i,j}$ by Eq 3. Inspired by (Sabour et al., 2017), we use the length of category vector $\boldsymbol{v_{j,*}}$ to represent the probability that an appropriate recipe with a specific category j exists. To get the category vector, we apply a non-linear squash function on the weighted sum $\boldsymbol{s_{j,*}}$ by Eq 4. By this means, short vectors get shrunk to almost zero length and long vectors get

---

[2] For a matrix $\boldsymbol{A}$, $a_{i,j}$ denotes the item at i-th row, j-th column , $\boldsymbol{a_{i,*}}$, $\boldsymbol{a_{*,j}}$ denotes the i-th row vector and j-th column vector respectively.

Algorithm 1 Selective Routing Algorithm

```
procedure $f_S(I, D, C)$
    Get the representation of the $i$-th ingredient by LSTM encoder: $\boldsymbol{h^{(i)}} \leftarrow I_i$
    Map $\boldsymbol{h^{(i)}}$ to the routing space: $\boldsymbol{U} = \{\boldsymbol{u_{1,*}}, \boldsymbol{u_{2,*}}, \boldsymbol{...u_{n,*}}\}, \boldsymbol{u_{i,*}} \leftarrow \boldsymbol{h^{(i)}M}$
    Initialize all the coupling coefficients of ingredient $i$ and category $j$: $b_{i,j} \leftarrow -\infty$
    for $di \in CI, j \in D$: $b_{di,j} \leftarrow \alpha$                                        ▷set ingredients demands
    Get selections by $r$-iteration routing algorithm: $\boldsymbol{B},\boldsymbol{O},\boldsymbol{V} \leftarrow f_R^r(\boldsymbol{U}, I, D, C, \boldsymbol{B})$
    return $\boldsymbol{O}$
procedure $f_R$ $(\boldsymbol{U}, I, D, C, \boldsymbol{B})$
    for all category $j \in D$: $\boldsymbol{o_{*,j}} \leftarrow \text{softmax}(\boldsymbol{b_{*,j}})$                  ▷softmax computes Eq.3
    for all category $j \in D$: $\boldsymbol{s_{j,*}} \leftarrow \sum_i o_{i,j}\boldsymbol{u_{i,*}}$
    for all category $j \in D$: $\boldsymbol{v_{j,*}} \leftarrow \text{squash}(\boldsymbol{s_{j,*}})$                   ▷squash computes Eq.4
    for all ingredient $i \in I$ and category $j \in D$: $b_{i,j} \leftarrow b_{i,j} + \boldsymbol{u_{i,*}} \cdot \boldsymbol{v_{j,*}}$
    for $j \in D \setminus CD$: $\boldsymbol{v_{j,*}} \leftarrow \boldsymbol{0}$                                  ▷set categories demands
    return $\boldsymbol{B},\boldsymbol{O},\boldsymbol{V}$
```

shrunk to a length slightly below 1 (Sabour et al., 2017). In the training phase (detailed in Section 4.3), the category vectors and routing weights are used to calculate the loss for routing module. When making predictions with user constraints C, we set the prior probabilities of desired ingredients CI to α to emphasize the ingredient preferences. The presetting will lead the routing to converge to a desired category. And we also mask the vectors of undesired category $(D \setminus CD)$ in each iteration. If the preferred category is not specified in CD, we extract the routing weights $\boldsymbol{o_{*,\hat{j}}}$ as the routing weights for generation model, where $\hat{j} = argmax_j ||\boldsymbol{v_{j,*}}||$ denotes the most possible category of the target recipe.

$$o_{i,j} = \frac{exp(b_{i,j})}{\Sigma_{k=1}^{m} exp(b_{i,k})}. \tag{3}$$

$$\boldsymbol{v_{j,*}} = \frac{||\boldsymbol{s_{j,*}}||^2}{1 + ||\boldsymbol{s_{j,*}}||^2} \frac{\boldsymbol{s_{j,*}}}{||\boldsymbol{s_{j,*}}||}. \tag{4}$$

3.2 Routing Enforced Generative Model (RGM)

The generation module shares the same LSTM encoder with RM. We augment the attention mechanism (Luong et al., 2015) to capture relevant ingredient information to help with predicting the current target word. The alignments $\boldsymbol{a_i} \in \mathbb{R}^{n_i}$ between the last target hidden state $\boldsymbol{h_{t-1}} \in \mathbb{R}^z$ and hidden states $\boldsymbol{H^{(i)}} \in \mathbb{R}^{n_i \times z}$ of the ingredient i is calculated as Eq 5, where $\boldsymbol{W}_T \in \mathbb{R}^{z \times z}$ is a linear transformation matrix for the ingredient representations. Different from the previous attention mechanism, we obtain the context vector $\boldsymbol{c_t} \in \mathbb{R}^z$ taking both routing weights and alignment vector into consideration as Eq 6 shows. In this way, the undesired ingredients (with lower routing weights) get lower attentions. We produce an attention hidden state by concatenating the context vector and the hidden state. And then we use an LSTM decoder to get the word distribution $\boldsymbol{p_t}$ formulated as Eq 7, where $\boldsymbol{\hat{Y}} = \{\hat{Y}_1, ..., \hat{Y}_{|\boldsymbol{\hat{Y}}|}\}$ denotes the word sequences of the target text. The word with highest probability in the distribution is selected as the generated word.

$$\boldsymbol{a_i} = softmax(\boldsymbol{h_{t-1}}\boldsymbol{W}_T(\boldsymbol{H^{(i)}})^\top). \tag{5}$$

$$\boldsymbol{c}_t = \Sigma_{i=1}^{n} o_{i,\hat{j}} \boldsymbol{a_i} \boldsymbol{H^{(i)}}. \tag{6}$$

$$\boldsymbol{p_t} = softmax(LSTM(\hat{Y}_{t-1}, [\boldsymbol{c_t}; \boldsymbol{h_{t-1}}])). \tag{7}$$

3.3 Model Training

We pre-train the routing module. We mix the input ingredients and target categories of n_r recipes as one datum to build a mixed training set $\boldsymbol{MT}$. The loss function of RM consists of two parts: classification loss and routing loss. For multiple classification, we use classification loss $\hat{L}_j$ for each category j as Eq 8, where $e_j = 1$ iff category j exists in the mixed target categories, otherwise $e_j = 0$. As for routing loss, we define the gold routing weights as $\boldsymbol{G} \in \mathbb{R}^{n \times m \times n_r}$. $g_{i,j,k} = 1$ iff the i-th ingredient in the inputs is used for the j-th category in the k-th recipe, otherwise $g_{i,j,k} = 0$. As there may be multiple input combinations for one target category in one mixed datum, we hope our predicted routing weights of the category have a good consistency with one gold combination. Therefore, we maximize the max sum of weights along the gold combinations as Eq 9. The loss function for RM is calculated on the mixed training set $\boldsymbol{MT}$ as Eq 10.

$$\hat{L}_j = e_j(1 - ||\boldsymbol{v_{j,*}}||)^2 + (1 - e_j)(||\boldsymbol{v_{j,*}}||)^2. \quad (8)$$

$$\hat{L_c} = 1 - \max_{j=1}^{m} \max_{k=1}^{n_r} \left\{ \sum_{i=1}^{n} g_{i,j,k}\, o_{i,j} \right\} \quad (9)$$

$$L_{RM} = \mathbb{E}_{\boldsymbol{MT}} \left(\sum_{j=1}^{m} \hat{L}_j + \hat{L_c} \right). \quad (10)$$

For training RGM, we use the expectation of negative log likelihood loss over the generation training set $\boldsymbol{GT}$ as Eq 11. The probability is modeled by the encoder and decoder of RGM with parameters $\boldsymbol{\theta}$. As RM and generative module (GM) share the encoders, the whole model is jointly trained by $L_{RGM} = L_{RM} + L_{GM}$.

$$L_{GM} = \mathbb{E}_{\boldsymbol{GT}} - logp(\hat{\boldsymbol{Y}}|I, D; \boldsymbol{\theta}). \quad (11)$$

4 Experiments

4.1 Data sets

To keep in line with the previous work on recipe generation (Yang et al., 2017), we use the recipe data from Allrecipe[3] to train the generative model. We exclude the recipes that contain less than 10 tokens or more than 500 tokens. As the vocabulary is limited in recipes, we keep all the words appearing in the training set. The vocabulary sizes of ingredients and recipes are 6,121 and 19,168 respectively. The training set $\boldsymbol{GT}$ contains 73,088 recipe data, while valid set and test set (Standard Inputs) each contains 8,000 recipe data. To explore the generality of our model, we build another test data set (Mixed Inputs). It mixes the ingredients of two recipes for each test case to provide redundant ingredients.

To pre-train the routing module, we use 312,707 ingredients with their corresponding recipe categories from Yummly[4]. We mix the input ingredients and target categories of nr = 2 recipes to build the mixed training set $\boldsymbol{MT}$.

4.2 Baseline Models

In this work, we investigate how to improve recipe generation over strong baselines in both our setting (Mixed Inputs) and common setting (Standard Inputs). We compare our routing enforced generative model against the baseline models below.

Attseq: As the bidirectional LSTM encoder has proved strong representation capability (Devlin et al., 2019). We use the model with bidirectional encoder and Luong attention decoder (Luong et al., 2015) as our baseline model.

Pointer: As the vocabulary used in instructional language is limited and there is a strong relationship between given ingredients and recipes, seq2seq model with the pointer network performs particularly well in previous recipe generation work (Yang et al., 2017). We use the pointer network (Vinyals et al., 2015) with ingredient attention, which provides comparable performance to reference-aware language model (Yang et al., 2017) and higher *BLEU*[5].

Retrieve: The model retrieves recipes from the training set according to the overlap of the input ingredients.

To explore the importance of routing algorithm, we report the performance of our model without routing module (**w/o RM**).

4.3 Training Details

Attseq, **Pointer** and our model **RGM** all use 2-layer LSTM encoders and decoders. All the hidden sizes in three generation models are 512. To avoid over-fitting, we set the dropout rates to 0.3 in these models. We use Adam (Kingma and Ba, 2014) as the optimizer and the learning rate is 0.0001. As for hyper parameters, we set the routing iteration $r = 3$,[6] weight increase factor $\alpha = 100$.

4.4 Automatic Evaluation

Metrics In order to evaluate the effectiveness of our methods, we introduce the automatic metrics as follows: *BLEU-4* (Papineni et al., 2002) is a commonly used metric to measure the quality of machine generated texts. *Dis2* (Li et al., 2016) is the ratio of distinct bi-grams in the generated recipes, which depicts the diversity[7]. We define the set of used ingredients in the model outputs and gold reference are $\boldsymbol{SO}$ and $\boldsymbol{SG}$ respectively. *Prec.* denotes the ratio of $\boldsymbol{SO} \cap \boldsymbol{SG}$ in $\boldsymbol{SO}$. *Rec.* denotes

---

[3] www.allrecipes.com

[4] www.yummly.com

[5] The performances of two models are also comparable in original settings (Yang et al., 2017)

[6] We discuss the performance of model with different iterations in appendix

[7] *Dis1* of all the models are quite small with negligible differences. So we only discuss *Dis2* in the paper.

	Mixed Inputs					Standard Inputs				
Models	*BLEU-4*	*Dis2*	*Prec.*	*Rec.*	*F1*	*BLEU-4*	*Dis2*	*Prec.*	*Rec.*	*F1*
Attseq	13.67	0.10	40.24	36.28	38.16	8.54	0.08	45.60	37.13	40.93
Pointer	14.73	0.23	**50.05**	40.55	44.80	7.50	0.18	51.60	40.69	45.50
Retrieve	11.45	**0.61**	30.10	**63.02**	40.74	10.54	**0.50**	32.38	**65.22**	43.27
RGM	**20.16**	0.35	46.11	55.90	**50.54**	**16.02**	0.35	**58.11**	62.26	**60.11**
w/o RM	18.77	0.24	45.80	43.61	44.68	13.28	0.18	54.41	51.36	52.84

Table 1: Results of Automatic Evaluation (%).

the ratio of $SO \cap SG$ in SG. *F1* is the harmonic average of the *Prec.* and *Rec.*, which is an overall measurement. For all the metrics, a higher value means better.

Analysis Results of generated texts from all the models when given Mixed Inputs or Standard Inputs are shown in Table 1. As we mixed ingredients of two recipes to create Mixed Inputs, we take each recipe as the ground truth respectively and report the max score over the two ground truths via automatic evaluation metrics. The general trends are consistent in both Standard Inputs and Mixed Inputs, so we discuss them together.

As the vocabulary used in instructional language is limited and there is a strong relationship between given ingredients and recipes, **Pointer** performs better than **Attseq** in almost all the evaluation metrics. Sometimes **Pointer** may directly copy ingredients from the given inputs in the generation process, and it achieves a rather high *Prec.* With overmuch attention on the limited ingredients, **Pointer** generates recipes of low *Rec.* On the contrary, **Retrieve** finds the recipes that contain most ingredients in the training set as outputs, which results in the highest *Rec.* But gaps exist in training set and test set, and the gold recipes from two sets might be different even if the inputs are the same, letting alone the retrieved outputs are always corresponding to the super sets of the given inputs in the test set. And thus **Retrieve** obtains the lowest *Prec.* In all collected data sets, the ingredient names in the ingredient lists may disagree with corresponding expressions in the recipes. We use ingredient mapping rather than word mapping to calculate the automatic evaluation metrics, because “green onion” is not the same ingredient as “onion”. However, “basil leaf” in the ingredient list is used as “basil” in the recipe and both expressions represent the same ingredient. Due to this inconformity, *Rec.* of **Retrieve** is not 1. Besides, the outputs are all handcrafted recipes with a higher diversity compared to the generative models.

Models	*Read.*	*Acc.*	*Crea.*	*Feas.*	*Overall*
Attseq	3.07*	2.70*	2.82*	2.76*	2.73*
Pointer	2.83*	2.57*	2.67*	2.75*	2.57*
Retrieve	3.87*	3.89*	3.69	3.63*	3.64*
RGM	**4.13**	**4.23**	**3.77**	**4.12**	**3.98**
w/o RM	4.01	3.61*	3.21*	3.84	3.52*
Gold	4.24	4.37	3.82	4.31	4.13

Table 2: Results of Human Evaluation. * denotes that our model outperforms the baseline model significantly in this aspect, based on two-tailed paired t-test with $p < 0.01$.

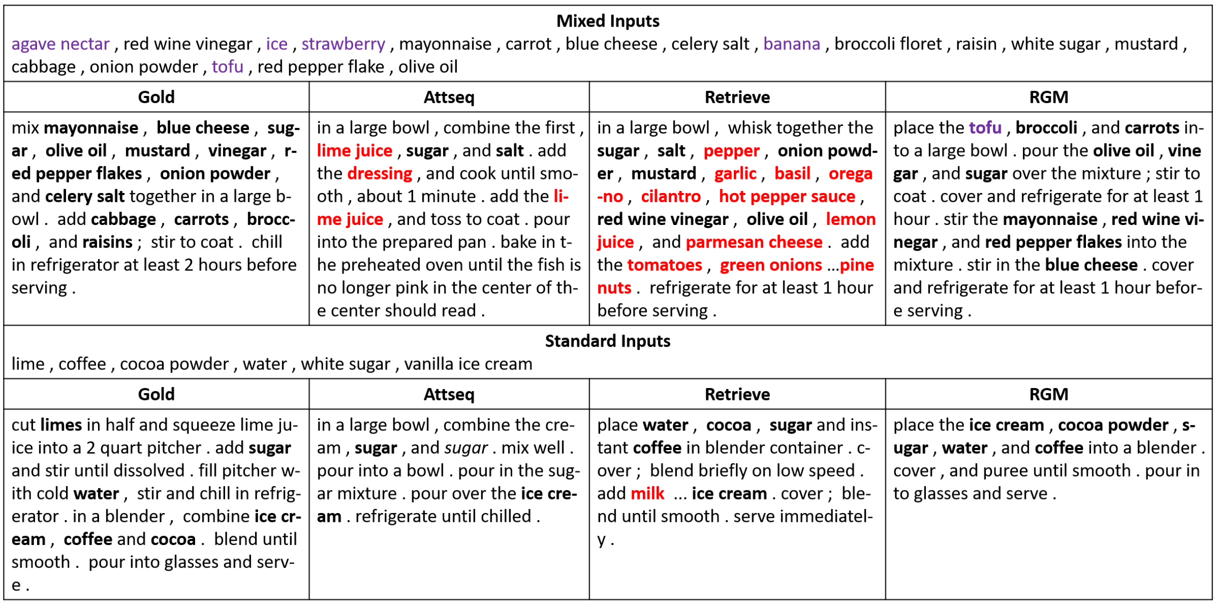
To explore the efficacy of selective routing, we remove the routing module in the test phase. Due to the strong representation capability of shared encoder, *BLUE-4* , *Prec.* and *F1* of **w/o RM** achieve evident promotion compared to **Attseq**. Combined with **RM**, our **RGM** achieves the best performance on *BLUE-4* and *F1* in both cases. And the recipes generated by **RGM** use words with the highest diversity among all the automatically generated recipes. This ablation study demonstrates the empirical contribution of routing algorithm. Automatic evaluation results demonstrate that our model learns the internal relationships of the ingredients well and can generate recipes with high quality.

4.5 Human Evaluation

Settings Because recipes are a kind of instructional language to teach people how to cook, performing well on the automatic metrics is not enough. For a more comprehensive evaluation, we sample 50 inputs and obtain 50 recipes generated by each model above and then get 50 groups of recipes (25 for each case) to do the human evaluation. We ask 9 judges[8] on Amazon Mechanical Turk to rate the recipes in a Likert scale ($\in [1, 5]$). Three native English speakers are asked to give a score on each recipe with the following descrip-

---

[8] For quality assurance, we choose the judges whose HIT approval rate is greater than 90.



Mixed Inputs agave nectar , red wine vinegar , ice , strawberry , mayonnaise , carrot , blue cheese , celery salt , banana , broccoli floret , raisin , white sugar , mustard , cabbage , onion powder , tofu , red pepper flake , olive oil			
Gold	**Attseq**	**Retrieve**	**RGM**
mix **mayonnaise** , **blue cheese** , **sugar** , **olive oil** , **mustard** , **vinegar** , **red pepper flakes** , **onion powder** , and **celery salt** together in a large bowl . add **cabbage** , **carrots** , **broccoli** , and **raisins** ; stir to coat . chill in refrigerator at least 2 hours before serving .	in a large bowl , combine the first , **lime juice** , **sugar** , and **salt** . add the **dressing** , and cook until smooth , about 1 minute . add the **lime juice** , and toss to coat . pour into the prepared pan . bake in the preheated oven until the fish is no longer pink in the center of the center should read .	in a large bowl , whisk together the **sugar** , **salt** , **pepper** , **onion powder** , **mustard** , **garlic** , **basil** , **oregano** , **cilantro** , **hot pepper sauce** , **red wine vinegar** , **olive oil** , **lemon juice** , and **parmesan cheese** . add the **tomatoes** , **green onions** ...**pine nuts** . refrigerate for at least 1 hour before serving .	place the **tofu** , **broccoli** , and **carrots** into a large bowl . pour the **olive oil** , **vinegar** , and **sugar** over the mixture ; stir to coat . cover and refrigerate for at least 1 hour . stir the **mayonnaise** , **red wine vinegar** , and **red pepper flakes** into the mixture . stir in the **blue cheese** . cover and refrigerate for at least 1 hour before serving .
Standard Inputs lime , coffee , cocoa powder , water , white sugar , vanilla ice cream			
Gold	**Attseq**	**Retrieve**	**RGM**
cut **limes** in half and squeeze lime juice into a 2 quart pitcher . add **sugar** and stir until dissolved . fill pitcher with cold **water** , stir and chill in refrigerator . in a blender , combine **ice cream** , **coffee** and **cocoa** . blend until smooth . pour into glasses and serve .	in a large bowl , combine the cream , **sugar** , and *sugar* . mix well . pour into a bowl . pour in the sugar mixture . pour over the **ice cream** . refrigerate until chilled .	place **water** , **cocoa** , **sugar** and instant **coffee** in blender container . cover ; blend briefly on low speed . add **milk** ... **ice cream** . cover ; blend until smooth . serve immediately .	place the **ice cream** , **cocoa powder** , **sugar** , **water** , and **coffee** into a blender . cover , and puree until smooth . pour into glasses and serve .

Figure 3: Examples of Generated Recipes.

tions: *Readability* denotes whether the recipe is fluent and easy to understand. *Accuracy* denotes whether the given ingredients are correctly used in the recipe. *Feasibility* denotes whether the recipe is feasible. *Creativity* denotes whether the recipe is innovative. *Overall* denotes the overall quality of the recipe.

Analysis The results in Table 2 show that there is a large gap between automatic evaluation and human evaluation on **Pointer**. It outperforms **Attseq** on automatic evaluation but gets the worst rating scores on human evaluation. It may be due to that **Pointer** sometimes reuses the same ingredients in a recipe for several times or even repeats phrases, which does not affect the automatic metrics much but discourages people from reading. This inconsistency suggests the deficiencies of the automatic evaluation. Another interesting discovery is that **Retrieve** achieves lower scores on all the aspects compared to our model. As **Retrieve** returns handcrafted recipes as outputs, scores of its *Readability* and *Feasibility* should have been higher than our model's. We compare the outputs of both models and find **Retrieve** outputs rather long recipes. On the test sets, the average word numbers of the outputs are 173.63 and 96.95 for **Retrieve** and **RGM** respectively, while gold recipes contain 104.41 words averagely. Longer texts mean that there are more operation steps or more ingredients used, which makes the recipe difficult to understand and follow. What's more, **Retrieve** outputs common recipes in the data set, while **RGM** generates recipes with novelty. Therefore our model also beats **Retrieve** on *Creativity*. Human evaluation demonstrates that effectively calculating the routing weights of ingredients is informative for recipe generation.

4.6 Case Study

For an intuitive comparison, we show some examples in Figure 3. As **Pointer** achieves rather low scores in human evaluation, we only show the recipes generated by two stronger baseline models here. We apply some ellipsis because **Retrieve** always outputs long texts[9]. The noise ingredients (given in the Mixed Inputs but not expected to use) are in purple and extraneous ingredients (not in the given inputs) are in red. The ingredients which are correctly used in the recipes are in bold black. Italic words denote that the ingredients are supposed to appear in the recipes and have been used before. In both cases, **Attseq** generates recipes containing few expected ingredients. Particularly, it introduces extraneous ingredients when given Mixed Inputs and incorrectly reuses "sugar" given Standard Inputs. As for **Retrieve**, it introduces quite a few extraneous ingredients in both cases. **Retrieve** outputs complicated recipes with overmuch ingredients and lengthy operation steps, which are not practical for most people. As a contrast, **RGM** uses most of the expected ingredients and only one noise ingredient,

Ingredients	celery seed , mustard , mayonnaise , horseradish , sour cream , green zucchini , dill weed , apple cider vinegar , cayenne pepper , yellow bell pepper , dark brown sugar , salt , cabbage	
Constraints	None	mustard
Recipes	in a large bowl , mix together the **cabbage** , **green onions** , and green **bell pepper** . in a separate bowl , whisk together the **mayonnaise** , **sour cream** , **salt** , **celery seed** , and **brown sugar** . pour over the cabbage mixture , and toss to coat . cover , and refrigerate at least 1 hour before serving .	in a medium bowl , mix **mayonnaise** , **sour cream** , **horseradish** , **brown sugar** , **mustard** , **celery seed** , **salt** , and **cayenne pepper** . mix in the **cabbage** and **green onions** . cover , and refrigerate at least 1 hour before serving .
Ingredients	flour , butter , thyme , lucerne egg , lucerne milk , black pepper , garlic , salt , chive , roast , yorkshire pudding	
Constraints	None	thyme , butter , roast
Recipes	preheat oven to 325 degrees f . in a medium bowl , whisk together **flour** , **salt** , and **pepper** . in a large bowl , whisk together **eggs** , **milk** , and **garlic** . add flour mixture to flour mixture , whisking until just combined . pour into a 9-inch pie plate . bake in the preheated oven until a toothpick inserted into the center comes out clean , about 45 minutes . let stand for 10 minutes before slicing .	preheat oven to 350 degrees f . place the **roast** in a roasting pan . in a small bowl , whisk together the **butter** , **flour** , **salt** , **pepper** , and **thyme** . pour the egg mixture over the *roast* . bake for 1 hour , or until a meat thermometer inserted into the center of the roast registers 140 degrees f for medium-rare . remove the roast from the oven and let stand for 10 minutes before slicing . meanwhile , in a medium bowl , whisk together the **eggs** , **milk** , *butter* , and **garlic** . add the *flour* and whisk until smooth . pour the sauce over the roast .
Ingredients	olive oil , salt , honey , curry powder , the dressing , garbanzo bean , apple cider vinegar , raisin , quinoa , black pepper , water , salted butter , couscou , green onion , celery , carrot , vegetable soup mix , almond , turmeric powder , parsley , preserved lemon , vegetable stock	
Constraints	None	Low Carb
Recipes	bring **water** and **quinoa** to a boil in a saucepan . reduce heat to medium low , cover , and simmer until *quinoa* is tender and liquid has been absorbed , 20 to 25 minutes . heat **olive oil** in a skillet over medium heat ; cook and stir **onion** and **celery** until tender , about 5 minutes . stir in **couscous** , **carrots** , *celery* , and **raisins** . cook and stir until *quinoa* is tender , about 5 minutes . stir **vegetable stock** and **honey** into *quinoa* mixture ; bring to a boil . reduce heat to low and simmer until *quinoa* is tender , about 10 minutes . stir *cous* , *raisins* , and **parsley** into *couscous* mixture ; season with **salt** and **pepper** .	heat **olive oil** in a large saucepan over medium heat . add **carrots** , **celery** , and **onion** ; cook and stir until tender , about 5 minutes . stir in **quinoa** , **vegetable stock** , and **water** . bring to a boil . reduce heat to low , cover , and simmer until *quinoa* is tender , about 15 minutes . stir in **couscous** , **raisins** , and **parsley** . season with **salt** and **pepper** .

Figure 4: Examples of Controllable Recipe Generation.

which proves that our routing module is effective for content selection. What's more, compared to attention-based model **Attseq**, **RGM** alleviates the problem of inappropriately repeating words.

4.7 Controllable Recipe Generation

Our model is different from existing methods mainly in two aspects: routing based selection model and recipe generation in accordance with constraints (user demands). For all the results discussed above, **RGM** selects ingredients and generates the recipes following the routing weights. In this section, we assign the constraints of ingredients or categories as Figure 4 shows. In the first example, the generated recipe does not use "mustard". We constrain the ingredient by promoting the initial weight of it in the selective routing algorithm. As a result, **RGM** generates the recipe with expected mustard. Further, we conduct experiments on constraining a number of ingredients and the results confirm the validity of the selective routing algorithm. Considering the second example, **RGM** uses 6 ingredients we input without any constraints. If a user especially prefers some ingredients like:" thyme", "butter" and "roast", we set corresponding constraints on them. The generated recipe exactly contains the assigned ingredients. For people having special tastes or demands, they need dishes of certain categories, like: "Low Sugar". In the third example, **RGM** first generates the recipe following the maximum likelihood without any constraints. The generated recipe is a "High Fiber" one. We then give a constraint as "Low Sugar". The new recipe contains almost the same ingredients as before except for "honey". It is well known that "honey" is a sweet produced by bees and some related insects. It should not appear in a "Low Sugar" recipe. And the operation steps are also adjusted accordingly. The results of extended experiments show that **RGM** is able to generate reasonable recipes with user demands.

5 Conclusion and Future Work

In this paper, we make an effort on introducing routing algorithm to enforce the recipe generation model. We model the internal relationships between ingredients by selective routing algorithm. Given ingredients with noises, our model selects reasonable ingredient collocations and generates recipes based on user demands. Extensive experiments shows that the generated recipes are not only fluent and feasible, but also creative. There are several directions to explore in the future. For example, the clustering ability of routing algorithm can be used to control the style of generated texts.

Abstract

Many English-as-a-second language learners have trouble using near-synonym words (*e.g.,* small vs. little; briefly vs. shortly) correctly, and often look for example sentences to learn how two nearly synonymous terms differ. Prior work uses hand-crafted scores to recommend sentences but have difficulty in adopting such scores to all the near-synonyms as near-synonyms differ in various ways. We notice that the helpfulness of the learning material would reflect on the learners' performance. Thus, we propose the inference-based learner-like agent to mimic learner behavior and identify good learning materials by examining the agent's performance. To enable the agent to behave like a learner, we leverages entailment modeling's capability of inferring answers from the provided materials. Experimental results show that the proposed agent is equipped with good learner-like behavior to achieve the best performance in both fill-in-the-blank (FITB) and good example sentence selection tasks. We further conduct a classroom user study with college ESL learners. The results of the user study show that the proposed agent can find out example sentences that help students learn more easily and efficiently. Compared to other models, the proposed agent improves the score of more than 17% of students after learning.

1 Introduction

Many English-as-a-second-language (ESL) learners have trouble using near-synonyms correctly (Liu and Zhong, 2014; Liu, 2013). "Near-synonym" refers to a word whose meaning is similar but not identical to that of another word, for instance, *establish* and *construct*. An experience common to many ESL learners is looking for example sentences to learn how two nearly synonymous words differ (Liu, 2013; Liu and Jiang, 2009). To facilitate the learner's learning process, our focus is on finding example sentences to clarify English near-synonyms.

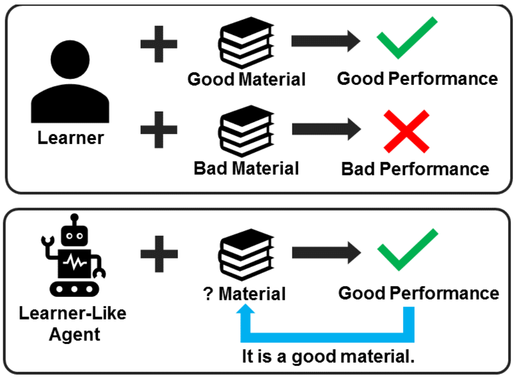

Figure 1: The Learner-Like Agent mimics learners' behavior of performing well when learning from good material and vice versa. We utilize such a behavior to find out helpful learning materials.

In previous work, researchers develop linguistic search engines, such as Linggle (Boisson et al., 2013) and Netspeak[1], to allow users to query English words in terms of n-gram frequency. However, these tools can only help people investigate the difference, where learners are required to make assumptions toward the subtlety and verify them with the tools, but can not tell the difference proactively. Other work attempts to automatically retrieve example sentences for dictionary entries (Kilgarriff et al., 2008); however, finding clarifying examples for near-synonyms is not the goal of such work. In a rare exception, Huang et al. (2017) retrieve useful examples for near-synonyms by defining a clarification score for a given English sentence and using it to recommend sentences. However, the sentence selection process depends on handcrafted scoring functions that are unlikely to work well for all near-synonym sets. For example, the difference between *refuse* and *reject* is their grammatical usages where we would use "refuse to verb" but not "reject to

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3807–3817,
November 16–20, 2020.

verb"; such a rule, yet, is not applicable for *delay* and *postpone* as they differ in sentiment where *delay* expresses more negative feeling. Though Huang et al. (2017) propose two different models to handle these two cases respectively, there is no clear way to automatically detect which model we should use for an arbitrary near-synonym set.

In the search for a better solution, we noted that ESL learners learn better with useful learning materials—as evidenced by their exam scores—whereas bad materials cause confusion. Such behavior can be used to assess the *usefulness* of example sentences as shown in Figure 1. Therefore, we propose a **Learner-Like Agent** which mimics human learning behavior to enable the ability to select good example sentences. This task concerns the ability to answer questions according to the example sentences for learning. As such, we transform this research problem to an entailment problem, where the model needs to decide whether the provided example sentence can entail the question or not. Moreover, to encourage learner-like behavior, we propose perturbing instances for model training by swapping the target confusing word to its near-synonyms. We conduct a lexical choice experiment to show that the proposed entailment modeling can distinguish the difference of near-synonyms. A behavior check experiment is used to illustrate that perturbing instances do encourage learner-like behavior, that is inferring answers from the provided materials. In addition, we conduct a sentence selection experiment to show that such learner-like behavior can be used for identifying helpfulness materials. Last, we conduct a user study to analyze near-synonym learning effectiveness when deploying the proposed agent on students.

Our contributions are three-fold. We *(i)* propose a learner-like agent which perturbs instances to effectively model learner behavior, *(ii)* use inference-based entailment modeling instead of context modeling to discern nuances between near-synonyms, and *(iii)* construct the first dataset of helpful example sentences for ESL learners.[2]

2 Related Works

This task is related to (*i*) learning material generation, (*ii*) near-synonyms disambiguation, and (*iii*) natural language inference.

Learning Material Generation. Collecting learning material is one of the hardest tasks for both teachers and students. Researchers have long been looking for methods to generate high-quality learning material automatically. Sumita et al. (2005); Sakaguchi et al. (2013) proposed approaches to generate fill-in-the-blank questions to evaluate students language proficiency automatically. Lin et al. (2007); Susanti et al. (2018); Liu et al. (2018) worked on generating good distractors for multiple-choice questions. However, there are only a few tasks working on automatic example sentence collection and generation. Kilgarriff et al. (2008); Didakowski et al. (2012) proposed a set of criteria for a good example sentences and Tolmachev and Kurohashi (2017) used sentence similarity and quality as features to extract high-quality examples. These tasks only focused on the quality of a single example sentence, whereas our goal in this paper is to generate an example sentence set that clarifies near-synonyms. The only existing work is from Huang et al. (2017), who designed the fitness score and relative closeness score to represent the sentence's ability to clarify near-synonyms. Our work enables the models to learn the concept of "usefulness" directly from data to reduce the possible issues of the human-crafted scoring function.

Near-synonyms Disambiguation. Unlike the language modeling task that aims at predicting the next word given the context, near-synonyms disambiguation focuses on differentiating the subtlety of the near-synonyms. Edmonds (1997) first introduced a lexical co-occurrence network with second-order co-occurrence for near-synonym disambiguation. Edmonds also suggested a fill-in-the-blank (FITB) task, providing a benchmark for evaluating lexical choice performance on near-synonyms. Islam and Inkpen (2010) used the Google 5-gram dataset to distinguish near-synonyms using language modeling techniques. Wang and Hirst (2010) encoded words into vectors in latent semantic space and applied a machine learning model to learn the difference. Huang et al. (2017) applied BiLSTM and GMM models to learn the subtle context distribution. Recently, BERT (Devlin et al., 2018) brought a big success in nearly all the Natural Language Processing tasks. Though BERT is not designed to differentiate near-synonyms, its powerful learning capability could be used to understand the subtlety lies in the near-synonyms. In this paper, our models are all designed on top of the pre-

---

[2] Dataset and code are available here: `https://github.com/joyyyjen/Inference-Based-Learner-Like-Agent`

trained BERT model.

Natural Language Inference. Our proposed model directly learns the difference and sentence quality by imitating the human reactions of learning material and behavior of learning from example sentences. The idea of learning from example is similar to natural language inference (NLI) task and recognizing question entailment (RQE) task. There are various NLI dataset varied in size, construction, genre, labels classes (Bowman et al., 2015; Williams et al., 2018; Khot et al., 2018; Lai et al., 2017). In the NLI task, each instance consists of two natural language text: a premise, a hypothesis, and a label indicating the relationship whether a premise entails the hypothesis. RQE, on the other hand, identifies entailment between two questions in the context of question answering. Abacha and Demner-Fushman (2016) used the definition of question entailment: "a question A entails a question B if every answer to B is also a complete or partial answer to A." Though NLI and RQE research has acquired lots of success, to the best of our knowledge, we are the first to attempt using these two tasks on language learning problems.

Poliak et al. (2018)'s recast version of the definite pronoun resolution (DPR) task inspired us to build learner-like agents with entailment modeling . In the original DPR problem, sentences contain two entities and one pronoun, and the mission is to link the pronoun to its referent (Rahman and Ng, 2012). In the recast version, the premises are the original sentences, and the hypothesis is the same sentence with the pronoun replaced with its correct (entailed) and incorrect (not-entailed) reference. We believe our proposed entailment modeling can help the model to understand the relationship between the given example sentence and question for the target near-synonym. Thus entailment modeling enables the learner-like agent to mimic human behavior through inference.

