For visually grounded NLG tasks, models are trained on preset training samples and evaluated on preset testing samples, and then results are reported on leaderboards. But would training or evaluating with different samples affect their performance? How reliable are those numbers? In this section, we study to what extent the sample variance during either training or testing affects the evaluation results. For simplicity, the number of parallel References Per visual Instance used for training or testing is denoted by RPI.

Effect of Testing Sample Variance Previous studies on automatic metrics (Vedantam et al., 2015; Anderson et al., 2016) show that more testing references lead to better evaluation accuracy. Here we aim at examining the effect of using different references for testing. Given n references per visual, we incrementally set the testing RPI as $1, 2, ..., n-1$, and randomly sample the testing references from all of the n references. For each RPI, the random sampling and evaluation process is conducted for 20 times. The model is trained on the complete training set.

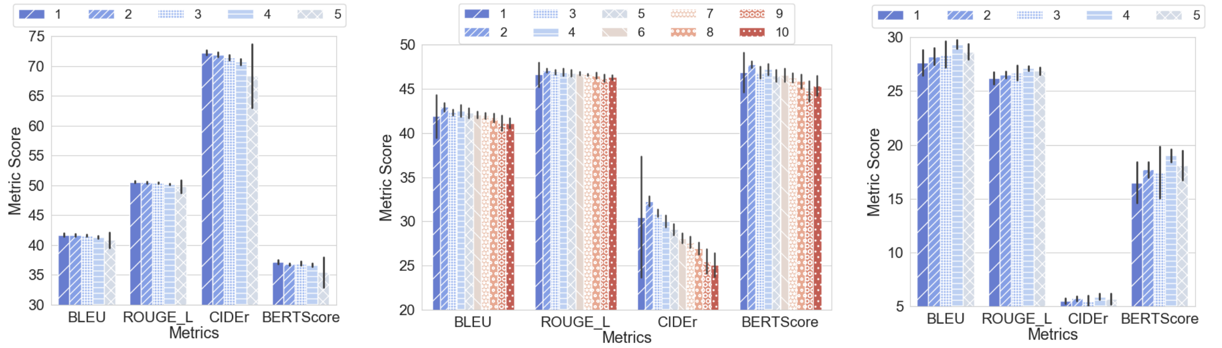
In Figure 2, we demonstrate the experiments on PASCAL-50s for image captioning and VATEX_en for video captioning, where the standard deviation of evaluation scores on those metrics are plotted over RPI. For all metrics, the standard deviation shrinks as more references are employed for testing, indicating the evaluation bias caused by sample variance may be mitigated by introducing more parallel references. However, most of the existing datasets have far less than 50 references. For example, according to Wang et al. (2019), 12 out of 15 datasets for video captioning have less than 3 parallel text references per video, but the variance on those metrics under 3 RPI is very high. This casts doubt on the reliability of the model's performance. For fairer model comparison, we hereby encourage researchers to (1) provide the evaluation set with more parallel references when collecting new datasets, and (2) report the variance of the model's metric scores as well when comparing to other models. Noticeably, the variance of the model's performance on CIDEr is significantly larger than on other metrics, which supplements the previous finding in Section 3 that CIDEr is very sensitive to the reference sample variance.

Effect of Training Sample Variance To investigate the effect of training sample variance, we train the models with different training RPI, from 1 to $n-1$. Similarly, we randomly sample the training references from n references. For each RPI, we repeat the random sampling and training process for 10 times on each dataset. The evaluation is conducted on the complete test set.

Figure 3 depicts the performance of BLEU, CIDEr and BERTScore on each dataset when the corresponding model is trained with different RPI. While the performance on all datasets improves with the increase of training RPI, experimental results show salient variance on all metric scores when the amount of training data is insufficient, which indicates the selection of training samples will influence the final performance. Furthermore, VIST displays notable score deviation on all three metrics, which suggests visual storytelling to be sensitive to the selection of training data.

5 More Visuals or More References?

When collecting a new visually-grounded NLG dataset with a certain budget, there often exists a decision between collecting more visual instances v.s. more text references for each visual. How



(a) MS COCO (b) VATEX_en (c) VIST

Figure 4: Performance when trained with varying training RPI on a fixed total number of visual-text sample pairs. Results on the captioning datasets COCO and VATEX_en are in favor of more visual diversity, while the visual storytelling model benefits more from more parallel text references.

many parallel references do we need to train a reliable model for visual-grounded text generation? Here we study the balance between the number of visual instances and the number of parallel text references in the datasets, and how these two factors affect the training performance for each task.

For each task, we fix the total number of training data samples (*i.e.*, unique visual-reference pairs), and set the training RPI to be $1, 2, ..., n$. We have $\#sample = \#visual\_instance * RPI$. More specifically, we train the image captioning model on MS COCO with 82,740 samples, and use 25,200 and 7,980 samples for training in the video captioning task and visual storytelling task respectively. Figure 4 illustrates the evaluation results for each task. For each RPI, we repeat the random sampling and training process for 10 times on each dataset. As the training RPI increases, the performance of the image captioning model and video captioning model declines on all four metrics, while the visual storytelling performance improves. This suggests that introducing more visual instances during training is beneficial for the captioning tasks, where the parallel references are all objective descriptions regarding the same visual. In contrast, the stories in VIST are more expressive and may refer to imaginary contents (Wang et al., 2018), leading to a much larger search space during generation. In this case, introducing more parallel references into training may help to train a more stable and better-performing storytelling model.

6 Conclusion

We study the sample variance in visually-grounded language generation, in terms of reference sample variance within datasets, effects of training or testing sample variance on metric scores, and the trade-off between the visual instance number and the parallel reference number per visual. Along with some intriguing findings, we urge researchers to report sample variance in addition to the metric scores when comparing models' performance. We also recommend that when collecting a new dataset, the test set should include more parallel references for fair evaluation, while for the training set, when the text generations are expected to be distinctive and complicated, more parallel references should be collected otherwise a larger variety of visual appearances is more favorable.

Beyond Instructional Videos:
Probing for More Diverse Visual-Textual Grounding on YouTube

Abstract

Pretraining from unlabelled web videos has quickly become the de-facto means of achieving high performance on many video understanding tasks. Features are learned via prediction of *grounded* relationships between visual content and automatic speech recognition (ASR) tokens. However, prior pretraining work has been limited to only instructional videos; *a priori,* we expect this domain to be relatively "easy:" speakers in instructional videos will often reference the literal objects/actions being depicted. We ask: can similar models be trained on more diverse video corpora? And, if so, what types of videos are "grounded" and what types are not? We fit a representative pretraining model to the diverse YouTube8M dataset, and study its success and failure cases. We find that visual-textual grounding is indeed possible across previously unexplored video categories, and that pretraining on a more diverse set results in representations that generalize to both non-instructional and instructional domains.

1 Introduction

Self-supervised pretraining approaches have recently been adapted to web videos (Sun et al., 2019a,b; Miech et al., 2019, 2020; Zhu and Yang, 2020; Amrani et al., 2020); the resulting models have achieved state-of-the-art performance on a wide range of video understanding tasks, e.g., dense caption generation, action localization, etc.

In general, the pretraining step requires a large, unlabelled corpus of web videos. The training objective aligns visual content (i.e., video segments) with automatic speech recognition (ASR) tokens, and the resulting representations are fine-tuned for downstream tasks. The assumption underlying this family of approaches is that, in the pretraining corpus, spoken words have *some* consistent, grounded relationship with the temporally corresponding visual content.

However, in contrast to the highly diverse corpora utilized for text-based pretraining (Wikipedia, Common Crawl, etc.), pretraining for web videos (so far) has been limited to instructional videos. This domain restriction is motivated by the commonly accepted notion that "procedural knowledge tends to be inherently multimodal" (Malmaud et al., 2015). We *expect* that the semantic information in video frames and ASR tokens is readily correlated in instructional videos. But corpus diversity brings significant benefits: in the text-only case, models can effectively represent diverse real-world entities (Roberts et al., 2020) precisely because pretraining is not restricted to, e.g., only fictional stories (Zhu et al., 2015).

In search of more general representations, our main question is: **does video-ASR pretraining "work" for more diverse pretraining corpora?** Are certain categories of non-instructional videos "groundable," thus enabling diverse representation learning? Or are some types too difficult, only acting as training noise? We conclude that: 1) grounding is indeed possible in a wide range of yet-to-be-computationally-exploited YouTube video categories, e.g., walk-throughs, vehicles, tech reviews, etc., with some harder than others; 2) transferable representations can be successfully learned by training on a more diverse set, which may provide more versatility.

2 Related Work

ASR is known to be a useful signal source in various instructional video understanding tasks (Gupta et al., 2017; Huang et al., 2017; Huang* et al., 2018; Moriya et al., 2019), e.g., action detection/classification (Yu et al., 2014; Alayrac et al., 2017; Chang et al., 2019; Kuehne et al., 2019),

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8812–8822,
November 16–20, 2020.

segmentation/captioning (Sener et al., 2015), and instruction alignment (Malmaud et al., 2015; Alayrac et al., 2016). A number of multimodal instructional video datasets have been proposed (Wang et al., 2019; Tang et al., 2019; Sanabria et al., 2018). A notable recent example of work addressing a non-instructional video corpus is Ignat et al. (2019), who analyze grounded-ness in lifestyle vlogs. Fouhey et al. (2018) highlight the difference between keyword search vs. implicitly mining action data of interest from a broader corpus (e.g., Bregler (1997); Gu et al. (2018)).

Operational grounding. Our work builds upon prior operational notions of grounding: if an algorithm is able to consistently predict specific visual-textual relationships, then that relationship is said to be "grounded" (Lu et al., 2008; Berg et al., 2010; Parikh and Grauman, 2011; Hill and Korhonen, 2014; Hessel et al., 2018). Yanai and Barnard (2005), for example, examine an image+text corpus and rank "substrings of text by how well their occurrence can be predicted from visual features." One shortcoming of any model-based operationalization of "grounding" is that only *positive* instances of groundedness can be identified: if one model fails to ground something, perhaps a better model could have.

3 Video-ASR pretraining + our model

Recent work in designing pretraining objectives: 1) assumes that ASR tokens have, on average, some correspondence to temporally co-occurring video frames within the same video; and 2) ignores clips that lack ASR. We consider a model that encapsulates both of these assumptions.[1] The model is a slight simplification of Miech et al. (2019), where a joint embedding for the visual content and ASR tokens is learned. While more sophisticated methods based on self-attention models have since been examined (e.g., Zhu and Yang (2020)), joint embedding models are still performant and offer greater interpretability, thus enabling our later error analyses.