3 Method

In this paper, we use *learner-like agent* to refer to a model that answers questions given examples. The goal of the learner-like agent is to answer fill-in-the-blank questions on near-synonyms selection. However, instead of answering the question from the agent's prior knowledge, the agent needs to answer the question using the information from the given examples. That is, if the given examples provide incorrect information, the agent should then come up with the wrong answer. This process is to simulate the learner behavior illustrated in the Figure 1. Since the model is required to infer the answer, we further formulate it as an entailment modeling problem to enable model's capability of inference. In this section, we (*i*) define the proposed learner-like agent, (*ii*) describe how to formulate it as an entailment modeling problem, and (*iii*) introduce the perturbed instances to further enhance the agent's learner behavior.

3.1 Learner-Like Agent

The overall structure of a learner-like agent is as follows: given six example sentences $\mathbb{E}$ (3 sentences for each word) and a fill-in-the blank question Q as an input instance, the model is to answer the question based on the example hints. We adopt BERT (Devlin et al., 2018) to fine-tune the task-specific layer of the proposed learner-like agent using our training data, equipping the learner-like agent with the ability to discern differences between near-synonyms. The input of our model contains the following:

- A question $Q^{w_i} = [q_1, q_2, .., q_n]$, where n is the length of the sentence and contains a word w_i from the near-synonym pair, where $i \in \{1, 2\}$ denotes word 1 or word 2;
- Example sentences set $\mathbb{E} = [E_1^{w_1}, ..., E_3^{w_1}, E_4^{w_2}, ..., E_6^{w_2}]$, where E^{w_i} denotes a sentence containing w_i;
- A [CLS] token for the classification position, and several [SEP] tokens used to label the boundary of the question and the example sentences, following the BERT settings.

The output will is the correct word for the input question, namely, w_1 or w_2.

We specifically define $E[w_j]^i$ where $i, j \in 1, 2$ to be the context of w_i. The example sentence of case (2) in Table 1 shows a case of $E[w_1]^1$ where the **target word** w_1 is *little* and the rest of the sentence is called **context** $E[\_]^1$. When we change *little* to *small* to create case (9), it is described as $E[w_2]^1$ meaning an example sentence where w_2 fills the position of w_1 in sentence E^{w_1}. This notation also applies to the question input $Q[w_j]^i$.

3.2 Inference-based Entailment Modeling

We apply NLI and RQE tasks in the learner-like agent question design. The goal of the **E**ntailment

Model Type	Case	Example Sentence	Question	Label
EMLA	(2)	After founding the Institute he had **[little]** time for composing, and appears to have concentrated exclusively on teaching.	When she finds out the truth, she makes a fateful decision to make the most of the **[little]** time they have together.	$\{\boldsymbol{entail}, \neg entail\}$
	(3)	After founding the Institute he had **[little]** time for composing, and appears to have concentrated exclusively on teaching.	This may be an incorporated town or city, a subentity of a large city or an unincorporated census-designated place, or a **[small]** unincorporated community.	$\{entail, \boldsymbol{\neg entail}\}$
	(4)	After founding the Institute he had **[little]** time for composing, and appears to have concentrated exclusively on teaching.	When she finds out the truth, she makes a fateful decision to make the most of the **[small]** time they have together.	$\{entail, \boldsymbol{\neg entail}\}$
	(5)	After founding the Institute he had **[little]** time for composing, and appears to have concentrated exclusively on teaching.	This may be an incorporated town or city, a subentity of a large city or an unincorporated census-designated place, or a **[little]** unincorporated community.	$\{entail, \boldsymbol{\neg entail}\}$
	(9)	After founding the Institute he had **[small]** time for composing, and appears to have concentrated exclusively on teaching.	When she finds out the truth, she makes a fateful decision to make the most of the **[small]** time they have together.	$\{\boldsymbol{entail}, \neg entail\}$
CMLA	(12)	After founding the Institute he had **[little]** time for composing, and appears to have concentrated exclusively on teaching. It makes me feel **[small]** when you keep things from me.	When she finds out the truth, she makes a fateful decision to make the most of the **[MASK]** time they have together.	$\{\boldsymbol{little}, small\}$
	(14)	It makes me feel **[little]** when you keep things from me. After founding the Institute he had **[small]** time for composing, and appears to have concentrated exclusively on teaching.	When she finds out the truth, she makes a fateful decision to make the most of the **[MASK]** time they have together.	$\{little, \boldsymbol{small}\}$
Inappropriate Example for EMLA		After founding the Institute he had **[small]** time for composing, and appears to have concentrated exclusively on teaching.	When she finds out the truth, she makes a fateful decision to make the most of the **[little]** time they have together.	$\{entail, \boldsymbol{\neg entail}\}$
Inappropriate Example for CMLA		It makes me feel **[little]** when you keep things from me. After founding the Institute he had **[small]** time for composing, and appears to have concentrated exclusively on teaching.	When she finds out the truth, she makes a fateful decision to make the most of the **[MASK]** time they have together.	$\{\boldsymbol{little}, small\}$

Table 1: Training instances for learner-like agents. The instances are associated with the corresponding equations. Case (9) and (14) are the perturbed instances. The inappropriate examples are used in section 4 for behavior check.

Modeling **L**earner-like **A**gent (**EMLA**) is to answer entailment questions given example sentences. We transform the original fill-in-the-blank question into an entailment question where the EMLA answers whether the given example sentence E entails the question sentence Q. If the word usage in the question sentence matches the word usage in the example sentence, the EMLA answers $entail$, or $\neg entail$ otherwise.

The EMLA M_e is described as

$$M_e(E^i_k, Q^j) = ans, \tag{1}$$

where ans—either $entail$ or $\neg entail$—is the prediction of the inference relationship of one of the six example sentences E^i_k, where $k \in \{1, 2, ..6\}$, and Q^j. To fill all the context possibilities of $Q[\_]^j$ for the same word in E^{w_i}, an example has the following four cases:

$$M_e(E[w_1]^1, Q[w_1]^1) = entail \tag{2}$$

$$M_e(E[w_1]^1, Q[w_2]^2) = \neg entail \tag{3}$$

$$M_e(E[w_1]^1, Q[w_2]^1) = \neg entail \tag{4}$$

$$M_e(E[w_1]^1, Q[w_1]^2) = \neg entail. \tag{5}$$

From the input and output of the instances (equations 2 to 5), we see that the target word and its context in Q^j for all cases except for equation 2 do not follow the example word usage. The examples of the instances are shown in Table 1. Equation 3 and equation 4 tell us that an example sentence of w_1 does not provide any information for the model to infer anything about w_2 so both of them result in *not entail*. The question of equation 5 is incorrect, as shown in the Table 1 case (5), so it would also lead to *not entail*.

After training the EMLA to understand the relation between example and question, we can convert its prediction $\{entail, \neg entail\}$ back into the fill-in-the-blank task by looking into the model predictions. Given the probability of $\{entail, \neg entail\}$, we know which term in the near-synonym pair is more appropriate in the context of $\{Q[\_]^1, Q[\_]^2\}$. If the question context and the example context match, then a word with a higher $entail$ probability is the answer. If they do not match, that with the higher $\neg entail$ probability is the answer.

3.3 Perturbed Instances

To encourage learner-like behavior, i.e., good examples lead to the correct answer, and vice versa, we propose introducing automatically generated perturbed instances to the training process.

A close look at the input and output of the instances (equations 2 to 5) shows that they consider only correct examples and their corresponding labels. We postulate that wrong word usage yields inappropriate examples; thus we perturb instances by swapping the current confusing word to its near-synonym as

$$M_e(E[\neg w_i]^i_k, Q^{w_j}) = \neg ans \tag{6}$$

where $\neg ans$ is $\{entail, \neg entail\} - ans$ and $E[\neg w_i]^{w_i}_k$ is the example sentence in which the contexts in w_1 and w_2 are swapped. The corresponding perturbed instances from equations 2 to

5 thus become

$$M_e(E[w_2]^1, Q[w_1]^1) = \neg entail \quad (7)$$
$$M_e(E[w_2]^1, Q[w_2]^2) = \neg entail \quad (8)$$
$$M_e(E[w_2]^1, Q[w_2]^1) = entail \quad (9)$$
$$M_e(E[w_2]^1, Q[w_1]^2) = \neg entail, \quad (10)$$

respectively, in which w_2's context becomes $E[\_]^1$. Again, only equation 9, where both the context and the word usage match, is *entail*. The example instance is shown in Table 1 case 9.

4 Experiments

We conducted three experiments: **lexical choice**, **behavior check**, and **sentence selection**. The lexical choice task assesses whether the model differentiates confusing words, the behavior check measures whether the model responds to the quality of learning material as learners do, and sentence selection evaluates the model's ability to explore useful example sentences.

4.1 Lexical Choice

Lexical choice evaluates the model's ability to differentiate confusing words. We adopted the fill-in-the-blank (FITB) task, where the model is asked to choose a word from a given near-synonym word pair to fill in the blank.

4.1.1 Baseline

Context modeling is a common practice for near-synonym disambiguation in which the model learns the context of the target word via the FITB task. For this we use a **C**ontext **M**odeling **L**earner-like **A**gent (**CMLA**) as the baseline based on BERT (Devlin et al., 2018) as a two-class classifier to predict which of w_1 or w_2 is more appropriate given a near-synonym word pair. The question for CMLA is a sentence whose target word, i.e., one of the confusing words, is masked; the model is to predict the masked target word.

The CMLA M_c is then described as

$$M_c(\mathbb{E}, Q[\text{MASK}]^i) = ans, \quad (11)$$

where $Q[\text{MASK}]^i$ fills the the position of w_i with MASK, and $ans \in \{w_1, w_2\}$ is the prediction of $[\text{MASK}]$ in the question, and $\mathbb{E}$ are the six example sentences.

$Q[\text{MASK}]^i$ is a question with the context of either w_1 or w_2. This raises a problem of the model deriving the answer only from Q^i,

$$M_c(\mathbb{E}, Q[\text{MASK}]^1) = w_1 \quad (12)$$
$$M_c(\mathbb{E}, Q[\text{MASK}]^2) = w_2 \quad (13)$$

Equations 12 and 13 risk the model to selects w_i given Q^i. To encourage learner-like behavior, we incorporate perturbed instances into the training process corresponding to equations 12 and 13 as

$$M_c(\neg\mathbb{E}, Q[\text{MASK}]^1) = w_2 \quad (14)$$
$$M_c(\neg\mathbb{E}, Q[\text{MASK}]^2) = w_1, \quad (15)$$

, where $\neg\mathbb{E} = [E[\neg w_2]^2_1, .., E[\neg w_2]^2_3, E[\neg w_1]^1_1, .., E[\neg w_1]^1_3]$

For context modeling , the perturbed instance has the additional benefit that it forces the model to make inferences based on the given example sentences, as illustrated in Table 1 case (14).

4.1.2 Dataset and Settings

We collected a set of near-synonym word pairs from online resources, including BBC[3], the Oxford Dictionary[4], and a Wikipedia page about commonly misused English words[5].

An expert in ESL education manually selected 30 near-synonym word pairs as our experimental material. We collected our data for both training and testing from Wikipedia on January 20, 2020. Words in the confusing word pair were usually of a specific part of speech. This guaranteed that the part of speech of the confusing word in the sentence pool matched that in target near-synonym word pair. To construct a balanced dataset, we randomly selected 5,000 sentences for each word; 4,000 sentences for each word in a near-synonym word pair were used to train the learner-like model and 1,000 sentences for testing.

For comparison, we trained four learner-like agents: EMLA, CMLA, EMLA without perturbed instances, and CMLA without perturbed instances. For the best learning effect, we empirically set the ratio of normal-to-perturbed instances to 2 : 1. The agents were trained using the Adam optimizer with a 30% warm-up ratio and a 5e-5 learning rate. The maximum total input sequence length after tokenization was 256; other settings followed the BERT configuration.

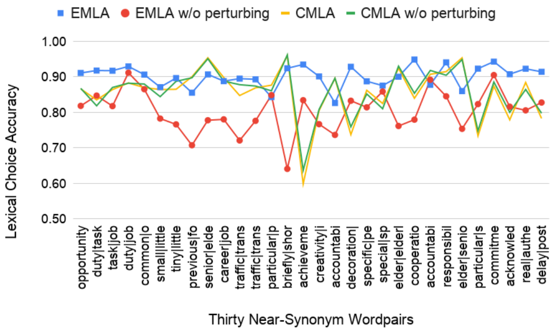

Figure 2: Visualization of lexical choice performance on near-synonym word pairs. Adding perturbed instances improves EMLA's ability of differentiating confusing words. However, perturbed instances does not cause big difference on CMLA.

	T-score	P-value
CMLA	24.54	2.06e-21
CMLA w/o perturbing	0.77	0.45
EMLA	92.12	2.43e-37
EMLA w/o perturbing	27.06	3.96e-22

Table 2: Except for context modeling without perturbed instances, all models respond to changes in learning material quality

4.1.3 Results and Discussion

We compared the EMLA and CMLA and Figure 2 shows the model performance on 30 word pairs. The average accuracy of EMLA and CMLA is 0.90 and 0.86, while that excluding perturbing instances is 0.80 and 0.86, respectively. On average, EMLA performs the best; when perturbed instances are not included in the training, its performance for lexical choice drops. We expected training with perturbed instances to worsen model performance in exchange for learner-like behavior. However, results show that the perturbed instances enhance the inference ability of EMLA. Also, CMLA models seem to be unaffected by perturbed instances (yellow vs. green lines); this could be because CMLA tends to memorize the input context instead of making an actual inference, which in NLI is recognized as bias (Chien and Kalita, 2020).

4.2 Behavior Check

The behavior check evaluates whether the agent learns as learners do; that is, a learner-like agent should perform well on FITB questions when the given learning materials are helpful, and should perform poorly when the materials are not helpful.

In this experiment, all models complete two FITB quizzes. For the first quiz, authentic sentences are provided as appropriate learning materials; for the second quiz, inappropriate learning materials are provided. These materials are considered inappropriate because they are automatically generated using the authentic sentences but replacing their target words with near-synonyms for training, resulting in confusion and wrong word usage, as illustrated in Table 1 (see the last two "Inappropriate example" rows). In other words, given inappropriate example sentences, if the model is truly inferring answers from the examples, the model should select the other choice in the same quiz question.

4.2.1 Results and Discussion

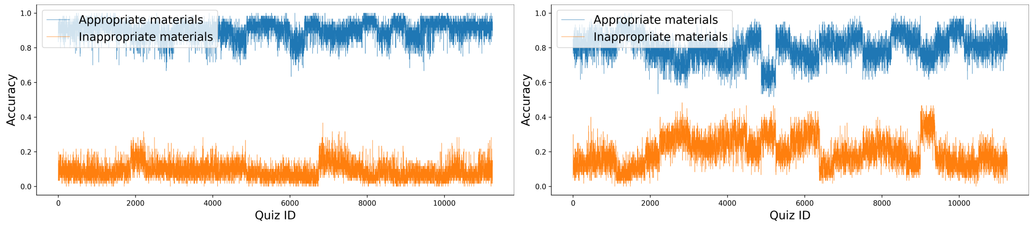
We recorded the accuracy of every question and combined the 30 pairs of near-synonym wordsets from the same model into one graph. As shown in Figure 3, even without perturbed instances, the learning effect of EMLA corresponds to the learning material quality. In contrast, CMLA without perturbed instances, as in the lexical choice task, is no worse when given inappropriate examples.

To determine whether the results of the two fill-in-the-blank quizzes are significantly different when given appropriate and inappropriate examples, we conducted a t-test. Table 2 shows that learner-like behavior is enabled in CMLA with perturbed instances, whereas EMLA learns like learners even without perturbed instances. This result conforms to that shown in Figure 3: the quiz results for both EMLA models can be clearly distinguished, and adding the perturbed instances to EMLA slightly magnifies their difference. However, the CMLA still relies on perturbed instances to learn the difference.

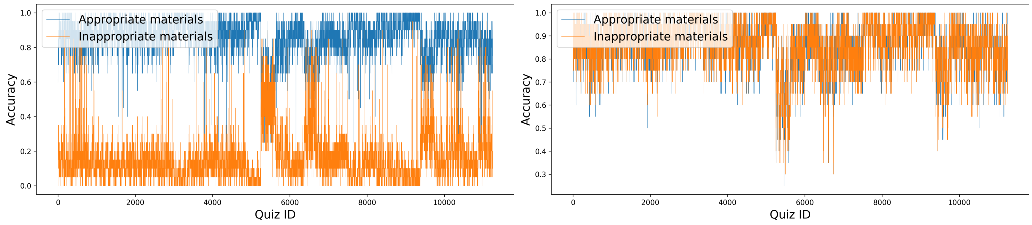
Looking more closely, we present Table 3, in which Δ is the difference in accuracy between two quizzes. The higher Δ is, the better the model differentiates confusing words. We measure the correlation between the lexical choice accuracy and Δ with the Pearson correlation coefficient and obtain a value of 0.87, which demonstrates a strong positive correlation.

4.3 Sentence Selection

In the sentence selection experiment, we evaluate the ability of the learner-like agent to select useful example sentences. Our assumption is straightforward. We give the agent a set of example sentences and evaluate its performance on a number of quizzes. If it does well on many quizzes, the example sentences are deemed helpful for learning



(a) EMLA (b) EMLA w/o perturbing



(c) CMLA (d) CMLA w/o perturbing

Figure 3: Behavior check visualization of quiz results given appropriate (blue) or inappropriate (orange) learning materials. Each quiz was completed 11250 times (375 example sentence sets for each of the 30 word pairs).

	Acc	**Δ**		**Acc**	**Δ**		**Acc**	**Δ**
accountability, responsibility	0.83	0.76	traffic, transportation	0.89	0.80	duty, task	0.92	0.84
particular, peculiar	0.84	0.73	tiny, little	0.90	0.79	real, authentic	0.92	0.86

career, job	0.89	0.80	delay, postpone	0.91	0.82	commitment, responsibility	0.94	0.88
traffic, transport	0.89	0.80	task, job	0.92	0.83	cooperation, collaboration	0.95	0.89

Table 3: Mapping of lexical performance and model ability to differentiate near-synonyms for 30 word pairs using entailment modeling . Acc is the lexical choice accuracy on appropriate examples and Δ is the difference in accuracy between the two quizzes.

confusing words.

4.3.1 Baseline

We compared agents with an implementation of Huang et al. (2017)'s Gaussian mixture model (GMM), which learns the distribution and semantics of the context. We set the number of Gaussian mixtures to 10 and trained the GMM with the dataset proposed here. In the testing phase, we retrieved the top three recommended sentences for each word in the confusing word pair and compared this to the expert's choices.

4.3.2 Evaluation Dataset

To evaluate the sentence selection, we employed an ESL teacher as an expert to carefully select the three best example sentences out of ten randomly selected, grammatically, and pragmatically correct examples for each word in all confusing word pairs.

Specifically, the evaluation dataset had a total of 600 example sentences. For each near-synonym pair, three sentences for each word were labeled as helpful example sentences. To select sentences that clearly clarify the semantic difference between near-synonyms, the ESL expert considered *suitability*, *informativeness*, *diversity*, *sentence complexity*, and *lexical complexity* during selection. For *suitability*, the expert considered whether the two near-synonym words in one confusing word pair were interchangeable in the current sentence. *Diversity* was considered when constructing the selected pool. *Suitability* and *diversity* are designed from the (Huang et al., 2017)'s conclusion. Other criteria are from Kilgarriff's good example sentence (Kilgarriff et al., 2008).

4.3.3 Selection Method

For the proposed good example sentence set, we selected an example sentence combination that helps EMLA or CMLA to achieve the highest accuracy in the quiz. That is, the example sentence set that leads to the highest learning performance.

One of a total of 14,400 ($C_3^{10} \times C_3^{10}$) example sentence sets, including six example sentences, was provided to the models to evaluate their helpfulness.

	Precision	Recall	F1
EMLA	0.33	0.71	**0.45**
CMLA	0.31	0.56	0.38
GMM	**0.37**	0.34	0.35

Table 4: Sentence selection results. When compared with the human annotation, entailment modeling achieves the highest F1 of 0.45.

Each example sentence set was used to answer a quiz composed of k questions. Here, k determines the representativeness and consistency of the testing result from each quiz. We used five independent quizzes to find a reliable k by calculating the correlation of their testing results. Finally, we empirically set k to 100, where the lowest correlation among 30 word pairs was 0.24, and the median was 0.67. That is, each quiz contained 100 questions.

When testing example sentence sets, multiple example sentence sets could achieve the same highest accuracy for the quiz. We considered them equally good so sentences in these sets were all treated as selected. Thus, our method would possibly suggest more example sentences than the gold labels.

4.3.4 Results and Discussion

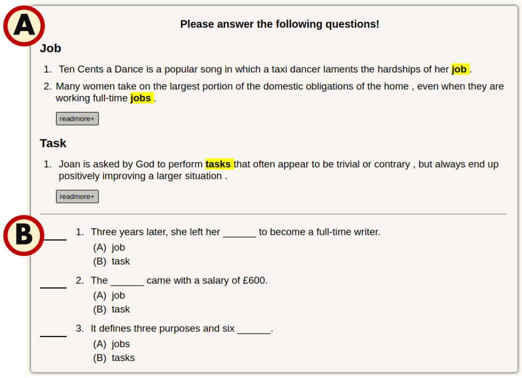
Table 4 shows the results of sentence selection. EMLA significantly outperforms CMLA and Huang's GMM in sentence selection. The improvement comes from the increasing recall, indicating that the proposed learner-like agent manages to find helpful example sentences for ESL learners.

5 Learner Study

We conducted a user study to see the effect of learning on example sentences selected by EMLA, CMLA, and a random baseline. In this learner study, a total of 29 Chinese-speaking college freshmen majored in English were recruited. All the participants were aged between 18 and 19. A proficiency test (Chen and Lin, 2011) was given before the study to identify their English level for further analysis.

5.1 Experimental Design and Material

We followed Huang et al. (2017)'s learner study design with some modification. The whole test consisted of a pre-test and a post-test section in a total of 80 minutes. The fill-in-the-blank multiple-choice question was used in both tests to examine students' understanding of near-synonym. A total of 30 word pairs were used to create 30 question sets where each set contained three questions. The questions are manually selected by an ESL expert from the wiki, Cambridge, or BBC dictionary. Figure 4 shows the interface of the post-test. In the pre-test, only the test panel, as shown in Figure 4 (B), was presented to students. The students were asked to finish the randomly assigned 15 question sets in the pre-test and a background questionnaire. During the post-test section, example sentences generated by EMLA, CMLA, or the random baseline will be presented in the example panel as shown in Figure 4 A. A maximum of three example sentences for each word can be obtained by clicking the *readme* button. The readme button can help us track how many example sentences were used for learning. Note that the students were asked to answer the same question sets in the post-test so we can measure the improvement they made between the pre-test and the post-test. For each question set, the model used for sentence selection was also randomly assigned in order to prevent learners from getting tired from the useless example sentences. Different from the sentence selection in Section 4.3, where all the combinations with the highest score in the quiz are selected, we picked the most common three example sentences from the combination to fulfill the experimental design. Here, we assume the most common three sentences for each word would be the best candidate in all the combinations.



Please answer the following questions!

Job

1. Ten Cents a Dance is a popular song in which a taxi dancer laments the hardships of her **job** .
2. Many women take on the largest portion of the domestic obligations of the home , even when they are working full-time **jobs** .

Task

1. Joan is asked by God to perform **tasks** that often appear to be trivial or contrary , but always end up positively improving a larger situation .

____ 1. Three years later, she left her ______ to become a full-time writer.
(A) job
(B) task

____ 2. The ______ came with a salary of £600.
(A) job
(B) task

____ 3. It defines three purposes and six ______.
(A) jobs
(B) tasks

Figure 4: The interface of the user study contains two panel, (A) the example sentence panel and (B) the test panel. The example sentence panel will only be presented in the post-test.

5.2 Results and Discussion

When learning from example sentences from EMLA, 16 students improved. Only 12 and 11 students improved when learning from CMLA and random baseline, suggesting that EMLA helped more. Figure 5 shows the students' improvement score versus proficiency score.

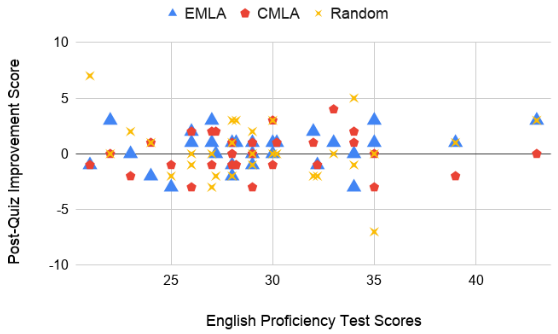


Figure 5: Improvement of 29 learner scores in respect to entailment modeling, context modeling, and random baseline. A total of 16 learners improved when learning on the material generated by entailment modeling.

		EMLA	CMLA	Random
Improvement	Above	0.75	0.42	0.00
	Below	0.18	-0.24	0.47
# Examples	Above	4.34*	4.43*	3.46*
	Below	5.42	5.41	5.41
Difficulty Rating	Above	2.40	2.36*	2.39
	Below	2.58	2.68	2.47

Table 5: Analysis of two groups. Above and Below stand for the above-average group and the below-average group respectively. EMLA helps the above-average group the most. We also find that the above-average group reads significantly fewer sentences than the below-average group. However, the below-average group rates the example sentences easier (scores range from 1 to 4 while 1 being “too difficult”).

To further understand students’ behaviors, we separated students into two groups using their English proficiency test scores. Students whose test scores were lower than the average score were grouped into the below-average group and were considered having lower English proficiency, and vice versa. The above-average group and the below-average group had 12 and 17 students respectively. The average improvement scores of the two groups are shown in Table 5. We can see the above-average students benefit more from example sentences while below-average benefit less or even confused by the example sentences. Again, EMLA helps above-average students the most. The random baseline provides a mixed result, and even the above-average students got affected. This echos results from Huang et al. (2017) where students can still learn from the random example sentences but more effort is needed to fully understand the near-synonym and the outcome is unstable. In Figure 5, we can find that there are two outliers in the random baseline. The one improved a lot is from the below-average group, and the other one worsen a lot is from the above-average group. This evidence shows the uncertainty of the random baseline.

We investigated the learner’s behavior during the post-test and their questionnaire response toward example difficulty. The result is also shown in Table 5. The above-average students read significantly fewer examples while they also rate examples more difficult. On the other hand, most of the below-average students read all the six examples and rate them relatively easier. Though many above-average students improved in the post-test, we found that there are two of them read less than three examples and thus performed worse in the post-test. Such a case suggests that reading a fair amount of example sentences is required to fully understand the near-synonym.

6 Conclusion

We introduce the learner-like agent, in particular EMLA, which differentiates the helpfulness of learning materials using inference. Entailment modeling, unlike common context-based near-synonymous word disambiguation, makes inferences to learn the relationship between the example sentences and the question, similar to human behavior. Context modeling in the learner-like agent relies upon additional perturbed examples to mimic human behavior, whereas EMLA already has this ability. The agent can be used to evaluate the helpfulness of learning materials, or—more interestingly—to select the best materials from a large candidate pool. We select good example sentences in practice, which confirms the usefulness of modeling learner behavior. Using the EMLA learner-like agent, we find more helpful learning material for learners, as demonstrated by the learner study. These demonstrate the usefulness of modeling learner behavior using an inference approach. In the future, we would like to explore if the learner-like agent can be extended to materials and data beyond the example sentences for near-synonyms.

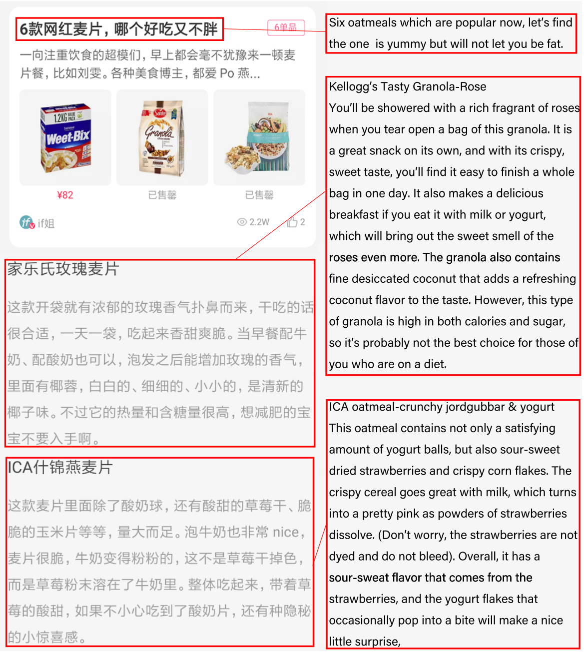
Abstract

As the E-commerce thrives, high-quality online advertising copywriting has attracted more and more attention. Different from the advertising copywriting for a single product, an advertisement (AD) post includes an attractive topic that meets the customer needs and description copywriting about several products under its topic. A good AD post can highlight the characteristics of each product, thus helps customers make a good choice among candidate products. Hence, multi-product AD post generation is meaningful and important. We propose a novel end-to-end model named S-MG Net to generate the AD post. Targeted at such a challenging real-world problem, we split the AD post generation task into two subprocesses: (1) select a set of products via the SelectNet (Selection Network). (2) generate a post including selected products via the MGenNet (Multi-Generator Network). Concretely, SelectNet first captures the post topic and the relationship among the products to output the representative products. Then, MGenNet generates the description copywriting of each product. Experiments conducted on a large-scale real-world AD post dataset demonstrate that our proposed model achieves impressive performance in terms of both automatic metrics as well as human evaluations.



6款网红麦片，哪个好吃又不胖

一向注重饮食的超模们，早上都会毫不犹豫来一顿麦片餐，比如刘雯。各种美食博主，都爱 Po 燕...

家乐氏玫瑰麦片

这款开袋就有浓郁的玫瑰香气扑鼻而来，干吃的话很合适，一天一袋，吃起来香甜爽脆。当早餐配牛奶、配酸奶也可以，泡发之后能增加玫瑰的香气，里面有椰蓉，白白的、细细的、小小的，是清新的椰子味。不过它的热量和含糖量很高，想减肥的宝宝不要入手啊。

ICA什锦燕麦片

这款麦片里面除了酸奶球，还有酸甜的草莓干、脆脆的玉米片等等，量大而足。泡牛奶也非常 nice，麦片很脆，牛奶变得粉粉的，这不是草莓干掉色，而是草莓粉末溶在了牛奶里。整体吃起来，带着草莓的酸甜，如果不小心吃到了酸奶片，还有种隐秘的小惊喜感。

Six oatmeals which are popular now, let's find the one is yummy but will not let you be fat.

Kellogg's Tasty Granola-Rose

You'll be showered with a rich fragrant of roses when you tear open a bag of this granola. It is a great snack on its own, and with its crispy, sweet taste, you'll find it easy to finish a whole bag in one day. It also makes a delicious breakfast if you eat it with milk or yogurt, which will bring out the sweet smell of the roses even more. The granola also contains fine desiccated coconut that adds a refreshing coconut flavor to the taste. However, this type of granola is high in both calories and sugar, so it's probably not the best choice for those of you who are on a diet.

ICA oatmeal-crunchy jordgubbar & yogurt

This oatmeal contains not only a satisfying amount of yogurt balls, but also sour-sweet dried strawberries and crispy corn flakes. The crispy cereal goes great with milk, which turns into a pretty pink as powders of strawberries dissolve. (Don't worry, the strawberries are not dyed and do not bleed). Overall, it has a sour-sweat flavor that comes from the strawberries, and the yogurt flakes that occasionally pop into a bite will make a nice little surprise.

Figure 1: A case of multi-product AD post (with translation) from Taobao. Due to space limitation, we only show the post title and the first two copywriting.

1 Introduction

With the fantastic development of the Internet, e-commerce has a rapid development and changes the customary shopping way of most people in the world. Advertising copywriting is a huge factor in e-commerce, and well-written advertising copywriting can encourage consumers to understand further and purchase products. However, there is an important restriction factor for traditional advertising copywriting, i.e., the writing efficiency of human copywriters cannot match the growth rate of new products. Many e-commerce websites, such as Amazon[1], Taobao[2] and JD[3], have billions of products, so it is impossible to write all copywriting manually. To address this issue, researchers pay more and more attention to the automatic advertising copywriting generation. The initial work (Wang et al., 2017) on automatic advertising copywriting generation is based on the predefined template. With the surge of deep learning techniques, the neural encoder-decoder framework shows remarkable effects on various text generation tasks, e.g., sum-

November 16–20, 2020.

marization (See et al., 2017; Chen et al., 2019b; Gao et al., 2019a, 2020), story generation (Fan et al., 2018; Li et al., 2019; Yao et al., 2019) and so on. The researchers from academia and industry begin to explore how to generate product advertising copywriting through deep learning methods. Zhang et al. (2019) propose a pointer-generator model to generate the product advertising copywriting whose patterns are controlled. Chen et al. (2019a) explore a new way to generate personalized product copywriting by enhancing the transformer with an extra knowledge base.

However, all the previous studies focus on copywriting generation for a single product. In such case, consumers need to compare among products and summarize the advantages and disadvantages of each product by themselves. This makes online shopping a challenging and time-consuming task for customers with high requirements for products. Consequently, a novel advertising copywriting format called multi-product AD post is becoming increasingly popular these years. A multi-product AD post contains several related products that either function similarly or match each other. Each product in the post has its own copywriting, and every copywriting will take full account of the topic of the post and other products' information. The characteristic information of each product can be highlighted by considering both the post topic and other products' information, so the post can let customers understand the characteristics of each product quickly. We show a case of AD post in Figure 1 and we can find the keyword "fat" in the post title and it's the reason for the first product copywriting to emphasize "high-calorie" attribute of the products. Meanwhile, besides the most basic information about cereal, copywriting about these two products emphasize the unique features, such as "rose" for the first product and "yogurt" for the second. However, the post writing is far more difficult than single product copywriting. First, it needs to select suitable products for writing in a post. Then the copywriter must consider the relationship between the post topic and the products to describe each product clearly. Meanwhile, to describe the unique characteristics of each product, the copywriter should also consider the information of other products in the post. Therefore, the multi-product AD post can only be used on a few hot products yet because of the low writing speed and the high cost. Thus, it is very necessary to realize the automatic generation of multi-product AD post.

Targeted to automatic multi-product AD post generation, we propose a two-stage model named S-MG Net. In this model, we split the multi-product AD post generation task into two subprocesses: (1) select a set of products via the SelectNet (Selection Network). (2) generate a post including selected products via the MGenNet (Multi-Generator Network). Concretely, we first propose an iterative attention mechanism called Select-Attention (SelectAttn) and build a model called SelectNet. SelectAttn allows the SelectNet to select the appropriate combination of the products based on the post topic and the relationship among the products. Then, we design the MGenNet inspired by the multi-agent communication method to generate each product's copywriting considering the topic and other products. In detail, we let each agent, i.e., the generator from MGenNet, generate product copywriting individually. Meanwhile, we propose an agent communication strategy that can let each agent obtain the information of other products when the product copywriting is generating. Finally, we combine all the generated copywriting to form the whole multi-product AD post.

In a nutshell, our contributions can be summarized as: (1) We propose the SelectNet which can select the appropriate combination of the products based on the post topic and the relationship among the products. (2) We build the MGenNet to generate the copywriting of each product based on the multi-agent communication framework. (3) We combine the above networks as an end-to-end S-MG Net which can generate attractive AD posts.

2 Related Work

Text generation. Text generation has become one of the hottest subfields of natural language processing. Previous researches mainly focus on several popular text generation tasks, such as dialogue generation (Serban et al., 2016; Tao et al., 2018a; Hu et al., 2019; Chan et al., 2019b) and story generation (Xu et al., 2018; Li et al., 2019; Yao et al., 2019). Bowman et al. (2016) are proposed to improve wording novelty. Serban et al. (2017) target to the intra-sentence consistency and thematic consistency is improved by Fan et al. (2018); Litschko et al. (2018). Besides, text generation from different data formats have also been widely studied in recent years, e.g., table-to-text generation (Liu et al., 2018), which can fit various data formats in real-world scenarios.

Multi-Agent Communication. CommNet proposed by Sukhbaatar et al. (2016) is the first deep learning framework for multi-agent communication. There are several previous works built on the CommNet framework, for example, researchers use the multi-agent communication method to play the starcraft games (Vinyals et al., 2017). Mordatch and Abbeel (2018) deal with natural language processing tasks such as machine translation and sentiment analysis with the multi-agent communication method. Celikyilmaz et al. (2018) present the first study using the multi-agent framework for summarization.

Product descriptions generation. Product description copywriting is critical for the e-commerce platform, and automatically generating the product description copywriting has attracted considerable interest from both academia and industry because of its importance. Wang et al. (2017) first focus on the product description generation task and incorporates the preset template to generate product descriptions automatically. With the development of deep learning, Zhang et al. (2019) proposed a pointer-based generation model with a dual encoder to generate product description and achieved the controlled patterns. Chen et al. (2019a) proposed a transformer-based model to generate personalized product descriptions by combining a knowledge graph as the extra knowledge base. Chan et al. (2019a) proposed use the entity label to enhance the fidelity of the product description.

3 Problem Formulation

To formulate the multi-product AD post generation task, we use P to denote a product candidate set which contains a lot of productions, namely $P = \{u^p_1, u^p_2, \cdots, u^p_{n_p}\}$, where u^p_i indicates the information[4] of i-th product in the set and n_p is the set size. Specifically, $u^p_i = \{w^p_{i,1}, w^p_{i,2}, \cdots, w^p_{i,n_{p,i}}\}$ is a text sequence which contains $n_{p,i}$ words. Meanwhile, the topic of the AD post is represented as $T = \{w^t_1, w^t_2, \cdots, w^t_{n_t}\}$ where w^t_i indicates the i-th word in the topic sequence and n_t is the length. The goal of our model is to generate a multi-product AD post $\hat{C} = \{\hat{u}^c_1, \hat{u}^c_2, \cdots, \hat{u}^c_{n_c}\}$ where $\hat{u}^c_i = \{\hat{w}^c_{i,1}, \hat{w}^c_{i,2}, \cdots, \hat{w}^c_{i,n_{c,i}}\}$ represents the copywriting of the i-th product in the post which contains $n_{c,i}$ words. Essentially, our model optimizes the parameters to maximize the probability $p(C|P, T)$ where C is the ground truth post. Note that we ignore the order of products in the post and regard each product as equal.

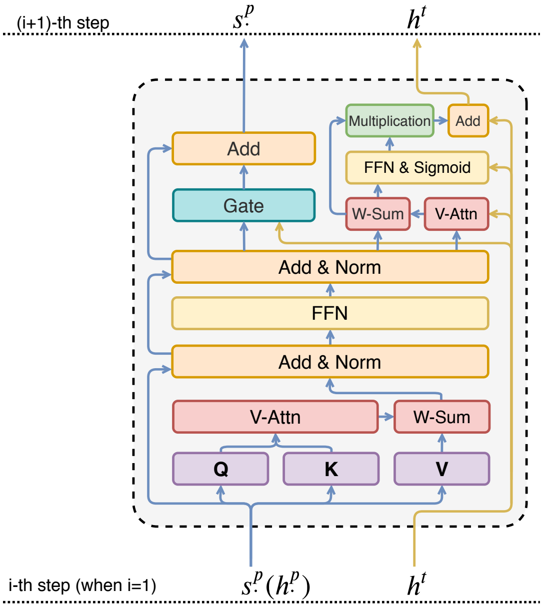

Figure 2: The SelectAttn mechanism. The V-Attn, W-Sum indicate the weight calculation and weighted sum respectively. The FFN indicates the Feed Forward Network. The first step input is $h^p_\cdot$, and others are the $s^p_\cdot$.

4 Proposed Model

As Figure 3 shows, our proposed S-MG Net model consists of Selection Network (SelectNet) and Multi-Generator Network (MGenNet).

4.1 Selection Network

We propose the Selection Network (SelectNet) to select the appropriate products from the input product candidate set. Inspired by self-attention mechanism proposed by Vaswani et al. (2017), we design the Select-Attention (SelectAttn) mechanism to capture the relationship among the products and the relationship between the post topic and each product. Note that the SelectAttn will iterate N time, we focus on one of these iterations for clarity. Figure 2 shows the structure of SelectAttn.

To begin with, we obtain the post topic T and the product candidate set P. More details of these symbols are mentioned in Section 3. First, we use an embedding matrix e to embed each word in T and P into a high-dimensional vector space. Then, we use an RNN encoder named topic encoder to encode the embedded post topic $e(T)$ to

---

[4] In this work, the product information comes from the product title which contains the attributes keywords of the product. Each product title can be regarded as a text sequence.

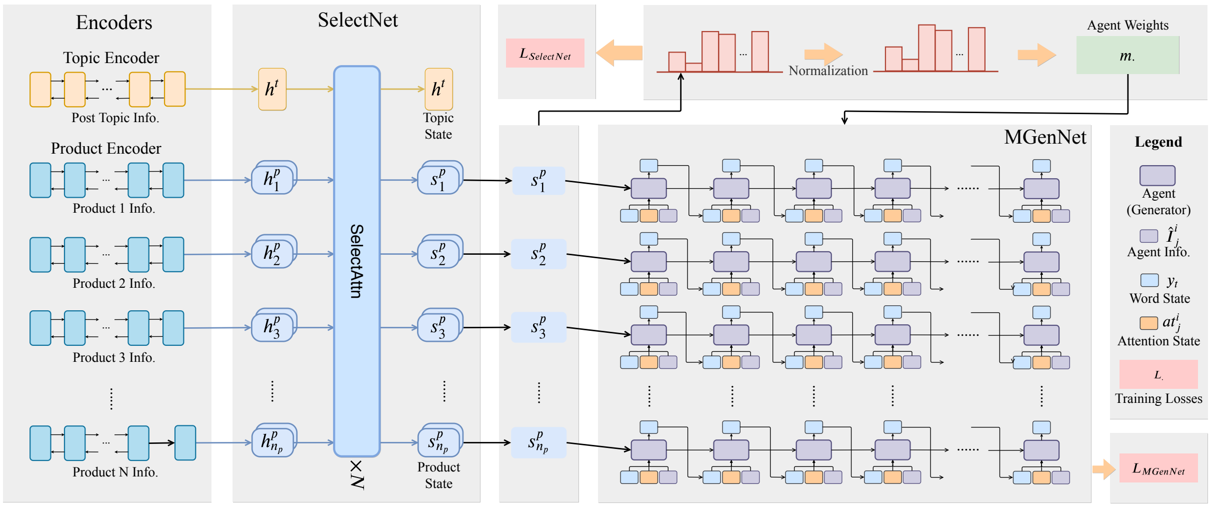

Figure 3: The overview of the end-to-end S-MG Net which is the combination of SelectNet and MGenNet model.

h^t. Similarly, we use another RNN encoder called product encoder to encode each embedded product information sequence $e(u_i^p)$ as the h_i^p, so we can obtain $h^P = \{h_1^p, h_2^p, \cdots, h_{n_p}^p\}$ which indicate all the product candidates.

To capture the relationship among the product candidates, we use the self-attention mechanism to conduct the interaction between $\{h_1^p, h_2^p, \cdots, h_{n_p}^p\}$. Concretely, we use three fully-connected layers to project h_i^p into three spaces, i.e., $Q_i = \text{FC}_q(h_i^p), K_i = \text{FC}_k(h_i^p), V_i = \text{FC}_v(h_i^p)$, where Q_i, K_i and V_i represent the query, the key and the value respectively. The attention module takes Q_i to attend to each $K_\cdot$[5], and uses these attention distribution results $\alpha_{i,\cdot} \in \mathbb{R}^N$ as the weights to obtain the weighted sum of v_i:

$$\begin{aligned} \alpha_{i,j} &= \frac{\exp\left(Q_i K_j\right)}{\sum_{n=1}^{n_p} \exp\left(Q_i K_n\right)}, \\ \beta_i &= \textstyle\sum_{j=1}^{n_p} \alpha_{i,j} v_j, \end{aligned} \tag{1}$$

where $\alpha_{i,j}$ denotes the attention weight of the i-th product, i.e., h_i^p, on the j-th product, i.e., h_j^p. Next, we add the original product representation h_i^p on β_i as the residential connection layer, as shown in:

$$\hat{s}_i^p = \text{LayerNorm}(h_i^p + \beta_i), \tag{2}$$

where LayerNorm indicates the Layer Normalization. Next, we apply a feed-forward layer on $\hat{s}_i^p$ to obtain the representation $\dot{s}_i^p$ and conduct the residential connection layer again:

$$\begin{aligned} \dot{s}_i^p &= \text{ReLU}(\hat{s}_i^p \cdot W_1 + b_1) \cdot W_2 + b_2, \\ \dot{s}_i^p &= \text{LayerNorm}(\dot{s}_i^p + \hat{s}_i^p), \end{aligned} \tag{3}$$

where W_1, W_2, b_1, b_2 are all trainable parameters. Then the normalization operation is applied as introduced before. The above operation can model the relationship among the products.

Next, to target at utilizing the relationship between post topic and each product, we propose to integrate the information of post topic into each product presentation $\dot{s}_i^p$ as additional prior information. We use a gate mechanism to control the fusion between topic information and each product representation and we add the product in the representation as the residential connection layer:

$$\begin{aligned} g_\cdot^p &= \text{Sigmoid}([\dot{s}_\cdot^p; h^t] \cdot W_g + b_g) \\ \widetilde{s}_\cdot^p &= g_\cdot^p \cdot h^t + (1 - g_\cdot^p) \cdot \dot{s}_\cdot^p, \\ s_\cdot^p &= \dot{s}_\cdot^p + \widetilde{s}_\cdot^p, \end{aligned} \tag{4}$$

where W_g, b_g are trainable parameter matrices. After adding post topic information to product representation, we use the raw product information to polish the topic representation. Concretely, we use the cross attention mechanism to obtain the information that we used to polish the topic representation h^t, the process is shown as below:

$$\begin{aligned} \gamma_i &= \frac{\exp\left(\dot{s}_i^p h^t\right)}{\sum_{j=1}^{n_p} \exp\left(\dot{s}_j^p h^t\right)}, \\ \delta &= \textstyle\sum_{i=1}^{n_p} \gamma_i \dot{s}_i^p. \end{aligned} \tag{5}$$

Inspired by GLU (Gehring et al., 2017), we use the product and topic information to control the amount of information of the δ. Finally, we add the δ to h^t to update the topic information as following:

$$\begin{aligned} g^t &= \text{Sigmoid}([\delta; h^t] \cdot W_t + b_t), \\ \widetilde{\delta} &= g^t \cdot \delta, \\ h^t &= h^t + \widetilde{\delta} \end{aligned} \tag{6}$$

---

[5] We use the subscript "·" to represent the any index, for example, $K_\cdot$ represents $K_1, K_2, \cdots, K_N$.

where W_t, b_t are all trainable parameters and h^t has been updated by the product information. We name the whole above operation as SelectAttn. Finally, we obtain the new product representations $s^P = \{s_1^p, s_2^p, s_3^p, \cdots, s_{n_p}^p\}$.

Lastly, we use these product representations from SelectAttn to select the products which can be shown in the AD post. After interacting with the post topic and other products, the product representations can describe the matching degree of the product with the target post. So the selection is based on the scores calculated from product representations. We can obtain the scores from below:

$$score_{\cdot} = \text{Sigmoid}(s_{\cdot}^p \cdot W_c), \tag{7}$$

where W_c represents a trainable matrix. Finally, we can obtain a group of probability samples, i.e., $\{score_1, score_2, \cdots, score_{n_p}\}$ as the final score. We use the scores to rank the products and use the top-M products as the selection result.

4.2 Multi-Generator Network

After we finish the selection process, we continue to generate the copywriting for each selected product. Inspired by Celikyilmaz et al. (2018), we propose to build Multi-Generator Network (MGenNet) based on the multi-agent framework and a generator is acting as an agent. In the following, we use agent to indicate the generator for more intuitive explanations.

As mentioned before, we rank the selection scores $\{score_1, score_2, \cdots, score_{n_p}\}$ and get the top-M products as selection result $\bar{s}^p = \{\bar{s}_1^p, \bar{s}_2^p, \bar{s}_3^p, \cdots, \bar{s}_M^p\}$ where $\{\hat{m}_1, \hat{m}_2, \hat{m}_3, \cdots, \hat{m}_M\}$ is the corresponding scores. We normalize these scores as:

$$m_{\cdot} = \frac{\hat{m}_{\cdot} - \text{Min}(\hat{m}_{\cdot})}{\text{Max}(\hat{m}_{\cdot}) - \text{Min}(\hat{m}_{\cdot})}, \tag{8}$$

where Min and Max indicate the operations which obtain the minimum and maximum value from the score set. Finally, we obtain $\{m_1, m_2, m_3, \cdots, m_M\}$ where $m_{\cdot}$ is a value in $[0, 1]$. We regard m_i as the importance of the i-th product in the AD post and use it as the weight of the agent which generates the copywriting of the i-th product.

We define each RNN cell as an agent and all RNN cells share the same parameters in this work for promoting the generation efficiency. We let every agent generate copywriting for one product individually. To initialize the each agent, we use a linear layer to cover all the selected product representation $\{\bar{s}_1^p, \bar{s}_2^p, \bar{s}_3^p, \cdots, \bar{s}_M^p\}$ to initialize the corresponding agent (RNN Cell) and the use a special token "<BOS>" as the input of the first step, which can be described as follows:

$$\begin{aligned} a_0^{\cdot} &= \text{ReLU}(\bar{s}_{\cdot}^p \cdot W_s) + b_s, \\ a_1^{\cdot} &= \text{Agent}(a_0^{\cdot}, e(\text{<BOS>})), \end{aligned} \tag{9}$$

where Agent indicates the operation of RNN and $a_i^{\cdot}$ represents the state of agent in i-th step. During the generation, we let the agents communicate with each other. In order to deliver useful information, we collect the status of all agents except themselves. Meanwhile, we use the agent weight $m_{\cdot}$ coming from Equation 8 to control the weight of the status. The process is as follows:

$$\begin{aligned} \hat{a}_j^{\cdot} &= a_j^{\cdot} \cdot m_{\cdot}, \\ I_j^i &= \{\hat{a}_j^1, \cdots, \hat{a}_j^{i-1}, \hat{a}_j^{i+1}, \cdots, \hat{a}_j^M\} \end{aligned} \tag{10}$$

where $\hat{a}_j^i$ represents the information coming from the i-th agent when j-th step and I_j^i represents the information set for i-th agent when j-th step.

Inspired by Celikyilmaz et al. (2018) and Sukhbaatar et al. (2016), we propose a multi-agent communication strategy to calculate practical information that the agent obtains from other agents in the generation process. We use the mean value of I_j^i shown in Equation 10 as the practical information for the i-th agent in the j-th step as:

$$\hat{I}_j^i = \frac{\text{sum}\{I_j^i\}}{M - 1}. \tag{11}$$

The $\hat{I}_j^i$ contains all the information of other agents, and the i-th agent can get more information as the prior for generating.

After obtaining the information $\hat{I}_j^i$, we attach it as an extra input to the corresponding agent. We use the below equation to express this process

$$\begin{aligned} y_t' &= ([y_t; \hat{I}_j^i; at_t^{\cdot}] \cdot W_y) + b_y, \\ a_{t+1}^{\cdot} &= \text{Agent}(a_t^{\cdot}, y_t'), \end{aligned} \tag{12}$$

where W_y, b_y are trainable parameters. y_t is the input of agent at t-th time step and the $at_t^{\cdot}$ is the attention vector which is calculated from the corresponding product RNN encoder status as same as Luong et al. (2015). Then, we use a linear layer to obtain the generated word. Finally, we can use the beam search algorithm to get all copywriting $\hat{C} = \{\hat{u}_1^d, \hat{u}_2^d, \cdots, \hat{u}_M^d\}$ which $\hat{u}_i^d = \{\hat{w}_{i,1}^d, \hat{w}_{i,2}^d, \cdots, \hat{w}_{i,L_{c,i}^n}^d\}$.

4.3 Training Objection

To start with, we combine SelectNet and MGenNet as an end-to-end framework. We launch the following objective to minimize the MLE loss between the ground truth and generated copywriting. Meanwhile, we minimize the loss between selected product ground truth in real multi-product AD post, and the objective function is:

$$\mathbb{L} = \lambda \mathbf{E}_\theta \log p(\hat{P}|P, T) + \gamma \mathbf{E}_\phi \log p(\hat{C}|\hat{P}, T), \tag{13}$$

where λ, γ are the weights for SelecctNet and MGenNet loss respectively. $\hat{P}$ indicates the selected product and $\hat{C}$ indicates the generated post.

5 Experiments

5.1 Dataset

We construct a multi-product AD post dataset collected from Bimai Qingdan (which means a list of goods you must buy) in Taobao. Millions of posts are composed by professional copywriters to introduce and recommend different products for online shoppers. Each post consists of several products with their images, description copywriting, and a title that reflects the topic of this post.

We extract the title of each post as the post topic T. To construct product candidate set P, we sample negative samples from the product set which have the same categories (such as food, clothes and so on.) with the positive samples, i.e., the products in the real post and the ratio of positive examples and negative examples is 6:9. After we select the products for the candidate set, we obtain the corresponding short product attributes title and regard them as product information $\{u_1^p, u_2^p, \cdots, u_{n_p}^p\}$. Naturally, the long product description copywriting of all products in the post are regarded as the target. As a result, we obtain 339,433 posts and randomly split them into 330,000 / 4,433 / 5,000 as training / validation / testing sets.

5.2 Hyperparameters.

The dimension of word embeddings is set to 256. The N of the SelectAttn in the SelectNet is set to 3. The vocabulary comprises the most frequent 50,000 words and we let the encoder and decoder share this common vocabulary. The product encoder and topic encoder in the SelectNet model are two bidirectional RNN with the LSTM cells, respectively. The agent decoder in MGenNet consists of a one-layer RNN with LSTMs. The hidden state sizes of both LSTM in encoder and decoder are set to 512. We set the size of mini-batch to 64 and all sequence inputs were padded with the special token "<PAD>" to a maximum sequence length of the batch. λ is set to 2 in the training process. During decoding, we employ the beam search with a beam size of 4 to generate a more fluent sentence. We train all models for 40 epoch and it took around 20 hours on GPUs for training. After each epoch, we evaluated our model on the validation set and chose the best performing model for testing. We use the Adam optimizer (Duchi et al., 2010) for all experiments and the learning rate is set to 1e-3.

Table 1: Criteria of human evaluation.

Readability	Is the copywriting grammatically formed and smooth?
Informativeness	Does the copywriting contains informative words?
Attractiveness	How attractive the post copywriting is?
Rationality	Is the product selection reasonable?

5.3 Baselines

To show the effectiveness of our model, several classical generation approaches are set as baselines. 1). **Seq2Seq** (Bahdanau et al., 2014). A classic and widely used text generation model. 2). **ConvSeq** (Gehring et al., 2017). A model combining the CNN and the Seq2Seq network. 3). **Transformer** (Vaswani et al., 2017). The state-of-the-art model in several text generation tasks. 4). **PCPG** (Zhang et al., 2019). A pattern-controlled product description generation model. We adapt it to our scenario. 5). **KOBE** (Chen et al., 2019a). A knowledge-based and personalized product description generation model based on Transformer. We adapt the model for our scenario by removing the personal module.

We cannot generate copywriting for each product individually when we don't know the corresponding relation. To apply these baseline models to our scenario, we separate the description text of each product in the post with a unique character "<SOP>" and then concatenate the whole text as the final target for training.

To analyze our SelectNet, we select several models for text matching as baselines. 1). **RNN** (Liu et al., 2016). A model uses RNN to model input as the hidden state to classify. 2). **SCN** (Wu et al., 2019). A classic retrieval model for response selection. The model lets the post title interact with product information and transforms interaction matrices into a matching vector with CNN. 3). **MRFN** (Tao et al., 2019). A strong retrieval-

Table 2: The automatic metric result of our model and baselines. Since the number of sentences generated by ConvSeq is extremely small, so evaluating the intra-dist metric is meaningless, and we omit the intra-dist score. The results of our methodologies are significant with p-value <0.05 measured by t-test over the best baseline.

Models	**Embedding Metrics**			**Inter-Distinct**				**Intra-Distinct**			
	Average	Greedy	Extrema	Dist-1	Dist-2	Dist-3	Dist-4	Dist-1	Dist-2	Dist-3	Dist-4
Seq2seq	0.9197	548.69	0.4293	0.937	3.183	6.655	9.940	20.77	28.38	31.07	33.41
ConvSeq	0.6049	326.99	0.1123	1.308	2.796	3.970	4.951	-	-	-	-
Transformer	0.8662	537.69	0.3941	1.473	4.427	9.099	13.59	25.23	33.83	39.79	45.48
PCPG	0.8830	540.41	0.3713	1.409	3.943	7.423	10.43	22.43	29.98	36.80	40.31
KOBE	0.8783	539.23	0.4023	1.523	5.334	11.34	18.32	26.46	37.43	43.23	53.84
S-MG$_C$	**0.9438**	560.45	**0.4481**	**1.763**	**8.051**	**18.37**	**28.30**	**44.66**	**66.22**	**73.57**	**78.96**
S-SG	0.8774	**566.86**	0.4280	1.294	4.059	8.479	12.71	24.76	33.06	38.72	44.09
S-MG	0.9428	558.62	0.4440	1.713	7.502	17.21	26.60	44.49	65.97	73.26	78.64

based model in response selection. Tao et al. (2019) encode the interaction between two texts from multiple kinds of representations and study how to fuse them. 4). **SETM** (Yang et al., 2019). It lets the post title interact with product text and uses the representation to obtain a weight matrix for each word. 5). **Self-Attn** (Vaswani et al., 2017). We use the self-attention mechanism to capture the relationship among the product candidates for product selection.

We also conduct the exploration of the MGenNet, and the setting is shown as follows 1). **S-MG$_C$.** Our proposed multi-agent generation framework with communication strategy. 2). **S-MG.** The original multi-agent generation framework without communication. 3). **S-SG.** We replace the MGenNet with a pretrained Transformer decoder and generate the whole post copywriting in one pass.

5.4 Evaluation Metrics

As mentioned in Section 3, we ignore the order of products in the post and regard each product as equal. Hence, traditional metrics such as BLEU and ROUGE, are unsuitable in this scenario. To evaluate the results of the generated AD post, we adopt the following widely used metrics.

Embedding Metrics. To obtain semantic matches between the generated copywriting and ground-truth, we perform evaluation using the embedding metrics. Following Gao et al. (2019b), we calculate three measures: 1) *Average*, cosine similarity between the averaged word embeddings in the two utterances (Mitchell and Lapata, 2008); 2) *Greedy*, i.e., greedily matching words in two utterances based on the cosine similarities, and the total scores are then averaged across all words (Rus and Lintean, 2012); 3) *Extrema*, cosine similarity between the largest values among the word embeddings in the two utterances (Forgues et al., 2014). The used word2vec embedding is trained by ourselves because there is no open-access e-commerce embedding.

Distinct Metrics. We use distinct scores to reflect the diversity of the copywriting. Dist-n is defined as the ratio of unique n-grams (n = 1,2,3,4) overall n-grams in the generated copywriting. Following Gu et al. (2018), we define *intra-dist* as the average of distinct values within each copywriting and *inter-dist* as the distinct value among all copywriting.

Human Evaluation. Because Tao et al. (2018b) mentioned that only using the automatic metrics to evaluate text quality can be misleading, we also conduct human evaluation. Three well-educated annotators are hired to evaluate the quality of generation, where the evaluation is conducted in a double-blind fashion. 200 randomly sampled copywriting generated by each model are rated by each annotator with four different aspects. Details of the criteria are illustrated in Table 1. All criteria are scored from 1 to 4, i.e., from bad to good.

6 Results and Analysis

6.1 Overall Performance

We report the performance of our proposed S-MG Net and baselines in terms of all the automatic metrics, and the results are shown in Table 2. Firstly, among all baselines, we find the KOBE model can obtain the best performance on the distinct metrics, and the Seq2seq model performs best on the em-

Table 3: The result of our proposed SelectNet model and baselines. Rank is the accuracy in Top-6 prediction compare with the ground-truth. The p-value of our results is smaller than 0.01 measured by t-test over the best baseline.

Model	Valid Set		Test Set	
	Acc	Rank	Acc	Rank
RNN	61.77	46.89	61.75	46.84
SCN	70.92	61.48	70.91	61.49
MRFN	75.45	71.32	75.23	71.62
SETM	71.22	61.90	69.53	59.47
Self-Attn	88.59	84.81	88.60	84.83
SelectNet	**90.22**	**86.88**	**90.22**	**86.89**

Table 4: Human evaluation with the strongest baselines. The Read., Info., Attract., Ration. indicate the Readability, Informativeness, Attractiveness and Rationality, respectively. The mean kappa value between annotators is 0.43.

Model	Read.	Info.	Attract.	Ration.
GroundTruth	3.982	3.812	3.882	3.902
Seq2seq	3.100	2.690	2.435	1.895
KOBE	3.415	2.885	3.095	2.835
S-MG$_C$	**3.645**	**3.395**	**3.500**	**3.145**

bedding metrics. In all, our proposed S-MG Net outperforms all baselines on almost all metrics, outperforming the strongest baseline KOBE in distinct metrics, by 15.76%, 50.94%, 68.78%, and 76.92% in terms of Inter-Dist-1, Inter-Dist-2, Intra-Dist-1, and Intra-Dist-2, respectively. Besides, S-MG Net outperforms the strongest baseline Seq2seq model in embedding metrics by 2.62%, 2.14% and 4.38% on *Average*, *Greedy* and *Extrema* score. Meanwhile, our model also performs well on human evaluation. As shown in the Table 4, S-MG Net obtains 6.73%, 17.68%, 13.09% and 10.93% improvement than the KOBE model in terms of readability, Informativeness, attractiveness and rationality scores. Overall, our proposed model brings an impressive improvement.

6.2 Discussions

Comparing with all baselines, our proposed SelectNet model achieves an impressive improvement. As shown in Table 3, through conducting the comparison between our SelectNet model and all baselines, we can find our SelectNet shows an impressive improvement than all baselines. For example, SelectNet outperforms the MRFN model on the testing set by 19.93% and 21.32% on the Test Acc score and Test Rank score. The improvement is very impressive.

The relationship between the products is crucial. Meanwhile, the relationship between post title and each product is also important for the improvement. As shown in Table 3, Self-Attn which captures the relationship among the products outperforms the strongest MRFN model by 17.77% and 18.44% on Acc score and Rank score on the testing set. According to such impressive improvement, we can learn the interaction between the products is crucial in this product selection process. Meanwhile, by comparing the Self-Attn model and our SelectNet model, we can find our SelectNet model which uses the relationship between post topic and each product can outperform the Self-Attn model by 1.62 and 2.06 in the Test Acc score and Test Rank score. It is clear that the interaction between post topic information and each product can improve the effects of the product selection.

Multi-agent generation brings a leap improvement. As we mentioned before, multi-agent generation framework is different from the traditional encoder-decoder framework which only contains one single decoder. As shown in Table 2, S-MG achieves a further improvement over all the encoder-decoder framework baselines. Specifically, S-MG wins over the best performing Seq2seq and KOBE model in the baselines. S-MG in the comparison of metrics, on the *Average*, *Greedy*, *Extrema* with the Seq2seq model, obtains improvements as 2.51%, 1.81%, 3.42%. Compare with the KOBE model, S-MG outperforms by 12.48% and 68.14% in the Inter-Dist-1 and Intra-Dist-1, respectively. Compared with the S-SG which combines the SelectNet with a single decoder, S-MG can also achieve 7.45% (*Average*), 3.74% (*Extrema*), 33.52% (Inter-Dist-1) and 79.68% (Intra-Dist-1) improvements. These impressive improvements show that S-MG Net outperforms the traditional encoder-decoder framework in the multi-product AD post generation task. Meanwhile, as the ablation experiment about the agent communication, we compare the S-MG$_C$ with the S-MG, and we can find the S-MG$_C$ outperform the S-MG in all metrics. According to the above analysis, we can learn that agent communication can improve the generation performance further.

Table 5: A generated copywriting. The (✓) represent this product is in the groundtruth and the (×) is the opposite.

Title	赶快解锁女装利器，从此迎接美好生活(Unlock the weapon of women's clothes, and welcome the beautiful life from now on)
Product Set	(×) 1. d ' zzit 地素夏专柜新款运动风半身裙(D'zzit's new sporty style skirt which is designed for the summer.) (✓) 2. vifille 同款刺绣撞色卫衣 (This hoodie has vibrant color and embroidery and it is so fashione that Vifille also wear it !) (✓) 3. beanpole 滨波女士宽松版印花卫衣(BEAN POLE's women hoodie with printing and it is loose for wearing.) (×) 4. 2016 夏季新款女装名媛条纹不规则假两件开叉露肩连衣裙夏中长款 (Fake two off-the-shoulder split women dresses with irregular stripes, and it is the special style in 2016) (×) 5. 优雅七分袖夏季宽松a字裙(It is an elegant summer A-line skirt with three-quarter sleeves.) (×) 6. 白夜宽松蝙蝠袖套头毛衣(White-night's bat-sleeved sweater, and it is loose for wearing.) (✓) 7. 果酱公主春新原创森系时尚气质卫衣 (Guojiang Princess's original fashion hoodie for the spring and you will be very comfortable because it is like fresh air.) (×) 8. 梦舒雅冬新款加厚加绒微喇裤修身(Mengshuaya's new thickened pants and it has fleecy trim.) (✓) 9. 七格格卫衣加绒半高领秋中长款宽松 (Qigege's hoodie with fleece trim and semi-high collar. It is the middle length for autumn. It is loose for wearing.) (×) 10. 休闲七分显瘦通勤正装裤(7-points pants for relaxing, it will make you look more thin.) (×) 11. yiner 冬时尚贴布侧条纹系带连衣裙(Yiner's fashion dress with side stripes and straps, it is suitable for winter.) (×) 12. loftshine 珞炫女装专柜大衣(Loftshine's clothing coat, it is designed for women.) (×) 13. 洋气短袖碎花小清新超仙气质雪纺衫(This skirt which has short sleeve and the broken flower is pure and fresh.) (✓) 14. 卫衣女nina mist 套头飘带(This hoodie is designed for women by Nina Mist's and it has a beautiful ribbon.) (✓) 15. 韩版学生蝙蝠袖连帽卫衣(Korean style hoodie with bat sleeve. It is suitable for students.)
S-MGc	• **[For Product 14]**: 这款卫衣采用了经典的圆领设计，简约大方，宽松的版型 (This hoodie adopts the classic round collar design, it is simple and generous. Meanwhile, its version is loose.) • **[For Product 7]**: 这款卫衣采用了柔软的针织面料，上身舒适又保暖 (This hoodie is soft and like air, and it keeps the body warm and comfortable.) • **[For Product 15]**: 韩版风格，充满优雅气息，版型宽松，上身就是时髦 (The hoodie is Korean style and elegant. Its loose version makes owner fashion.) • **[For Product 9]**: 中长款的长度，百搭不挑身形，版型宽松，上身就是时髦 (The hoodie is middle length and it is suitable for multiple body shapes. Its loose version makes owner fashion.) • **[For Product 2]**: 精致的刺绣，点缀着整体的时尚不呆板，经典的圆领 (This clothes has delicate embroidery which shows the fashion, and it has classic round collar.) • **[For Product 3]**: 这是来自BEAN POLE 的卫衣，适合女士在休闲场合穿着 (This is a hoodie from BEAN POLE and it is suitable for casual wearing.)

6.3 Case Study

Table 5 shows the generated multi-product AD post of our proposed S-MG Net model. In the product candidate set, almost all products are related to women's clothes and it is hard for SelectNet to conduct the product selection only depends on the topic information. In this case, our SelectNet selects a product set consisting of 6 hoodies and it is categorical that these 6 hoodies can match each other. It proves that the relationship between the products is crucial in our SelectAttn mechanism. Meanwhile, our model can generate an informative and attractive multi-product AD post. The copywriting for each product is unique and informative.

7 Conclusion and Future Work

In this paper, we explore the multi-product AD post generation which is meaningful for both academic researches and industrial applications. Due to the characteristics of such a new task, most existing classical text generation schemes do not work well. To fill this gap, we propose an end-to-end S-MG Net model that uses the SelectNet to select the combination of products associated with each other and uses the MGenNet to generate the copywriting for each product. After stitching the generated copywriting together, we can obtain a well-formed multi-product AD post. Experiments conducted a large-scale real-world product description dataset demonstrate that our proposed model achieves promising and impressive performance.

Owing to the promising results of the proposed two-stage model, we could degenerate this process into more specific sub-processes. Moreover, we will conduct further exploration of the multi-product AD post form, including more vivid multimedia information, such as pictures and videos.

Acknowledgments

We would like to thank the anonymous reviewers for their constructive comments. We would also like to thank Yongliang Wang from Ant Group for his suggestions and help. A Dataset

A.1 Data Collection

Since there are few previous studies about the post generation for advertisement, there is not any public dataset that we can use directly. Thus we construct an multi-product AD post dataset from scratch and our raw data is coming from a content scenario platform named Bimai Qingdan (which means a list of goods you must buy) in Taobao. Millions of posts are composed of professional paid copywriters to introduce and recommend different products for online shoppers to make the products more popular. Each post consists of several items (products) with their images, description copywriting, and a title that reflects the topic of this post. For example, a post that recommends some make-ups may consist of products like different perfumes and have a title like "start a new gorgeous day and become the most beautiful lady in the street."

We extract the title of each post as the post topic T. To construct product candidate set P introduced in Section 3, we sample negative samples from the product set which have the same categories (such as food, clothes and so on.) with the positive samples, i.e., the products in the real post. After we select the products in the candidate set, we obtain the corresponding short product description title which contains the attribute keywords and regard them as product information $\{u_1^p, u_2^p, \cdots, u_{n_p}^p\}$ mentioned in Section 3. Naturally, the long product description copywriting of all products in the post are regarded as the target C for our work. We keep all the posts that contain six products and the number of the negative samples is fixed to nine in all experiments.

A.2 Data Filtering

To clear our data, we filter the text length of each post and guarantee all post title consists of 7 to 14 words, the lengths of each product title are between 3 and 15, and the description text of each product has more than 10 words and less than 35 words. Finally, we obtain a clean and reasonable dataset through the above filtering operations. Finally, we obtain 339433 posts and randomly split them into 330,000/4,433/5,000 as training/validation/testing sets. More details are shown in Table 6.

Table 6: Some statistics about our dataset.

Text Type	Post Title	Product Title	Product Description
Min Length	7	3	10
Max Length	14	15	35
Size	339k	5,085k	2,034k

B More Implementation Details

B.1 Pretraining

To enhance the performance of our model, we conducted two pre-training procedures. First, we use each product information and its corresponding copywriting in the training data to build a pre-training dataset and use this pre-training dataset to pretrain the encoder-encoder framework, which consists of the product encoder in SelectNet and Decoder consist of the agents (RNN) in MGenNet. We save the parameters when the loss is the lowest on the eval dataset. Based on the parameters pretrained in the first step, SelectNet is pre-trained. The process keeps about 20 epoch and proves the SelectNet can converge.

B.2 Configurations

All our proposed models are implemented in PyTorch (Paszke et al., 2019) version 1.0 and Python 3.6. The experiments are conducted on a Linux server equipped with 8 NVIDIA V100-SXM2-16GB GPUs. The system of the Linux server is the AliOS.

B.3 Real-Life E-commerce Scenario

Product candidate sets in the real-life e-commerce scenario in Taobao Mobile are always too huge to be used directly into our model. Targeted to this issue, we use the retrieval tool ElasticSearch[6] to search the products which are related to the key words we want to express in the multi-product AD post title. We rank those products by the related degree and obtain the Top-15 or Top-20 related products as the new product candidate set.