Model details. The similarity between clip i and ASR caption j, $s_{i,j}$, is estimated by computing the cosine similarity between their corresponding embeddings in the joint space. Joint embedding models are parameterized using gated, multi-layer feedforward networks. The visual features we use as input are: frame-wise 2D Inception-v1 pretrained for object detection (Szegedy et al., 2015; Sun et al., 2017) and 3D CNN S3D-G features pretrained for action recognition (Xie et al., 2018; Kay et al., 2017). The language feature inputs are 300 dimensional vectors per word-type; these are fine-tuned during the training process. Max pooling is used for both token embeddings and for per-frame visual features to achieve a single visual and textual embedding for each clip.[2]

During training, temporally corresponding (clip, ASR caption) pairs are sampled ("$\mathcal{P}$ositive" cases). For each positive case, a set of mismatched "$\mathcal{N}$egative" cases is also sampled both from other videos and from the same video in equal proportion. In contrast to Miech et al. (2019), we control for clip length, and sample temporally *fixed-length* segments. In initial experiments with variable-length segments, we found that our models were capable of "cheating" the grounding task by aligning longer (and shorter, respectively) clips with longer (and shorter) ASR captions, largely ignoring content. Thus, this simplifying choice makes our error analysis significantly more straightforward, and results in minimal performance change. We use 5 second segments, but results are similar with 10 or 30 second windows (see Appendix E). To generate segments, we initially randomly sample 256 per video before discarding ones that have no temporally-accompanying ASR. Segments may overlap, though results are similar without overlaps (see Appendix D). The following hinge loss is minimized for margin δ:

$$\sum_{i,j \in \mathcal{P},\mathcal{N}} \max(0, \delta + s_{i,j} - s_{i,i}) + \max(0, \delta + s_{j,i} - s_{i,i}) \tag{1}$$

We trained with Adam (Kingma and Ba, 2015), a learning rate of .001, and set $\delta = .1$, but didn't undertake significant hyperparameter optimization. We terminate training after 300K steps.

CrossTask replication. To verify that our model simplifications didn't significantly hinder performance, we replicated key experiments from Miech et al. (2019). In particular, we sought to gather the pretraining corpus they used, HowTo100M, which consists of 1.22M videos. Because of, e.g., users deleting videos, we were able to gather features for only 87% of the original set, 1.06M videos.

---

[1] While more complicated models are possible, our goal is to conduct an error analysis of a simple, representitive model, not to necessarily achieve state-of-the-art results.

[2] When training on YouTube-600K the vocabulary size is 61K.

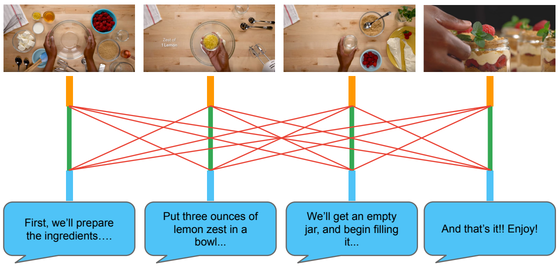

Figure 1: Intra-video AUC metric: the model scores all possible links between clips and ASR captions within a single video; the model is rewarded for assigning higher similarity to **temporally-aligned segments** versus **mismatched ones**.

Category	% videos
BBC	74.1%
President (USA)	71.7%
Hair conditioner	71.1%
Madden NFL	69.3%
Wig	67.9%
Magic (card game)	67.9%
Booster pack	67.4%
Raw foodism	66.5%
NBA 2K14	65.2%
Silver	65.2%

(a) Most ASR

Category	% videos
Pachinko	0.4%
Jumbotron	0.4%
Chipmunk	0.3%
Taiko no Tatsujin	0.2%
Yo-kai Watch	0.1%
Zee Bangla	0.1%
Karaoke box	0.1%
Wangan Midnight	0.1%
Caporales	0.0%
Military band	0.0%

(b) Least ASR

Table 1: Categories of YouTube8M with the highest and lowest availability of English ASR (minimum 1K videos); corpus mean = 17%.

We verify the performance of our model using the CrossTask localization task (Zhukov et al., 2019). While we defer details to the original paper, the goal of CrossTask is to temporally localize a set of procedural steps for a task in an unlabelled/unsegmented video depicting that task. An algorithm's performance is evaluated with a recall metric (higher is better). We follow the evaluation procedure given in Miech et al. (2019), except instead of embedding each frame individually, we embed a sliding 5-second window of video clips.

Our simplified model trained on less data performs comparably to Miech et al. (2019)'s. We achieve 32.6 recall, while they report 33.6 recall; for reference, a supervised upper-bound without pre-training achieves 31.6 recall (full results and more details are in Appendix B).

Measuring visual-textual alignment. Viewed through the lens of link prediction between truly co-occuring (clip, ASR) pairs, Eq. 1 can be seen as a differentiable approximation of AUC (Rendle et al., 2009). Thus, we propose to operationally measure the groundedness using *intra-video* AUC: a single score is assigned to each video, rewarding the model if it is able to successfully align temporal pairs within the same video (and penalizing it if not). Fig. 1 presents a visualization of this method. One notable advantage of AUC versus other link prediction metrics is that it is insensitive to the label distribution: shorter videos are not systematically assigned higher scores simply because there are fewer incorrect links.

4 A More Diverse Corpus

YouTube-600K. YouTube8M (Abu-El-Haija et al., 2016) is a dataset of 6.1M YouTube videos,[3] where each video is labeled across 3K categories, ranging from "cooking" to "games" to "nature." It is among the largest and most diverse publicly available dataset of YouTube videos. Due to user deletions and videos without detected spoken words, we are able to collect ASR via the YouTube API for 1.4M (29%) videos; we further filtered to 817K videos tagged with English ASR.[4] There is an extremely wide variance of ASR availability per category, e.g., 74% of "BBC" videos (a category that generally contains news videos by the broadcaster) have ASR, whereas almost no "Military band" videos do (Table 1). While the percentage of ASR-available videos is higher in many instructional video categories, e.g., "cooking" at 31%, "cosmetics" at 44%, etc., many non-instructional categories on YouTube have ASR available (e.g., "silver" at 65%; mostly videos about coins). Maintaining the train / validation split of the original data release yields 639K training videos (henceforth referred to as YouTube-600K) and 167K validation-set videos.

Human annotation of "Is-it-instructional" While a qualitative examination of YouTube8M reveals clear topical and stylistic diversity compared to domain-restricted corpora, we quantitatively verify that YouTube8M does not consist of mostly instructional videos.

We sample 6.8K videos with English ASR from the validation set for human labeling. Each video is shown to three paid annotators, who each provide a Yes/No answer to the question: "Does this

---

[3] v3 of the dataset is smaller than v1/v2, due to videos becoming unavailable over time and other refinements.

[4] We expect that non-English videos will similarly be an excellent source of visual-textual grounding training data, particularly for under-resourced languages. We focused on English to simplify our error analyses. But in future work, we expect to not impose such a limitation.

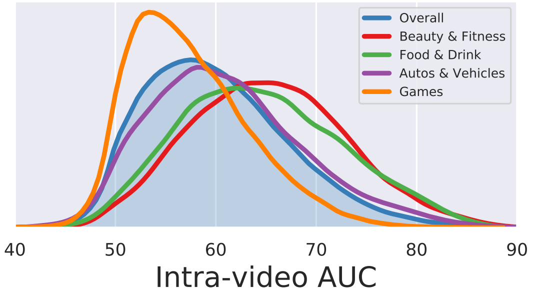

Figure 2: Distribution of intra-video AUC scores, grouped by meta category, compared to the overall distribution.

Domain	Example Categories (AUC)
Vehicles	Crossover SUV (70); Sedan (69); Minivan (69); Station wagon (68)
Walkthroughs	Hotel Suite (71); Apartment (69); Dining room (68); Living room (68)
Advertising	Advertising (68); Television advertisement (66); Infomercial (63)
Tech Reviews	CNET (66), Netbook (65), Asus (63) IPhone 5S (64), MacBook (64)
Toys	Funko (66); Monster High (64); Figurine (64) Action Figure (64)
Appliances	Home appliance (65); Washing machine (64); Kitchen stove (64)
Places	Greenhouse (62) University (61); Amusement park (59)

Table 2: Domains with high operational groundability.

video focus on real-world human actions accompanied by procedural language that explains what is happening on screen in reasonable detail?" Note that our definition of "instructional" intends to include the usual "how-to" videos, but also attempts to capture a more general notion of "instructional-ness". For instance, an un-boxing video where parts of a product are *taken out and assembled* along with corresponding narration should receive "Yes", whereas a video showing only a product from different angles should receive "No", due to a lack of narrated human actions.

After a pilot study with a few iterations over the guidelines and examples, the annotators reach high agreement: in 96% of cases, all three judges are unanimous. From these annotations, we estimate that around 74% of the videos in the YouTube-600K corpus are **not** instructional, even for the generalized notion of "instructional-ness." For reference, Miech et al. (2019) conduct an analysis of 100 videos from HowTo100M (constructed with the intention to focus on how-to videos) and estimate that 71% are instructional.

The annotated *i3-video* corpus (**i**s-**i**t-**i**nstructional-video) is available for download.[5] One potential use-case: consider an automated tool designed exclusively for use on instructional videos. A classifier trained on our labelled corpus could be used to determine if applying the automated tool is appropriate or not for an unlabelled input video.

Which categories are easiest/hardest? We train our model on YouTube-600K, and compute intra-video AUC for each of the 178K validation videos. First, we average all videos labeled with a particular category to produce a per-category AUC score. The performance in a vast majority of categories is above the 50 AUC (random) baseline, and ranges from 51 ("Mixtape") to 76 ("Muffin"). To make sure that the model is not succeeding simply because a category happened to be frequent in the dataset, we note the correlation between category AUC and category frequency is essentially zero ($\rho = .02, p > .58$). This suggests that at least *some* aspect of most categories of videos can be visual-textually grounded.

We next coarsely aggregate the YouTube8M categories into meta-categories, e.g., "Food and Drink."[6] The AUC distribution of 4 popular meta categories relative to the overall AUC distribution is given in Fig. 2. In general, the grounding succeeds most readily on makeup/hair videos (e.g., "Eye liner" AUC $= 74$, "Updo" AUC $= 68$, etc.) and cooking videos (e.g., "Vegetarian cuisine" AUC $= 71$), domains that have been previously used in video grounding work. Besides these already-studied domains, other high-scoring category types emerge (Table 2). Conversely, some categories are more difficult for the model, e.g., video game categories like "RuneScape" AUC $=$ 54 and "First-person shooter" AUC $= 55$; speakers in these videos often reference diverse topics unrelated to the game itself. Non-video-game categories can also be difficult, e.g., "Unidentified flying object" AUC $= 56$, "Dashcam" AUC $= 54$.