Form2Seq : A Framework for Higher-Order Form Structure Extraction

Milan Aggarwal[1], **Hiresh Gupta**[2], **Mausoom Sarkar**[1], **Balaji Krishnamurthy**[1]
Media and Data Science Research Labs, Adobe[1]
Adobe Experience Cloud[2]

Abstract

Document structure extraction has been a widely researched area for decades with recent works performing it as a semantic segmentation task over document images using fully-convolution networks. Such methods are limited by image resolution due to which they fail to disambiguate structures in dense regions which appear commonly in forms. To mitigate this, we propose Form2Seq, a novel sequence-to-sequence (Seq2Seq) inspired framework for structure extraction using text, with a specific focus on forms, which leverages relative spatial arrangement of structures. We discuss two tasks; 1) Classification of low-level constituent elements (TextBlock and empty fillable Widget) into ten types such as field captions, list items, and others; 2) Grouping lower-level elements into higher-order constructs, such as Text Fields, ChoiceFields and ChoiceGroups, used as information collection mechanism in forms. To achieve this, we arrange the constituent elements linearly in natural reading order, feed their spatial and textual representations to Seq2Seq framework, which sequentially outputs prediction of each element depending on the final task. We modify Seq2Seq for grouping task and discuss improvements obtained through cascaded end-to-end training of two tasks versus training in isolation. Experimental results show the effectiveness of our text-based approach achieving an accuracy of 90% on classification task and an F1 of 75.82, 86.01, 61.63 on groups discussed above respectively, outperforming segmentation baselines. Further we show our framework achieves state of the results for table structure recognition on ICDAR 2013 dataset.

1 Introduction

Various works (Hao et al., 2016; He et al., 2017; Wick and Puppe, 2018; Yang et al., 2017) have studied semantic structure extraction for documents. Structure extraction is necessary for digitizing documents to make them re-flowable and index-able, which is useful in web-based services (Alam and Rahman, 2003; Gupta et al., 2007; Khemakhem et al., 2018; Rahman and Alam, 2003). In this work, we look at a complex class of documents i.e., Forms that are used to capture user data by organizations across various domains such as government services, finance, administration, and healthcare. Such industries that have been using paper or PDF forms would want to convert them into an appropriate digitized version (Rahman and Alam, 2003) (such as an HTML). Once these forms are made re-flowable, they can be made available across devices with different form factors(Alam and Rahman, 2003; Gupta et al., 2007). This facilitates providing better form filling experiences and increases the ease of doing business since their users can interact with forms more conveniently and enables other capabilities like improved handling of filled data, applying validation checks on data filled in fields, consistent form design control[1].

To enable **dynamic rendering** of a form while **re-flowing** it, we need to extract its structure at multiple levels of hierarchy. We define TextBlock to be a logical block of self contained text. Widgets are spaces provided to fill information. Some low level elementary structures such as text and widgets can be extracted using auto-tagging capabilities of tools like Acrobat from the form PDF. However, such PDFs do not contain data about higher-order structures such as Text Fields, ChoiceGroups etc.

Document structure extraction has been studied extensively with recent works employing deep learning based fully convolution neural networks (He et al., 2017; Wick and Puppe, 2018; Yang et al., 2017) that perform semantic segmentation (Long et al., 2015; Chen et al., 2014; Noh et al., 2015) on

Figure 1: Different types of TextBlocks(Blue), Widgets(Red) & higher order groups(orange) - ChoiceGroups, Choice Fields, Text Fields in a form. A text field comprises of 1) textblock(referred as text field caption) that describes what to fill & 2) collection of widgets(text widgets). A choice group comprises of a title & collection of choice fields. Textblocks & widgets are classified into different types based on higher order group they are part of.

document image. Such methods perform well at extracting coarser structures but fail to extract closely spaced structures in form images (as discussed in the Experiments section). With increase in image resolution, number of activations(forward pass) and gradients(backward pass) increase at each network layer which requires more GPU memory during training. Since GPU memory is limited, they downscale the original image at the input layer which makes it difficult to disambiguate closely spaced structures, especially in dense regions(occurring commonly in forms) which leads to merging.

Figure 1 shows different types of TextBlocks, Widgets and higher order groups. Given text blocks and widgets as input, our Form2Seq framework classifies them between different type categories. We hypothesize that type classification of lower level elements can provide useful cues for extracting higher order constructs which are comprised of such smaller elements. We establish our hypothesis for the task of extracting ChoiceGroups, Text Fields and Choice Fields. A Text Field is composed of textblock(textual caption) and associated widgets, as shown in figure 1. A choice group is a collection of boolean fields called choice fields with an optional title text (choice group title) that describes instructions regarding filling it. We study fillable constructs as they are intrinsic and unique to forms and contain diverse elementary structures.

The spatial arrangement of lower level elements with respect to other elements in a form are correlated according to the type of construct. For instance, a list item usually follows a bullet in the reading order; field widgets are located near the field caption. Similarly, elements that are part of same higher-order group tend to be arranged in a spatially co-located manner. To leverage this in our Form2Seq framework, we perform a bottom up approach where we first classify lower level elements into different types. We arrange these elements in natural reading order to obtain a linear sequence. This sequence is fed to Seq2Seq (Sutskever et al., 2014) where each element's text and spatial representation is passed through a BiLSTM. The output of BiLSTM for each element is sequentially given as input to an LSTM (Hochreiter and Schmidhuber, 1997) based decoder which is trained to predict the category type. For grouping task, we modify the framework to predict id of the group each lower level element is part of. Here the model is trained to predict same group id for elements that are part of same group. Our contributions can be listed as:

- We propose Form2Seq framework for forms structure extraction, specifically for the tasks of element type classification and higher order group extraction.
- We show effectiveness of end-to-end training of both tasks through our proposed framework over performing group extraction alone.
- We perform ablations to establish role of text in improving performance on both tasks. Our approach outperforms image segmentation baselines.

- Further, we perform table structure recognition by grouping table text into rows and columns achieving state of the art results on ICDAR 2013 dataset.

2 Related Work

Earlier works for document layout analysis have mostly been rule based relying on hand crafted features for extracting coarser structures such as graphics and text paragraphs (Lebourgeois et al., 1992). Approaches like connected components and others, were also used for extracting text areas(Ha et al., 1995a) and physical layouts(Simon et al., 1997). These approaches can be classified into top-down (Ha et al., 1995b) or bottom-up (Drivas and Amin, 1995). The bottom-up methods focus on extracting text-lines and aggregating them into paragraphs. Top-down approaches detect layout by subdividing the page into blocks and columns.

With the advancement in deep learning, recent approaches have mostly been fully convolution neural network (FCN) based that eliminate need of designing complex heuristics (Yang et al., 2017; He et al., 2017; Wick and Puppe, 2018). FCNs were successfully trained for semantic segmentation (Long et al., 2015) which has now become a common technique for page segmentation. The high level feature representations make FCN effective for pixel-wise prediction. FCN has been used to locate/recognize handwritten annotations, particularly in historical documents (Kölsch et al., 2018). Wigington et al. proposed a model that jointly learns handwritten text detection and recognition using a region proposal network that detects text start positions and a line follow module which incrementally predicts the text line that should be subsequently used for reading.

Several methods have addressed regions in documents other than text such as tables, figures etc. Initial deep learning work that achieved success in table detection relied on selecting table like regions on basis of loose rules which are subsequently filtered by a CNN (Hao et al., 2016). He et al. proposed multi-scale, multi-task FCN comprising of two branches to detect contours in addition to page segmentation output that included tables. They additionally use CRF (Conditional Random Field) to make the segmented output smoother. However, segmentation based methods fail to disambiguate closely spaced structures in form images due to resolution limitations as discussed in experiments section. Graliński et al. introduced the new task of recognising only useful entities in long documents on two new datasets. FUNSD (Jaume et al., 2019) is a small-scale dataset for form understanding comprising of 200 annotated forms. In comparison, our Forms Dataset is much larger having richer set of annotations. For task of figure extraction from scientific documents, (Siegel et al., 2018) introduced a large scale dataset comprising of 5.5 million document labels. They find bounding boxes for figures in PDF by training Overfeat (Sermanet et al., 2013) on image embeddings generated using ResNet-101.

Few works have explored alternate input modalities such as text for other document related tasks. Extracting pre-defined and commonly occurring named entities from invoices like documents(using text and box coordinates) has been the main focus for some prior works (Katti et al., 2018; Liu et al., 2019; Denk and Reisswig, 2019; Majumder et al., 2020). Text and document layouts have been used for learning BERT (Devlin et al., 2019) like representations through pre-training and then combined with image features for information extraction from documents (Xu et al., 2020; Garncarek et al., 2020). However, our work focuses on extracting a much more generic, diverse, complex, dense, and hierarchical document structure from Forms. Document classification is a partly related problem that has been studied using CNN-only approaches for document verification (Sicre et al., 2017). Yang et al. have designed HAN which hierarchically builds sentence embeddings and then document representation using multi-level attention mechanism. Other works explored multi-modal approaches, using MobileNet (Howard et al., 2017) and FastText (Bojanowski et al., 2017) to extract visual and text features respectively, which are combined in different ways (such as concatenation) for document classification (Audebert et al., 2020). In contrast, we tackle a different task of form layout extraction which requires recognising different structures.

Yang et al. also proposed a multimodal FCN (MFCN) to segment figures, tables, lists etc. in addition to paragraphs from documents. They concatenate a text embedding map to feature volume. We consider image based semantic segmentation approaches as baselines for the tasks proposed. We compare the performance of our approach with 1) their FCN based method and 2) DeepLabV3+ (Chen et al., 2018), which is state of the art deep learning model for semantic segmentation.

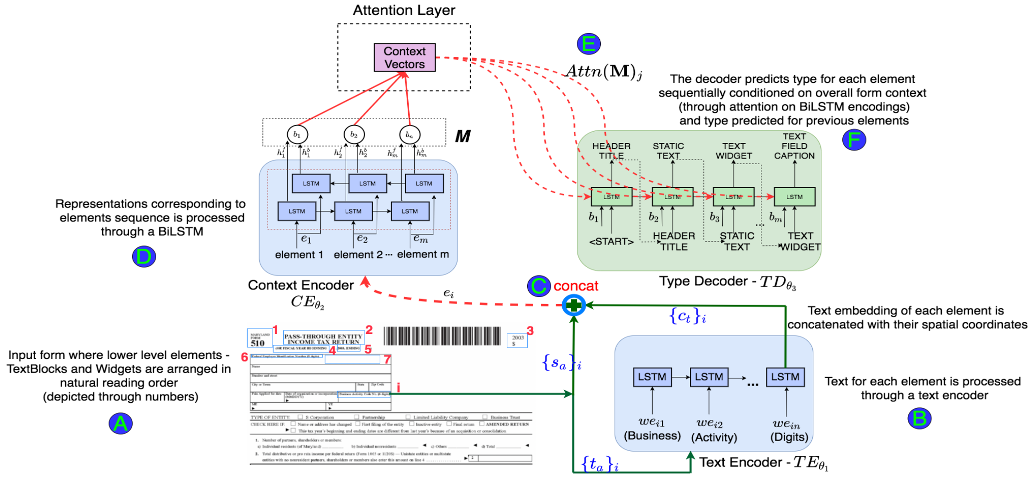

Figure 2: Model Architecture for element type classification. Different stages are annotated with letters.

3 Methodology

The spatial arrangement of a lower element among its neighbouring elements is dependent on the class of element. For instance, a list item usually follows a bullet in the reading order. Similarly, elements that are part of the same higher-order group tend to be arranged in a spatially co-located pattern. To leverage relative spatial arrangement of all elements in a form together, we arrange them according to a natural reading order (left to right and top to bottom arrangement), encode their context aware representations sequentially using text and spatial coordinates and use them for prediction. For each task, the decoder predicts the output for each element sequentially, conditioning it on the outputs of elements before it in the sequence in an auto-regressive manner (just like sentence generation in NLP). For group extraction task, our model assigns a group id to each element conditioning it on ids predicted for previous elements. This is essential to predict correct group id for current element (for instance, consider assigning same group id to elements that are part of same group).

Let a form be comprising of a list of TextBlocks (f_t) and list of widgets (f_w). We arrange $f_e = f_t \bigcup f_w$ according to natural reading order to obtain arranged sequence a_e which is used as input for both the tasks ('A' in figure 2).

3.1 Element Type Classification

Let t_a and s_a be the list of text content and spatial coordinates (x,y,w,h) corresponding to a_e, where x and y are pixel coordinates from top left corner in image and w & h denote width and height of an element respectively. Our type classification model comprises of three sub-modules namely Text Encoder (TE) which encodes the text representation of each element, Context Encoder (CE) which produces context aware embedding for each element in the sequence, and Type Decoder (TD) which sequentially predicts type output. We discuss each of these modules in detail.

Text Encoder : Consider an element $\{a_e\}_i$ having text $\{t_a\}_i$ comprising of words $\{w_{i1}, w_{i2}, ..., w_{in}\}$. Since the text information is obtained through PDF content, the words often contain noise, making use of standard word vectors difficult. To mitigate this, we obtain word embeddings using python library *chars2vec*[2]. This gives a sequence of embeddings $\{we_{i1}, we_{i2}, ..., we_{in}\}$ which is given as input to an LSTM - TE_{θ_1}, that processes the word embeddings such that the cell state $\{c_t\}_i$ after processing last word is used as text representation for $\{a_e\}_i$ ('B' in figure 2). A widget's textual representation is taken as a vector of 0s.

Context Encoder : Consider a sequence element $\{a_e\}_i$ with corresponding textual representation $\{c_t\}_i$ and spatial coordinates $\{s_a\}_i$. These are concatenated ('C' in figure 2)) together to obtain $\{e\}_i$ representing the element. The sequence e obtained is given as input to a BiLSTM - CE_{θ_2}, which produces a context aware embedding $\{b\}_i$ for each element in the sequence ('D' in figure 2).

Type Decoder : The output from the previous stage is given as input to a final LSTM based decoder - TD_{θ_3}, that sequentially outputs the category type for each element ('F' in figure 2). Specifically, the decoder at time step i is given input

---

[2] https://github.com/IntuitionEngineeringTeam/chars2vec

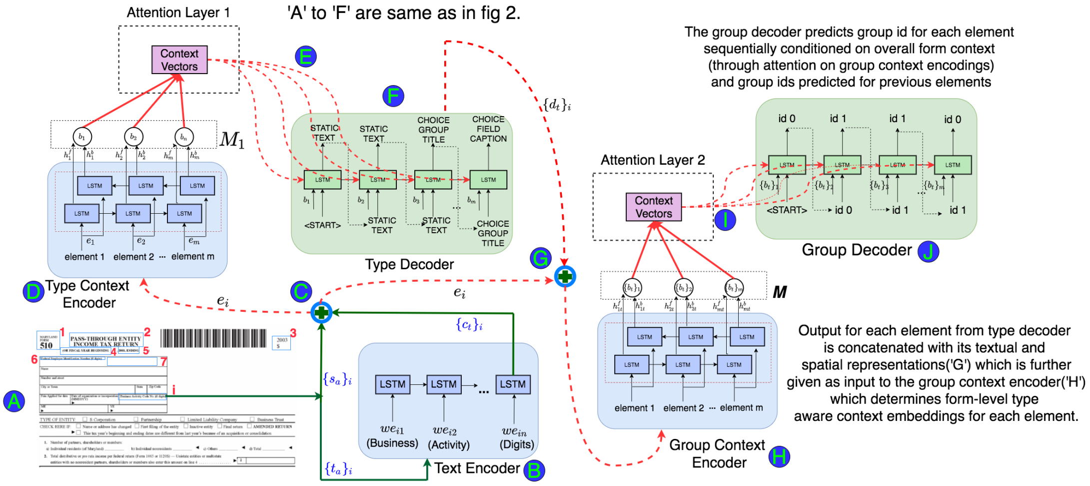

Figure 3: Architecture of our best performing model for group extraction leveraging type model shown in figure 2.

$\{b\}_i$ to predict the type class of i^{th} element. Additionally, we use Bahdnau attention mechanism (Bahdanau et al., 2014) to make TD_{θ_3} attend on context memory M ('E' in figure 2) at each time step of decoding, where M is obtained by stacking $\{b_1; b_2; ..\}$ column-wise. This is to make it easier for decoder to focus on specific elements in sequence while predicting type for current element since elements sequence in a form tends to be very long. A linear layer with softmax activation is used over the decoder outputs for type classification.

We train all 3 modules - TE_{θ_1}, CE_{θ_2} and TD_{θ_3} together using teacher forcing technique (Williams and Zipser, 1989) and standard cross entropy loss.

3.2 Higher Order Group Identification

Our second task is to identify larger groups. Consider one such group - ChoiceGroup, comprising of a collection of TextBlocks and Widgets having different semantics(illustrated in figure 1). A ChoiceGroup contains 1) an optional choice group title which contains details and instructions regarding filling it; and 2) a collection of choice fields which are boolean fields such that each field comprises of a textual caption - choice field caption, and one or more choice field widgets. We formulate target label prediction for this task as that of predicting a cluster/group id for each element. Consider the element sequence a_e such that elements $\{\{a_e\}_{i1}, \{a_e\}_{i2}, ...\}$ are part of a group. We assign this group a unique number and train the model to predict same group number for each of these elements. Elements that are not part of any group are assigned a reserved group i.e. 0.

We adopt a similar model as used for type classification except instead of type decoder, we have Group Decoder (GD_{θ_4}) such that projection layer classifies each element into one of the groups. We hypothesize that category type of elements can be a useful clue for group decoder. To leverage the type information, we study a variant of our model - Cascaded Model, where we have a common text encoder but separate context encoders - CE_T & CE_G, and decoders - TD & GD, for the two tasks. Specifically, given a sequence of elements a_e with combined textual and spatial representations e ('C' in figure 3), we first first feed them into type context encoder (CE_T, 'D' in figure 3) and type decoder (TD, 'F' in figure 3) as before to obtain decoder output sequence d_t for each element. We modify the output types to categories which are relevant to the grouping task - ChoiceGroup Title, TextField Caption, ChoiceField Caption, ChoiceWidget, Text Widget, other TextBlocks. Since an element can be part of a field which is contained in choice group, we use two separate FC layers on decoder output to predict separate group ids for the element while determining choice groups and fields.

TD outputs are concatenated with e for each element ('G' in figure 3) and given as input to group context encoder CE_G to obtain contextual outputs sequence b_t ('H' in figure 3). The group decoder GD ('J' in figure 3) uses the sequence b_t as input and attention memory ('I' in figure 3) during decoding. For d_t, we purposely use outputs of type decoder LSTM and not final type projection layer outputs as determined empirically in experiments section. All five modules - TE, CE_T, TD, CE_G and GD are trained end-to-end for both tasks simultaneously.

Model	Choice Widget	Text Widget	Choice GroupTitle	Choice Caption	TextField Caption	Header Title	Section Title	Bullet	List Item	Static Text	Overall
$DLV3+$	68.24	96.66	57.90	76.28	86.10	83.55	55.43	48.89	75.94	69.37	84.18
$MFCN$	0.0	81.25	0.0	0.0	46.87	69.42	**71.47**	90.03	54.26	11.29	48.59
A_T (ours)	67.77	85.92	56.18	66.81	80.72	82.38	57.20	82.70	81.84	70.24	76.92
B_T (ours)	90.84	**98.26**	76.81	89.55	**91.36**	83.28	57.02	91.58	**90.91**	82.18	88.87
C_T (ours)	**91.83**	96.89	**78.93**	**90.53**	91.27	**85.88**	67.48	**93.55**	90.78	**85.31**	**90.06**

Table 1: Element type classification accuracy of different ablation methods and baselines. Here A_T, B_T and C_T are different Form2Seq variants. A_T gets only element's spatial coordinates as input, B_T gets additional single bit depicting if an element is a TextBlock or a Widget in addition to their spatial coordinates, and C_T gets both textual and spatial information as inputs but does not receive the additional bits provided to B_T.

4 Experiments

4.1 Dataset

Forms Dataset: We have used our Forms Dataset comprising of 23K forms[3] across different domains - automobile, insurance, finance, medical, government (court, military, administration). We employed annotators to mark bounding box of higher order structures in form images as well as lower level constituent elements for each structure. There were multiple rounds of review where we suggested specific cases for each structure and patterns for correction to annotators. We discuss distribution of different structures across (train/test) splits for 10 element types : TextField Caption (129k/31.6k), TextField Widget (222k/533k), Choice Field Caption (35k/8.9k), ChoiceField Widget (39.2k/9.94k), ChoiceGroup Title (8.92k/2.28k), Header Title (10.2k/2.57k), Section Title (28.5k/7.25k), Bullet (56.4k/14.2k), List Item (58.9k/14.7k), Static Text (241.k/61.2k). For higher order structures, distribution of text fields and choice fields is same as that for their captions while for choice groups it is (15.5k/1.76k). Each form was tagged by an annotator(both lower and higher-level structures) and then reviewed by some other annotator. In $\sim$85% forms, no corrections were made but some minor corrections were made in the rest 15% cases after review phase.

ICDAR 2013: We also evaluate our approach on the table structure recognition task on ICDAR 2013 dataset. It comprises of 156 tables from two splits - US and EU set. We extract the images from the pdfs and train our model to extract the table structure by grouping table text into rows and columns. We divide 156 tables into a set of 125 tables for training and 31 for testing following the strategy employed by (Siddiqui et al., 2019) and compare the performance of our approach with them.

4.2 Implementation Details

For text encoder TE, we fix size of text in a TextBlock to maximum 200 words. We use chars2vec model which outputs 100 dimensional embedding for each word and fix LSTM size to 100. For type classification, we use a hidden size of 500 for both forward and backward LSTMs in CE_T and a hidden size of 1000 for decoder TD with size of attention layer kept at 500. We tune all hyper-parameters manually based on validation set performance. Final type projection layer classifies each element into one of 10 categories. For grouping task, both isolated and cascaded model have exactly same configuration for CE_G and GD as for type modules. For cascaded model, type projection layer classifies each element into relevant type categories as discussed in Methodology section. We train all models using Adam Optimizer (Kingma and Ba, 2014) at a learning rate of 1×10^{-3} on a single Nvidia 1080Ti GPU. We determined and used largest batch size(=8) that fits memory.

4.3 Results and Discussion

Type Classification : Results for type classification are summarized in Table 1. We compare three models; A_T - where we only give elements' spatial coordinates as input, B_T - where we additionally give a single bit depicting if an element is a TexBlock or a Widget, and C_T where both textual and spatial information is given as input. Using only coordinates yields inferior results since the model only has information regarding arrangement of elements. Adding textblock/widget flag significantly improves the overall accuracy by $\sim$ 12% (A_T to B_T). Adding textual information (model C_T) improves the overall accuracy by 1.19% to

---

[3] Due to legal issues, we cannot release entire dataset. However, the part we plan to release will be large comprising of rich annotations and representative of our entire diverse set. It will be made available at: `https://github.com/Form2Seq-Data/Dataset`

Figure 4: Predictions for a form snippet: Adding text input helps Form2Seq identify title which improves grouping.

90.06%. The accuracy for SectionTitle improves substantially from 57.02% to 67.48% and shows an improvement of 0.99%, 2.12%, 0.98%, 2.6%, 1.97%, 3.13% for ChoiceWidget, ChoiceGroupTitle, ChoiceCaption, HeaderTitle, Bullet and StaticText respectively.

Group Identification : We report precision and recall numbers for the task of group extraction. Segmentation methods commonly use area overlap thresholds such as Intersection over Union(IoU) while matching expected and predicted structures(we evaluate baselines with an IoU threshold of 0.4). For our method, given a set of ground truth groups $\{g_1, g_2, g_3, ..., g_m\}$ and a set of predicted groups $\{p_1, p_2, p_3, ..., p_k\}$, we say a group p_i matches g_j iff the former contains exactly the same TextBlocks and Widgets as the latter. It takes into account all the lower elements which constitute the group (necessary to measure structure extraction performance). Thus, this metric is stricter than IoU based measures with any threshold since a group predicted by our method and evaluated to be correct implies that bounding box of prediction(obtained by taking the union of elements in it) will exactly overlap with expected group.

We first analyse the performance of our method on extracting choice groups. We consider different variants of our approach : 1) model A_G - grouping in isolation; 2) model B_G - both type and grouping task simultaneously with shared context encoder, type decoder attends on context encoder outputs while group decoder attends on context encoder outputs and type decoder outputs separately; 3) model C_G - type identification trained separately, its classification outputs is given as input to group context encoder non-differentiably; 4) model D_G - same as B_G except separate context encoders for two tasks and softmax outputs concatenated with textual and spatial vectors as input to group context encoder; 5) model E_G - same as D_G except instead of softmax outputs, type decoder LSTM outputs are used; and 6) F_G(noText) - same as E_G except spatial coordinates with isText signal used as input.

Model	Recall	Precision	F-Score
$DLV3+$	35.65	57.95	44.14
$MFCN$	16.97	11.86	13.96
A_G(ours)	51.18	55.48	53.24
B_G(ours)	53.18	56.22	54.65
C_G(ours)	55.9	57.15	56.51
D_G(ours)	50.82	54.88	52.77
E_G(ours)	**58.67**	**60.81**	**59.72**
F_G(ours)	55.32	56	55.65

Table 2: Comparison between F-scores of different models and baselines for ChoiceGroup Identification only. A_G to F_G are different variants of Form2Seq.

Table 2 shows joint training of both tasks improves F-score from 53.24 to 54.65 (A_G to B_G) with improvement of 1.86 if type information is incorporated non-differentiably(B_G to C_G). Our best performing model(E_G) achieves an F-score of 59.72. We observe that using type projection layer softmax outputs instead results in poor performance(E_G vs D_G). We observe that using **text** in Form2Seq(E_G) performs 4.07 points better in F-score vs. ablation F_G(w/o text). It can be seen in figure 4 that F_G misses choice group title(red), while Form2Seq with text(E_G) extracts complete choice group[4].

Comparison with baselines : We consider two image semantic segmentation baselines - DeepLabV3+ (DLV3+) (Chen et al., 2018) and MFCN (Yang et al., 2017). For fair comparison, we implement two variants of each baseline - 1) only form image is given as input; 2) textblocks and widgets masks are given as prior inputs with image. We train both variants with an aspect ratio preserving resize of form image to 792x792. For MFCN, loss for different classes are scaled according to pixel area as described in their work. To classify type of an element, we post process prediction masks for

---

[4] Please refer to supplementary for more visualisations

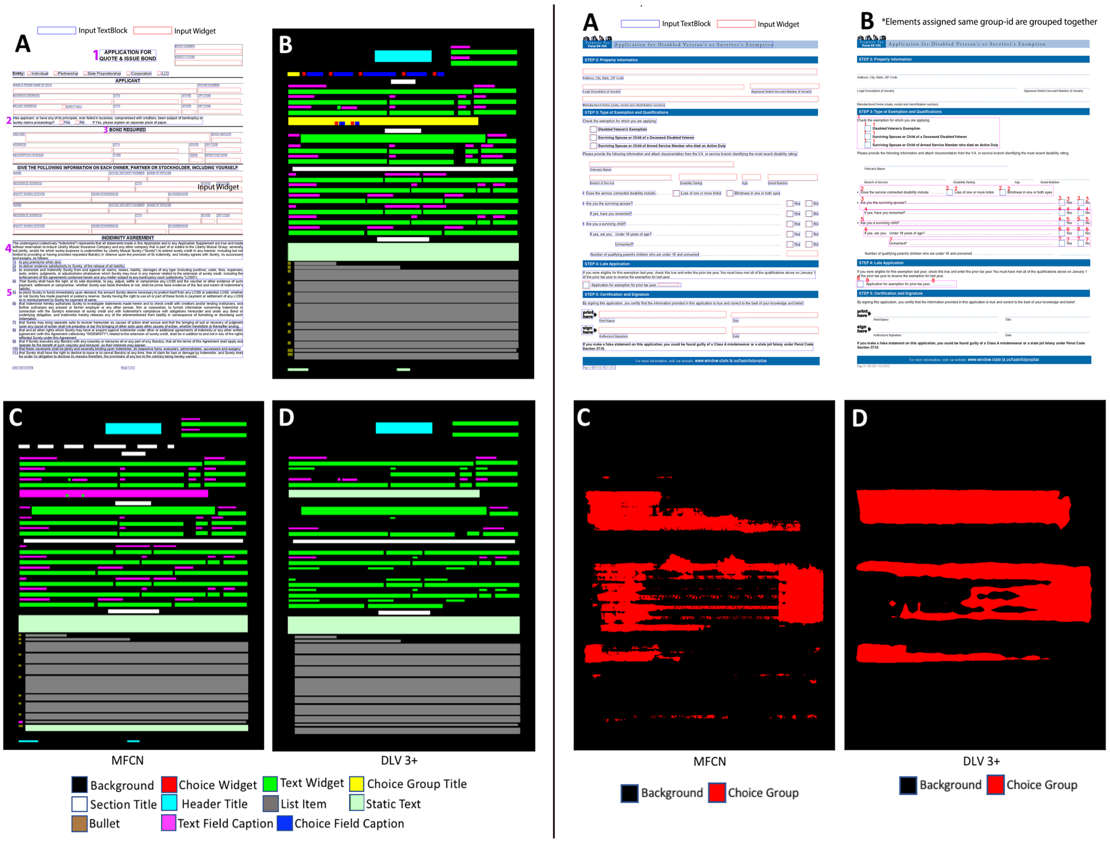

Figure 5: Examples of type classification (left) and choice group extraction (right). Top row shows form (A) and our outputs (B). For type predictions, we visualise our classification outputs as mask for understanding, and show post processed baseline outputs(through majority voting based on predicted masks). We can see that our Form2Seq framework makes better classifications for elements (2,3,5) marked in the top left image (1=Header Title, 2=Choice Group Title, 3=Section Title, 4=Static Text and 5=Bullet). For grouping task, elements highlighted with the same number by our model are predicted as part of same group(zoom in for viewing). Bottom row shows baseline segmentation outputs (C and D).

baselines by performing a majority voting among pixels contained inside it for that particular element. For MFCN, without prior variant performed better, unlike DLV3+. We report metrics corresponding to better variant. As can be seen in table 1, our best performing model (C_T) significantly outperforms both baselines in accuracy. Our model performs better for almost all category types. We observe that DLV3+ and MFCN are not able to perform well for all type classes simultaneously - DLV3+ performs sub-optimally for ChoiceWidget, Bullet and StaticText while MFCN performs poorly for ChoiceWidget, ChoiceGroup Title, Choice Field Caption even after loss scaling. We believe since forms are dense, such methods fail to distinguish different regions and capture complex concepts, for instance MFCN predicts ‘2’(shown in figure 5 (left)) as text field caption instead of choice group title due to widgets present around it.

For baselines, we match expected groups with segmented outputs through IoU overlap, keeping a threshold (0.40) for determining correct match. Since higher order groups span across different lower elements boundaries, it is not possible to leverage them to refine group masks predicted by baselines. Our proposed model (evaluated with stricter measure) outperforms DLV3+ (better baseline) by 15.58 in F-Score(as can be seen in Table 2), even though it has lesser parameters(31.2 million) than DLV3+(59.4 million). Further, our main model (E_G) when evaluated through IoU overlap threshold of 0.40 achieves even higher recall, precision, F-Score of **74.3**, **78.6** and **76.3** respectively. Figure 5 shows outputs obtained using our approach and baseline methods. For grouping task (right), DLV3+ recognises couple of choice groups correctly but provides incomplete predictions in remaining regions, often merging them owing to its disability to disambiguate groups in dense areas. MFCN could not capture

Construct	DLV3+			MFCN			Ours		
	R	P	F	R	P	F	R	P	F
Text Field	43.64	34.63	38.62	37.12	38.94	38.0	**71.59**	**80.6**	**75.82**
Choice Field	61.93	44.42	51.73	31.45	14.24	19.6	**83.48**	**88.71**	**86.01**
Choice Group	43.25	53.5	47.83	30.99	26.85	28.77	**59.27**	**64.2**	**61.63**

Table 3: Recall(R), Precision(P) and F-score(F) of different methods on extracting different group structures together - text field, choice field and choice group simultaneously.

Model	Table-Rows			Table-Columns			Average		
	P	R	F1	P	R	F1	P	R	F1
Baseline (Siddiqui et al., 2019)	**95.3**	94.2	94.8	91.6	92.6	92.1	93.4	93.4	93.4
Ours	94.2	**96.1**	**95.1**	**95.7**	**92.9**	**94.3**	**95.0**	**94.5**	**94.7**

Table 4: Comparison with baseline on Table Structure Recognition (identifying rows and columns) task on ICDAR-2013 dataset.

horizontal context between Choice group Title and Choice Fields and outputs broken predictions. In comparison, our model extracted 7 out of 8 choice groups correctly.

Extracting Higher Order Constructs Simultaneously: We train our model to detect choice groups, text fields and choice fields together. To enable baseline methods to segment these hierarchical and overlapping structures simultaneously in separate masks, we use separate prediction heads on penultimate layer's output. Table 3 shows the results obtained. Our method works consistently well for all the structures outperforming the baselines.

Table Structure Recognition : We further evaluate our proposed framework on a different task of grouping text in a table into rows and columns on publicly available ICDAR 2013 dataset. The input to our framework is the sequence of texts (arranged in natural reading order as usual) present in a table. We train our model to predict same group id for texts present in the same row and simultaneously detect columns in a similar manner using a separate prediction head. As a post processing step, we consider different sets of texts which are aligned vertically (sharing common horizontal span along the x-axis). We then consider the column group ids predicted by the model and assign majority column id (determined for a set using texts present in it) to all the texts in the set. The re-assigned ids are then used to determine different groups of texts to recognise columns. We perform similar processing while determining the final rows. Siddiqui et al. proposed to perform this task through constrained semantic segmentation achieving state-of-the-art results. Table 4 summarises the results obtained and compares our approach with (Siddiqui et al., 2019) showing our method obtains better F1 score for both rows, columns and average metrics (as used and reported in their paper).

5 Conclusion

We present an NLP based Form2Seq framework for form document structure extraction. Our proposed model uses only lower level elements - textblocks & widgets without using visual modality. We discuss two tasks - element type classification and grouping into larger constructs. We establish improvement in performance through text info and joint training of two tasks. We show that our model performs better compared to current semantic segmentation approaches. Further we also perform table structure recognition (grouping texts present in a table into rows and columns) achieving state-of-the-art results. We are also releasing a part of our forms dataset to aid further research in this direction.

Abstract

Like many Natural Language Processing tasks, Thai word segmentation is domain-dependent. Researchers have been relying on transfer learning to adapt an existing model to a new domain. However, this approach is inapplicable to cases where we can interact with only input and output layers of the models, also known as "*black boxes*". We propose a filter-and-refine solution based on the stacked-ensemble learning paradigm to address this black-box limitation. We conducted extensive experimental studies comparing our method against state-of-the-art models and transfer learning. Experimental results show that our proposed solution is an effective domain adaptation method and has a similar performance as the transfer learning method.

1 Introduction

Word Segmentation (WS) is an essential process for several Natural Language Processing (NLP) tasks such as Part-of-Speech (PoS) tagging and Machine Translation (MT). The accuracy of WS significantly affects the accuracy of these NLP tasks, as shown in experimental results from Nguyen et al. and Chang et al.

While WS is considered relatively simple in English, it is still an open problem in languages without explicitly defined word delimiters, such as Thai, Chinese, and Japanese. However, unlike Chinese and Japanese, Thai WS did not receive much research attention. There are only six notable publications (Chormai et al., 2019; Nararatwong et al., 2018; Kongyoung et al.; Noyunsan et al.; Thanadechteemapat and Fung; Tongtep and Theeramunkong) on Thai WS for the past ten years. On the other hand, there are at least eight papers from well-established conferences on Chinese and Japanese WS (Li et al., 2019; Aguirre and Aguiar, 2019; Zhou et al.; Ma et al., 2018; Gong et al., 2017; Chen et al., 2017; Zhou et al., 2017; Cai et al., 2017) within only the last two years. This investigation focuses on the segmentation of Thai words since it is a challenging problem that has an excellent opportunity to improve, especially in the area of *domain adaptation*.

Like many NLP tasks, Thai WS is domain-dependent. For instance, Chormai et al. (2019) recorded an accuracy drop from 91% to 81% when their model trained on a generic domain corpus (Kosawat et al., 2009) was tested on a social media one (bact' et al., 2019). Results from our analysis (Section 3) also conform to these findings.

One way to solve the domain dependency problem is through Transfer Learning (TL), which is a common technique in domain adaptations (Schuster et al.; Chang et al.). However, TL may not be applicable when working with a commercial API or a model that does not support weight adjustments (Chormai et al., 2019; Chuang, 2019; Ikeda, 2018). We call this type of model a *black box*.

In this paper, we propose a stacked-ensemble learning solution to overcome the black-box limitation. Instead of making changes to the existing model directly, we build a separate model to improve the accuracy of predictions made by the black box. Our solution comprises two parts, Domain-Generic (DG) and Domain-Specific (DS). The pre-trained black box handles the Domain-Generic part, and a new model is constructed to handle the Domain-Specific part. All samples go through Domain-Generic, which makes initial predictions. We rank all predictions according to uncertainty and send the top-k uncertain predictions to Domain-Specific for further consideration. We combine the predictions from Domain-Specific with the remaining from Domain-Generic to form the final predictive results.