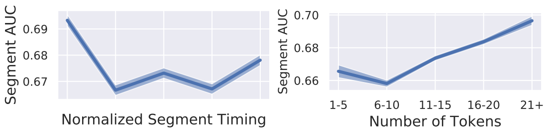
We next ask: *are instructional videos indeed easier to operationally ground?* While human judgements of instructional-ness and intra-video AUC are positively correlated $\rho = .20$ ($p \ll 0$), the low magnitude of this correlation provides additional empirical confirmation that other types of videos are also promising.

Within-category observations. To this point,

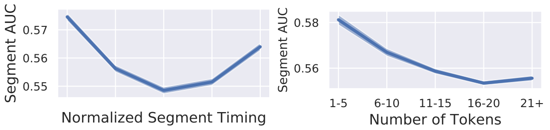
---

[5] https://github.com/google-research-datasets/i3-video

[6] These meta-categories are called "verticals," and are released with YouTube8M.



(a) Action Figure (64 category AUC)



(b) Call of Duty (55 category AUC)

Figure 3: Correlation between per-segment AUC scores and segment timing within video (left column) and the number of tokens in a segment (right column)

we have identified broad categories of YouTube videos that are more groundable than others. However, it is not yet clear *why*, e.g., the algorithm gets 64 AUC on “Action Figure,” or 55 AUC on “Call of Duty” (a first-person shooter game). We now define a *segment-level* AUC metric, analogous to the intra-video AUC metric previously defined: it quantifies how readily *individual ASR captions* are temporally localized by the model within the same video (see Menon and Elkan (2011) for a description of different AUC variants).

Before examining the relationship between content-based features and segment-level AUC, contextual factors must be considered. Fig. 3 illustrates clear relationships 1) between ASR caption placement within a video and segment AUC (segments at the very beginning and very end of videos tend to be easier); and 2) between the number of tokens in an ASR caption and segment AUC. For “Action Figure”, ASR segments with more words are easier (this is the case with most categories), but for “Call of Duty”, the opposite is true.

After controlling for contextual variables, we train OLS regression models to predict segment AUC from lexical unigram features, while controlling for timing/length features. Lexical features add predictive capacity ($p \ll .01$, F-test). While we find some patterns predictive of segment AUC for both categories, e.g., intro/outro-language (e.g., “hey”, “welcome”, “peace”), we also observe topical patterns, e.g., several unigrams associated with specific action figure body parts (“knee”, “shoulder”, “joint”, etc.) are positively associated with segment AUC.

5 Implications for Pretraining

While we’ve thusfar shown that self-grounding is possible for a diverse set of domains, do we *gain* anything by training on a more diverse corpus? Or do difficult-to-ground videos introduce noise and degrade representations for downstream tasks?

We compare two versions of our model: one with parameters learned from training on the diverse YouTube-600K corpus (M_{Diverse}), and one with parameters learned from a domain-specific corpus of 1M instructional videos ($M_{\mathsf{Instructional}}$).

First, we evaluate each model’s capacity to localize instructional steps on the CrossTask (Zhukov et al., 2019) dataset. M_{Diverse} performs admirably, even with significant domain mismatch and fewer pretraining videos: recall drops by only 15% (32.6 → 27.4) when swapping from $M_{\mathsf{Instructional}}$ to M_{Diverse}.

We next evaluate each model’s performance on the same-video clip alignment task over a diverse set of videos: the sample of 6.8K human-annotated videos from the YouTube8M validation set. In terms of intra-video AUC, M_{Diverse} outperforms $M_{\mathsf{Instructional}}$ on 59% of videos. If we split the data across the “Is-it-instructional” human judgements and compare the two models in each subset, $M_{\mathsf{Instructional}}$ “wins” in 57% of the instructional videos, whereas M_{Diverse} “wins” in 65% of non-instructional cases.

In short: both models achieve reasonable performance under instructional vs. non-instructional train/test domain mismatch. Taken together, this is a promising result for future pretraining work with more diverse corpora: at least for these evaluations, good performance on an instructional video grounding task is still possible under domain shift. And while the comparison of intra-video AUC is not necessarily definitive, it suggests that diverse corpora may provide more versatility, and we look forward to exploring this further in future work.

6 Conclusion

Peeking through the lens of a joint embedding model, we probe into learning visual-textual grounding over a more diverse corpus of YouTube videos vs. prior work. We find that learning visual-textual grounding is possible across many yet-to-be-explored categories of YouTube videos, and that it’s possible to learn generalizable representations from a more diverse video set.

A Additional Model Details

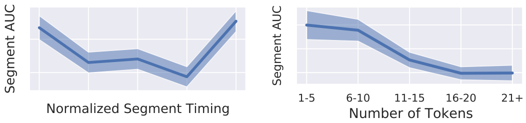
We adapt Miech et al. (2019)'s joint embedding model that pre-trains by aligning ASR tokens with corresponding video frames. The main difference between our implementation and theirs is how we generated (ASR, caption) pairs. While we considered generating clips according to their methodology, we ran into two problems. First, in early experiments, we found that the interpretability our error analysis was significantly impacted by varying clip length. For example: we were worried that it might not be consistent to compare the model's ability to temporally ground a 1s clip vs. a 15 second clip. There was also high correlation between caption length and temporal clip duration, which further complicated interpretation. Sampling clips of uniform duration solved these problems.

Second, Miech et al. (2019)'s temporal segmentation was generated by relying on the *scrolling timing* of the ASR tokens on the YouTube, i.e., the time that YouTube decides to generate a linebreak, removing a line of caption from the screen. Via manual inspection, we found that scrolling time was temporally unreliable, e.g., the time in which ASR captions scroll on YouTube often differs significantly from when particular words were said. Instead, we sample 256 candidate 5 second segments uniformly at random from the video, and then discard segments that have no corresponding ASR.

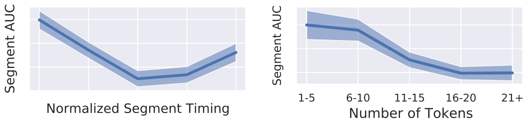
Additional visual feature details. For 2D features, we sample frames at 1FPS from all of the videos in our corpus, resize frames to be 256 by 256, and pass them through Inception-v1 (Szegedy et al., 2015) pretrained on JFT (Sun et al., 2017). For 3D convolutional networks, we follow a similar procedure to (Sun et al., 2019), sample frames at 30FPS, aggregate frames into one second non-overlapping clips of 1 second each, and run an S3D-G (Xie et al., 2018) network that is pretrained on the Kinetics action recognition dataset (Kay et al., 2017). Both 2D and 3D features are L2 normalized. The result of this process is a 2524-D feature vector for each second of video in our corpus.

B Comparison to HowTo100M

The full per-task recall comparisons are given in Table 3. Our results, like those of Miech et al. (2019), use Zhukov et al. (2019)'s dynamic programming postprocessing method. We found that it usually resulted in a small performance increase.



(a) Action Figure (64 category AUC)



(b) Call of Duty (54 category AUC)

Figure 4: Correlation between per-segment AUC scores and segment timing within video (left column) and the number of tokens in a segment (right column) for the 140K checkpoint (compare to the 300K checkpoint in the main paper).

Our simplified model performs only slightly worse (3%) than Miech et al. (2019)'s. While we argue that our model is certainly still representative, there are several reasons why this gap might exist. For example, there may be a regularizing effect when the model is allowed to view clips of varying length. Furthermore, our feature set was different; we used different (but comparable) base neural networks for feature extraction. Also, our model is trained on less data due to authors deleting their videos. Finally — we didn't tune the training hyperparameters for our model/implementation, e.g., hinge size, learning rate, batch size, etc.

C Stability of results to checkpoint

To ensure the results related to intra-video AUC were insensitive to the particular choice of model checkpoint, we re-did the experiments in §4 using a version of our model checkpointed at 140K iterations vs. the 300K presented in the main paper; these experiments were conducted over 21K dev videos instead of the full 167K dev videos presented in the main paper. Figures+tables in that section were consistent with the presented results, and the qualitative observations about the "Action Figure" category held (see Figure 4 for replicated figures).

D Stability of results to overlapping windows

When we generate our windows at training and testing time to compute intra-video AUC, given that

Table 3: Comparison between our simplified model and Miech et al. (2019)'s model on CrossTask, and the effect of pretraining the model on YouTube-600K instead of HowTo100M. Note that HowTo100M → Crosstask results are pre-trained on less data when compared to the original works due to video deletion.

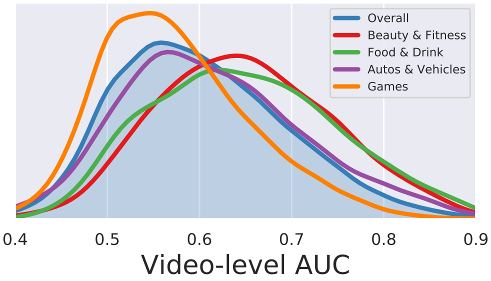

Figure 5: Meta-category AUC with window size of 5, but test-time windows are sampled without overlap.

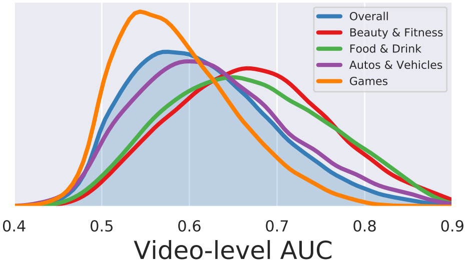
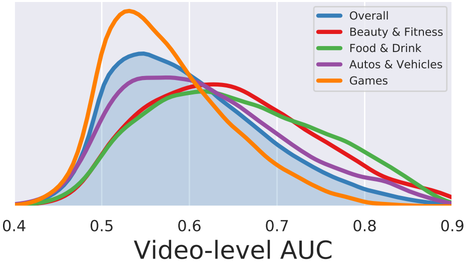
we sample 256 candidates per video (and then filter out clips without associated temporal ASR), the windows frequently overlap. We ran additional experiments to ensure that our results held when we sampled non-overlapping clips at testing time.

We computed an alternate version of the intra-video AUC results using a 140K training iteration checkpoint. Instead of sampling 256 segments at testing time, we only (randomly) sample up to 10 segments, but force them to be non-overlapping. There are some videos that are discarded in this process. For 1/500 videos (or so) we cannot sample non-overlapping segments. However, among the majority of videos for which the sampling is successful, the Spearman correlation with the category-level results allowing for overlap is $\rho = .98$. Figure 5 reproduces the meta-category plot from the main paper, but with test-time segments sampled without overlap.