We conducted extensive experimental studies to assess our solution's performance against a base-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3841–3847,
November 16–20, 2020. ©2020 Association for Computational Linguistics

line model and transfer learning solutions. We also applied our *Stacked-Ensemble Filter-and-Refine (SEFR)* technique to Chinese and Japanese. Experimental results showed that our proposed solution achieved the accuracy level comparable to those of transfer learning solutions in Thai. For Chinese and Japanese, we showed that model adaptation using the SEFR technique could improve the performance of black-box models when used in a cross-domain setting.

Our contributions are as follows. First, we propose a novel solution for adapting a black-box model to a new domain by formulating the problem as an ensemble learning one. Second, we derive a filter-and-refine method to speed up the inference process without sacrificing accuracy in some cases. Third, we conducted extensive experimental studies; experimental results validate the effectiveness of our solution. Fourth, we make our code available at: `github.com/mrpeerat/SEFR_CUT`

2 Stacked-Ensemble Method

2.1 Pipeline Structure

Figure 1 displays the pipeline structure of the proposed SEFR method, which consists of a *Domain-Generic (DG) black box*, *uncertainty filtering*, and a *Domain-Specific (DS) model*. Each character enters the pipeline through the Domain-Generic black box, which gives a softmax or logistic score from the Domain-Generic model as output. We then use this output to calculate the uncertainty score. Uncertainty values are used to rank and filter samples that need reexamination by the Domain-Specific model. We then merge the results from Domain-Specific with the direct answers from Domain-Generic to form the final answers.

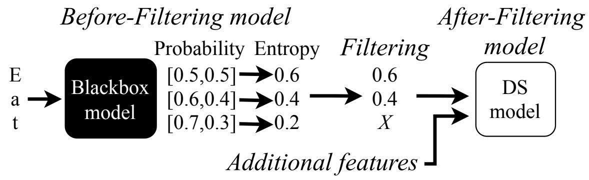

Figure 1: Overview of our *Stacked-Ensemble Filter-and-Refine (SEFR)* method

2.2 Pipeline Implementation

In this subsection, we consider how to implement the pipeline in Figure 1 effectively.

An effective filter and refine pipeline should have the following properties. First, before the filter, there is a general-decision maker that can make most decisions reasonably well. Second, the filter should be able to separate out decisions not requiring further consideration. Third, after the filter, there is a decision maker that can make the remaining decisions better than the general-decision maker. Using filter and refine can help reduce the computation time and avoid unnecessary errors from the Domain-Specific model which might not be as robust as the Domain-Generic model.

Before-Filtering Model. In our pipeline, the general-decision maker is the Domain-Generic black box. Specifically, we use the state-of-the-art pre-trained model (Rakpong Kittinaradorn, 2019; Chormai et al., 2019) constructed from a generic-domain corpus (Kosawat et al., 2009) to ensure the best possible performance in general cases.

Filtering. The prediction of an out-of-domain sample is likely to have an entropy higher than that of an in-domain one. Hence, we use the softmax entropy to separate the results from Domain-Generic into two groups: (i) *high-uncertainty predictions* that need further consideration from Domain-Specific; (ii) *low-uncertainty predictions* that we keep the results unchanged. The exact cutoff point can be fine-tune as a hyperparameter.

After-Filtering — Model. As stated earlier, the model placed after filtering should perform a certain task better than the one placed before filtering, which is domain specificity in this case. Hence, we use a Domain-Specific model trained with target-domain data to refine the uncertain predictions made by Domain-Generic. In theory, a Domain-Specific model can be constructed using any learning method. However, a DNN-based method may be inapplicable in a data-poor setting, which is the case in this investigation. As a result, we focus on classical learning methods that historically provide good results in WS problems, such as *Logistic Regression (LR)*, *Support Vector Machine (SVM)*, and *Conditional Random Field (CRF)*. Figure 2 shows performance evaluation results from different Domain-Specific implementations. As can be seen, CRF gave the best performance in comparison to other models.

After-Filtering — Input Features. We consider the following 4 sets of features. First, we use the n-gram windows to capture the context. Second, we use the dictionary index to identify whether each character can start a word (Horsuwan et al.). The next two feature sets are meta features obtained from the Domain-Generic model, i.e., the softmax output and the softmax entropy.

3 Performance Evaluation

We evaluated our SEFR solution against state-of-the-art models on nine benchmark corpora from three languages. Specifically we studied the effect of our SEFR method and report the performance by adapting a black-box model to a new domain by formulating the problem as an ensemble learning.

3.1 Performance Evaluation on Thai

Competitive Methods. Two state-of-the-art models for Thai WS were chosen as our competitive methods, i.e., DeepCut (Rakpong Kittinaradorn, 2019) and AttaCut-SC (Chormai et al., 2019). Both are deep learning models based on the *Convolution Neural Network (CNN)*. We also created two SEFR solutions using DeepCut and AttaCut-SC as the Domain-Generic model, and we called them SE+DeepCut and SE+AttaCut-SC, respectively. As domain-adaptation baselines, we applied transfer learning to DeepCut and AttaCut-SC and called them TL-DeepCut and TL-AttaCut-SC, respectively. We note that the authors of DeepCut provided the weights trained on the BEST corpus. We used the same architecture and parameter settings to update these weights on Wisesight and TNHC(Table 1). Attacut-SC does not provide weights to perform TL and requires retraining of the model. We trained the AttaCut-SC model using *BEST-2010* corpus (Kosawat et al., 2009) to obtain the best training weights to perform TL, where 90% of the data was used for training. We compared our method with a model pre-trained on BEST-2010 and then transferred to the target task.

Model	# Epoch	Batch Size	Optimizer	Learning rate
DeepCut	[3,10]	[256, 512, 2048, 4096, 8192]	Adam	0.001
AttaCut-SC	[3,10]	[256, 512, 2048, 4096, 8192]	Adam	0.001

Table 1: Parameter settings in Deepcut and AttaCut.

Datasets and Metrics. We evaluated our propose solution and the competitive methods using two Thai corpora. Wisesight (WS160) is a small scale corpus used for sentimental analysis on tweets. TNHC is a collection of Thai classical literature. Wisesight and TNHC are mostly used in domain adaptation experiments. See Table 2 for details. The model training was performed on 80% of the training set while the other 20% was used for tuning of hyperparameters, including the value of top-k.

The performance of the Thai WS is typically evaluated using F1 scores at the character level. However, if a word is wrongly tokenized, it may affect the tokenization of the following words. To avoid the overestimation of WS performance, we also evaluated the F1 scores at the word level.

Lang.	Corpora	# Sentence	# Word
TH	Wisesight	1K [0.16K]	22K [3.9K]
TH	TNHC	13K [7K]	374K [239K]
CN	AS	636K [13K]	4.8M [110K]
CN	CITYU	46K [1.1K]	1.2M [28K]
CN	MSR	56K [3.5K]	1.4M [91K]
CN	PKU	7.7K [1.1K]	371K [48K]
JP	GSD	7K [0.5K]	159K [12K]
JP	Modern	0.6K [0.16K]	11K [2.6K]
JP	PUD	0.7K [0.19K]	19K [5K]

Table 2: Summary of WS corpora (# Training [# testing]), TH = Thai, CN = Chinese, and JP = Japanese.

Experimental Studies. *Our Method vs Thai Competitive methods.* In this part of the paper, we compared our SEFR method against the state-of-the-art Thai WS methods on WS160 and TNHC. The experimental results given in Tables 3 and 4 show that for all corpora, i.e., WS160 and TNHC, our method (*SE+DeepCut*) outperformed the state-of-the-art DeepCut in the domain adaptation experiment. Moreover, *SE+AttaCut-SC* outperformed AttaCut-SC and TL-AttaCut-SC for all corpora. In particular, for the TNHC corpus, *SE+DeepCut* performed better than DeepCut by 1.7% and 0.3% at the character and word levels, i.e., char F1 and word F1, respectively. *SE+AttaCut-SC* outperformed AttaCut-SC and the different was 13.9% and 22.2% at the character and word levels respectively. The F1 Score gap between *SE+DeepCut* and TL-DeepCut was about 1.1% at the character level and 10.5% at the word level for both corpora. However, for AttaCut-SC, *SE+AttaCut-SC* performed better than TL in every corpus averaging about 12.9% at the character level and 12.7% at the word level. This result showed that our method could provide reasonable performance despite the low-accuracy predictions provided by the base model.

Effect of Top-k Percentage Entropy Selection. Figure 2 shows the effect of top-k percentage entropy selection on test sets of WS160 and TNHC using DeepCut as the Domain-Generic model. As expected of a filter and refine method, recall improves as the k value increases. Most of the recall improvements are from the lower range k values,

Method	Target = WS160	
	Char F1 (%)	Word F1 (%)
DeepCut	93.8	84.0
AttaCut-SC	93.5	84.0
TL-DeepCut	96.3	90.6
TL-AttaCut-SC	94.1	85.0
SE+DeepCut (k=100)	95.2	87.4
SE+AttaCut-SC (k=49)	94.5	85.6

Table 3: Performance comparison on WS160.

Method	Target = TNHC	
	Char F1 (%)	Word F1 (%)
DeepCut	93.5	75.4
AttaCut-SC	80.8	63.3
TL-DeepCut	95.4	88.6
TL-AttaCut-SC	81.2	71.8
SE+DeepCut (k=36)	95.2	84.1
SE+AttaCut-SC (k=100)	93.7	83.9

Table 4: Performance comparison on TNHC.

showing the effectiveness of the entropy-based filtering. For WS160, the F1 peaks at $k = 100$ due to the fact that precision also keeps increasing at every k value. In this case, our filter and refine method can be viewed as a re-scoring method. This is due to the effectiveness of *CRF*(Figures 2c and 2f) classifier. As shown in Figure 2, unlike *CRF*, increasing the k value past a certain threshold negatively affects the performance of *SVM*(Figures 2a and 2d) and *LR*(Figures 2b and 2e) models due to their weaker performance. Removing certain input features to the *CRF* model such as the sotfmax output also decrease the overall performance. For the TNHC dataset the best k value is around 30% showing the importance of filtering to reduce the potential candidates.

3.2 Evaluation on Chinese and Japanese.

Chinese Word Segmentation (CWS). In this experiment, we used the existing CWS model called PyWordSeg (Chuang, 2019) with character-level ELMO embedding. Normally, CWS categorizes characters into four classes: (i) beginning (B), (ii) internal (I), (iii) ending (E), and (iv) single-word (S) (Li et al., 2019). However, PyWordSeg classifies each character as boundary or non-boundary character which is similar to Thai WS, so we used the same feature as Thai WS in this experiment. We performed the experiment on *SIGHAN 2005* dataset (see Table 2) as a single corpora experiment not domain switch like Thai. However, PyWordSeg did not provide a probabilistic prediction that can be used to measure the uncertainty score on English and Pinyin characters. Therefore, we left out those sentences from the evaluation. Note that the released PyWordSeg code does not lend itself for straightforward transfer learning experiments, exemplifying our use case of treating models as black boxes.

For the CWS task, we evaluated our method on four corpora including AS, CityU, PKU, and MSR using the character-level F1. The results shown in Table 5 indicate that our method is better than the competitors.

Method	Corpus			
	AS	CITYU	MSR	PKU
PyWordSeg	98.4	98.6	85.3	83.2
SE+PyWordSeg (k=90,100,80,100)	98.5	98.8	94.5	94.0

Table 5: Comparison between our method on CWS.

Japanese Word Segmentation (JWS). In this experiment, we performed JWS using Nagisa (Ikeda, 2018), trained on the *Balanced Corpus of Contemporary Written Japanese (BCCWJ)* (Maekawa et al.). This model categorizes characters into four classes: (i) beginning (B) (ii) middle (M) (iii) ending (E), and (iv) single-word (S) (Kitagawa and Komachi, 2018).

We performed experiments using the *Universal Dependencies 2.5* dataset (Asahara et al., 2018) on the GSD, Modern, and PUD subset (see Table 2). The results given in Table 6 indicate that our method outperformed JWS on all corpora. Specifically, our method reports performance improvement of 3% on GSD, 4.7% on Modern, and 11.5% on PUD using the character-level F1.

Method	Corpus		
	GSD	Modern	PUD
Nagisa	87.1	87.1	78.8
SE + Nagisa (k=100,100,100)	90.1	91.8	90.3

4 Conclusion

We proposed a novel solution for adapting a black-box model to a new domain by formulating it as an ensemble learning problem. We conducted extensive experimental studies using nine benchmark corpora from three languages. For Thai Word Segmentation, the results showed that our method is an effective domain adaptation method and has similar performance as the transfer learning method. The results from Japanese and Chinese Word Segmentation experiments showed that our method could improve the performance of Japanese and Chinese black-box models.

Table 8: Parameter settings in CRF.

Evaluation measures. we measured the F1 scores for both character and world levels. For the character level, we used Sklearn (precision_recall_fscore_support) with binary average. For the word level, we applied the same practice as AttaCut (Chormai et al., 2019) in measuring the recall and precision. The performance comparison of our method on BEST corpus with DeepCut and AttaCut-SC is displayed in Table 10.

Ablation study: Feature. We also measured how different feature types affect the performance of our proposed solution, SE+DeepCut. Results are shown in Table 9. Note how the softmax features have the largest effect on performance, showing the importance of the DG model.

A.2 Error Analysis And Random Samples.

We performed an error analysis on Wisesight (test set) corpus for DeepCut and SE+DeepCut to show how we improve the baseline model. As shown

SE + AttaCut-SC (k=98)	98.0	89.8

Table 10: Performance comparison on BEST-2010.

in Figure 3, DeepCut was trained on BEST corpus where the annotation rules grouped words into a compound word resulting in a model that produced large word chunks. However, with not much English word in the corpus and no hashtag segmentation samples to train the model, DeepCut failed to segment English words correctly. On the other hand, the SE+DeepCut method was training on Wisesight (training set) therefore the behavior of our method is to split a compound word into multiple single word and our method can perform on English word and hashtag better than DeepCut. Thus, we need more data on the social media domain to support these domain characteristics with a good annotation guideline of data. We also add the random examples from Thai, Chinese, and Japanese the result are given in Figure 4.

DagoBERT: Generating Derivational Morphology with a Pretrained Language Model

Valentin Hofmann[*‡], **Janet B. Pierrehumbert**[†*], **Hinrich Schütze**[‡]

`valentin.hofmann@ling-phil.ox.ac.uk`

Abstract

Can pretrained language models (PLMs) generate derivationally complex words? We present the first study investigating this question, taking BERT as the example PLM. We examine BERT's derivational capabilities in different settings, ranging from using the unmodified pretrained model to full finetuning. Our best model, DagoBERT (Derivationally and generatively optimized BERT), clearly outperforms the previous state of the art in derivation generation (DG). Furthermore, our experiments show that the input segmentation crucially impacts BERT's derivational knowledge, suggesting that the performance of PLMs could be further improved if a morphologically informed vocabulary of units were used.

1 Introduction

What kind of linguistic knowledge is encoded by pretrained language models (PLMs) such as ELMo (Peters et al., 2018), GPT-2 (Radford et al., 2019), and BERT (Devlin et al., 2019)? This question has attracted a lot of attention in NLP recently, with a focus on syntax (e.g., Goldberg, 2019) and semantics (e.g., Ethayarajh, 2019). It is much less clear what PLMs learn about other aspects of language. Here, we present the first study on the knowledge of PLMs about derivational morphology, taking BERT as the example PLM. Given an English cloze sentence such as `this jacket is _____ .` and a base such as `wear`, we ask: can BERT generate correct derivatives such as `unwearable`?

The motivation for this study is twofold. On the one hand, we add to the growing body of work on the linguistic capabilities of PLMs. Most PLMs segment words into subword units (Bostrom and Durrett, 2020), e.g., `unwearable` is segmented into `un`, `##wear`, `##able` by BERT's WordPiece tokenizer (Wu et al., 2016). The fact that many of these subword units are derivational affixes suggests that PLMs might acquire knowledge about derivational morphology (Table 1), but this has not been tested. On the other hand, we are interested in derivation generation (DG) per se, a task that has been only addressed using LSTMs (Cotterell et al., 2017; Vylomova et al., 2017; Deutsch et al., 2018), not models based on Transformers like BERT.

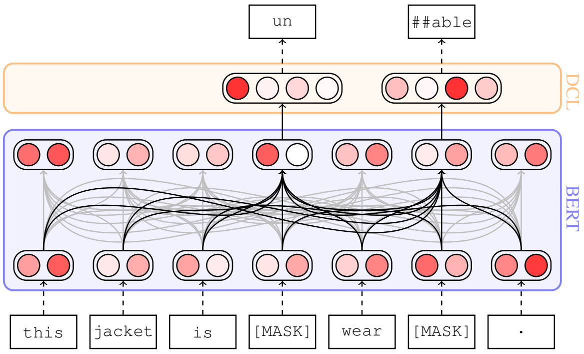

Figure 1: Basic experimental setup. We input sentences such as `this jacket is unwearable .` to BERT, mask out derivational affixes, and recover them using a derivational classification layer (DCL).

Type	Examples
Prefixes	`anti`, `auto`, `contra`, `extra`, `hyper`, `mega`, `mini`, `multi`, `non`, `proto`, `pseudo`
Suffixes	`##able`, `##an`, `##ate`, `##ee`, `##ess`, `##ful`, `##ify`, `##ize`, `##ment`, `##ness`, `##ster`

Table 1: Examples of derivational affixes in the BERT WordPiece vocabulary. Word-internal WordPiece tokens are marked with `##` throughout the paper.

Contributions. We develop the first framework for generating derivationally complex English words with a PLM, specifically BERT, and analyze BERT's performance in different settings. Our best model, DagoBERT (Derivationally and generatively optimized BERT), clearly outperforms an LSTM-based model, the previous state of the art.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3848–3861,
November 16–20, 2020.

We find that DagoBERT's errors are mainly due to syntactic and semantic overlap between affixes. Furthermore, we show that the input segmentation impacts how much derivational knowledge is available to BERT, both during training and inference. This suggests that the performance of PLMs could be further improved if a morphologically informed vocabulary of units were used. We also publish the largest dataset of derivatives in context to date.[1]

2 Derivational Morphology

Linguistics divides morphology into inflection and derivation. Given a lexeme such as `wear`, while inflection produces word forms such as `wears`, derivation produces new lexemes such as `unwearable`. There are several differences between inflection and derivation (Haspelmath and Sims, 2010), two of which are particularly important for the task of DG.[2]

First, derivation covers a much larger spectrum of meanings than inflection (Acquaviva, 2016), and it is not possible to predict in general with which of them a particular lexeme is compatible. This is different from inflectional paradigms, where it is automatically clear whether a certain form will exist (Bauer, 2019). Second, the relationship between form and meaning is more varied in derivation than inflection. On the one hand, derivational affixes tend to be highly polysemous, i.e., individual affixes can represent a number of related meanings (Lieber, 2019). On the other hand, several affixes can represent the same meaning, e.g., `ity` and `ness`. While such competing affixes are often not completely synonymous as in the case of `hyperactivity` and `hyperactiveness`, there are examples like `purity` and `pureness` or `exclusivity` and `exclusiveness` where a semantic distinction is more difficult to gauge (Bauer et al., 2013; Plag and Balling, 2020). These differences make learning functions from meaning to form harder for derivation than inflection.

Derivational affixes differ in how productive they are, i.e., how readily they can be used to create new lexemes (Plag, 1999). While the suffix `ness`, e.g., can attach to practically all English adjectives, the suffix `th` is much more limited in its scope of applicability. In this paper, we focus on productive affixes such as `ness` and exclude unproductive affixes such as `th`. Morphological productivity has been the subject of much work in psycholinguistics since it reveals implicit cognitive generalizations (see Dal and Namer (2016) for a review), making it an interesting phenomenon to explore in PLMs. Furthermore, in the context of NLP applications such as sentiment analysis, productively formed derivatives are challenging because they tend to have very low frequencies and often only occur once (i.e., they are hapaxes) or a few times in large corpora (Mahler et al., 2017). Our focus on productive derivational morphology has crucial consequences for dataset design (Section 3) and model evaluation (Section 4) in the context of DG.

3 Dataset of Derivatives

We base our study on a new dataset of derivatives in context similar in form to the one released by Vylomova et al. (2017), i.e., it is based on sentences with a derivative (e.g., `this jacket is unwearable .`) that are altered by masking the derivative (`this jacket is _____ .`). Each item in the dataset consists of (i) the altered sentence, (ii) the derivative (`unwearable`) and (iii) the base (`wear`). The task is to generate the correct derivative given the altered sentence and the base. We use sentential contexts rather than tags to represent derivational meanings because they better reflect the semantic variability inherent in derivational morphology (Section 2). While Vylomova et al. (2017) use Wikipedia, we extract the dataset from Reddit.[3] Since productively formed derivatives are not part of the language norm initially (Bauer, 2001), social media is a particularly fertile ground for our study.

For determining derivatives, we use the algorithm introduced by Hofmann et al. (2020a), which takes as input a set of prefixes, suffixes, and bases and checks for each word in the data whether it can be derived from a base using a combination of prefixes and suffixes. The algorithm is sensitive to morpho-orthographic rules of English (Plag, 2003), e.g., when `ity` is removed from `applicability`, the result is `applicable`, not `applicabil`. Here, we use BERT's prefixes, suffixes, and bases as input to the algorithm. Drawing upon a comprehensive list of 52 productive pre-

---

[1] We make our code and data publicly available at `https://github.com/valentinhofmann/dagobert`.

[2] It is important to note that the distinction between inflection and derivation is fuzzy (ten Hacken, 2014).

[3] We draw upon the entire Baumgartner Reddit Corpus, a collection of all public Reddit posts available at `https://files.pushshift.io/reddit/comments/`.

		P			S			PS

Table 2: Data summary statistics. The table shows statistics of the data used in the study by frequency bin and affix type. We also provide example derivatives with `anti` (P), `ness` (S), and `un##able` (PS) for the different bins. μ_f: mean frequency per billion words; n_d: number of distinct derivatives; n_s: number of context sentences.

fixes and 49 productive suffixes in English (Crystal, 1997), we find that 48 and 44 of them are contained in BERT's vocabulary. We assign all fully alphabetic words with more than 3 characters in BERT's vocabulary except for stopwords and previously identified affixes to the set of bases, yielding a total of 20,259 bases. We then extract every sentence including a word that is derivable from one of the bases using at least one of the prefixes or suffixes from all publicly available Reddit posts.

The sentences are filtered to contain between 10 and 100 words, i.e., they provide more contextual information than the example sentence above.[4] See Appendix A.1 for details about data preprocessing. The resulting dataset comprises 413,271 distinct derivatives in 123,809,485 context sentences, making it more than two orders of magnitude larger than the one released by Vylomova et al. (2017).[5] To get a sense of segmentation errors in the dataset, we randomly pick 100 derivatives for each affix and manually count missegmentations. We find that the average precision of segmentations in the sample is .960±.074, with higher values for prefixes (.990±.027) than suffixes (.930±.093).

For this study, we extract all derivatives with a frequency $f \in [1, 128)$ from the dataset. We divide the derivatives into 7 frequency bins with $f = 1$ (B1), $f \in [2, 4)$ (B2), $f \in [4, 8)$ (B3), $f \in [8, 16)$ (B4), $f \in [16, 32)$ (B5), $f \in [32, 64)$ (B6), and $f \in [64, 128)$ (B7). Notice that we focus on low-frequency derivatives since we are interested in productive derivational morphology (Section 2). In addition, BERT is likely to have seen high-frequency derivatives multiple times during pretraining and might be able to predict the affix because it has memorized the connection between the base and the affix, not because it has knowledge of derivational morphology. BERT's pretraining corpus has 3.3 billion words, i.e., words in the lower frequency bins are very unlikely to have been seen by BERT before. This observation also holds for average speakers of English, who have been shown to encounter at most a few billion word tokens in their lifetime (Brysbaert et al., 2016).

Regarding the number of affixes, we confine ourselves to three cases: derivatives with one prefix (P), derivatives with one suffix (S), and derivatives with one prefix and one suffix (PS).[6] We treat these cases separately because they are known to have different linguistic properties. In particular, since suffixes in English can change the POS of a lexeme, the syntactic context is more affected by suffixation than by prefixation. Table 2 provides summary statistics for the seven frequency bins as well as example derivatives for P, S, and PS. For each bin, we randomly split the data into 60% training, 20% development, and 20% test. Following Vylomova et al. (2017), we distinguish the lexicon settings SPLIT (no overlap between bases in train, dev, and test) and SHARED (no constraint on overlap).

4 Experiments

4.1 Setup

To examine whether BERT can generate derivationally complex words, we use a cloze test: given a sentence with a masked word such as `this jacket is` ______ `.` and a base such as `wear`, the task is to generate the correct derivative such as `unwearable`. The cloze setup has been previously used in psycholinguistics to probe derivational morphology (Pierrehumbert, 2006; Apel and

---

[4] We also extract the preceding and following sentence for future studies on long-range dependencies in derivation. However, we do not exploit them in this work.

[5] Due to the large number of prefixes, suffixes, and bases, the dataset can be valuable for any study on derivational morphology, irrespective of whether or not it focuses on DG.

[6] We denote affix bundles, i.e., combinations of prefix and suffix, by juxtaposition, e.g., `un##able`.

Lawrence, 2011) and was introduced to NLP in this context by Vylomova et al. (2017).

In this work, we frame DG as an affix classification task, i.e., we predict which affix is most likely to occur with a given base in a given context sentence.[7] More formally, given a base b and a context sentence $\mathbf{x}$ split into left and right contexts $\mathbf{x}^{(l)} = (x_1, \dots, x_{d-1})$ and $\mathbf{x}^{(r)} = (x_{d+1}, \dots, x_n)$, with x_d being the masked derivative, we want to find the affix $\hat{a}$ such that

$$\hat{a} = \arg\max_{a} P\left(\psi(b, a) | \mathbf{x}^{(l)}, \mathbf{x}^{(r)}\right), \qquad (1)$$

where ψ is a function mapping bases and affixes onto derivatives, e.g., $\psi($`wear`, `un##able`$) =$ `unwearable`. Notice we do not model the function ψ itself, i.e., we only predict derivational categories, not the morpho-orthographic changes that accompany their realization in writing. One reason for this is that as opposed to previous work, our study focuses on low-frequency derivatives, for many of which ψ is not right-unique, e.g., `ungoogleable` and `ungooglable` or `celebrityness` and `celebritiness` occur as competing forms in the data.

As a result of the semantically diverse nature of derivation (Section 2), deciding whether a particular prediction $\hat{a}$ is correct or not is less straightforward than it may seem. Taking again the example sentence `this jacket is` _____ . with the masked derivative `unwearable`, compare the following five predictions:

- $\psi(b, \hat{a}) =$ `wearity`: ill-formed;
- $\psi(b, \hat{a}) =$ `wearer`: well-formed, syntactically incorrect (wrong POS);
- $\psi(b, \hat{a}) =$ `intrawearable`: well-formed, syntactically correct, semantically dubious;
- $\psi(b, \hat{a}) =$ `superwearable`: well-formed, syntactically correct, semantically possible, but did not occur in the example sentence;
- $\psi(b, \hat{a}) =$ `unwearable`: well-formed, syntactically correct, semantically possible, and did occur in the example sentence.

These predictions reflect increasing degrees of derivational knowledge. A priori, where to draw the line between correct and incorrect predictions on this continuum is not clear, especially with respect to the last two cases. Here, we apply the most conservative criterion: a prediction $\hat{a}$ is only judged correct if $\psi(b, \hat{a}) = x_d$, i.e., if $\hat{a}$ is the affix in the masked derivative. Thus, we ignore affixes that might potentially produce equally possible derivatives such as `superwearable`.

Table 3: Performance (MRR) of pretrained BERT for prefix prediction with different segmentations. Best score per column in gray, second-best in light-gray.

We use mean reciprocal rank (MRR), macro-averaged over affixes, as the evaluation measure (Radev et al., 2002). We calculate the MRR value of an individual affix a as

$$\mathrm{MRR}_a = \frac{1}{|D_a|} \sum_{i \in D_a} \mathrm{R}_i^{-1}, \qquad (2)$$

where D_a is the set of derivatives containing a, and R_i is the predicted rank of a for derivative i. We set $\mathrm{R}_i^{-1} = 0$ if $\mathrm{R}_i > 10$. Denoting with $\mathcal{A}$ the set of all affixes, the final MRR value is given by

$$\mathrm{MRR} = \frac{1}{|\mathcal{A}|} \sum_{a \in \mathcal{A}} \mathrm{MRR}_a \,. \qquad (3)$$

4.2 Segmentation Methods

Since BERT distinguishes word-initial (`wear`) from word-internal (`##wear`) tokens, predicting prefixes requires the word-internal form of the base. However, only 795 bases in BERT's vocabulary have a word-internal form. Take as an example the word `unallowed`: both `un` and `allowed` are in the BERT vocabulary, but we need the token `##allowed`, which does not exist (BERT tokenizes the word into `una`, `##llo`, `##wed`). To overcome this problem, we test the following four segmentation methods:

HYP. We insert a hyphen between the prefix and the base in its word-initial form, yielding the tokens `un`, `-`, `allowed` in our example. Since both prefix and base are guaranteed to be in the BERT vocabulary (Section 3), and since there are no tokens starting with a hyphen in the BERT vocabulary, BERT always tokenizes words of the form prefix-hyphen-base into prefix, hyphen, and base, making this a natural segmentation for BERT.

---

[7] In the case of PS, we predict which affix bundle (e.g., `un##able`) is most likely to occur.

Table 6: Performance (MRR) of prefix-suffix (PS) models. Best score per column in gray, second-best in light-gray.

INIT. We simply use the word-initial instead of the word-internal form, segmenting the derivative into the prefix followed by the base, i.e., `un`, `allowed` in our example. Notice that this looks like two individual words to BERT since `allowed` is a word-initial unit.

TOK. To overcome the problem of INIT, we segment the base into word-internal tokens, i.e., our example is segmented into `un`, `##all`, `##owed`. This means that we use the word-internal counterpart of the base in cases where it exists.

PROJ. We train a projection matrix that maps embeddings of word-initial forms of bases to word-internal embeddings. More specifically, we fit a matrix $\hat{\mathbf{T}} \in \mathbb{R}^{m \times m}$ (m being the embedding size) via least squares,

$$\hat{\mathbf{T}} = \arg\min_{\mathbf{T}} ||\mathbf{ET} - \mathbf{E}_{\#\#}||_2^2, \qquad (4)$$

where $\mathbf{E}, \mathbf{E}_{\#\#} \in \mathbb{R}^{n \times m}$ are the word-initial and word-internal token input embeddings of bases with both forms. We then map bases with no word-internal form and a word-initial input token embedding $\mathbf{e}$ such as `allow` onto the projected word-internal embedding $\mathbf{e}^\top \hat{\mathbf{T}}$.

Table 7: Performance on Vylomova et al. (2017) dataset. We report accuracies for comparability. LSTM (V): LSTM in Vylomova et al. (2017). Best score per column in gray, second-best in light-gray.

We evaluate the four segmentation methods on the SHARED test data for P with pretrained $\text{BERT}_{\text{BASE}}$, using its pretrained language modeling head for prediction and filtering for prefixes. The HYP segmentation method performs best (Table 3) and is adopted for BERT models on P and PS.

4.3 Models

All BERT models use $\text{BERT}_{\text{BASE}}$ and add a derivational classification layer (DCL) with softmax activation for prediction (Figure 1). We examine three BERT models and two baselines. See Appendix A.2 for details about implementation, hyperparameter tuning, and runtime.

DagoBERT. We finetune both BERT and DCL on DG, a model that we call DagoBERT (short for

Type	Clusters
Prefixes	{`bi`, `demi`, `fore`, `mini`, `proto`, `pseudo`, `semi`, `sub`, `tri`}, {`arch`, `extra`, `hyper`, `mega`, `poly`, `super`, `ultra`}, {`anti`, `contra`, `counter`, `neo`, `pro`}, {`mal`, `mis`, `over`, `under`}, {`inter`, `intra`}, {`auto`, `de`, `di`, `in`, `re`, `sur`, `un`}, {`ex`, `vice`}, {`non`, `post`, `pre`}
Suffixes	{`##al`, `##an`, `##ial`, `##ian`, `##ic`, `##ite`}, {`##en`, `##ful`, `##ive`, `##ly`, `##y`}, {`##able`, `##ish`, `##less`}, {`##age`, `##ance`, `##ation`, `##dom`, `##ery`, `##ess`, `##hood`, `##ism`, `##ity`, `##ment`, `##ness`}, {`##ant`, `##ee`, `##eer`, `##er`, `##ette`, `##ist`, `##ous`, `##ster`}, {`##ate`, `##ify`, `##ize`}

Table 8: Prefix and suffix clusterings produced by Girvan-Newman after 4 graph splits on the DagoBERT confusion matrix. For reasons of space, we do not list clusters consisting of only one affix.

Derivationally **a**nd **g**eneratively **o**ptimized **BERT**). Notice that since BERT cannot capture statistical dependencies between masked tokens (Yang et al., 2019), all BERT-based models predict prefixes and suffixes independently in the case of PS.

BERT+. We keep the model weights of pretrained BERT fixed and only train DCL on DG. This is similar in nature to a probing task.

BERT. We use pretrained BERT and leverage its pretrained language modeling head as DCL, filtering for affixes, e.g., we compute the softmax only over prefixes in the case of P.

LSTM. We adapt the approach described in Vylomova et al. (2017), which combines the left and right contexts $\mathbf{x}^{(l)}$ and $\mathbf{x}^{(r)}$ of the masked derivative by means of two BiLSTMs with a character-level representation of the base. To allow for a direct comparison with BERT, we do not use the character-based decoder proposed by Vylomova et al. (2017) but instead add a dense layer for the prediction. For PS, we treat prefix-suffix bundles as units (e.g., `un##able`).

In order to provide a strict comparison to Vylomova et al. (2017), we also evaluate our LSTM and best BERT-based model on the suffix dataset released by Vylomova et al. (2017) against the reported performance of their encoder-decoder model.[8] Notice Vylomova et al. (2017) show that providing the LSTM with the POS of the derivative increases performance. Here, we focus on the more general case where the POS is not known and hence do not consider this setting.

Random Baseline (RB). The prediction is a random ranking of all affixes.

5 Results

5.1 Overall Performance

Results are shown in Tables 4, 5, and 6. For P and S, DagoBERT clearly performs best. Pretrained BERT is better than LSTM on SPLIT but worse on SHARED. BERT+ performs better than pretrained BERT, even on SPLIT (except for S on B7). S has higher scores than P for all models and frequency bins, which might be due to the fact that suffixes carry POS information and hence are easier to predict given the syntactic context. Regarding frequency effects, the models benefit from higher frequencies on SHARED since they can connect bases with certain groups of affixes.[9] For PS, DagoBERT also performs best in general but is beaten by LSTM on one bin. The smaller performance gap as compared to P and S can be explained by the fact that DagoBERT as opposed to LSTM cannot learn statistical dependencies between two masked tokens (Section 4).

The results on the dataset released by Vylomova et al. (2017) confirm the superior performance of DagoBERT (Table 7). DagoBERT beats the LSTM by a large margin, both on SHARED and SPLIT. We also notice that our LSTM (which predicts derivational categories) has a very similar performance to the LSTM encoder-decoder proposed by Vylomova et al. (2017).

5.2 Patterns of Confusion

We now analyze in more detail the performance of the best performing model, DagoBERT, and contrast it with the performance of pretrained BERT. As a result of our definition of correct predictions (Section 4.1), the set of incorrect predictions is heterogeneous and potentially contains affixes resulting in equally possible derivatives. We are hence interested in patterns of confusion in the data.

---

[8] The dataset is available at `https://github.com/ivri/dmorph`. While Vylomova et al. (2017) take morpho-orthographic changes into account, we only predict affixes, not the accompanying changes in orthography (Section 4.1).

[9] The fact that this trend also holds for pretrained BERT indicates that more frequent derivatives in our dataset also appeared more often in the data used for pretraining BERT.