(a) Window size = 10



(b) Window size = 30

Figure 6: Meta-category AUC using models trained with alternate window sizes of $t = 10, 30$ seconds. The main paper results are with $t = 5$ second windows.

E Additional Window Sizes

The results presented in the main paper use a temporal window size of five seconds. We were curious as to the stability of our observations with respect to the choice of this window size. While changing the window size, to an extent, changes the nature of the task, we ran with window size 10s and window size 30s to measure the stability of the results.

Category-level AUC. We computed the intra-video AUC values for the models trained with alternate window sizes. Largely, while the individual AUC values may change by a point or two, the relative pattern stayed the same. The per-category Spearman correlation with the results for the $t = 5$ windows was high: $\rho = .99$ for $t = 10$ and $\rho = .96$ for $t = 30$ (both correlations are true with $p \ll .001$). It should be noted that there are marginal differences in the development set videos used for the experiments at $t = 5, 10, 30s$: because experiments were run at different times, due

to video deletion, 2% fewer videos were available for later experiments. Figure 6 recreates the meta-category plot from the main paper with the different window sizes; Tables 4 and 5 report the same category-level AUC values as the table in the main paper. Overall, the results are very similar.

Transfer learning. In the main paper, we explored the differences between models trained on YouTube-600K vs. HowTo100M. Here, we conducted the same YouTube8M self-grounding experiments as described in the main paper (varying the training set) with $w = 10$ instead of $w = 5$. The results are very similar. In terms of intra-video AUC, M_{Diverse} (trained on YouTube-600K) outperforms $M_{\mathsf{Instructional}}$ (trained on HowTo100M) on 58% of videos (compared to 59% for $w = 5$ in the main paper). If we split the data across the "Is-it-instructional" human judgements and compare the two models in each subset, $M_{\mathsf{Instructional}}$ "wins" in 57% of the instructional videos (compared to 57% for $w = 5$ in the main paper), whereas M_{Diverse} "wins" in 63% of non-instructional cases (compared to 65% for $w = 5$ in the main paper).

F Additional Reproducability Information

The models were trained and evaluated on a mix of TPU and GPU clusters. Depending on the particular hardware, the training process takes roughly 1 or 2 days to get 300K training iterations. While we make no particular claim about parameter/time efficiency, the number of parameters of our models are similar to HowTo100M's, i.e., roughly 50M. The runtime of our model is relatively fast — on GPUs, batches of hundreds of videos can be processed in seconds. For hyperparameters not specifically described, we mirror the choices made in the HowTo100M public repo.[7] For evaluating CrossTask, we wrote our own recall computing code that mirrors the setup publicly released by the authors;[8] this includes several ad-hoc decisions, e.g., computing the floor/ceiling of temporal annotations in CrossTask to form the window, and only counting a "hit" when the predicted time is strictly *less* than the ceiling (rather than less than or equal).

Hierarchical Graph Network for Multi-hop Question Answering

Yuwei Fang, Siqi Sun, Zhe Gan, Rohit Pillai, Shuohang Wang, Jingjing Liu

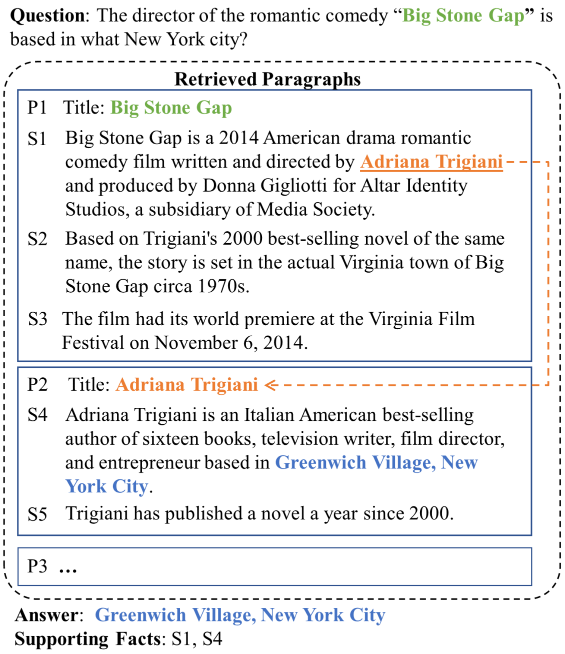
Abstract

In this paper, we present Hierarchical Graph Network (HGN) for multi-hop question answering. To aggregate clues from scattered texts across multiple paragraphs, a hierarchical graph is created by constructing nodes on different levels of granularity (questions, paragraphs, sentences, entities), the representations of which are initialized with pre-trained contextual encoders. Given this hierarchical graph, the initial node representations are updated through graph propagation, and multi-hop reasoning is performed via traversing through the graph edges for each subsequent sub-task (e.g., paragraph selection, supporting facts extraction, answer prediction). By weaving heterogeneous nodes into an integral unified graph, this hierarchical differentiation of node granularity enables HGN to support different question answering sub-tasks simultaneously. Experiments on the HotpotQA benchmark demonstrate that the proposed model achieves new state of the art, outperforming existing multi-hop QA approaches.[1]

1 Introduction

In contrast to one-hop question answering (Rajpurkar et al., 2016; Trischler et al., 2016; Lai et al., 2017) where answers can be derived from a single paragraph (Wang and Jiang, 2017; Seo et al., 2017; Liu et al., 2018; Devlin et al., 2019), many recent studies on question answering focus on multi-hop reasoning across multiple documents or paragraphs. Popular tasks include WikiHop (Welbl et al., 2018), ComplexWebQuestions (Talmor and Berant, 2018), and HotpotQA (Yang et al., 2018).

An example from HotpotQA is illustrated in Figure 1. In order to correctly answer the question ("The director of the romantic comedy 'Big Stone Gap' is based in what New York city"), the model is required to first identify *P1* as a relevant paragraph, whose title contains the keywords that appear in the question ("*Big Stone Gap*"). *S1*, the first sentence of *P1*, is then chosen by the model as a supporting fact that leads to the next-hop paragraph *P2*. Lastly, from *P2*, the span "*Greenwich Village, New York City*" is selected as the predicted answer.



Question: The director of the romantic comedy "**Big Stone Gap**" is based in what New York city?

Retrieved Paragraphs

P1 Title: **Big Stone Gap**

S1 Big Stone Gap is a 2014 American drama romantic comedy film written and directed by **Adriana Trigiani** and produced by Donna Gigliotti for Altar Identity Studios, a subsidiary of Media Society.

S2 Based on Trigiani's 2000 best-selling novel of the same name, the story is set in the actual Virginia town of Big Stone Gap circa 1970s.

S3 The film had its world premiere at the Virginia Film Festival on November 6, 2014.

P2 Title: **Adriana Trigiani**

S4 Adriana Trigiani is an Italian American best-selling author of sixteen books, television writer, film director, and entrepreneur based in **Greenwich Village, New York City**.

S5 Trigiani has published a novel a year since 2000.

P3 ...

Answer: **Greenwich Village, New York City**
Supporting Facts: S1, S4

Figure 1: An example of multi-hop question answering from HotpotQA. The model needs to identify relevant paragraphs, determine supporting facts, and then predict the answer correctly.

Most existing studies use a retriever to find paragraphs that contain the right answer to the question (*P1* and *P2* in this case). A Machine Reading Comprehension (MRC) model is then applied to the selected paragraphs for answer prediction (Nishida et al., 2019; Min et al., 2019b). However, even after successfully identifying a reasoning chain through multiple paragraphs, it still remains a critical challenge how to aggregate evidence from scattered

November 16–20, 2020. ©2020 Association for Computational Linguistics

sources on different granularity levels (e.g., paragraphs, sentences, entities) for joint answer and supporting facts prediction.

To better leverage fine-grained evidences, some studies apply entity graphs through query-guided multi-hop reasoning. Depending on the characteristics of the dataset, answers can be selected either from entities in the constructed entity graph (Song et al., 2018; Dhingra et al., 2018; De Cao et al., 2019; Tu et al., 2019; Ding et al., 2019), or from spans in documents by fusing entity representations back into token-level document representation (Xiao et al., 2019). However, the constructed graph is mostly used for answer prediction only, while insufficient for finding supporting facts. Also, reasoning through a simple entity graph (Ding et al., 2019) or paragraph-entity hybrid graph (Tu et al., 2019) lacks the ability to support complicated questions that require multi-hop reasoning.

Intuitively, given a question that requires multiple hops through a set of documents to reach the right answer, a model needs to: (i) identify paragraphs relevant to the question; (ii) determine strong supporting evidence in those paragraphs; and (iii) pinpoint the right answer following the garnered evidence. To this end, Graph Neural Network with its inherent message passing mechanism that can pass on multi-hop information through graph propagation, has great potential of effectively predicting both supporting facts and answer simultaneously for complex multi-hop questions.

Motivated by this, we propose a **H**ierarchical **G**raph **N**etwork (HGN) for multi-hop question answering, which empowers joint answer/evidence prediction via multi-level fine-grained graphs in a hierarchical framework. Instead of only using entities as nodes, for each question we construct a hierarchical graph to capture clues from sources with different levels of granularity. Specifically, four types of graph node are introduced: *questions*, *paragraphs*, *sentences* and *entities* (see Figure 2). To obtain contextualized representations for these hierarchical nodes, large-scale pre-trained language models such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) are used for contextual encoding. These initial representations are then passed through a Graph Neural Network for graph propagation. The updated node representations are then exploited for different sub-tasks (e.g., paragraph selection, supporting facts prediction, entity prediction). Since answers may not be entities in the graph, a span prediction module is also introduced for final answer prediction.

The main contributions of this paper are threefold: (i) We propose a Hierarchical Graph Network (HGN) for multi-hop question answering, where heterogeneous nodes are woven into an integral hierarchical graph. (ii) Nodes from different granularity levels mutually enhance each other for different sub-tasks, providing effective supervision signals for both supporting facts extraction and answer prediction. (iii) On the HotpotQA benchmark, the proposed model achieves new state of the art in both Distractor and Fullwiki settings.