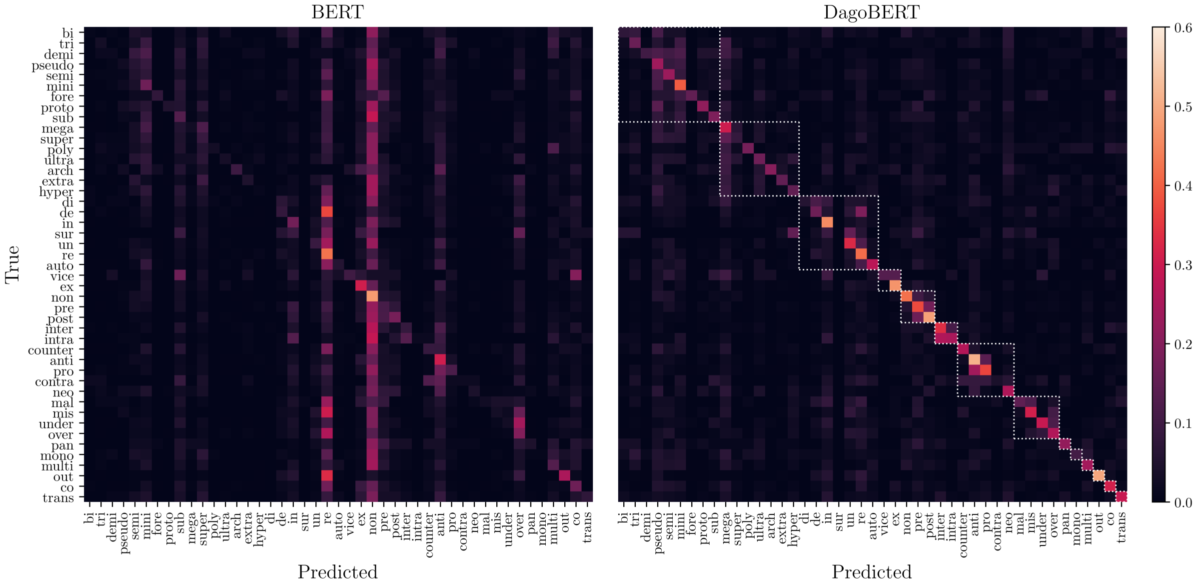

Figure 2: Prefixes predicted by BERT (left) and DagoBERT (right). Vertical lines indicate that a prefix has been overgenerated (particularly `re` and `non` in the left panel). The white boxes in the right panel highlight the clusters produced by Girvan-Newman after 4 graph splits.

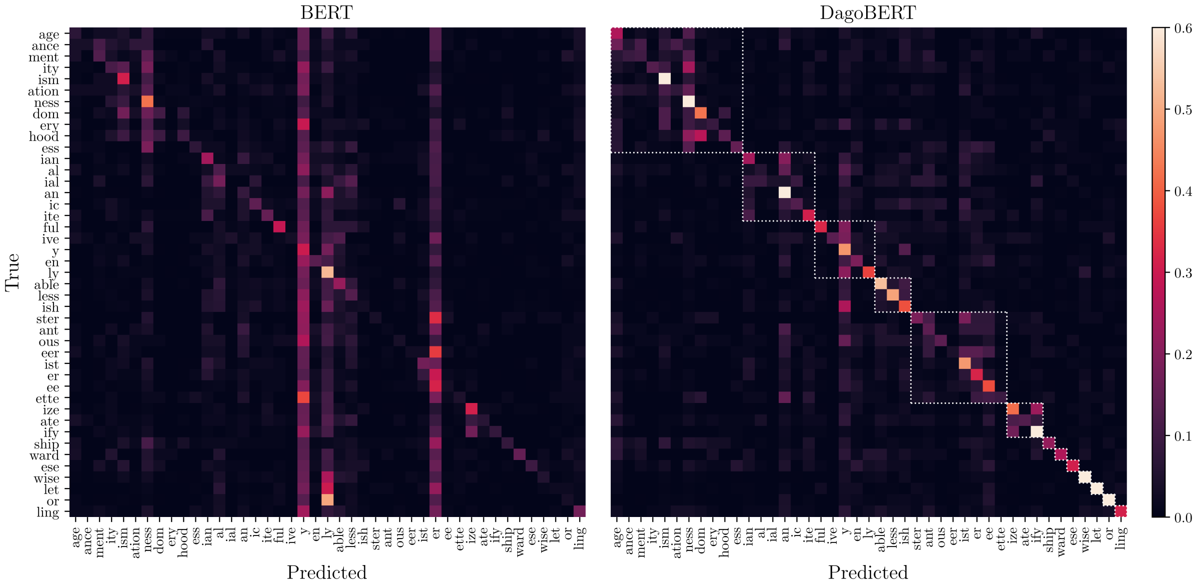

Figure 3: Suffixes predicted by pretrained BERT (left) and DagoBERT (right). Vertical lines indicate that a suffix has been overgenerated (particularly `y`, `ly`, and `er` in the left panel). The white boxes in the right panel highlight the clusters produced by Girvan-Newman after 4 graph splits.

We start by constructing the row-normalized confusion matrix $\mathbf{C}$ for the predictions of DagoBERT on the hapax derivatives (B1, SHARED) for P and S. Based on $\mathbf{C}$, we create a confusion graph $\mathcal{G}$ with adjacency matrix $\mathbf{G}$, whose elements are

$$G_{ij} = \lceil C_{ij} - \theta \rceil, \tag{5}$$

i.e., there is a directed edge from affix i to affix j if i was misclassified as j with a probability greater than θ. We set θ to 0.08.[10] To uncover the community structure of $\mathcal{G}$, we use the Girvan-Newman algorithm (Girvan and Newman, 2002), which clusters the graph by iteratively removing the edge with the highest betweenness centrality.

The resulting clusters reflect linguistically interpretable groups of affixes (Table 8). In particular, the suffixes are clustered in groups with common

---

[10] We tried other values of θ, but the results were similar.

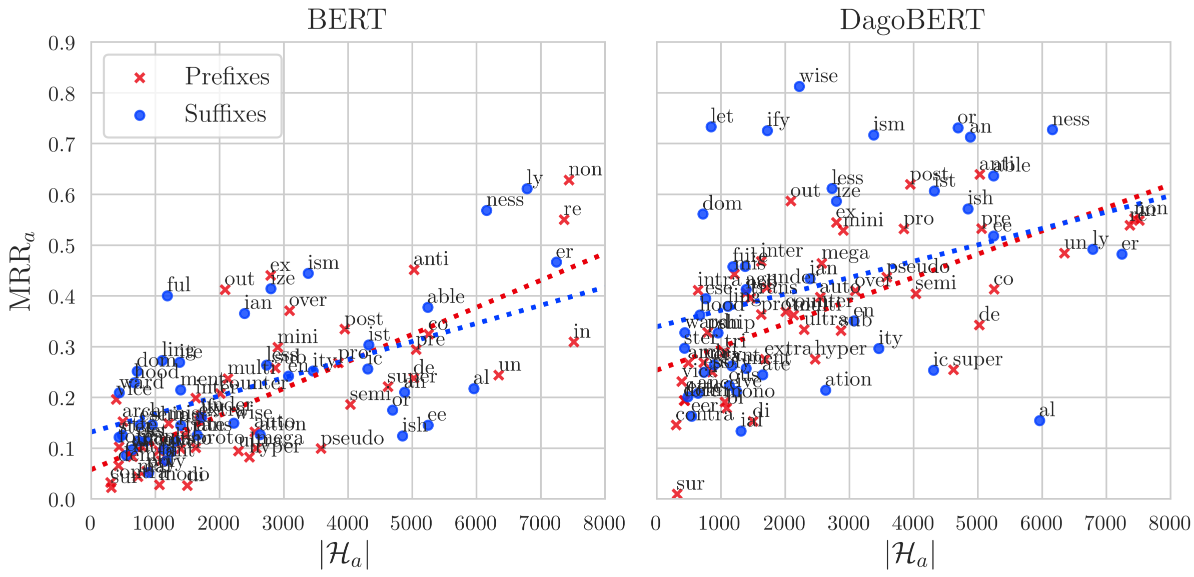

Figure 4: Correlation between number of hapaxes and MRR for pretrained BERT (left) and DagoBERT (right) on B1. The highly productive suffix `y` at $(12662, 0.49)$ (left) and $(12662, 0.62)$ (right) is not shown.

POS. These results are confirmed by plotting the confusion matrix with an ordering of the affixes induced by all clusterings of the Girvan-Newman algorithm (Figure 2, Figure 3). They indicate that even when DagoBERT does not predict the affix occurring in the sentence, it tends to predict an affix semantically and syntactically congruent with the ground truth (e.g., `ness` for `ity`, `ify` for `ize`, `inter` for `intra`). In such cases, it is often a more productive affix that is predicted in lieu of a less productive one. Furthermore, DagoBERT frequently confuses affixes denoting points on the same scale, often antonyms (e.g., `pro` and `anti`, `pre` and `post`, `under` and `over`). This can be related to recent work showing that BERT has difficulties with negated expressions (Ettinger, 2020; Kassner and Schütze, 2020). Pretrained BERT shows similar confusion patterns overall but overgenerates several affixes much more strongly than DagoBERT, in particular `re`, `non`, `y`, `ly`, and `er`, which are among the most productive affixes in English (Plag, 1999, 2003).

To probe the impact of productivity more quantitatively, we measure the cardinality of the set of hapaxes formed by means of a particular affix a in the entire dataset, $|\mathcal{H}_a|$, and calculate a linear regression to predict the MRR values of affixes based on $|\mathcal{H}_a|$. $|\mathcal{H}_a|$ is a common measure of morphological productivity (Baayen and Lieber, 1991; Pierrehumbert and Granell, 2018). This analysis shows a significant positive correlation for both prefixes ($R^2 = .566$, $F(1, 43) = 56.05$, $p < .001$) and suffixes ($R^2 = .410$, $F(1, 41) = 28.49$, $p < .001$): the more productive an affix, the higher its MRR value. This also holds for DagoBERT's predictions of prefixes ($R^2 = .423$, $F(1, 43) = 31.52$, $p < .001$) and suffixes ($R^2 = .169$, $F(1, 41) = 8.34$, $p < .01$), but the correlation is weaker, particularly in the case of suffixes (Figure 4).

5.3 Impact of Input Segmentation

We have shown that BERT can generate derivatives if it is provided with the morphologically correct segmentation. At the same time, we observed that BERT's WordPiece tokenizations are often morphologically incorrect, an observation that led us to impose the correct segmentation using hyphenation (HYP). We now examine more directly how BERT's derivational knowledge is affected by using the original WordPiece segmentations versus the HYP segmentations.

We draw upon the same dataset as for DG (SPLIT) but perform binary instead of multi-class classification, i.e., the task is to predict whether, e.g., `unwearable` is a possible derivative in the context `this jacket is _____ .` or not. As negative examples, we combine the base of each derivative (e.g., `wear`) with a randomly chosen affix different from the original affix (e.g., `##ation`) and keep the sentence context unchanged, resulting in a balanced dataset. We only use prefixed derivatives for this experiment.

	FROZEN								FINETUNED

Table 9: Performance (accuracy) of BERT on morphological well-formedness prediction with morphologically correct segmentation versus WordPiece tokenization. Best score per column in gray.

We train binary classifiers using $\text{BERT}_{\text{BASE}}$ and one of two input segmentations, the morphologically correct segmentation or BERT's WordPiece tokenization. The BERT output embeddings for all subword units belonging to the derivative in question are max-pooled and fed into a dense layer with a sigmoid activation. We examine two settings: training only the dense layer while keeping BERT's model weights frozen (FROZEN), or finetuning the entire model (FINETUNED). See Appendix A.3 for details about implementation, hyperparameter tuning, and runtime.

Morphologically correct segmentation consistently outperforms WordPiece tokenization, both on FROZEN and FINETUNED (Table 9). We interpret this in two ways. Firstly, the type of segmentation used by BERT impacts how much derivational knowledge can be learned, with positive effects of morphologically valid segmentations. Secondly, the fact that there is a performance gap even for models with frozen weights indicates that a morphologically invalid segmentation can blur the derivational knowledge that is in principle available and causes BERT to force semantically unrelated words to have similar representations. Taken together, these findings provide further evidence for the crucial importance of morphologically valid segmentation strategies in language model pretraining (Bostrom and Durrett, 2020).

6 Related Work

PLMs such as ELMo (Peters et al., 2018), GPT-2 (Radford et al., 2019), and BERT (Devlin et al., 2019) have been the focus of much recent work in NLP. Several studies have been devoted to the linguistic knowledge encoded by the parameters of PLMs (see Rogers et al. (2020) for a review), particularly syntax (Goldberg, 2019; Hewitt and Manning, 2019; Jawahar et al., 2019; Lin et al., 2019) and semantics (Ethayarajh, 2019; Wiedemann et al., 2019; Ettinger, 2020). There is also a recent study examining morphosyntactic information in a PLM, specifically BERT (Edmiston, 2020).

There has been relatively little recent work on derivational morphology in NLP. Both Cotterell et al. (2017) and Deutsch et al. (2018) propose neural architectures that represent derivational meanings as tags. More closely related to our study, Vylomova et al. (2017) develop an encoder-decoder model that uses the context sentence for predicting deverbal nouns. Hofmann et al. (2020b) propose a graph auto-encoder that models the morphological well-formedness of derivatives.

7 Conclusion

We show that a PLM, specifically BERT, can generate derivationally complex words. Our best model, DagoBERT, clearly beats an LSTM-based model, the previous state of the art in DG. DagoBERT's errors are mainly due to syntactic and semantic overlap between affixes. Furthermore, we demonstrate that the input segmentation impacts how much derivational knowledge is available to BERT. This suggests that the performance of PLMs could be further improved if a morphologically informed vocabulary of units were used.

A Appendices

A.1 Data Preprocessing

We filter the posts for known bots and spammers (Tan and Lee, 2015). We exclude posts written in a language other than English and remove strings containing numbers, references to users, and hyperlinks. Sentences are filtered to contain between 10 and 100 words. We control that derivatives do not appear more than once in a sentence.

A.2 Hyperparameters

We tune hyperparameters on the development data separately for each frequency bin (selection criterion: MRR). Models are trained with categorical cross-entropy as the loss function and Adam (Kingma and Ba, 2015) as the optimizer. Training and testing are performed on a GeForce GTX 1080 Ti GPU (11GB).

DagoBERT. We use a batch size of 16 and perform grid search for the learning rate $l \in \{1 \times 10^{-6}, 3 \times 10^{-6}, 1 \times 10^{-5}, 3 \times 10^{-5}\}$ and the number of epochs $n_e \in \{1, \ldots, 8\}$ (number of hyperparameter search trials: 32). All other hyperparameters are as for BERT$_{\text{BASE}}$. The number of trainable parameters is 110,104,890.

BERT+. We use a batch size of 16 and perform grid search for the learning rate $l \in \{1 \times 10^{-4}, 3 \times 10^{-4}, 1 \times 10^{-3}, 3 \times 10^{-3}\}$ and the number of epochs $n_e \in \{1, \dots, 8\}$ (number of hyperparameter search trials: 32). All other hyperparameters are as for BERT$_{\text{BASE}}$. The number of trainable parameters is 622,650.

LSTM. We initialize word embeddings with 300-dimensional GloVe (Pennington et al., 2014) vectors and character embeddings with 100-dimensional random vectors. The BiLSTMs consist of three layers and have a hidden size of 100. We use a batch size of 64 and perform grid search for the learning rate $l \in \{1 \times 10^{-4}, 3 \times 10^{-4}, 1 \times 10^{-3}, 3 \times 10^{-3}\}$ and the number of epochs $n_e \in \{1, \dots, 40\}$ (number of hyperparameter search trials: 160). The number of trainable parameters varies with the type of the model due to different sizes of the output layer and is 2,354,345 for P, 2,354,043 for S, and 2,542,038 for PS models.[11]

Table 10 lists statistics of the validation performance over hyperparameter search trials and provides information about the best validation performance as well as corresponding hyperparameter configurations.[12] We also report runtimes for the hyperparameter search.

For the models trained on the Vylomova et al. (2017) dataset, hyperparameter search is identical as for the main models, except that we use accuracy as the selection criterion. Runtimes for the hyperparameter search in minutes are 754 for SHARED and 756 for SPLIT in the case of DagoBERT, and 530 for SHARED and 526 for SPLIT in the case of LSTM. Best validation accuracy is .943 ($l = 3 \times 10^{-6}$, $n_e = 7$) for SHARED and .659 ($l = 1 \times 10^{-5}$, $n_e = 4$) for SPLIT in the case of DagoBERT, and .824 ($l = 1 \times 10^{-4}$, $n_e = 38$) for SHARED and .525 ($l = 1 \times 10^{-4}$, $n_e = 33$) for SPLIT in the case of LSTM.

A.3 Hyperparameters

We use the HYP segmentation method for models with morphologically correct segmentation. We tune hyperparameters on the development data separately for each frequency bin (selection criterion: accuracy). Models are trained with binary cross-entropy as the loss function and Adam as the optimizer. Training and testing are performed on a GeForce GTX 1080 Ti GPU (11GB).

For FROZEN, we use a batch size of 16 and perform grid search for the learning rate $l \in \{1 \times 10^{-4}, 3 \times 10^{-4}, 1 \times 10^{-3}, 3 \times 10^{-3}\}$ and the number of epochs $n_e \in \{1, \dots, 8\}$ (number of hyperparameter search trials: 32). The number of trainable parameters is 769. For FINETUNED, we use a batch size of 16 and perform grid search for the learning rate $l \in \{1 \times 10^{-6}, 3 \times 10^{-6}, 1 \times 10^{-5}, 3 \times 10^{-5}\}$ and the number of epochs $n_e \in \{1, \dots, 8\}$ (number of hyperparameter search trials: 32). The number of trainable parameters is 109,483,009. All other hyperparameters are as for BERT$_{\text{BASE}}$.

Table 11 lists statistics of the validation performance over hyperparameter search trials and provides information about the best validation performance as well as corresponding hyperparameter configurations. We also report runtimes for the hyperparameter search.

---

[11] Since models are trained separately on the frequency bins, slight variations are possible if an affix does not appear in a particular bin. The reported numbers are for B1.

[12] Since expected validation performance (Dodge et al., 2019) may not be correct for grid search, we report mean and standard deviation of the performance instead.

Abstract

Taking greedy decoding algorithm as it should be, this work focuses on further strengthening the model itself for Chinese word segmentation (CWS), which results in an even more fast and more accurate CWS model. Our model consists of an attention only stacked encoder and a light enough decoder for the greedy segmentation plus two highway connections for smoother training, in which the encoder is composed of a newly proposed Transformer variant, Gaussian-masked Directional (GD) Transformer, and a biaffine attention scorer. With the effective encoder design, our model only needs to take unigram features for scoring. Our model is evaluated on SIGHAN Bakeoff benchmark datasets. The experimental results show that with the highest segmentation speed, the proposed model achieves new state-of-the-art or comparable performance against strong baselines in terms of strict closed test setting.

1 Introduction

Chinese word segmentation (CWS) is the task of delimiting word boundaries in a sentence, as a basic and essential task for Chinese and many other East Asian languages which are written without explicit word delimiters, and thus different from alphabetical languages like English.

Learning from an annotated corpus with segmentation, the CWS task may be generally modeled as a decoder which performs segmentation based on a scoring module in terms of contextual feature based representations. Table 1 summarizes typical CWS models according to their decoding ways. Markov models such as (Ng and Low, 2004) and (Zheng et al., 2013) depend on the maximum entropy model or maximum entropy Markov model both with Viterbi decoding. Besides, conditional random field (CRF) or Semi-CRF for sequence labeling has been used for both traditional and neural models though with different representations (Peng et al., 2004; Andrew, 2006; Wang and Xu, 2017; Ma et al., 2018).

Recent neural CWS research have been concerned about the following three perspectives (Emerson, 2005).

Decoder. As CWS is a kind of structure learning task, the decoder module generally determines which type of detailed algorithm should be adopted for segmentation, also it may limit the capability of defining feature. As shown in Table 2, not all models can support the word-level features as CWS is a task to predict word boundary. Thus recent works focus on finding more general or flexible decoder design to make model learn the representation of segmentation more effective such as (Cai and Zhao, 2016; Cai et al., 2017).

Encoder. Practice in various natural language processing tasks has shown that effective representation is essential to the performance improvement. For such a module in neural models, it is more than an encoder now, which is regarded as the most improvement perspective against traditional models. Thus for better CWS, it is crucial to encode the input character, word or sentence into a distinguishable representation. Table 2 summarizes regular feature sets for typical CWS models including ours as well. The building blocks that encoders use include recurrent neural network (RNN) and convolutional neural network (CNN), and long short-term memory (LSTM) network.

External resources and pre-trained embedding. Using external resource such as pre-trained embeddings or language representation provides

an alternative for performance improvement other than designing better models (Yang et al., 2017). SIGHAN Bakeoff therefore defines two types of evaluation settings, closed test limits all the data for learning not to be beyond the given training set, while open test does not take this limitation (Emerson, 2005). This work will focus on the closed test setting by finding a better model design for further CWS.

Generally speaking, both the major difference between traditional and neural models, and what mostly distinguishes the neural models are about the way to represent input sentences, while the options of decoding algorithms are bounded to how to formalize the CWS into a structural learning task. As shown in Table 1, using Markov contextualized features, Markov models and CRF-based models are capable of using Viterbi decoders with polynomial time complexity. Furthermore, to accommodate more rich features means that the model has to take a deeper structural learning which also requires more complex decoding algorithms (Zhang and Clark, 2007; Cai and Zhao, 2016). However, for such a case, deterministic decoding algorithms may have an intractable complexity, thus it forces the model to use an approximate beam search strategy luckily with low-order polynomial time complexity $O(Mnb^2)$, where b is beam width,n is the sentence size, and M is a constant representing the model complexity. When the beam width b=1, the beam search will reduce to greedy algorithm with a much better time complexity $O(Mn)$.

To make the decoding practical, the beam width b has to be carefully tuned for a tradeoff between accuracy and efficiency: A larger b will make the learning and segmentation extremely slow, while a small b cannot sufficiently guarantee the segmentation performance. However, there has long been a unheeded observation that good enough representations can offer good enough segmentation even though only using a greedy segmentation algorithm. (Sproat and Emerson, 2003) create a topline evaluation by using only using vocabulary from test set to perform a greedy segmentation (maximum matching), which yields around 99% F-scores on all datasets. For neural models, (Cai et al., 2017) verify that if the representations are good enough, beam width 1 can still give state-of-the-art performance compared to their early model with a full beam search decoder in (Cai and Zhao, 2016). Therefore, undertaking a fixed greedy segmentation algorithm, this paper only focuses on more effective encoder design for even better representation.

Our model only consists of attention mechanisms as building blocks plus two highway connections via a virtual hidden layer for smooth training. Our model is simply stacked by a variant of Transformer encoder (Vaswani et al., 2017) and a biaffine attention scorer (Dozat and Manning, 2017). Empowered by the self-attention mechanism, the Transformer has been good at capturing long-range dependencies for input sentence. We propose Gaussian-masked Directional (GD) multi-head attention to facilitate the learning of localness, position and directional information for CWS, so that we have the proposed GD-Transformer.

With our further improved encoder, our model uses only simple unigram features to generate representation of sentences for scoring. Our model will be strictly evaluated on benchmark datasets from SIGHAN Bakeoff shared task in terms of closed test setting, and experimental results show that our model achieves new state-of-the-art.

The technical contributions of this paper can be summarized as follows.

- To especially enhance the representation of localness information and directional information, we propose a new Gaussian-masked Directional Transformer encoder.
- Motivated from a simple design idea, we present a new CWS model which is stacked with only attention blocks.
- With a powerful enough encoder, for the first time, we show that unigram (character) features plus greedy segmentation algorithm can support yielding strong performance instead of using diverse n-gram (character and word) features and highly complex decoding algorithms.

2 Related Work

(Xue, 2003) first formalize CWS as a sequence labeling task, considering CWS as a supervised learning from annotated corpus with human segmentation. (Peng et al., 2004) further adopt standard sequence labeling tool CRFs for CWS modeling, achieving new state-of-the-art. (Zhao et al., 2006b) show that different character tag sets can make essential impact for segmentation performance. (Zhao et al., 2006a) propose a CWS system developed for Bakeoff-2006 based on CRF, which is based on their proposed 6-tag set for character position tagging and achieved state-of-the-art performance at then. (Zhao and Kit, 2007) present a novel Character tagging based CRF framework which is capable of exploiting global information for performance enhancement.

Neural word segmentation has been widely used to minimize the efforts in feature engineering. (Zheng et al., 2013) first introduce the neural model into CWS with sliding-window based sequence labeling. (Chen et al., 2015) use LSTM to enhance the learning of long distance information.

However, introducing neural models themselves does not really introduce substantial performance improvement in terms of strict closed test of SIGHAN Bakeoff according to (Zhao et al., 2017). Most researchers actually seek help from joint learning, extra learning resources including dictionaries, pre-trained embedding, deeper information extracted from training set and so on. (1) For joint learning, (Lyu et al., 2016) explore a joint model that performs segmentation, POS-Tagging and chunking simultaneously. (Zhang et al., 2017) present a joint model to enhance the segmentation of Chinese microtext by performing CWS and informal word detection simultaneously. (2) For extra resources or clues, (Wang et al., 2019b) propose to incorporate unlabeled and partially-labeled data.

Only a few researches are known for concentrating on strengthening the model itself. To accommodate more rich features through a more broadly structural modeling (Cai and Zhao, 2016) propose a neural framework that eliminates context windows and utilize complete segmentation history. (Wang and Xu, 2017) propose a character-based convolutional neural model to capture n-gram features automatically and an effective approach to incorporate word embeddings. (Cai et al., 2017) further improve the model in (Cai and Zhao, 2016) and show that a greedy segmenter can perform fast and accurately in terms of only presenting effective representations. This work follows this line of research by offering even strengthened model design from simple idea, including the least building block type for encoder (attention only), the least feature type for scoring (unigram only) and the least computational complexity for decoding (greedy segmentation).

The original Transformer encoder consists of a stack of **N** identical layers and each layer has one multi-head self-attention layer and one position-wise fully connected feed-forward layer (Vaswani et al., 2017). One residual connection is around two sub-layers and followed by layer normalization. Several variants are proposed to enhance ability of capturing the localness relationship. (Shaw et al., 2018) propose an effcient way to incorporate relative and absolute position representation. (Yang et al., 2018) cast localness modeling as a learnable Gaussian bias to enhance the ability of capturing useful local context. (Kim et al., 2020) propose a Transformer with Gaussian-weighted self-attention to improved speech-enhancement performance. (Zhang et al., 2020b) propose using syntax to guide the text modeling based on self-attention network sponsored Transformer-based encoder. Transformer based pre-trained language

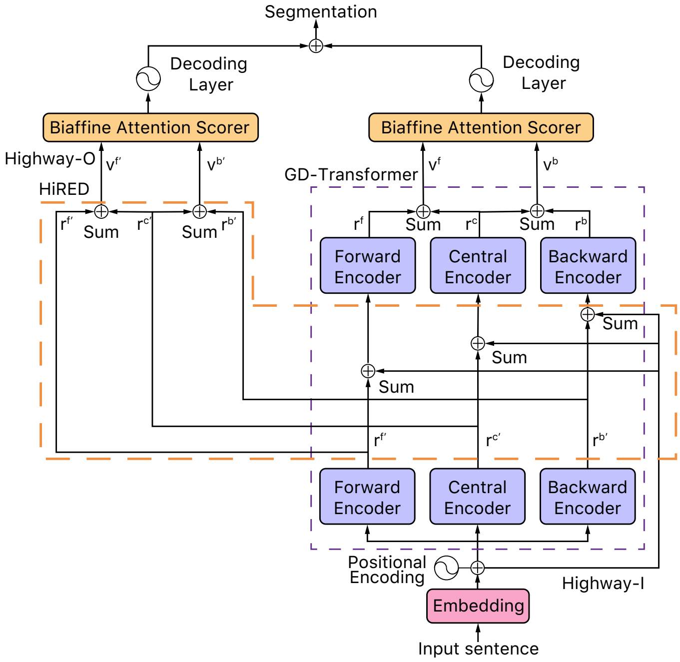

Figure 1: The architecture of our model.

models have become a standard performance enhancement means for various NLP tasks (Zhang et al., 2020a).

3 Models

Our model for CWS task is composed of an encoder to represent the input and a decoder based on the encoder to perform actual segmentation. Figure 1 is the architecture of our model. The model feeds sentence into encoder. Embedding captures the vector e of the input character sequences of c. The encoder maps vector sequences of e to two sequences of vector which are v^b and v^f as the representation of sentences. With v^b and v^f, the biaffine scorer scores each segmentation gaps which makes our decoder is as simple as one layer, using a threshold to directly and greedily predict every word boundaries of the input.

3.1 Gaussian-Masked Directional Transformer

The standard Transformer encoder consists of a stack of **N** identical layers and each has one multi-head self-attention layer and one position-wise fully connected feed-forward layer. One residual connection is around two sub-layers and followed by layer normalization (Vaswani et al., 2017).

The proposed Gaussian-masked Directional (GD) Transformer encoder adopts two key architecture revisions over the standard Transformer. (1) Our encoder includes three parallel directional encoding pipelines instead of only one bidirectional encoder in the original Transformer. (2) By replacing the standard multi-head self-attention with the proposed Gaussian-masked Directional (GD) multi-head self-attention which captures representations from different directions, the resulted encoder may gain better ability of capturing the localness information and position information for the importance of adjacent characters.

Encoder Stacks In CWS task, word boundary forms a gap between two adjacent characters and divides one sequence into two parts, one part in front of the gap and one part in the rear of it. The forward encoder and backward encoder are proposed to capture information of two directions which correspond to two parts divided by the gap. Assuming that one unidirectional encoder can capture information from one particular direction, we stack three parallel encoding modules, forward, backward and center encoders as shown in Figure 1.

The central encoder is to capture information from both directions, which is with the same architecture as the original Transformer. Standard scaled dot-product attention matrix is calculated by dotting query Q with all keys K. For the forward encoder, we forcibly set all values inside the attention matrix representing the character pair relation after the concerned character as 0 so that the encoder can focus on the forward characters. For the backward encoder, we take the similar matrix value setting operations.

The encoder respectively outputs one forward and one backward representations for each position, and then both are fused with the representation given by the center encoder to form the updated forward and backward representations, respectively.

$$v^b = r^b + r^c, v^f = r^f + r^c,$$

where v^b and v^f represent the backward and forward representation, respectively, r^b, r^c and r^f are representations from backward encoder, center encoder and forward encoder, respectively.

Gaussian-Masked Directional Multi-Head Attention Similar as scaled dot-product attention in the original Transformer (Vaswani et al., 2017), our proposed Gaussian-masked directional attention can be described as a function to map queries and key-value pairs to the representation of input. Here queries, keys and values are all vectors. Standard scaled dot-product attention is calculated by dotting query Q with all keys K, dividing each values by $\sqrt{d_k}$, where $\sqrt{d_k}$ is the dimension of keys, and apply a softmax function to generate the weights in the attention:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V \quad (1)$$

Different from scaled dot-product attention, Gaussian-masked directional attention expects to pay attention to the adjacent characters of each positions and cast the localness relationship between characters as a fix Gaussian weight for attention. We assume that the Gaussian weight only relies on the distance between characters.

Firstly we introduce the Gaussian weight matrix G=(g_{ij}) which presents the localness relationship between each two characters:

$$g_{ij} = \Phi(dis_{ij}) = \sqrt{\frac{2}{\sigma^2\pi}}\int_{-\infty}^{-dis_{ij}} exp(-\frac{x^2}{2\sigma^2})dx \quad (2)$$

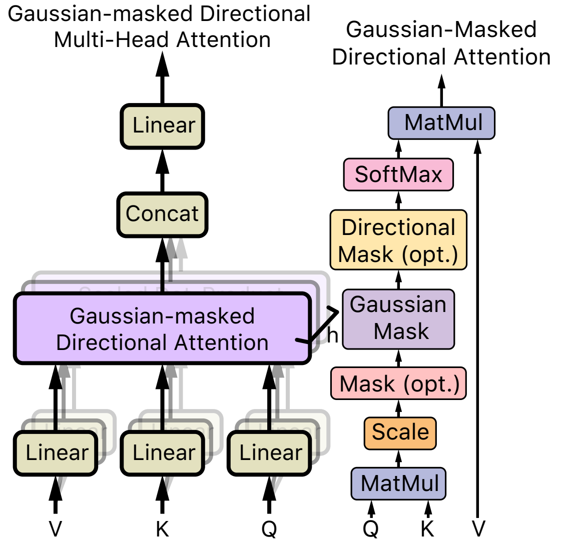
where g_{ij} is the Gaussian weight between character i and j, dis_{ij} is the distance between character i and j, $\Phi(x)$ is the cumulative distribution function of Gaussian, σ is the standard deviation of Gaussian function and it is a hyperparameter in our method. Eq. (2) ensures the Gaussian weight equals 1 when dis_{ij} is 0. The larger distance between characteristics, the smaller the weight is, which lets one character affect its neighbors more than those non-neighbors.

To combine the Gaussian weight to the self-attention, we produce the Hadamard product of Gaussian weight matrix G and the score matrix produced by QK^T

$$AG(Q, K, V) = softmax(\frac{QK^T * G}{\sqrt{d_k}})V \quad (3)$$

where AG as the Gaussian-masked attention ensures that adjacent characters have a stronger relationship than those non-neighbored ones.

The scaled dot-product attention models the relationship between two characters without regard to their distances in one sequence. For CWS task, the weight between adjacent characters should be more important while it is hard for self-attention to achieve the effect explicitly because the self-attention cannot get the order of sentences directly. The Gaussian-masked attention adjusts the weight between characters and their adjacent character to a larger value which stands for the effect of adjacent characters.



(a) The architecture of Gaussian-masked directional multi-head attention.

(b) The Gaussian-masked directional attention.

Figure 2: Illustration of Gaussian-masked directional multi-head attention.

For forward and backward encoder, the self-attention sub-layer needs to use a triangular matrix mask to let the self-attention focus on different weights:

$$g_{ij}^f = \begin{cases} g_{ij}, & pos_j \leq pos_i, \\ -\infty, & others. \end{cases}$$
$$g_{ij}^b = \begin{cases} g_{ij}, & pos_i \leq pos_j, \\ -\infty, & others. \end{cases} \quad (4)$$

where pos_i is the position of character c_i. The triangular matrix for forward and backward encode are: $\begin{bmatrix} 1 & 0 & \cdots & 0 \\ 1 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 1 \end{bmatrix} \begin{bmatrix} 1 & 1 & \cdots & 1 \\ 0 & 1 & \cdots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{bmatrix}$

Similar as (Vaswani et al., 2017), we use multi-head attention to capture information from different dimension positions as Figure 2(a) and get Gaussian-masked directional multi-head attention GMH as follows,

$$GMH(Q, K, V) = Concat(head_1, ..., head_h)W_m,$$
$$head_i = AG(QW_i^q, KW_i^k, VW_i^v) \quad (5)$$

where $W_i^q, W_i^k, W_i^v \in \mathbb{R}^{d_k \times d_h}$ is the parameter matrices to generate heads, W_m is a parameter matrices of $\mathbb{R}^{d_k \times d_k}$ to generate the attention, d_k and

d_h are dimensions of model and one head, respectively.

3.2 Biaffine Attention Scorer

Our model straightforwardly predicts gap between two adjacent characters as word boundary or not. In detail, we set a label value 1 to indicate word boundary, and 0 means no word boundary. Such a gap labeling task thus requires information of the two adjacent characters. In the meantime, the relationship between adjacent characters can be represented as the gap label.

Biaffine attention scorer is used to label the gap (Dozat and Manning, 2017; Li et al., 2018; Cai et al., 2018; Zhou and Zhao, 2019; He et al., 2019). The distribution of labels in a labeling task is often uneven. Biaffine attention uses bias terms to alleviate the burden of the fixed bias term and get the prior probability which makes it different from bilinear attention. The distribution of the gap is uneven that is similar as other labeling task, which makes biaffine available for our task.

Biaffine attention scorer labels the target depending on information of independent unit and the joint information of two units. In biaffine attention, the score s_{ij} of characters c_i and c_j $(i < j)$ is calculated by:

$$\begin{aligned} s_{ij} &= BiaffinalScorer(v_i^f, v_j^b) \\ &= (v_i^f)^T W v_j^b + U(v_i^f \oplus v_j^b) + b \end{aligned} \tag{6}$$

where v_i^f and v_i^b represent respectively the forward and backward information of c_j, W, U and b are all learnable parameters. W is a matrix with shape $(d_i \times N \times d_j)$ and U is a $(N \times (d_i + d_j))$ matrix where d_i is the dimension of vector v_i^f and N is the number of labels.