2 Related Work

Multi-Hop QA Multi-hop question answering requires a model to aggregate scattered pieces of evidence across multiple documents to predict the right answer. WikiHop (Welbl et al., 2018) and HotpotQA (Yang et al., 2018) are two recent datasets designed for this purpose. Existing work on HotpotQA Distractor setting focuses on converting the multi-hop reasoning task into single-hop subproblems. Specifically, QFE (Nishida et al., 2019) regards evidence extraction as a query-focused summarization task, and reformulates the query in each hop. DecompRC (Min et al., 2019b) decomposes a compositional question into simpler sub-questions and leverages single-hop MRC models to answer the sub-questions. A neural modular network is also proposed in Jiang and Bansal (2019b), where neural modules are dynamically assembled for more interpretable multi-hop reasoning. Recent studies (Chen and Durrett, 2019; Min et al., 2019a; Jiang and Bansal, 2019a) have also studied the multi-hop reasoning behaviors that models have learned in the task.

Graph Neural Network Recent studies on multi-hop QA also build graphs based on entities and reasoning over the constructed graph using graph neural networks (Kipf and Welling, 2017; Veličković et al., 2018). MHQA-GRN (Song et al., 2018) and Coref-GRN (Dhingra et al., 2018) construct an entity graph based on co-reference resolution or sliding windows. Entity-GCN (De Cao et al., 2019) considers three different types of edges that connect different entities in the entity graph. HDE-Graph (Tu et al., 2019) enriches information in the entity graph by adding document nodes and creating interactions among documents, entities and answer candidates. Cognitive Graph QA (Ding

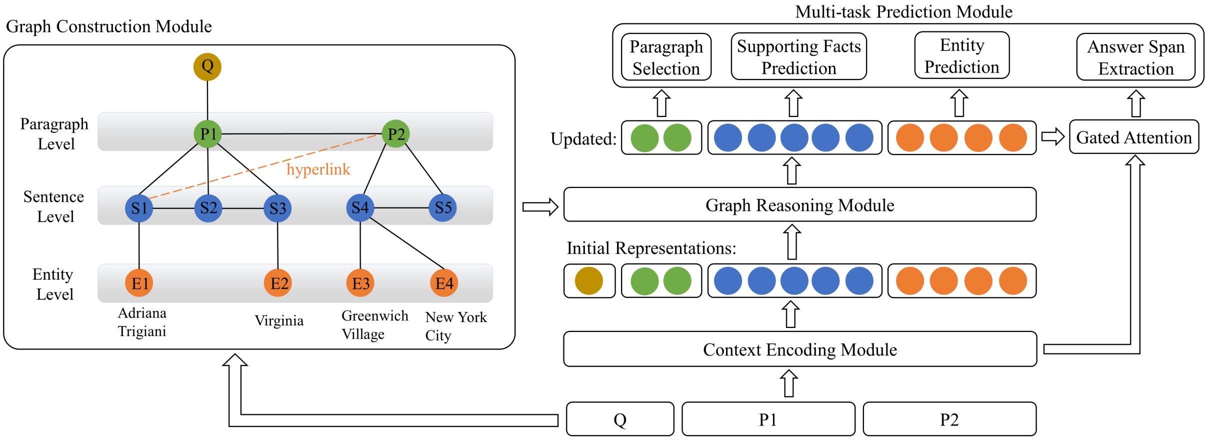

Figure 2: Model architecture of Hierarchical Graph Network. The constructed graph corresponds to the example in Figure 1. Green, blue, orange, and brown colors represent paragraph (P), sentence (S), entity (E), and question (Q) nodes, respectively. Some entities and hyperlinks are omitted for simplicity.

et al., 2019) employs an MRC model to predict answer spans and possible next-hop spans, and then organizes them into a cognitive graph. DFGN (Xiao et al., 2019) constructs a dynamic entity graph, where in each reasoning step irrelevant entities are softly masked out and a fusion module is designed to improve the interaction between the entity graph and documents.

More recently, SAE (Tu et al., 2020) defines three types of edge in the sentence graph based on the named entities and noun phrases appearing in the question and sentences. C2F Reader (Shao et al., 2020) uses graph attention or self-attention on entity graph, and argues that this graph may not be necessary for multi-hop reasoning. Asai et al. (2020) proposes a new graph-based recurrent method to find evidence documents as reasoning paths, which is more focused on information retrieval. Different from the above methods, our proposed model constructs a hierarchical graph, effectively exploring relations on different granularities and employing different nodes to perform different tasks.

Hierarchical Coarse-to-Fine Modeling Previous work on hierarchical modeling for question answering is mainly based on a coarse-to-fine framework. Choi et al. (2017) proposes to use reinforcement learning to first select relevant sentences and then produce answers from those sentences. Min et al. (2018) investigates the minimal context required to answer a question, and observes that most questions can be answered with a small set of sentences. Swayamdipta et al. (2018) constructs lightweight models and combines them into a cascade structure to extract the answer. Zhong et al. (2019) proposes to use hierarchies of co-attention and self-attention to combine information from evidence across multiple documents. Different from the above methods, our proposed model organizes different granularities in a hierarchical manner and leverages graph neural network to obtain the representations for different downstream tasks.

3 Hierarchical Graph Network

As illustrated in Figure 2, the proposed Hierarchical Graph Network (HGN) consists of four main components: (i) Graph Construction Module (Sec. 3.1), through which a hierarchical graph is constructed to connect clues from different sources; (ii) Context Encoding Module (Sec. 3.2), where initial representations of graph nodes are obtained via a RoBERTa-based encoder; (iii) Graph Reasoning Module (Sec. 3.3), where graph-attention-based message passing algorithm is applied to jointly update node representations; and (iv) Multi-task Prediction Module (Sec. 3.4), where multiple subtasks, including paragraph selection, supporting facts prediction, entity prediction, and answer span extraction, are performed simultaneously.

3.1 Graph Construction

The hierarchical graph is constructed in two steps: (i) identifying relevant multi-hop paragraphs; and (ii) adding edges representing connections between sentences/entities within the selected paragraphs.

Paragraph Selection We first retrieve paragraphs whose titles match any phrases in the question (title matching). In addition, we train a paragraph ranker based on a pre-trained RoBERTa encoder, followed by a binary classification layer, to rank the probabilities of whether the input paragraphs contain the ground-truth supporting facts. If multiple paragraphs are found by title matching, only two paragraphs with the highest ranking scores are selected. If title matching returns no results, we further search for paragraphs that contain entities appearing in the question. If this also fails, the paragraph ranker will select the paragraph with the highest ranking score. The number of selected paragraphs in the first-hop is at most 2.

Once the first-hop paragraphs are identified, the next step is to find facts and entities within the paragraphs that can lead to other relevant paragraphs (*i.e,*, the second hop). Instead of relying on entity linking, which could be noisy, we use hyperlinks (provided by Wikipedia) in the first-hop paragraphs to discover second-hop paragraphs. Once the links are selected, we add edges between the sentences containing these links (source) and the paragraphs that the hyperlinks refer to (target), as illustrated by the dashed orange line in Figure 2. In order to allow information flow from both directions, the edges are considered as bidirectional.

Through this two-hop selection process, we are able to obtain several candidate paragraphs. In order to reduce introduced noise during inference, we use the paragraph ranker to select paragraphs with top-N ranking scores in each step.

Nodes and Edges Paragraphs are comprised of sentences, and each sentence contains multiple entities. This graph is naturally encoded in a hierarchical structure, and also motivates how we construct the hierarchical graph. For each paragraph node, we add edges between the node and all the sentences in the paragraph. For each sentence node, we extract all the entities in the sentence and add edges between the sentence node and these entity nodes. Optionally, edges between paragraphs and edges between sentences can also be included in the final graph.

Each type of these nodes captures semantics from different information sources. Thus, the hierarchical graph effectively exploits the structural information across all different granularity levels to learn fine-grained representations, which can locate supporting facts and answers more accurately than simpler graphs with homogeneous nodes.

An example hierarchical graph is illustrated in Figure 2. We define different types of edges as follows: (i) edges between question node and paragraph nodes; (ii) edges between question node and its corresponding entity nodes (entities appearing in the question, not shown for simplicity); (iii) edges between paragraph nodes and their corresponding sentence nodes (sentences within the paragraph); (iv) edges between sentence nodes and their linked paragraph nodes (linked through hyperlinks); (v) edges between sentence nodes and their corresponding entity nodes (entities appearing in the sentences); (vi) edges between paragraph nodes; and (vii) edges between sentence nodes that appear in the same paragraph. Note that a sentence is only connected to its previous and next neighboring sentence. The final graph consists of these seven types of edges as well as four types of nodes, which link the question to paragraphs, sentences, and entities in a hierarchical way.

3.2 Context Encoding

Given the constructed hierarchical graph, the next step is to obtain the initial representations of all the graph nodes. To this end, we first combine all the selected paragraphs into context C, which is concatenated with the question Q and fed into pre-trained Transformer RoBERTa, followed by a bi-attention layer (Seo et al., 2017). We denote the encoded question representation as $\mathbf{Q} = \{\mathbf{q}_0, \mathbf{q}_1, \ldots, \mathbf{q}_{m-1}\} \in \mathbb{R}^{m\times d}$, and the encoded context representation as $\mathbf{C} = \{\mathbf{c}_0, \mathbf{c}_1, ..., \mathbf{c}_{n-1}\} \in \mathbb{R}^{n\times d}$, where m, n are the length of the question and the context, respectively. Each $\mathbf{q}_i$ and $\mathbf{c}_j \in \mathbb{R}^d$.

A shared BiLSTM is applied on top of the context representation $\mathbf{C}$, and the representations of different nodes are extracted from the output of the BiLSTM, denoted as $\mathbf{M} \in \mathbb{R}^{n\times 2d}$. For entity/sentence/paragraph nodes, which are spans of the context, the representation is calculated from: (i) the hidden state of the backward LSTM at the start position, and (ii) the hidden state of the forward LSTM at the end position. For the question node, a max-pooling layer is used to obtain its representation. Specifically,

$$\begin{aligned}
\mathbf{p}_i &= \text{MLP}_1\left(\left[\mathbf{M}[P^{(i)}_{start}][d{:}];\mathbf{M}[P^{(i)}_{end}][{:}d]\right]\right)\\
\mathbf{s}_i &= \text{MLP}_2\left(\left[\mathbf{M}[S^{(i)}_{start}][d{:}];\mathbf{M}[S^{(i)}_{end}][{:}d]\right]\right)\\
\mathbf{e}_i &= \text{MLP}_3\left(\left[\mathbf{M}[E^{(i)}_{start}][d{:}];\mathbf{M}[E^{(i)}_{end}][{:}d]\right]\right)\\
\mathbf{q} &= \text{max-pooling}(\mathbf{Q})\,, \qquad (1)
\end{aligned}$$

where $P^{(i)}_{start}$, $S^{(i)}_{start}$, and $E^{(i)}_{start}$ denote the start position of the i-th paragraph/sentence/entity node. Similarly, $P_{end}^{(i)}$, $S_{end}^{(i)}$, and $E_{end}^{(i)}$ denote the corresponding end positions. MLP$(\cdot)$ denotes an MLP layer, and $[;]$ denotes the concatenation of two vectors. As a summary, after context encoding, each $\mathbf{p}_i$, $\mathbf{s}_i$, and $\mathbf{e}_i \in \mathbb{R}^d$, serves as the representation of the i-th paragraph/sentence/entity node. The question node is represented as $\mathbf{q} \in \mathbb{R}^d$.

3.3 Graph Reasoning

After context encoding, HGN performs reasoning over the hierarchical graph, where the contextualized representations of all the graph nodes are transformed into higher-level features via a graph neural network. Specifically, let $\mathbf{P} = \{\mathbf{p}_i\}_{i=1}^{n_p}$, $\mathbf{S} = \{\mathbf{s}_i\}_{i=1}^{n_s}$, and $\mathbf{E} = \{\mathbf{e}_i\}_{i=1}^{n_e}$, where n_p, n_s and n_e denote the number of paragraph/sentence/entity nodes in a graph. In experiments, we set $n_p = 4$, $n_s = 40$ and $n_e = 60$ (padded where necessary), and denote $\mathbf{H} = \{\mathbf{q}, \mathbf{P}, \mathbf{S}, \mathbf{E}\} \in \mathbb{R}^{g \times d}$, where $g = n_p + n_s + n_e + 1$, and d is the feature dimension of each node.

For graph propagation, we use Graph Attention Network (GAT) (Veličković et al., 2018) to perform message passing over the hierarchical graph. Specifically, GAT takes all the nodes as input, and updates node feature $\mathbf{h}_i'$ through its neighbors $\mathcal{N}_i$ in the graph. Formally,

$$\mathbf{h}_i' = \text{LeakyRelu}\Big(\sum_{j \in \mathcal{N}_i} \alpha_{ij} \mathbf{h}_j \mathbf{W}\Big)\,, \tag{2}$$

where $\mathbf{h}_j$ is the j^{th} vector from $\mathbf{H}$, $\mathbf{W} \in \mathbb{R}^{d \times d}$ is a weight matrix[2] to be learned, and α_{ij} is the attention coefficients, which can be calculated by:

$$\alpha_{ij} = \frac{\exp(f([\mathbf{h}_i; \mathbf{h}_j]\mathbf{w}_{e_{ij}}))}{\sum_{k \in \mathcal{N}_i} \exp(f([\mathbf{h}_i; \mathbf{h}_k]\mathbf{w}_{e_{ik}}))}\,, \tag{3}$$

where $\mathbf{w}_{e_{ij}} \in \mathbb{R}^{2d}$ is the weight vector corresponding to the edge type e_{ij} between the i-th and j-th nodes, and $f(\cdot)$ denotes the LeakyRelu activation function. In a summary, after graph reasoning, we obtain $\mathbf{H}' = \{\mathbf{h}_0', \mathbf{h}_1', \ldots, \mathbf{h}_g'\} \in \mathbb{R}^{g \times d}$, from which the updated representations for each type of node can be obtained, *i.e.*, $\mathbf{P}' \in \mathbb{R}^{n_p \times d}$, $\mathbf{S}' \in \mathbb{R}^{n_s \times d}$, $\mathbf{E}' \in \mathbb{R}^{n_e \times d}$, and $\mathbf{q}' \in \mathbb{R}^d$.

Gated Attention The graph information will further contribute to the context information for answer span extraction. We merge the context representation $\mathbf{M}$ and the graph representation $\mathbf{H}'$ via a gated attention mechanism:

$$\begin{aligned}
\mathbf{C} &= \text{Relu}(\mathbf{M}\mathbf{W}_m) \cdot \text{Relu}(\mathbf{H}'\mathbf{W}_m')^{\text{T}} \\
\bar{\mathbf{H}} &= \text{Softmax}(\mathbf{C}) \cdot \mathbf{H}' \\
\mathbf{G} &= \sigma([\mathbf{M}; \bar{\mathbf{H}}]\mathbf{W}_s) \cdot \text{Tanh}([\mathbf{M}; \bar{\mathbf{H}}]\mathbf{W}_t),
\end{aligned} \tag{4}$$

where $\mathbf{W}_m \in \mathbb{R}^{2d \times 2d}$, $\mathbf{W}_m' \in \mathbb{R}^{2d \times 2d}$, $\mathbf{W}_s \in \mathbb{R}^{4d \times 4d}$, $\mathbf{W}_t \in \mathbb{R}^{4d \times 4d}$ are weight matrices to learn. $\mathbf{G} \in \mathbb{R}^{n \times 4d}$ is the gated representation which will be used for answer span extraction.

3.4 Multi-task Prediction

After graph reasoning, the updated node representations are used for different sub-tasks: (i) paragraph selection based on *paragraph* nodes; (ii) supporting facts prediction based on *sentence* nodes; and (iii) answer prediction based on *entity* nodes and context representation $\mathbf{G}$. Since the answers may not reside in entity nodes, the loss for entity node only serves as a regularization term.

In our HGN model, all three tasks are jointly performed through multi-task learning. The final objective is defined as:

$$\begin{aligned}
\mathcal{L}_{joint} = \mathcal{L}_{start} + \mathcal{L}_{end} + \lambda_1 \mathcal{L}_{para} + \lambda_2 \mathcal{L}_{sent} \\
+ \lambda_3 \mathcal{L}_{entity} + \lambda_4 \mathcal{L}_{type}\,,
\end{aligned} \tag{5}$$

where λ_1, λ_2, λ_3, and λ_4 are hyper-parameters, and each loss function is a cross-entropy loss, calculated over the logits (described below).

For both paragraph selection ($\mathcal{L}_{para}$) and supporting facts prediction ($\mathcal{L}_{sent}$), we use a two-layer MLP as the binary classifier:

$$\mathbf{o}_{sent} = \text{MLP}_4(\mathbf{S}'),\ \mathbf{o}_{para} = \text{MLP}_5(\mathbf{P}')\,, \tag{6}$$

where $\mathbf{o}_{sent} \in \mathbb{R}^{n_s}$ represents whether a sentence is selected as supporting facts, and $\mathbf{o}_{para} \in \mathbb{R}^{n_p}$ represents whether a paragraph contains the ground-truth supporting facts.

We treat entity prediction ($\mathcal{L}_{entity}$) as a multi-class classification problem. Candidate entities include all entities in the question and those that match the titles in the context. If the ground-truth answer does not exist among the entity nodes, the entity loss is zero. Specifically,

$$\mathbf{o}_{entity} = \text{MLP}_6(\mathbf{E}')\,. \tag{7}$$

The entity loss will only serve as a regularization term, and the final answer prediction will only rely on the answer span extraction module as follows.

---

[2] Note that we omit the bias term for all the weight matrices in the paper to save space.

Table 1: Results on the test set of HotpotQA in the Distractor setting. HGN achieves state-of-the-art results at the time of submission (Dec. 1, 2019). (†) and (⋆) indicates unpublished and concurrent work. RoBERTa-large (Liu et al., 2019) is used for context encoding.

The logits of every position being the start and end of the ground-truth span are computed by a two-layer MLP on top of $\mathbf{G}$ in Eqn.(4):

$$\mathbf{o}_{start} = \text{MLP}_7(\mathbf{G}), \ \mathbf{o}_{end} = \text{MLP}_8(\mathbf{G}) . \quad (8)$$

Following previous work (Xiao et al., 2019), we also need to identify the answer type, which includes the types of span, entity, yes and no. We use a 3-way two-layer MLP for answer-type classification based on the first hidden representation of $\mathbf{G}$:

$$\mathbf{o}_{type} = \text{MLP}_9(\mathbf{G}[0]) . \quad (9)$$

During decoding, we first use this to determine the answer type. If it is "yes" or "no", we directly return it as the answer. Overall, the final cross-entropy loss ($\mathcal{L}_{joint}$) used for training is defined over all the aforementioned logits: $\mathbf{o}_{sent}, \mathbf{o}_{para}, \mathbf{o}_{entity}, \mathbf{o}_{start}, \mathbf{o}_{end}, \mathbf{o}_{type}$.

4 Experiments

In this section, we describe experiments comparing HGN with state-of-the-art approaches and provide detailed analysis on the model and results.

4.1 Dataset

We use HotpotQA dataset (Yang et al., 2018) for evaluation, a popular benchmark for multi-hop QA. Specifically, two sub-tasks are included in this dataset: (i) Answer prediction; and (ii) Supporting facts prediction. For each sub-task, exact match (EM) and partial match (F1) are used to evaluate model performance, and a joint EM and F1 score is used to measure the final performance, which encourages the model to take both answer and evidence prediction into consideration.

There are two settings in HotpotQA: *Distractor* and *Fullwiki* setting. In the Distractor setting, for each question, two gold paragraphs with ground-truth answers and supporting facts are provided, along with 8 'distractor' paragraphs that were collected via a bi-gram TF-IDF retriever (Chen et al., 2017). The Fullwiki setting is more challenging, which contains the same training questions as in the Distractor setting, but does not provide relevant paragraphs for test set. To obtain the right answer and supporting facts, the entire Wikipedia can be used to find relevant documents. Implementation details can be found in Appendix B.

4.2 Experimental Results

Results on Test Set Table 1 and 2 summarize results on the hidden test set of HotpotQA. In Distractor setting, HGN outperforms both published and unpublished work on every metric by a significant margin, achieving a Joint EM/F1 score of 47.11/74.21 with an absolute improvement of 2.44/1.48 over previous state of the art. In Fullwiki setting, HGN achieves state-of-the-art results on

Table 2: Results on the test set of HotpotQA in the Fullwiki setting. HGN achieves state-of-the-art results at the time of submission (Feb. 11, 2020). (†) indicates unpublished work. RoBERTa-large (Liu et al., 2019) and ALBERT-xxlarge-v2 (Lan et al., 2020) are used for context encoding, and SemanticRetrievalMRS is used for retrieval. Leaderboard: https://hotpotqa.github.io/.

Joint EM/F1 with 2.57/1.08 improvement, despite using an inferior retriever; when using the same retriever as in SemanticRetrievalMRS (Yixin Nie, 2019), our method outperforms by a significant margin, demonstrating the effectiveness of our multi-hop reasoning approach. In the following sub-sections, we provide a detailed analysis on the sources of performance gain on the dev set. Additional ablation study on paragraph selection is provided in Appendix D.