In our model, the biaffine scorer uses both the forward and backward character information on either side of the gap to distinguish the position of characters. Figure 3 is an example of gap labeling. The bidirectional scoring ensures that the boundaries of words can be determined by adjacent characters with different directional information. The score vector of the gap is formed by the probability of being a boundary of word. Further, the model generates all boundaries using activation function in a greedy decoding way.

3.3 Highway Connections via Hidden Layer

To smooth the training and fully exploit representations from hidden states, we additionally introduce two Highway connections (Srivastava et al., 2015) via a virtual hidden layer which is called Hidden Representations for Early Decoding (HiRED) in the middle of the Transformer encoder. In our model design, we always put the HiRED layer in the central position among all layers of the encoder, thus the HiRED layer divides each directional encoder (forward, backward or center) pipelines into two parts (front and rear) as shown in Figure 1.

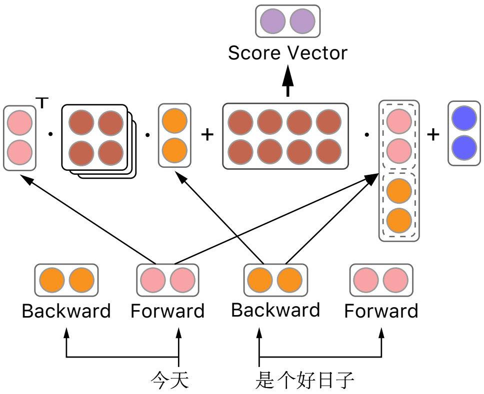


Figure 3: An example of biaffine scorer labeling the gap. The biaffine attention scorer only uses the forward information of front character and the backward information of character to label the gap.

For the highway connection specifications, the first connection (called Highway-I) respectively feeds the input embedding to the rear pipelines of the three directional encoders by adding into the embeddings from HiRED layer. Suppose that three front directional encoders respectively give encoding output, $r^{f'}$, $r^{c'}$ and $r^{b'}$. Then the corresponding three rear directional encoders will receive input as $e + r^{f'}$, $e + r^{c'}$ and $e + r^{b'}$. To feed the second connection (called Highway-O), we perform the same summing as the main encoder output,

$v^{b'} = r^{b'} + r^{c'}$, $v^{f'} = r^{f'} + r^{c'}$,

then let $v^{f'}$ and $v^{b'}$ as the HiRED output go through another same biaffine scorer and a decoder as that of the main encoder. The two decoder layers together give a sum loss for the entire model.

Biaffine attentin scorer makes it possible to generate a segmentation by using output of HiRED with little cost during training. With this segmentation, we add representation of characters which belong to the same word together and get a new vector, which plays a similar role as a word embedding. This vector will be fed to encoder layer behind HiRED directly. The operations in HiRED layer can also be viewed as one attention. It makes the model focus on adjacent characters which may be likely in one word.

3.4 Training Objective

The training target of our model is to let the biaffine attention scorer approach the the gold score vector according to the gold segmentation. We adopt cross entropy (CE) loss for training,

$$q_i^j = -s_{i,i+1}^j + \log(\exp(s_{i,i+1}^0) + \exp(s_{i,i+1}^1)),$$

$$CE = \frac{1}{l}\sum_{i=1}^{l}(q_i^1 p + q_i^0(1-p))$$

where q_i^j is the log-probability of the i-th gap labeled as $j \in \{1,0\}$. Here 1 indicates word boundary and 0 means not. $s_{i,i+1}^j$ is the biaffine score of i-th gap labeled as j. p is the ground-truth probability which can only be 0 or 1. l is the number of gaps in one input sentence.

4 Experiments

4.1 Experimental Settings

Data Our models are trained and evaluated on benchmark datasets from SIGHAN Bakeoff 2005 (Emerson, 2005) which has four datasets, PKU, MSR, AS and CITYU. Table 3 shows the statistics of train data. F-score is to evaluate the performance.

Embedding Initialization Our model only adopts unigram features, so we only train character embeddings. On closed test, we use embeddings initialized randomly. On open test, our character embeddings are pre-trained on Chinese Wikipedia corpus by word2vec (Mikolov et al., 2013) toolkit. The corpus for pre-training is converted to simplified Chinese[1] and trivially segmented into characters.

Hyperparameters Our hyperparameter settings are in Table 4. All the settings are tuned on development sets[2]. We set the standard deviation of Gaussian function in Eq. (2) to 2. Each training batch contains sentences with at most 4096 tokens.

Optimizer To train our model, we use the Adam (Kingma and Ba, 2015) optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$. The learning rate schedule is the same as (Vaswani et al., 2017):

$lr = d^{-0.5} \cdot \min(step^{-0.5}, step \cdot warmup_{step}^{-1.5})$
where d is the dimension of embeddings, $step$ is the step number of training and $warmup_{step}$ is the step number of warmup. When the number of step is smaller than the step of warmup, the learning rate increases linearly and then decreases.

Hardware and Implements Our models are trained on a single CPU (Intel i7-5960X) and an nVidia 1080 Ti GPU, in terms of an implementation using Pytorch 1.0[3].

4.2 Results

Tables 5 compares recent models and ours in terms of closed test setting, showing that our model achieves new state-of-the-art and outperforms all the other models in MSR and AS. In the meantime, our model can achieve state-of-the-art efficiency.

Our models are also compared to the latest neural models in terms of open test setting in which any external resources, especially pre-trained embeddings or language models are allowedly used. Table 6 shows that our models get comparable results in AS and MSR though unremarkable ones in CITYU and PKU.

However, it is well known that comparing models accurately is hard for open test setting. Though

external strengths like pre-trained embeddings or models can indeed improve the performance, it is difficult to determine which factor exactly makes such a contribution, the model itself, the resource or the better using of the resource. In terms of closed test setting, that is also the reason why this work keeps focusing on improvement of the model design itself.

	PKU	**MSR**	**AS**	**CITYU**

Our Method	95.5	97.7	95.7	96.4

Table 6: F1 scores in open test.

Compared with other LSTM models, our model performs better in AS and MSR than in CITYU and PKU. We attribute the performance difference to the impact of dataset sizes. Namely, the larger size is, the better model performs. For small corpus, the model tends to be overfitting.

Table 5 also shows the decoding time in different datasets. Our model finishes the segmentation with the least decoding time in all four datasets, thanks to the architecture of model which only takes attention mechanism as basic block, only adopts unigram features and a greedy decoding strategy from the very beginning.

4.3 Ablation Studies

This subsection presents ablation studies on MSR and PKU datasets to verify the benefits of each individual component in our model[4].

Gaussian-masked Directional Transformer. Table 7 gives the result of model with different Gaussian-masked directional self-attention. The third column and the fifth column are the difference of performance between GD-Transformer and other models. The results show that our full model GD-Transformer significantly outperforms the original Transformer by a large performance margin. Removing either Gaussian mask or directional mask will put negative impact over the performance of our model, which shows that both masks are indispensably necessary for our model performance.

-Directional mask	95.1	-0.3	97.4	-0.2
Transformer	94.1	-1.3	96.5	-1.1

Table 7: F1 scores on models removing different components from GD-Transformer.

Highway Connections. Table 8 gives the results of our model respectively removing the highway connections and the related HiRED layer part, which shows that each highway takes its contribution to the overall performance. However, the comparison shows that introducing all the components makes our model training much faster.

Directional Encoder. Table 9 gives the results of our models respectively removing the forward, center and backward encoders, which impacts performance of our model and shows that directional encoder and undirectional encoders are all indispensable for our model. The third column and the fifth column are the difference of performance between our full model and our models removing one encoder.

---

[4] Following (Cai et al., 2017), we show the results on the respective test set for either dataset, as SIGHAN Bakeoff did not provide official development sets.

Models	PKU		MSR	
	F_1	Training (hours)	F_1	Training (hours)
Our full model	95.5	33	97.6	15
-Highway-I	95.2	60	97.5	96
-Highway-O	95.3	45	97.4	102
-both highways	95.1	80	97.5	105

Table 9: F1 scores of results on model removing different encoder from model.

5 Conclusion

For Chinese word segmentation, upholding the belief that a better representation is all we need and thus taking a greedy decoder for fast segmentation as the basis, we only focus on the encoder design and propose an attention mechanism only based CWS model. Our model uses the proposed GD-Transformer encoder to take sequence input and biaffine attention scorer to directly predict the word boundaries. To improve the ability of capturing the localness and directional information, Gaussian-masked directional multi-head attention in the GD-Transformer replaces the standard self-attention in the original Transformer. With powerful enough encoding ability, our model only needs unigram features for scoring instead of various n-gram features in previous work. Our model is evaluated on standard benchmark SIGHAN Bakeoff datasets, which shows not only our model performs segmentation faster than any previous models but also gives new higher or comparable segmentation performance against previous state-of-the-art models.

Abstract

Word-level information is important in natural language processing (NLP), especially for the Chinese language due to its high linguistic complexity. Chinese word segmentation (CWS) is an essential task for Chinese downstream NLP tasks. Existing methods have already achieved a competitive performance for CWS on large-scale annotated corpora. However, the accuracy of the method will drop dramatically when it handles an unsegmented text with lots of out-of-vocabulary (OOV) words. In addition, there are many different segmentation criteria for addressing different requirements of downstream NLP tasks. Excessive amounts of models with saving different criteria will generate the explosive growth of the total parameters. To this end, we propose a joint multiple criteria model that shares all parameters to integrate different segmentation criteria into one model. Besides, we utilize a transfer learning method to improve the performance of OOV words. Our proposed method is evaluated by designing comprehensive experiments on multiple benchmark datasets (e.g., Bakeoff 2005, Bakeoff 2008 and SIGHAN 2010). Our method achieves the state-of-the-art performances on all datasets. Importantly, our method also shows a competitive practicability and generalization ability for the CWS task.

1 Introduction

In the extensive researches on natural language processing (NLP), most of the tasks are based on word-level methods because word is the smallest linguistic unit in natural languages. It has rich feature information. However, the situation is totally different when dealing with the Chinese language. There is not clearly delimiter between Chinese words, instead the blank space is regarded as a delimiter in most western languages. Different segmentation results may lead to different feature information. Thus, Chinese word segmentation (CWS) is an essential task, which will significantly affect the effectiveness of downstream Chinese NLP tasks. Recently, the approaches for CWS have already achieved a good performance in large-scale annotated corpora, as reported by related researches (Huang and Zhao, 2007; Zhao et al., 2019). Most of the effective approaches fall into two major research fields: the statistical machine learning method and the neural network method. The former is mainly based on Conditional Random Fields (CRF), which is considered as the most effective statistical machine learning method for CWS (Zhao and Kit, 2008; Zhao et al., 2010). However, the statistical machine learning method always heavily relies on hand-craft features. To minimize the efforts in feature engineering, more and more researches are focus on neural network method (Pei et al., 2014; Chen et al., 2015a,b). Furthermore, following the rapid development of neural network models, variations on neural network methods for CWS have already gained comparable results as the state-of-the-art statistical machine learning techniques (Cai et al., 2017; Zhou et al., 2017; Ma et al., 2018; Meng et al., 2019).

Table 1: Illustration of different segmentation criteria on three popular datasets

Nevertheless, there are still two important issues on the CWS task. One important issue is that almost all effective methods are limited by large-scale annotated corpora, these methods will lead to a weak generalization ability. The results may decline rapidly when the methods deal with

a cross-domain situation. Since there are many out-of-vocabulary (OOV) words in cross-domain scenarios, and the character feature information is different in another unrelated domain. For example, the Chinese character "莫(Mo/not to do)" is always trained as a surname of Chinese people in most domains, especially when a slice "莫言(Mo Yan/not to say)" appears in a sentence, it probably should be a Chinese person who won the Nobel Prize for literature. However, the situation is totally different in the Chinese novel. In Chinese novel domain, "莫(Mo/not to do)" always means "not to do something". When the slice "莫言(Mo Yan/not to say)" appears in a famous Chinese novel, the meaning of "莫言(Mo Yan/not to say)" is "do/does not to say" definitely. The current methods hardly segment it correctly because of the low generalization ability and robustness. The other important issue is that Chinese word segmentation criterion is multiple, and most novel methods depend on large-scale corpora. If the large-scale corpora have different criteria, which are shown in Table 1, the method that is trained by a heterogeneous criterion corpus is hard to segment correctly. In the previous researches, the usual solutions are to train different models to adapt to multiple segmentation criteria.

In this paper, we propose a joint multiple criteria method for both standard and cross-domain simplified Chinese word segmentation. The method utilizes a novel pre-trained (RoBERTa-WWM) model (Cui et al., 2019), which adequately trained a rich Chinese character vector embedding. With the richness of the pre-trained model, our method for CWS can obtain a robust generalization ability to deal with the cross-domain situation. In order to further improve the performance of the model, we consider improving the amount of training data through the process of transfer learning. We adopt a strategy that integrates several different segmentation criteria into a single straightforward model. The benefit is that we do not need many models to fit multiple segmentation criteria, and the method improves the amount of training data in disguised simultaneously.

To sum up, the contributions of this paper are as follows.

- We present a straightforward transfer learning method based on RoBERTa to solve CWS problems mentioned above, and make use of the rich pre-trained model that extracted abundant feature information and linguistic context, making the word-formation ability of the model strong. The method achieves state-of-the art performance on in-domain and cross-domain CWS benchmarks.
- There is a large number of parameters in the RoBERTa-based model. We share all the parameters without complex neural network architectures in the training step. It can control the explosive growth of the total parameters while improves the performances on several datasets for CWS.
- Our proposed method is straightforward and effective. We do not need to devise much manual information such as lexicon, n-gram feature, and statistical information. It matches with the benefits of neural network properly.

2 Related Work

Since Xue (2003) first formalizes CWS task as a sequence labeling problem, many researches depending on supervised machine learning methods have already achieved good performance for CWS. Peng et al. (2004) utilized the CRF methods for CWS, since then CRF became the most popular machine learning method for CWS task. Variations of CRF based model achieved good performances for CWS (Tseng et al., 2005; Zhao and Kit, 2008; Zhao et al., 2010; Sun et al., 2012; Zhang et al., 2013). With the development of neural network, more and more researchers made gradual progress with a wide range of neural methods (Zheng et al., 2013; Pei et al., 2014; Chen et al., 2015a,b; Cai and Zhao, 2016; Cai et al., 2017), and the performances on neural methods have already approximated state-of-the-art performances on statistical methods.

Neural network methods can incorporate the information in the model easily and effectively by means of automatic feature extraction. Thus, it is possible to train multiple segmentation criteria into a single model well with neural network methods while it is a challenge on previous statistical methods. Chen et al. (2017) was first to propose a multi-criteria learning method for CWS, in which the method adopted shared layers and private layers. However, there is still a gap with independent segmentation criterion method. He et al. (2018) improved the performance on the same base Bi-LSTM (bidirectional Long Short-Term Memory Network) (Graves and Schmidhuber, 2005) model, it adopted a simple and effective method to integrate differ-

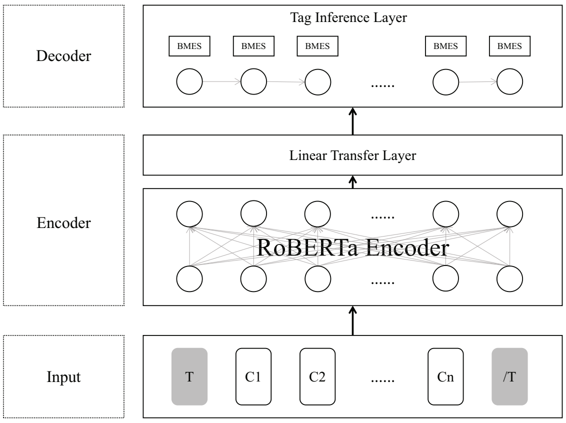

Figure 1: An overview of proposed model architecture.

ent segmentation criteria by adding two tags in a sentence (Johnson et al., 2017). Qiu et al. (2019) changed the base model to Transformer (Vaswani et al., 2017), and Huang et al. (2019) utilized BERT (Devlin et al., 2018) that is based on Transformer to extract feature information. Both of these two methods achieved the state-of-the-art performances on benchmark datasets.

The approaches mentioned above mainly focus on in-domain benchmarks, and there is still much room for improvement using the neural network method (Huang et al., 2017; Zhang et al., 2018; Zhao et al., 2018; Ye et al., 2019). Most of these methods leverage external resources to alleviate the OOV issue. Our proposed method is inspired by this thought, and uses rich pre-trained embeddings to relieve the weakness in cross-domain. The method not only solves the multiple segmentation criteria issue with a straightforward architecture, but also solves the cross-domain CWS problem. With the help of the pre-trained embedding, the transfer learning method does not need to learn from scratch, and has a robust generalization ability.

3 Model Architecture

Figure 1 shows our proposed model architecture which is quite brief. We do not pay attention to complicating the neural network. Meanwhile, the strategy of integrating criteria is first proposed on Johnson et al. (2017) for machine translation transfers multiple segmentation criteria into one model with minimal effort.

3.1 Encode Layer

According to Ma et al. (2018), the complexity of a neural network for CWS can hardly affect the performance since the CWS is a task on the superficial linguistic representation. The features of the characters are shallow. There will be a competitive performance on simple neural network architecture. The real factor that leads to the gap of CWS task is under-training instead of bad-training. Thus, we utilize the Whole Word Masking RoBERTa model, which is trained by large unlabeled Chinese data.

The input of encode layer consists of three parts that are token embedding $\mathbf{E}_t$, position embedding $\mathbf{E}_p$ and segment embedding $\mathbf{E}_s$. Given a character sentence $C = \{C_1C_2C_3...C_{n-2}C_{n-1}C_n\}$ as the input. The position sequence of the input is $P = \{P_1P_2P_3...P_{n-2}P_{n-1}P_n\}$. The sequence is converted to a vector matrix $\mathbf{E}_t$. P is also mapped into a feature matrix $\mathbf{E}_p$. Because of the specificity for CWS, all segment embeddings of the sequences are regarded as the same mapping relation $\mathbf{E}_s$. The input is

$$\mathbf{E}_{input} = E_t + E_p + E_s \tag{1}$$

The encode layer consists of several transformer encoders(Vaswani et al., 2017), and it is bidirectional. The transformer encoder utilizes several multi-head self-attention layers to extract the contextual feature for each character. The multi-head self-attention layer adopts "Scaled Dot-Product Attention" to compute representation. The "Scaled Dot-Product Attention" function is:

$$Attention\,(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \tag{2}$$

where Q, K, V represents a query and a set of key-value pairs through a linear transformation respectively, and d_k is the dimension of K.

Instead of performing a single attention function, the multi-head self-attention layer can extract contextual features from different representation spaces. Given an input sequence of vector $E_{input} \in \mathbb{R}^{L*d_{model}}$, where L is the length of the sequence, and d_{model} is the dimension of it. A multi-head self-attention layer is:

$$MultiHead\,(E_{input}) = [head_1, ..., head_k]\,W^O \tag{3}$$

$$head_i = Attention\left(E_{input}W_i^Q, E_{input}W_i^K, E_{input}W_i^V\right) \tag{4}$$

where W^O, W_i^Q, W_i^K, W_i^V are trainable parameters. And a layer normalization is adopted in the end of each multi-head self-attention layer.

With the rich pre-trained model, the trainable parameters have already been covered with a wealth of character information in the hidden states. These feature information could compensate for the weaknesses of unknown characters. To adapt the pre-trained model to CWS, we utilize a linear transfer layer to integrate the hidden states into CWS.

3.2 Multiple Criteria on Solution

There are many parameters in the pre-trained model, so it would be impractical to train different models for dealing with different criteria and domains. Inspired by the similarity with the method, it needs to integrate different languages into one model. Our proposed strategy considers criteria as languages. The straightforward and effective method is that each of the input sentences attaches a pair of tag identifiers $< tag > and < /tag >$ at the beginning and end of the sentence respectively. tag represents the specific criterion or domain. For instance, if an input sentence C belongs to "PKU" datasets, the sentence changes into $< pku > C < /pku >$ as the input of encode layer. These specific identifiers can affect the contextual representation within the scope of the sentence. It is similar to domain-aware protection, making the correct decision matching criterion or domain of the unsegmented sentence. We do not pay attention to producing external computing. And it will save much room for creating model architectures.

3.3 Tag Inference

According to Xue (2003), our proposed method also converts CWS task to a character based sequence labeling problem. One commonly used labeling set is a 4-tag set $T = \{B, M, E, S\}$, representing the **b**egin, **m**iddle, **e**nd of a word, or a **s**ingle character forming a word. The aim of the character based sequence labeling task is to find the most possible path of $Y^* = \{Y_1 Y_2 ... Y_{n-1} Y_n\}$:

$$Y^* = \underset{Y \in T^n}{argmax}\, p\,(Y|X) \tag{5}$$

hidden state size	768
optimizer	Bert Adam
learning rate	uniform-float[1e-5,**2e-5**,1e-4]
batch size	uniform-integer[16,32,**64**]
dropout	uniform-float[**0.1**,0.2,0.3,0.5]
epochs	15

Table 3: The hyper-parameters settings, the best assignments are highlighted.

In the previous methods, many researchers adopted a CRF decode layer to improve the performance for sequence labeling task (Lample et al., 2016). In particular, the core algorithm of the neural CRF layer is a transition matrix during the decode step. The transition matrix can learn constraint rules between two tags in order to enhance accuracy. It is effective for most complicated NLP tasks. However, the ability of improving accuracy is limited by utilizing the CRF layer because there is a high accuracy of each character tag itself on our model. Meanwhile CRF layer will have larger time complexity and space complexity. So we utilize a lightweight decode layer $Softmax$, which increases smaller time complexity. The loss function is cross-entropy:

$$Loss\,(y, y^*) = -\sum_{x} y(x) log y^*(x) \tag{6}$$

where y denotes the gold sequence labeling, y^* denotes the output of decode layer.

4 Experiment

4.1 Datasets and Experimental Setup

For verifying the high performance of the joint multiple criteria model in transfer learning for in-domain and cross-domain CWS, we do comparative experiments on several simplified Chinese

Models		PKU	MSRA	CTB	CNC	UDC	SXU	ZX	Avg.In4

Table 4: The results on test data of 7 standard CWS datasets. Here, F and R_{oov} represent F1 value and the recall of OOV words respectively. "Avg.In4" is the average of PKU, MSRA, CTB and SXU. The maximum values of evaluation are highlighted for each dataset.

datasets, including Bakeoff 2005, Bakeoff 2008, SIGHAN 2010 (cross-domain datasets), and other open datasets. The sizes of corpora are shown in Table 2. We randomly pick 10% sentences from the training data as the development data for model tuning. Similar to a previous paper (Cai et al., 2017), we convert all digits, punctuation, and Latin letters to half-width, dealing with the full/half-width mismatch between training and test data. The continuous Latin characters and digits are generalized to a unique token. Note that there is no training data for the cross-domain datasets, so the tag of cross-domain datasets is set to PKU which is the most similar to them.

4.2 Multiple Criteria Result

We follow the majority of hyper-parameters of the original RoBERTa-WWM model, adjusting a few crucial hyper-parameters. The hypter-parameters and search ranges that are shown in Table 3. We deploy the model on GPU(Nvidia Tesla K40c). One epoch with 1.7M tokens costs about 6 hours in the training step. Our implementation is based on Pytorch (Wolf et al., 2019; Paszke et al., 2019), a dynamic neural graph framework for deep learning.[1]

Table 4 shows the results of both single criterion method and multiple criteria method on several benchmark datasets.

We first compare our method with the previous popular methods. Three of them are based on LSTM neural architecture (Chen et al., 2017; He et al., 2018; Gong et al., 2019). Our method and Qiu et al. (2019) are based on Transformer. It is observed that the performance on Transformer is better than it on LSTM from the table. In particular, our method utilizes the pre-trained embedding that is more effective on all seven simplified Chinese benchmark datasets. A full-training language model can improve the generalization ability and robustness of model.

Furthermore, our proposed method adopts a strategy to integrate all training datasets into one model.

---

Table 6: The results by adopting differnt layers of the pre-trained model on PKU. Here "P" is the precision, "R" is the recall, "F" is the F1-value and "R_{oov}" is the recall of OOV words.

It not only reduces the sum of parameters by N (the number of different segmentation criteria) times, but also improves the performances slightly on four (PKU, MSRA, CTB, SXU) of seven datasets. The most important thing is that the knowledge of multiple segmentation criteria is merged together by our method. We also compared some open datasets with He et al. (2018). Our proposed method has a significant improvement compared to the previous works. Note that the R_{oov} of CNC is relatively lower than others. One possible reason is that the training set of CNC is extensive, the OOV words are almost the unconventional words. It is challenging to segment them on current technology. The other possible reason is that there are some errors in the corpus itself.

4.3 Cross-domain Result

We compare our model with the previous effective methods for cross-domain CWS, shown in Table 5. No matching development set is provided for the cross-domain datasets, so we follow hyper-parameters of PKU set. Both of statistical method (non-DL) and neural network method (DL) have competitive performances on cross-domain datasets. However, according to the results in Table 5, it is observed that neural CWS methods fall short of the performances compared with statistical methods in the previous works. With external resources, some neural CWS methods are close to the previous state-of-the-art performances for cross-domain CWS (Zhao et al., 2018; Zhang et al., 2018). For verifying the contribution of the pre-trained model, we adopt a popular neural architecture (Bi-LSTM) as the baseline model, and utilize the pre-trained embedding based on the baseline model to improve the performance. The difference between these two methods reflects the role of pre-trained embedding partly. It effectively alleviates the OOV issue by using rich pre-trained embedding instead of modifying the model architecture. From the results, the pre-trained method has already achieved the best performance of statistical methods. It supplies a gap on a pure neural CWS model that does not utilize any external resources. Our proposed transfer learning method not only takes full advantages of pre-trained embedding, but also adopts a strategy to increase the scale of training sample in disguise. As we know, the scale of training samples is the key to improve the performance with neural methods. Our method has achieved state-of-the-art performance compared with the previous non-DL and DL methods on all of four cross-domain SIGHAN 2010 datasets.

Methods	PKU	MSRA

Ma et al. (2018)	96.1	97.4
Huang et al. (2019)	96.6	97.9
Meng et al. (2019)	96.7	**98.3**
Ours	**96.9**	**98.3**

Table 7: The F1-values on PKU and MSRA Bakeoff 2005 datasets. The maximum values of evaluation are highlighted for each column.

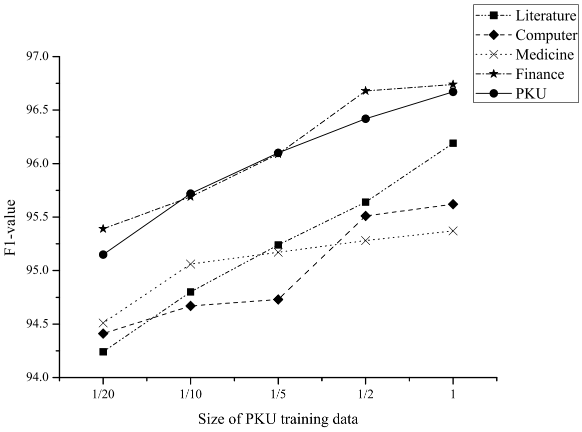

Figure 2: The F1-values of our method on PKU and cross-domain SIGHAN 2010 datasets. The X-axis represents the size of training set, the Y-axis represents the F1-values. The icons of different datasets are described at the top right of the figure.

4.4 Generalization Ability

Most of the present neural CWS methods adopt the pre-trained embedding to avoid the OOV problem. To varying degrees, the pre-trained embedding improves the performances of the neural CWS method. In other words, how to utilize the pre-trained embedding is a key to enhance the generalization ability of a neural CWS method. We adopt several types of pre-trained embeddings, the results are shown in Table 6. Indeed, the different pre-trained embeddings improve the performance of the baseline model. However, our method that utilizes the concept of transfer learning improves the generalization ability more forcefully. In particular, the performances of our method on PKU and MSRA benchmark datasets are state-of-the-art, shown in Table 7.

Another influencing factor of a supervised neural method is the size of the training set. In particular, the Transformer needs a large size of the training set more than other previous neural architectures. We utilize different sizes of PKU training data to evaluate the performances on 5 datasets that include four cross-domain datasets and a PKU benchmark dataset, shown in Figure 2. It is observed that there is a better performance on a larger size of the training set. In other words, we can enhance the generalization ability by adding training data. Under the premise of not adding manual annotation, we might utilize the multiple criteria available to make the model more robust. According to the results of several experiments, our method shows a competitive practicability and generalization ability.

4.5 Error Analysis

In order to guide future research directions for Chinese word segmentation, we analyze three typical types of errors in our method by manual and non-manual.

The first one is that there are many errors due to annotation inconsistency or annotation errors. For instance, the word “操作系统(operating system)” occurs nine times annotated as “操作(operate)+系统(system)” and more than ten times as “操作系统(operating system)” in the same context. There are many similar situations in the corpora through the consistency checking. Besides, “国故(national cultural heritage)” should be regarded as a word that is even difficult for a Chinese to understand. In the context “他通过整理国故而帮助建立了学说”(He established a doctrine by concluding national cultural heritage), the gold result is given as “他(He)/通过(pass by)/整理(conclude)/国(nation)/故(heritage)/而(while)/帮助(help)/建立(establish)/了(an empty word)/学说(doctrine)”. Furthermore, the word “国故(national cultural heritage)” is separated into two single words. Words that are difficult to understand are high probability wrong in gold results. Unfortunately, These errors come from the original corpus itself, so we argue that it is not an algorithm problem. It might be proceeded with amending the corpus.

The second one is that the model hesitates when a prefix/suffix might be an independent single word. For instance, “案(file)” is a suffix word, frequently appeared in a word together with another two characters like “修正案(amendment)” and “走私案(smuggling case)”. When the model predicts “犯罪(crime)案(case)”, it is great probability to merge them together incorrectly. Similarly, the prefix/suffix problem is trapped in the issue of consistency commonly.

The last one is that the performances of the longer OOV words are unsatisfactory. In particular, some longer personal names that do not contain clearly feature information are hard to segment. Unlike "约翰大卫(John David)" and "柴可夫斯基(Tchaikovsky)" that are obviously treated as an English name and a Russian name, the sequence of "山(mountain)鹿(deer)素(element)行(walk)" is segmented as four single words, while it is a Japanese researcher (Yamaga Sokou). In addition, the errors not only limit to personal names, but also distinguish the word boundary incorrectly. Should "国营企业(state-owned enterprise)" be segmented as one word or two words "国营(state-owned)+企业(enterprise)"? It is hard to segment correctly for human, the model absolutely struggles to distinguish the boundary.

5 Conclusion

In this paper, we construct a transfer layer structure that leverages the pre-trained feature information for CWS and exploit a transfer tag to boost joint multiple criteria learning. The model could relieve the OOV problem for Chinese word segmentation and achieves the best performance in comparison with state-of-the-art techniques for both in-domain and out-of-domain Chinese word segmentation. Extensive experiments on seven in-domain and four cross-domain datasets for Chinese word segmentation confirm the superiority of our model over all other advanced methods. In summary, the advantages of our model are twofold. First, the model has a stronger robustness with a straightforward transfer learning method. The performance of our model is better, especially when dealing with high OOV rate data. Second, our model effectively solves the parameters exploding due to different segmentation criteria. We do not need to design any redundant structures. Nevertheless, there is still a gap in a real-word situation. In the future, we will continue studying the efficiency of the neural architecture, and pay attention to improving the speed of both training and testing steps on an ever-increasing dataset. In particular, we will enhance the practicability of Chinese word segmentation to improve the effectiveness of other downstream Chinese NLP tasks.

Abstract

Cross-lingual semantic role labeling (SRL) aims at leveraging resources in a source language to minimize the effort required to construct annotations or models for a new target language. Recent approaches rely on word alignments, machine translation engines, or preprocessing tools such as parsers or taggers. We propose a cross-lingual SRL model which only requires annotations in a source language and access to raw text in the form of a parallel corpus. The backbone of our model is an LSTM-based semantic role labeler jointly trained with a semantic role compressor and multilingual word embeddings. The compressor collects useful information from the output of the semantic role labeler, filtering noisy and conflicting evidence. It lives in a multilingual embedding space and provides direct supervision for predicting semantic roles in the target language. Results on the Universal Proposition Bank and manually annotated datasets show that our method is highly effective, even against systems utilizing supervised features.[1]

1 Introduction

Semantic role labeling (SRL) is the task of identifying the arguments of semantic predicates in a sentence and labeling them with a set of predefined relations (e.g., "who" did "what" to "whom," "when," and "where"). It has emerged as an important technology for a wide spectrum of applications ranging from machine translation (Aziz et al., 2011; Marcheggiani et al., 2018) to information extraction (Christensen et al., 2011), and summarization (Khan et al., 2015).

There have been considerable efforts on developing annotated resources for semantic role labeling (Palmer et al., 2005; Zaghouani et al., 2010) which in turn have greatly facilitated the development of the various models designed to automatically predict semantic roles. Recent years have seen the successful application of neural network models to SRL (Zhou and Xu, 2015; He et al., 2017; Marcheggiani et al., 2017) which forego the need for extensive feature engineering. Despite recent advances in representational learning, a perennial problem with building SLR systems lies in the paucity of training data since semantic role annotations are available for only a handful of the world's languages. As a result, much previous work has focused on *cross-lingual* SRL which aims at leveraging existing resources in a source language to minimize the effort required to construct a model or annotations for a new target language.

Annotation projection is a popular approach which transfers annotations from a source to a target language via automatic word alignments (Padó and Lapata, 2005; van der Plas et al., 2011; Aminian et al., 2019). Although very intuitive, it is sensitive to the quality of the parallel data, the performance of the source-language SRL model, and the accuracy of alignment tools, all of which introduce noise. *Translation-based* approaches (Täckström et al., 2012; Fei et al., 2020; Rasooli and Collins, 2015) aim to alleviate the noise brought by the the source-side labeler by directly translating the gold-standard data into the target language. A third alternative is *model transfer* where a source-language model is modified in a way that it can be directly applied to a new language, e.g., by employing cross-lingual word representations (Täckström et al., 2012; Swayamdipta et al., 2016; Daza and Frank, 2019a) and universal POS tags (McDonald et al., 2013).

Word alignment noise poses serious problems for both annotation-projection and translation-based methods (the latter still rely on alignment tools to transfer word-level labels from source to

---

target). For example, there could be many-to-one alignments, leading to semantic role conflicts in the target language. Some form of filtering is often introduced to reduce the impact of this noise, e.g., parallel sentence pairs are discarded according to projection density (Aminian et al., 2019) or alignment confidence (Fei et al., 2020). In addition, translation-based approaches rely on high performance translation engines, which are often trained on large-scale parallel corpora. Unfortunately, neither adequate MT nor high-quality parallel data can be guaranteed when dealing with low-resource languages. Model transfer is an appealing alternative, however, it relies on accurate features based on lemmas, POS tags, and syntactic parse trees (Kozhevnikov and Titov, 2013; Fei et al., 2020) which are themselves obtained with access to additional annotation. It is not realistic to assume that treebank-style resources will be available for low-resource languages.

In this paper, we propose a novel method for cross-lingual SRL which does not rely on word alignments, machine translation or pre-processing tools such as parsers or taggers. Aside from semantic role annotations in the source language, we only assume access to raw text in the form of a parallel corpus. The backbone of our model is an LSTM-based semantic role labeler jointly trained with multi-lingual word embeddings and a semantic role compressor. The compressor distills useful information pertaining to arguments, predicates and their roles from the output of the semantic role labeler (e.g., by automatically filtering unrelated or conflicting information). Importantly, the compressor lives in a multilingual space and can provide direct supervision for predicting semantic roles in the target language, sidestepping intermediaries like word-level alignments and machine translation.

For evaluation, we make use of several multilingual benchmarks. These include the Universal Proposition Bank (UPB; Akbik et al. 2016), a recently released resource which contains semi-automatically created annotations under a unified labeling scheme for several languages, and a French corpus (van der Plas et al., 2010) which follows PropBank-style annotations (Palmer et al., 2005). We also release two additional manually labeled resources in Chinese and German, which we hope will be useful for future research.[2] Experimental results show that our method is highly effective across languages and annotation schemes, even compared against systems making use of supervised features.