Effectiveness of Hierarchical Graph As described in Section 3.1, we construct our graph with four types of nodes and seven types of edges. For ablation study, we build the graph step by step. First, we only consider edges from question to paragraphs, and from paragraphs to sentences, *i.e.*, only edge type (i), (iii) and (iv) are considered. We call this the PS Graph. Based on this, entity nodes and edges related to each entity node (corresponding to edge type (ii) and (v)) are added. We call this the PSE Graph. Lastly, edge types (vi) and (vii) are added, resulting in the final hierarchical graph.

As shown in Table 4, the use of PS Graph improves the joint F1 score over the plain RoBERTa model by 2.81 points. By further adding entity nodes, the Joint F1 increases by 0.30 points. This indicates that the addition of entity nodes is helpful, but may also bring in noise, thus only leading to limited performance improvement. By including edges among sentences and paragraphs, our final hierarchical graph provides an additional improvement of 0.24 points. We hypothesize that this is due to the explicit connection between sentences that leads to better representations.

Effectiveness of Pre-trained Language Model To verify the effects of pre-trained language models, we compare HGN with prior state-of-the-art methods using the same pre-trained language models. Results in Table 5 show that our HGN variants outperform DFGN, EPS and SAE, indicating the performance gain comes from better model design.

4.3 Analysis

In this section, we provide an in-depth error analysis on the proposed model. HotpotQA provides two reasoning types: "bridge" and "comparison". "Bridge" questions require the identification of a bridge entity that leads to the answer, while "comparison" questions compare two entities to infer the answer, which could be *yes*, *no* or *a span of text*. For analysis, we further split "comparison" questions into "comp-yn" and "comp-span". Table 6 indicates that "comp-yn" questions are the easiest, on which our model achieves 88.5 joint F1 score. HGN performs similarly on "bridge" and "comp-span" with 74 joint F1 score, indicating that there is still room for further improvement.

To provide a more in-depth understanding of our

Category	Question	Answer	Prediction	Pct (%)
Annotation	Were the films Tonka and 101 Dalmatians released in the same decade?	1958 Walt Disney Western adventure film	No	9

Question	Ans F1	Sup F1	Joint F1	Pct (%)
comp-yn	93.45	94.22	88.50	6.19
comp-span	79.06	91.72	74.17	13.90
bridge	81.90	87.60	73.31	79.91

Table 6: Results of HGN for different reasoning types. 'Pct' is short for 'Percentage'.

model's weaknesses (and provide insights for future work), we randomly sample 100 examples in the dev set with the answer F1 as 0. After carefully analyzing each example, we observe that these errors can be roughly grouped into six categories: (i) *Annotation*: the annotation provided in the dataset is not correct; (ii) *Multiple Answers*: questions may have multiple correct answers, but only one answer is provided in the dataset; (iii) *Discrete Reasoning*: this type of error often appears in "comparison" questions, where discrete reasoning is required to answer the question correctly; (iv) *Commonsense & External Knowledge*: to answer this type of question, commonsense or external knowledge is required; (v) *Multi-hop*: the model fails to perform multi-hop reasoning, and finds the final answer from wrong paragraphs; (vi) *MRC*: model correctly finds the supporting paragraphs and sentences, but predicts the wrong answer span.

Note that these error types are not mutually exclusive, but we aim to classify each example into only one type, in the order presented above. For example, if an error is classified as 'Commonsense & External Knowledge' type, it cannot be classified as 'Multi-hop' or 'MRC' error. Table 3 shows examples from each category (the corresponding paragraphs are omitted due to space limit).

We observed that a lot of errors are due to the fact that some questions have multiple answers with the same meaning, such as "*a body of water* vs. *creek*", "*EPA* vs. *Environmental Protection Agency*", and "*American-born* vs. *U.S. born*". In these examples, the former is the ground-truth answer, and the latter is our model's prediction. Secondly, for questions that require commonsense or discrete reasoning (*e.g.*, "*second*" means "*Code#02*"[3], "*which band has more members*", or "*who was born earlier*"), our model just randomly picks an entity as answer, as it is incapable of performing this type of reasoning. The majority of the errors are from either multi-hop reasoning or MRC model's span selection, which indicates that there is still room for further improvement. Additional examples are provided in Appendix F.

4.4 Generalizability Discussion

The hierarchical graph can be applied to different multi-hop QA datasets, though in this paper mainly tailored for HotpotQA. Here we use Wikipedia hyperlinks to connect sentences and paragraphs. An alternative way is to use an entity linking system to make it more generalizable. For each sentence node, if its entities exist in a paragraph, an edge can be added to connect the sentence and paragraph nodes. In our experiments, we restrict the number of multi-hops to two for the HotpotQA task, which can be increased to accommodate other datasets. The maximum number of paragraphs is set to four for HotpotQA, as we observe that using more documents within a maximum sequence length does not help much (see Table 9 in the Appendix). To generalize to other datasets that need to consume longer documents, we can either: (i) use sliding-window-based method to chunk a long sequence into short ones; or (ii) replace the BERT-based backbone with other transformer-based models that are capable of dealing with long sequences (Beltagy et al., 2020; Zaheer et al., 2020; Wang et al., 2020).

5 Conclusion

In this paper, we propose a new approach, Hierarchical Graph Network (HGN), for multi-hop question answering. To capture clues from different granularity levels, our HGN model weaves heterogeneous nodes into a single unified graph. Experiments with detailed analysis demonstrate the effectiveness of our proposed model, which achieves state-of-the-art performances on the HotpotQA benchmark. Currently, in the Fullwiki setting, an off-the-shelf paragraph retriever is adopted for selecting relevant context from large corpus of text. Future work includes investigating the interaction and joint training between HGN and paragraph retriever for performance improvement.

A Datasets

There are two benchmark settings in HotpotQA: *Distractor* and *Fullwiki* setting. They both have 90k training samples and 7.4k development samples. In the Distractor setting, there are 2 gold paragraphs and 8 distractors. However, 2 gold paragraphs may not be available in the Fullwiki Setting. Therefore, the Fullwiki setting is more challenge which requires to search the entire Wikipedia to find relevant documents. For both settings, there are 90K hidden test samples. More details about the dataset can be found in Yang et al. (2018).

B Implementation Details

Our implementation is based on the Transformer library (Wolf et al., 2019). To construct the proposed hierarchical graph, we use spacy[4] to extract entities from both questions and sentences. The numbers of entities, sentences and paragraphs in one graph are limited to 60, 40 and 4, respectively. Since HotpotQA only requires two-hop reasoning, up to two paragraphs are connected to each question. Our paragraph ranking model is a binary classifier based on the RoBERTa-large model. For the Fullwiki setting, we leverage the retrieved paragraphs and the paragraph ranker provided by Yixin Nie (2019). We finetune on the training set for 8 epochs, with batch size as 8, learning rate as 1e-5, λ_1 as 1, λ_2 as 5, λ_3 as 1, λ_4 as 1, LSTM dropout rate as 0.3 and GNN dropout rate as 0.3. We search hyperparameters for learning rate from $\{$1e-5, 2e-5, 3e-5$\}$, λ_2 from $\{1, 3, 5\}$ and dropout rate from $\{0.1, 0.3, 0.5\}$.

C Computing Resources

We conduct experiments on 4 Quadro RTX 8000 GPUs. The parameters of each component in HGN are summarized in Table 7. The computation bottleneck is mainly from RoBERTa. The best model of HGN took around 12 hours for training, which is almost the same as the RoBERTa-large baseline.

Components	#Parameters
RoBERTa	355M
Bi-Attention	0.62M
BiLSTM	1.44M
GNN	29M
Multi-task Layer	0.55M

Table 7: Number of parameters for each component in HGN.

D Effectiveness of Paragraph Selection

The proposed HGN relies on effective paragraph selection to find relevant multi-hop paragraphs. Table 8 shows the performance of paragraph selection on the dev set of HotpotQA. In DFGN, paragraphs are selected based on a threshold to maintain high recall (98.27%), leading to a low precision (60.28%). Compared to both threshold-based and pure Top-N-based paragraph selection, our two-step para-

---

[4] https://spacy.io

Method	Precision	Recall	#Para.
Threshold-based	60.28	98.27	3.26
Top 2 from ranker	93.43	93.43	2
Top 4 from ranker	49.39	98.48	4
1st hop	96.10	59.74	1.24
2 paragraphs (ours)	**94.53**	94.53	2
4 paragraphs (ours)	49.45	**98.74**	4

Table 8: Performance of paragraph selection on the dev set of HotpotQA based on BERT-base.

graph selection process is more accurate, achieving 94.53% precision and 94.53% recall. Besides these two top-ranked paragraphs, we also include two other paragraphs with the next highest ranking scores, to obtain a higher coverage on potential answers. Table 9 summarizes the results on the dev set in the Distractor setting, using our paragraph selection approach for both DFGN and the plain BERT-base model. Note that the original DFGN does not finetune BERT, leading to much worse performance. In order to provide a fair comparison, we modify their released code to allow finetuning of BERT. Results show that our paragraph selection method outperforms the threshold-based one in both models.

Model	Ans F1	Sup F1	Joint F1
DFGN (paper)	69.38	82.23	59.89
DFGN			
+ threshold-based	71.90	83.57	63.04
+ 2 para. (ours)	72.53	83.57	63.87
+ 4 para. (ours)	**72.67**	83.34	63.63
BERT-base			
+ threshold-based	71.95	82.79	62.43
+ 2 para. (ours)	72.42	83.64	63.94
+ 4 para. (ours)	**72.67**	**84.86**	**64.24**

Table 9: Results with selected paragraphs on the dev set in the Distractor setting.

E Case Study

We provide two example questions for case study. To answer the question in Figure 3 (left), Q needs to be linked with $P1$. Subsequently, the sentence $S4$ within $P1$ is connected to $P2$ through the hyperlink (*"John Surtees"*) in $S4$. A plain BERT model without using the constructed graph missed $S7$ as additional supporting facts, while our HGN discovers and utilizes both pieces of evidence as the connections among $S4$, $P2$ and $S7$ are explicitly encoded in our hierarchical graph.

For the question in Figure 3 (right), the inference chain is $Q \rightarrow P1 \rightarrow S1 \rightarrow S2 \rightarrow P2 \rightarrow S3$. The plain BERT model infers the evidence sentences $S2$ and $S3$ correctly. However, it fails to predict $S1$ as the supporting facts, while HGN succeeds, potentially due to the explicit connections between sentences in the constructed graph.

F Additional Examples for Error Analysis

Below, we provide additional examples for error analysis, where "Q" denotes question, "A" denotes answer provided with dataset and "P" denotes the prediction of proposed model. A full list of all the 100 examples is provided in Table 10 and 11.