Our contributions can be summarizes as follows: (a) we propose a knowledge-lean model which does not rely on alignments, machine translation or sophisticated linguistic preprocessing; (b) we introduce the concept semantic role compressor which is important at filtering noisy information and can be potentially useful for other crosslingual tasks (e.g., dependency parsing); (3) we release two manually annotated datasets which will further advance cross-lingual semantic role labeling complementing previous work (Aminian et al., 2019; Fei et al., 2020) which reports result on semi-automatically created annotations).

2 Model

Figure 1 provides a schematic overview of our model. We assume we have access to semantic role annotations in a source language (e.g., English) and a parallel corpus of source-target sentences (e.g., English-French). Our model is jointly trained to predict semantic roles in the source *and* target languages. It has two main components, namely a semantic role *labeler*, and a semantic role *compressor*. The role labeler consists of:

- an input layer which takes *multilingual* word embeddings and predicate indicator embeddings as input;
- a bidirectional LSTM (BiLSTM) encoder which takes as input the representation of each word in a sentence and produces context-dependent representations;
- a biaffine scorer to calculate the score of each semantic role for each word.

While the semantic role compressor consists of:

- an input layer which again combines multilingual word embeddings and semantic role distributions for each word in the sentence;
- a bidirectional LSTM (BiLSTM) encoder which produces compressed semantic role information for an input sentence;
- a biaffine scorer which calculates the similarity between compressed representations of semantic roles and input words.

In the following sections we describe these two components more formally.

---

[2] Our annotations are available from `https://github.com/RuiCaiNLP/ZH_DE_Datasets`.

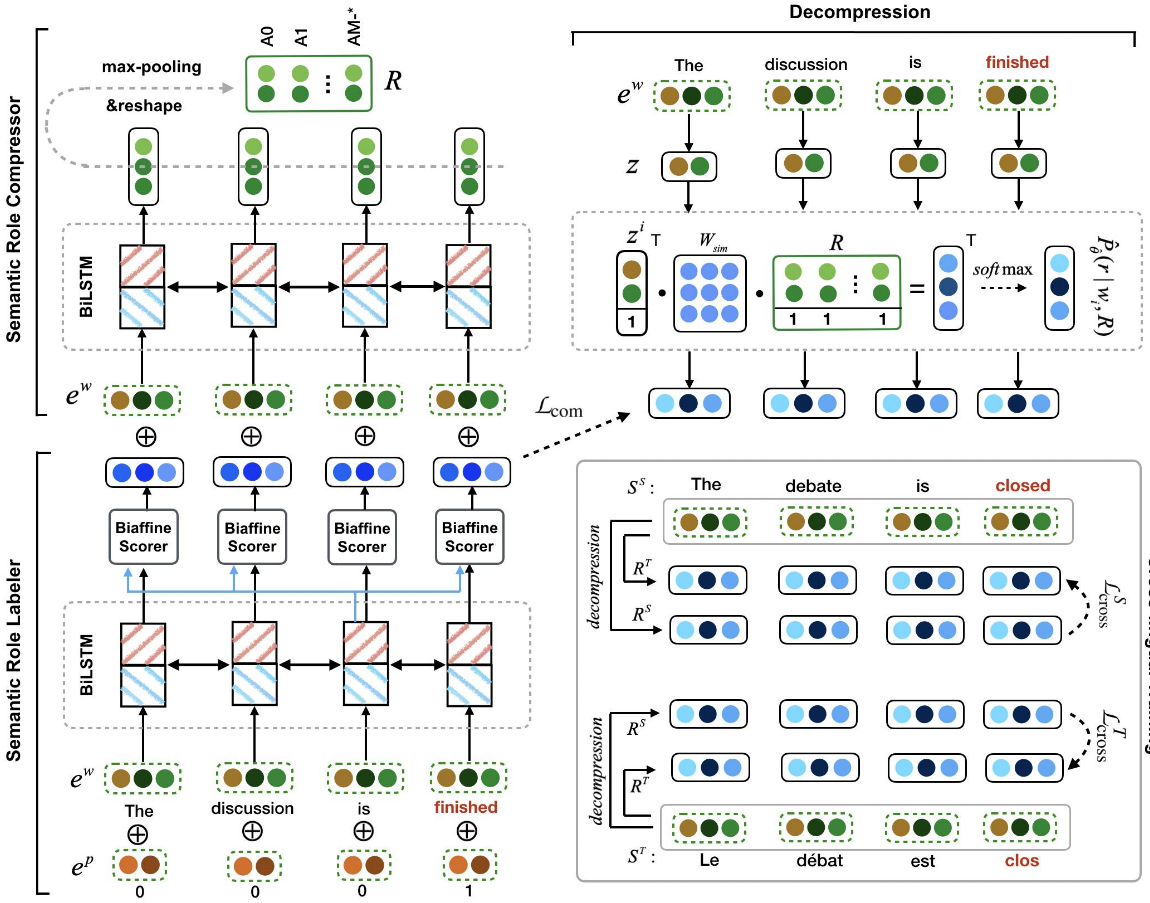

Figure 1: Model overview: semantic role labeler (left-bottom) and semantic role compressor (left-top). The right-top part presents the process of decompression after obtaining R. The right-bottom part illustrates cross-lingual training given an English-French sentence pair (S^S and S^T) from the Europarl parallel Corpus, where R^S and R^T are the output of the compressor taking S^S and S^T as input, respectively. Best viewed in color.

2.1 Semantic Role Labeler

Input Layer and Encoder For each sentence, the representation of i-th word w_i is the concatenation of *multilingual* contextualized word embeddings $e^w_{w_i}$ and *predicate* indicator embedding $e^p_{w_i}$. The former are pretrained on a large-scale unlabeled corpus and their parameters stay frozen during the training of our model. Predicate embeddings are randomly initialized and updated constantly during model training. Unlike previous supervised SRL approaches (Roth and Lapata, 2016; Cai and Lapata, 2019; He et al., 2019), our model does not make use of any syntactic information (e.g., POS-tags, dependency relations) since we cannot assume it will be available for low-resource languages.

Following Marcheggiani et al. (2017), sentences are represented using a multi-layer bi-directional LSTM (Hochreiter and Schmidhuber, 1997); the BiLSTM receives at time step t representation x for each word and recursively computes two hidden states, one for the forward pass ($\overrightarrow{h}_t$), and another one for the backward pass ($\overleftarrow{h}_t$). Each word is the concatenation of its forward and backward LSTM state vectors $h_t = \overrightarrow{h}_t \circ \overleftarrow{h}_t$.

Biaffine Role Scorer Once the high-level BiLSTM encoder produces representations h for each word, two distinct non-linear transformations are applied to predicate w_p (being considered at the time) and word w_i, respectively:

$$\begin{aligned} h'_{w_p} &= f(W_p h_{w_p} + b_p) \\ h'_{w_i} &= f(W_w h_{w_i} + b_w) \end{aligned} \tag{1}$$

where f is a non-linear activation function (we use Leaky ReLu). The score $s(r_j, h'_{w_i}, h'_{w_p})$ of semantic role r_j between current predicate w_p and word w_i is calculated as:

$$\begin{aligned} s(r_j, h'_{w_i}, h'_{w_p}) = {} & h'^{\top}_{w_i} W_{r_j} h'_{w_p} \\ & + U_{r_j}(h'_{w_i} \circ h'_{w_p}) + b_{r_j} \end{aligned} \tag{2}$$

where W_{r_j}, U_{r_j}, and b_{r_j} are parameters specific to role r_j, and are updated during training.

Both the binaffine role scorer and SRL encoder are illustrated in Figure 1 (bottom left part).

Predicate Identification and Disambiguation The SRL labeler presented thus far assumes that predicates are known. Although in most SRL datasets predicates are explicitly annotated, such annotations are absent from unlabeled parallel data, and our model would need to automatically identify predicates if it were to be useful in practice. To this end, we run two modules on top of the sentence encoder in order to identify the predicate and disambiguate its senses. Each module is a multilayer perceptron (MLP) with a softmax layer, and is trained jointly with semantic role labeler.

2.2 Semantic Role Compressor

The semantic role compressor operates over the output of the semantic role labeler; it aims to relate each semantic role to specific words and compress this information into a fixed-size matrix.

Semantic Information Compression Although the semantic role labeler produces a label for each word in the sentence, most words will bear the label "NULL", which indicates that they are not arguments of the predicate of interest. In order to provide useful supervision to the target language, we filter out information about non-argument words. Specifically, we compress the output of the semantic role labeler into a hidden representation which only records information about arguments. In theory, each semantic role appears no more than once in a sentence, so we propose to use a fixed-size matrix $R \in \mathbb{R}^{n_r \times d_r}$ to represent compressed information, where n_r is the size of semantic role set, and d_r denotes the length of hidden representation for each semantic role.

The semantic role compressor will bind word w_i to its corresponding role. Like the semantic role labeler, the compressor also operates over word embeddings (see upper left part in Figure 1); for sentence S, word w_i is represented by $P_\theta(r|w_i, w_p, S) \circ e^w_{w_i}$, where $e^w_{w_i}$ is the multilingual embedding of w_i, and $P_\theta(r|w_i, w_p, S)$ is the probability distribution over roles produced by the semantic role labeler:

$$\begin{aligned} P_\theta(r|w_i, w_p, S) = \text{softmax}\{&s(r_1, h'_{w_i}, h'_{w_p}), \\ &\ldots, s(r_{n_r}, h'_{w_i}, h'_{w_p})\} \end{aligned} \quad (3)$$

where θ are the parameters of the semantic role labeler. Analogously to the semantic role labeler, a multi-layer BiLSTM yields sentence representations (see upper block in Figure 1). At time step t, forward and backward hidden states $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$ are concatenated and then fed to a non-linear layer. A max-pooling layer thereafter gathers global information from hidden features at each time step, and compresses them into a fixed-size vector:

$$R = \max_{t=1}^{n} f(W_1[\overrightarrow{h}_t \circ \overleftarrow{h}_t] + b_1) \quad (4)$$

where W_1 is a weight matrix, b_1 is a bias term for the hidden state vector, and n is the length of sentence. For the sake of decompression (see next section), R is reshaped from a vector into a matrix with n_r rows and d_r columns (see very top in Figure 1, left side).

Decompression Semantic roles in a sentence can be obtained by combining compressed information in R with the multilingual embedding of each word, and this process is referred to as decompression. Concretely, for i-th word and j-th role, we use a biaffine scorer[3] to calculate the similarity between $e^w_{w_i}$ and R_j. We first perform a non-linear transformation for word embedding $e^w_{w_i}$:

$$z_i = f(W_2 e^w_{w_i} + b_2) \quad (5)$$

where z_i contains hidden features for word w_i. And then, use a biaffine scorer to calculate the similarity score between z_i and R_j:

$$\begin{aligned} \hat{s}(z_i, R_j) &= z_i \top W_{sim} R_j \\ &+ U_{sim}(z_i \circ R_j) + b_{sim} \end{aligned} \quad (6)$$

where W_{sim}, U_{sim}, and b_{sim} are parameters updated during training. For word w_i, the final probability distribution over semantic roles is obtained by applying a softmax operation on the scores of all semantic roles:

$$\begin{aligned} \hat{P}_{\hat{\theta}}(r|w_i, R) = \text{softmax}\{&\hat{s}(z_i, R_1), \\ &\ldots, \hat{s}(z_i, R_{n_r})\} \end{aligned} \quad (7)$$

where $\hat{\theta}$ are the parameters of the compressor. Figure 1 (right upper part) illustrates decompression.

Gaussian Noise In order to improve the robustness of the compressor, we inject Gaussian noise to word embeddings. This is an effective regularization method (Liu et al., 2019) which improves

---

[3] The score for the label "NULL" is fixed to 0, as R does not record information for non-argument words.

the model's ability to generalize to unseen inputs from different languages. The final embeddings are: $e^w = [e^w_{w_1} + N_1, \ldots, e^w_{w_n} + N_n]$, where $\mathbf{N} \sim \mathcal{N}(0, 0.1\mathbf{I})$ and n is the length of the sentence.

2.3 Training

In our learning setting, semantic role annotations are only available in the source-language. We therefore rely on (unlabeled) parallel data to provide cross-lingual supervision for the target-language. During each iteration, we randomly select a batch from the annotated source-language for supervised training and a batch from the parallel data for cross-lingual training.

Supervised Training We train the semantic role labeler in the source language in a supervised fashion, using a cross-entropy loss objective:

$$\mathcal{L}_{\text{ce}} = \frac{1}{n}\sum_{i=1}^{n} t_i \log P_\theta(r|w_i, w_p, S) \tag{8}$$

where n is the length of sentence and $t_i \in \mathbb{R}^{n_r}$ are one-hot ground truth representations. When training the compressor network, the objective is defined as the KL-divergence between the input distribution (produced by semantic role labeler) and the output distribution of the compressor:

$$\mathcal{L}_{\text{com}} = \frac{1}{n}\sum_{i=1}^{n} D(P_\theta(r|w_i, w_p, S), \hat{P}_{\hat{\theta}}(r|w_i, R)) \tag{9}$$

where D is a distance function between probability distributions (we use the Kullback-Leibler divergence). The final objective $\mathcal{L}_{\text{sup}}$ for supervised learning is the sum of $\mathcal{L}_{\text{ce}}$ and $\mathcal{L}_{\text{com}}$.

Cross-lingual Training Given an *unlabeled* parallel source-target sentence pair (S^S and S^T), we first perform predicate identification on both sentences and randomly choose a predicate w_p^S in S^S as the current predicate of interest. We then find, amongst all words identified as predicates in S^T, predicate w_p^T which has the highest word embedding similarity with w_p^S.

Table 1: Annotated data used in our experiments. We show the English source annotations (left column) used for *training* and corresponding target annotations used for *testing* in various languages.

By feeding word embeddings and predicate information into our model, we obtain compressed role representations R^S and R^T for source and target sentences S^S and S^T. Recall that we must apply decompression in order to obtain role specific information for S^S and S^T. Since decompression operates over multilingual representations, it is relatively straightforward to obtain semantic roles for source and target sentences. In fact, we apply R^S and R^T on both S^S and S^T and compare the outcome (see Figure 1, bottom part, right side). The training objectives are defined as:

$$\mathcal{L}^S_{\text{cross}} = \frac{1}{n_S}\sum_{i=1}^{n} D(\hat{P}_{\hat{\theta}}(r|w_i^S, R^S), \hat{P}_{\hat{\theta}}(r|w_i^S, R^T)) \tag{10}$$

$$\mathcal{L}^T_{\text{cross}} = \frac{1}{n_T}\sum_{i=1}^{n} D(\hat{P}_{\hat{\theta}}(r|w_i^T, R^S), \hat{P}_{\hat{\theta}}(r|w_i^T, R^T)) \tag{11}$$

where n_S and n_T are the length of S^S and S^T, respectively.

In order to improve the performance of the semantic role compressor on the source and target language, we train it using parallel sentence pairs by minimizing:

$$\mathcal{L}^S_{\text{com}} = \frac{1}{n_S}\sum_{i=1}^{n} D(P_\theta(r|w_i^S, w_p^S, S^S), \hat{P}_{\hat{\theta}}(r|w_i^S, R^S)) \tag{12}$$

$$\mathcal{L}^T_{\text{com}} = \frac{1}{n_T}\sum_{i=1}^{n} D(P_\theta(r|w_i^T, w_p^T, S^T), \hat{P}_{\hat{\theta}}(r|w_i^T, R^T)) \tag{13}$$

The final training loss during cross-lingual training $\mathcal{L}_{\text{cross}}$ is the sum of above losses:

$$\mathcal{L}_{\text{cross}} = \mathcal{L}^S_{\text{cross}} + \mathcal{L}^T_{\text{cross}} + \mathcal{L}^S_{\text{com}} + \mathcal{L}^T_{\text{com}} \tag{14}$$

3 Experiments

3.1 Datasets

We trained our model using English as the source language and obtained semantic role labelers in German (DE), Spanish (ES), Finish (FI), French (FR), Italian (IT), Portuguese (PT), and Chinese (ZH). For English, we used the Proposition Bank (v3; Palmer et al. 2005) and the annotations provided as part of the CoNLL-09 shared task (Hajič et al., 2009). We used the Europarl parallel corpus (Koehn, 2005) for the European languages and a large-scale EN-ZH parallel corpus (Xu, 2019) for Chinese. We provide details regarding the size of the parallel corpora in the Appendix. We compared our model against previous methods on the Universal Proposition Bank (UPB, v1.0; Akbik et al. 2016), which is built upon the Universal Dependency Treebank (UDT, v1.4) and the Proposition Bank (PB, v3.0). All languages in the UBP follow a unified dependency-based SRL annotation scheme. In order to comply with this scheme, we converted argument spans in the English Proposition Bank to dependency-based arguments by labeling the syntactic head of each span.

As UPB adopts a semi-automatic annotation procedure, it unavoidably contains a certain amount of errors. We therefore also tested our model on manually annotated datasets which are few and far between, presumably due to the labeling effort involved. An existing dataset (van der Plas et al., 2010) provides SRL labels for French following an annotation scheme similar to CoNLL-09 for English (Hajič et al., 2009). The CoNLL-09 shared task provides semantic role annotations for seven languages, but the role sets differ across languages, and it is far from trivial to unify them. To this end, we created two manual resources, by randomly sampling 258 German and 304 Chinese sentences from UPB. The manual annotation was performed by native speakers following the annotation guidelines of UPB which in turn follows the English Proposition Bank. Table 1 provides a breakdown of labeled data used in our experiments.

3.2 Model Configuration

Our model was implemented in PyTorch and optimized using the Adam optimizer (Kingma and Ba, 2014). Word embeddings were initialized using the officially released multilingual BERT (base; cased version; Devlin et al. 2019). The parameters of BERT are fixed during training in order to preserve the cross-lingual nature of the embeddings. Hyperparameter values (for all languages) are shown in Table 2.

Hyperparameters	value
multilingual BERT embeddings size	768
predicate indicator embeddings size	16
batch size	30
learning rate	0.001
Bi-LSTM hidden states size	400
BiLSTM depth	3
hidden feature size in biaffine scorer	300
Bi-LSTM hidden states size	256
BiLSTM depth	2
compressed role representation size	30
hidden feature size in biaffine scorer	30

Table 2: Hyperparameter settings for input and training (first block), semantic role labeler (second block) and semantic role compressor (third block).

3.3 Results on Universal Proposition Bank

We compared our model against several baselines on the UPB test set. These include two transfer methods: *Bootstrap* (Aminian et al., 2017) and *CModel* (Aminian et al., 2019), which perform annotation projection through parallel data and filter word alignments empirically. We also report the results of two strong mixture-of-experts models which focus on combining language specific features automatically (*MOE*; Guo et al. 2018), and also on learning language-invariant features with a multinomial adversarial network as a shared feature extractor (*MAN-MOE*; Chen et al. 2019). We also include a recently proposed translation-based model (*PGN*; Fei et al. 2020) which performs competitively on UPB; this system directly translates the source annotated corpus into the target language, and then performs annotation projection and filtering similar to *Bootstrap* and *CModel*.

Table 3 shows labeled F-scores (using automatically predicted predicate senses) on the test portion of the Universal Proposition Bank. The various languages are ordered according to their typological distance to English based on word order (Ahmad et al., 2019a) with Portuguese being closest and Finnish farthest. As can be seen, our model outperforms previous systems on DE, FR and PT, and is on average better. It is worth noting that, in addition to pretrained word-alignment tools, both *Bootstrap* and *PGN* utilize supervised part-of-speech (POS) tags for the target language. However, our model still achieves the best average F-score (61.1%) without employing any additional features. Pairwise differences in F_1 between our model *MAN-MOE*, *CModel*, and *PGN*) are all statistically significant ($p < 0.05$) using stratified shuffling (Noreen, 1989).

3.4 Results on Human-labeled Data

As UPB annotations are semi-automatic and possibly contain projection errors, we further compared

Table 4: Results (F_1) on manually annotated test sets for German, French, and Chinese. Pairwise differences between our model and previous systems are all statistically significant ($p < 0.05$) using stratified shuffling (Noreen, 1989).

our model against manual annotations on French, German, and Chinese (see Table 1). Since previous models have not provided results on these datasets, we re-implemented three strong comparison systems, i.e., *CModel*, *MAN-MOE*, and *PGN*. Details on our implementation are in the Appendix.

Our results are summarized in Table 4, where languages are ordered in terms of their word order distance to English (Ahmad et al., 2019a). We note that our approach significantly outperforms previously published models on these three languages. All systems perform best on French which is perhaps unsurprising given that it is closest to English and worst on Chinese which is least related to English. This suggests that transferring SRL annotations between languages with similar word orders could be an easier task.

3.5 Ablation Study and Analysis

To investigate the contribution of the semantic role compressor and cross-lingual training, we conducted a series of ablation studies on the manually annotated DE, FR, and ZH datasets. Evaluation in these experiments excludes the accuracy of predicate disambiguation, since we wish to focus on the SRL model per se.

Our experiments are summarized in Table 5. The first block shows the performance of the full model.

Models	DE	FR	ZH
Ours	63.4	68.8	60.4
w/o BERT	47.7	52.6	44.5
w/o BERT (+position)	55.3	60.5	53.0
w/o Gaussian noise	61.7	66.2	57.7
w/o cross-lingual training	52.5	59.8	49.5
w/o compressor (+attention)	51.7	59.5	47.1

Table 5: Ablations on manually annotated datasets.

In the second block, we assess the effect of different kinds of word representations. First, we substitute multilingual BERT embeddings with MUSE embeddings (Lample et al., 2018), which were obtained by aligning (monolingual) fastText embeddings for various languages onto a universal space. We can see that the performance of our model drops significantly. One important reason is that MUSE embeddings are not contextualized; as a result, a word appearing multiple times in the same sentence will receive the same embedding, even when it occupies different semantic roles, which in turn leads to conflicts during decompression. One solution is concatenating MUSE with word position embeddings during compression and decompression (see Appendix for details). This improves SRL performance from 47.7% (DE), 52.6% (FR), and 44.5% (ZH) to 55.3%, 60.5% and 53.0%, but is still inferior to the original model. Next, we remove Gaussian noise from the model and as can be seen there is a drop in performance indicating that it further boosts SRL accuracy.

In the third block, we remove cross-lingual training, and observe a significant drop in F-score over the full model. In order to verify the need for semantic role compression, we substitute the compressor with an attention-based module (Bahdanau et al., 2015) and proceed to train our model as described in Section 2.3. Specifically, we obtain soft alignments and use these to weight all annotations $P_\theta(r|w_i, w_p, S)$, thereby obtaining an expectation over role assignments. The alignment module and the basic semantic role labeler are trained jointly during cross-lingual training. We can see that performance drops substantially for all three languages compared to the full model. The reason might be that the output of the semantic role labeler is noisy and attention often creates labeling conflicts (e. two words show high confidence for the same semantic role). However, our compressor can filter out this noise and resolve conflicts more effectively.

French	*SRL only*	Ours	Frequency(%)
A0	71.9	83.6	26%
A1	65.7	78.8	37%
A2	37.8	43.6	7%
AM-*	46.7	48.5	30%

Chinese	*SRL only*	Ours	Frequency(%)
A0	59.2	63.7	18%
A1	59.9	74.4	38%
A2	38.6	65.6	15%
AM-*	36.0	37.3	29%

Table 6: Results (F_1) on French and Chinese test sets grouped by gold role labels.

In Table 6, we present model performance for French and Chinese for different (gold) role labels. We compare the full model against an *SRL only* model without cross-lingual training. As shown in Table 6, cross-lingual training improves SRL performance in French and Chinese on all semantic roles.[4] For French, the most significant improvement comes from A1; for Chinese, cross-lingual training benefits labeling A1 and A2 significantly. Compared with A0, A1, and A2, the improvements on AM-* (modifiers for current predicate) are modest for both French and Chinese. One possible reason is that the head words of A0, A1 and A2 are usually nouns or adjectives, which tend to have fixed positions in parallel sentence pairs. However, modifiers can be optional and have more varied positions within and across languages, which increases the difficulty for cross-lingual learning.

4 Related Work

There has been a great deal of interest in cross-lingual transfer learning for SRL (Padó and Lapata, 2009; van der Plas et al., 2011; Kozhevnikov and Titov, 2013; Tiedemann, 2015; Zhao et al., 2018; Chen et al., 2019; Aminian et al., 2019; Fei et al., 2020). The majority of previous work has focused on two types of approaches, namely annotation projection and model transfer.

A variety of methods have been proposed to improve the quality of annotation projections due to alignment noise. These range from word and argument filtering techniques (Padó and Lapata, 2005, 2009), to learning syntax and semantics jointly (van der Plas et al., 2011), and iterative bootstrapping (Akbik et al., 2015; Aminian et al., 2017). In an attempt to reduce the reliance on supervised lexico-syntactic features for the target language, Aminian et al. (2019) make use of word and character features, and filter projected annotations according to projection density. Model transfer does not require parallel corpora or word alignment tools; nevertheless, it relies on accurate features such as POS tags (McDonald et al., 2013) or syntactic parse trees (Kozhevnikov and Titov, 2013) to enhance the ability to generalize across languages. Adversarial training is commonly used to extract language-agnostic features thereby improving the performance of cross-lingual systems (Chen et al., 2019; Ahmad et al., 2019b).

Translation-based approaches have been gaining popularity in cross-lingual dependency parsing (Rasooli and Collins, 2015; Tiedemann, 2015; Conneau et al., 2018) and have recently been applied to SRL (Fei et al., 2020). Daza and Frank (2019b) propose a cross-lingual encoder-decoder model that simultaneously translates *and* generates sentences with semantic role annotations in a resource-poor target language. Rather than *creating* annotations or models for a target language, other work aims to exploit the similarities between languages. Mulcaire et al. (2018) combine resources for multiple languages to create *polyglot* semantic role labelers and show that polyglot training can result in better labeling accuracy than a monolingual labeler.

An obstacle for developing cross-lingual SRL models is the absence of a unified annotation scheme for all languages. Although the CoNLL-09 shared task (Hajič et al., 2009) provides annotations for seven languages, the labeling schemes and role sets are not shared. To this end, van der Plas et al. (2010) build a French SRL dataset, following an annotation scheme similar to CoNLL-09 for English. Some recent cross-lingual SRL models (Aminian et al., 2017, 2019; Fei et al., 2020) make use of the publicly available Universal Proposition Bank (UPB; Akbik et al. 2015; Akbik and Li 2016), which annotates predicates and semantic roles following the English Proposition Bank 3.0 (Palmer et al., 2005). Since annotation projection is involved in the construction of UPB, the quality of UPB is also influenced by the quality of the parallel data, the performance of the source-language SRL model, and the accuracy of alignment tools.

---

[4] The proportion of A2 in Chinese is higher than in French, as the two languages follow different annotation schemes.

5 Conclusions

In this paper we developed a cross-lingual SRL model and demonstrated it can effectively leverage unlabeled parallel data without relying on word alignments or any other external tools. We have also contributed two quality controlled datasets (compatible with PropBank-style guidelines) which we hope will be useful for the development of cross-lingual models. Directions for future work are many and varied. Although our focus has been on dependency-based SRL, our model can be easily adapted to span-based annotations (Carreras and Màrquez, 2005; Pradhan et al., 2013). In this case, the semantic role compressor could be modified to represent entire spans rather than just head words while decompression would remain unchanged (it would still output a probability distribution for each word over all semantic roles). We also plan to extend our framework to semi-supervised learning, where a small number of annotations might also be available in the target language.

Acknowledgments

This work was supported by the European Research Council (award number 681760, "Translating Multiple Modalities into Text"). We thank the anonymous reviewers for their helpful feedback; we are grateful to Ling Jiang and Sabine Webber for their meticulous annotation efforts in the creation of our SRL datasets.

A Positional Features

When using non-contextualized MUSE embeddings (see the ablation study in Section 3.5), we resort to position embeddings to distinguish words appearing multiple times in the same sentence. Unlike standard transformers where positional features are bound to word indices, the positional features we used for word w_i just record the number of words which are same as w_i and appeared before w_i (shown in Figure 2).

Figure 2: Positional features for English-French parallel sentences.

We adopt these new positional features for two reasons. Firstly, during cross-lingual training, the length of parallel sentences S^S and S^T is usually different. More importantly, for i-th word w_i in S^S, its correspondence w'_j in S^T is not the i-th word in S^T in most cases. When performing cross-lingual training, it is important that w_i and w'_j have the same position embeddings, so that they can obtain similar result after decompression. As shown in Figure 2, *he* ("il" in French) appears twice in the English sentence, and its French counterpart shares the same positional features. Experimental results show that positional features can effectively improve cross-lingual training. However, there are still cases when the word order changes dramatically after translation and our position features do not work. The only solution seems to be to use contextualized embeddings like multilingual BERT or multilingual ELMo, where every word in a sentence will be assigned unique embeddings.

B External Tools

When implementing previous models, we used Google Translate[5] as our translation engine, and giza++[6] to obtain word alignments. Besides source-language corpus, translated corpus is also used for the training of *PGN* and *MAN-MOE*. When preprocessing the Chinese part in EN-ZH parallel corpus (containing about 5 million sentence pairs), we use Jieba[7] for tokenization. The Chinese testset in UPB is in traditional Chinese, and we use Zhtools[8] to convert it to simplified Chinese to be compatible with our EN-ZH parallel corpus which is also in simplified Chinese.

C Parallel Corpus Size

Europarl provides parallel data between English and 21 European languages. We evaluated our model on six European languages. Table 7 give the size of the various parallel corpora used in our experiments.

Language	size
German	1,920,209
Spanish	1,965,734
Finnish	1,924,942
Italian	1,909,115
Portuguese	1,960,407
French	2,007,723

Table 7: Number of sentence pairs in Europarl for six languages.

Leveraging Declarative Knowledge in Text and First-Order Logic for Fine-Grained Propaganda Detection

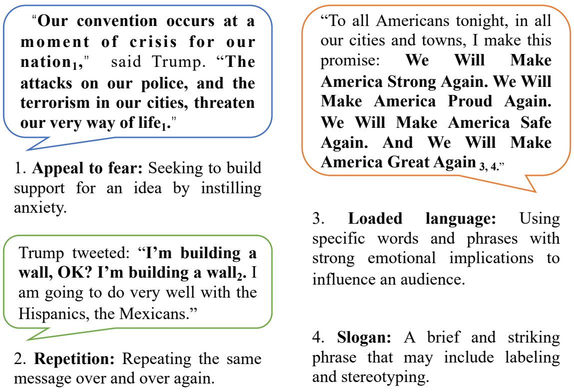
Abstract

We study the detection of propagandistic text fragments in news articles. Instead of merely learning from input-output datapoints in training data, we introduce an approach to inject declarative knowledge of fine-grained propaganda techniques. Specifically, we leverage the declarative knowledge expressed in both first-order logic and natural language. The former refers to the logical consistency between coarse- and fine-grained predictions, which is used to regularize the training process with propositional Boolean expressions. The latter refers to the literal definition of each propaganda technique, which is utilized to get class representations for regularizing the model parameters. We conduct experiments on Propaganda Techniques Corpus, a large manually annotated dataset for fine-grained propaganda detection. Experiments show that our method achieves superior performance, demonstrating that leveraging declarative knowledge can help the model to make more accurate predictions.

1 Introduction

Propaganda is the approach deliberately designed with specific purposes to influence the opinions of readers. Different from the fake news which is entirely made-up and has no verifiable facts, propaganda is possibly built upon an element of truth, and conveys information with strong emotion or somewhat biased. This characteristic makes propaganda more effective and unnoticed through the rise of social media platforms. Some examples of propagandistic texts and definitions of corresponding techniques are shown in Figure 1.



"**Our convention occurs at a moment of crisis for our nation**$_1$," said Trump. "**The attacks on our police, and the terrorism in our cities, threaten our very way of life**$_1$."

1. **Appeal to fear:** Seeking to build support for an idea by instilling anxiety.

Trump tweeted: "**I'm building a wall, OK? I'm building a wall**$_2$. I am going to do very well with the Hispanics, the Mexicans."

2. **Repetition:** Repeating the same message over and over again.

"To all Americans tonight, in all our cities and towns, I make this promise: **We Will Make America Strong Again. We Will Make America Proud Again. We Will Make America Safe Again. And We Will Make America Great Again**$_{3,4}$."

3. **Loaded language:** Using specific words and phrases with strong emotional implications to influence an audience.

4. **Slogan:** A brief and striking phrase that may include labeling and stereotyping.

Figure 1: Examples of propagandistic texts, and definitions of corresponding propaganda techniques (**Bold** denotes propagandistic texts).

We study the problem of fine-grained propaganda detection in this work, which is possible thanks to the recent release of Propaganda Techniques Corpus (Da San Martino et al., 2019). Different from earlier works (Rashkin et al., 2017; Wang, 2017) that mainly study propaganda detection at a coarse-grained level, namely predicting whether a document is propagandistic or not, the fine-grained propaganda detection requires to identify the tokens of particular propaganda techniques in news articles. Da San Martino et al. (2019) propose strong baselines in a multi-task learning manner, which are trained by binary detection of propaganda at sentence level and fine-grained propaganda detection over 18 techniques at token level. Such data-driven methods have the merits of convenient end-to-end learning and strong generalization, however, they cannot guarantee the consistency between sentence-level and token-level predictions. In addition, it is appealing to integrate human knowledge into data-driven approaches.

In this paper, we introduce an approach named ***LatexPRO*** that leverages <u>l</u>ogical <u>a</u>nd <u>tex</u>tual knowledge for <u>pro</u>paganda detection. Following Da San Martino et al. (2019), we develop a BERT-based multi-task learning approach as the base

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3895–3903,
November 16–20, 2020.

model, which makes predictions for 18 propaganda techniques at both sentence level and token level. Based on that, we inject two types of knowledge as additional objectives to regularize the learning process. Specifically, we exploit logic knowledge by transforming the consistency between sentence-level and token-level predictions with propositional Boolean expressions. Besides, we use the textual definition of propaganda techniques by first representing each of them as a contextual vector and then minimizing the distances to corresponding model parameters in semantic space.

We conduct extensive experiments on Propaganda Techniques Corpus (PTC) (Da San Martino et al., 2019), a large manually annotated dataset for fine-grained propaganda detection. Results show that our knowledge-augmented method significantly improves a strong multi-task learning approach. In particular, our model greatly improves precision, demonstrating leveraging declarative knowledge expressed in both first-order logic and natural language can help the model to make more accurate predictions. More importantly, further analysis indicates that augmenting the learning process with declarative knowledge reduces the percentage of inconsistency in model predictions.

The contributions of this paper are summarized as follows:

- We introduce an approach to leverage declarative knowledge expressed in both first-order logic and natural language for fine-grained propaganda techniques.
- We utilize both types of knowledge as regularizers in the learning process, which enables the model to make more consistent between sentence-level and token-level predictions.
- Extensive experiments on the PTC dataset (Da San Martino et al., 2019) demonstrate that our method achieves superior performance with high F_1 and precision.

2 Task

Task Definition. Following the previous work (Da San Martino et al., 2019), we conduct experiments on two different granularities tasks: sentence-level classification (SLC) and fragment-level classification (FLC). Formally, in both tasks, the input is a plain-text document d. A document includes a set of propagandistic fragments T, in that each fragment is represented as a sequence of contiguous characters $t = [t_i, ..., t_j] \subseteq d$. For the SLC task, the target is to predict whether a sentence is propagandistic which can be regarded as a binary classification problem. For the FLC task, the target is to predict a set S with propagandistic fragments $s = [s_m, ..., s_n] \subseteq d$ and identify $s \in S$ to one of the propagandistic techniques.

Table 1: The statistics of all 18 propaganda techniques.

Dataset. This paper utilizes Propaganda Techniques Corpus (PTC) (Da San Martino et al., 2019) for experiments. PTC is a manually annotated dataset for fine-grained propaganda detection, containing 293/ 57/ 101 articles and 14,857/ 2,108/ 4,265 corresponding sentences for training, validation and testing, respectively. Each article is annotated with the start and end of the propaganda text span as well as the type of propaganda technique. As the annotations of the official testing set are not publicly available, we divided the official validation set into a validation set of 22 articles and a test set of 35 articles. The statistics of all 18 propaganda techniques and their frequencies (instances per technique) are shown as Table 1.