Category: Annotation

Question: In the 1962 German Grand Prix, a racer came second. What did this racer found?
Ground-truth Supporting Facts: S4, S7

P1 1962 German Grand Prix
S1 The 1962 German Grand Prix was a Formula One motor race held at the Nürburgring on 5 August 1962.
…
S4 John Surtees finished second for the Lola team and Porsche driver Dan Gurney came in third.
P2 John Surtees
S5 John Surtees was an English Grand Prix motorcycle road racer and Formula One driver.
…
S7 He founded the Surtees Racing Organisation team that competed as a constructor in Formula One, Formula 2 and Formula 5000 from 1970 to 1978.

Prediction: **HGN**: S4, S7; **w/o Hierarchical Graph**: S4

Question: What is the birthplace of the Senator who represents the first of 62 districts in the State Senate?
Ground-truth Supporting Facts: S1, S2, S3

P1 New York's 1st State Senate district
S1 New York's 1st State Senate district is one of 62 districts of the New York State Senate.
S2 It is currently represented by Senator Kenneth LaValle (R).
P2 Kenneth LaValle
S3 Kenneth P. LaValle (born May 22, 1939 in Brooklyn, New York) represents District 1 in the New York State Senate, …
S4 First elected in 1976, he is the chair of the Higher Education Committee in the State Senate.

Prediction: **HGN**: S1, S2, S3; **w/o Hierarchical Graph**: S2, S3

Abstract

State-of-the-art models for multi-hop question answering typically augment large-scale language models like BERT with additional, intuitively useful capabilities such as named entity recognition, graph-based reasoning, and question decomposition. However, does their strong performance on popular multi-hop datasets really justify this added design complexity? Our results suggest that the answer may be no, because even our simple pipeline based on BERT, named QUARK, performs surprisingly well. Specifically, on HotpotQA, QUARK outperforms these models on both question answering and support identification (and achieves performance very close to a RoBERTa model). Our pipeline has three steps: 1) use BERT to identify potentially relevant sentences *independently* of each other; 2) feed the set of selected sentences as context into a standard BERT span prediction model to choose an answer; and 3) use the sentence selection model, now with the chosen answer, to produce supporting sentences. The strong performance of QUARK resurfaces the importance of carefully exploring simple model designs before using popular benchmarks to justify the value of complex techniques.

1 Introduction

Textual Multi-hop Question Answering (QA) is the task of answering questions by combining information from multiple sentences or documents. This is a challenging reasoning task that requires QA systems to identify relevant pieces of information in the given text and learn to compose them to answer a question. To enable progress in this area, many datasets (Welbl et al., 2018; Talmor and Berant, 2018; Yang et al., 2018; Khot et al., 2020) and models (Min et al., 2019b; Xiao et al., 2019; Tu et al., 2020) with varying complexities have been proposed over the past few years. Our work focuses on HotpotQA (Yang et al., 2018), which contains 105,257 multi-hop questions derived from two Wikipedia paragraphs, where the correct answer is a span in these paragraphs or yes/no.

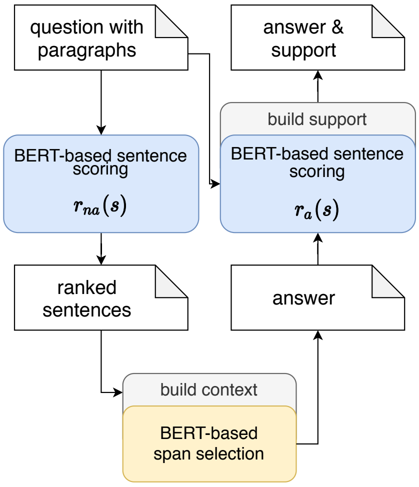

Figure 1: Overview of the QUARK model, with a question and context paragraphs as input. In both blue boxes, sentences are scored independently from one another. $r_{na}(s)$ and $r_a(s)$ use the same model architecture with different weights.

Due to the multi-hop nature of this dataset, it is natural to assume that the relevance of a sentence for a question would depend on the other sentences considered to be relevant. E.g., the relevance of "Obama was born in Hawaii." to the question "Where was the 44th President of USA born?" depends on the other relevant sentence: "Obama was the 44th President of US." As a result, many approaches designed for this task focus on *jointly* identifying the relevant sentences (or paragraphs) via mechanisms such as cross-document attention, graph networks, and entity linking.

Our results question this basic assumption. We show that a simple model, QUARK (see Fig. 1), that first identifies relevant sentences from each

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8839–8845,
November 16–20, 2020. ©2020 Association for Computational Linguistics

paragraph *independent* of other paragraphs, is surprisingly powerful on this task: By using only the context of the corresponding paragraph, QUARK can recover all gold supporting sentences within the top-5 sentences. For QA, it uses a standard BERT (Devlin et al., 2019) span prediction model (similar to current published models) on the output of this module. Additionally, QUARK exploits the inherent similarity between the relevant sentence identification task and the task of generating an explanation given the answer from a QA module: it uses the same architecture for both tasks.

We show that this independent sentence scoring model results in a simple QA pipeline that outperforms other BERT models in both 'distractor' and 'fullwiki' settings of HotpotQA. In the distractor setting (10 paragraphs, including two gold, provided as context), QUARK achieves joint scores (answer and support prediction) within 0.75% of the current state of the art. Even in the fullwiki setting (all 5M Wikipedia paragraphs as context), by combining our sentence selection approach with a commonly used paragraph selection approach (Nie et al., 2019),[1] we outperform all previously published BERT models. In both settings, the only models scoring higher use RoBERTa (Liu et al., 2019), a more robustly trained language model that is known to outperform BERT across various tasks.

While our design uses multiple transformer models (now considered a standard starting point in NLP), our contribution is a simple pipeline without any bells and whistles, such as NER, graph networks, entity linking, etc. The closest effort to QUARK is by Min et al. (2019a), who also propose a simple QA model for HotpotQA, but don't consider the support task and fall several points short of SOTA on the QA task due to reasoning over only one paragraph at a time.

Finally, our ablation study demonstrates that the sentence selection module benefits substantially from using context from the corresponding paragraph. It also shows that running this module a second time, with the chosen answer as input, results in more accurate support identification.

2 Related Work

Most approaches for HotpotQA attempt to capture the interactions between the paragraphs by either relying on cross-attention between documents or sequentially selecting paragraphs based on the previously selected paragraphs.

While Nishida et al. (2019) also use a standard Reading Comprehension (RC) model, they combine it with a special Query Focused Extractor that identifies relevant sentences by updating a RNN state representation in each step, allowing the model to capture dependencies between sentences across time-steps. Xiao et al. (2019) propose a Dynamically Fused Graph Networks (**DFGN**) model that first creates an entity graph from paragraphs, dynamically extracts sub-graphs, and fuses them with paragraph representations. The Select, Answer, Explain (**SAE**) model (Tu et al., 2020) also first selects relevant documents and uses them to produce answers and explanations. However, it relies on a self-attention over *all* document representations to capture potential interactions. Additionally, it relies on a Graph Neural Network (GNN) to answer the questions. Hierarchical Graph Network (**HGN**) model (Fang et al., 2020) builds a hierarchical graph with three levels: entities, sentences and paragraphs to allow for joint reasoning. **DecompRC** (Min et al., 2019b) takes a completely different approach of learning to decompose the question (using additional annotations) and then answer the decomposed questions using a standard single-hop RC system.

Others such as Min et al. (2019a) have noticed that many HotpotQA questions can be answered just based on a single paragraph. However, they did not consider the support identification task (which we show can also be done independently). While they achieve strong (but not quite SOTA) QA performance by *only reasoning over a single paragraph*, we show that interaction is actually valuable for QA! Specifically, by using relevant sentences spread across multiple paragraphs, our simple model outperforms previous models with more complex interactions. We thus view QUARK as a different, stronger baseline for multi-hop QA.

In the fullwiki setting, each question has no associated context and models are expected to select paragraphs from Wikipedia. To be able to scale to such a large corpus, the proposed systems often select the paragraphs independent of each other. A recent retrieval method in this setting is Semantic Retrieval (Nie et al., 2019) where first the paragraphs are selected based on the question, followed by individual sentences from these para-

---

[1] While their approach selects the paragraphs jointly using the link structure, our sentence selection approach is still independent of the other paragraphs.

graphs. However, unlike our approach, they do not use the paragraph context to select the sentences, missing key context needed to identify relevance.

3 Pipeline Model: QUARK

Our model works in three steps. First, we score individual sentences from an input set of paragraphs D based on their relevance to the question. Second, we feed the highest-scoring sentences to a span prediction model to produce an answer to the question. Third, we score sentences from D a second time to identify the supporting sentences using the answer. These three steps are implemented using the two modules described next in Sections 3.1 and 3.2.

3.1 Sentence Scoring Module

In the distractor setting, HotpotQA provides 10 context paragraphs that have an average length of 41.4 sentences and 1106 tokens. This is too long for standard LM-based span-prediction—most models scale quadratically with the number of tokens, and some are limited to 512 tokens. This motivates selecting a few relevant sentences E to reduce the size of the input to the model without losing important context. In a similar vein, the support identification subtask of HotpotQA also involves selecting a few sentences that best explain the chosen answer. We solve both of these problems with the same transformer-based sentence scoring module, with slight variation in its input.

We score every sentence s from every paragraph $p \in D$ independently by feeding the following sequence to the model: `[CLS] question [SEP] p [SEP] answer [SEP]`. This sequence is the same for every sentence in the paragraph, but the segment ID for the sentence being classified is set to 1 for tokens from the sentence, and to 0 for the rest. Each annotated support sentence forms a positive example and all other sentences from D form the negative examples. Note that our classifier scores each sentence independently and never sees sentences from two paragraphs at the same time. (details in App. A.1)

We train two variants of this model: (1) $r_{na}(s)$ is trained to score sentences given a question but no answer (`answer` is replaced with a `[MASK]` token); and (2) $r_a(s)$ is trained to score sentences given a question and its gold answer. We use $r_{na}(s)$ for relevant sentence selection and $r_a(s)$ for support identification.

3.2 Question Answering Module

To find answers to questions, we use Wolf et al. (2019)'s implementation of Devlin et al. (2019)'s span prediction model. To achieve our best score, we use their *BERT-Large-Cased* model with whole-word masking and SQuAD (Rajpurkar et al., 2016) fine-tuning.[2] We fine-tune this model on the HotpotQA dataset with input QA context E from $r_{na}(s)$. Since BERT models have a hard limit of 512 word-pieces, we use $r_{na}(s)$ to select the most relevant sentences that can fit within this limit, as described next. (See Appendix A.2 for training details.)

To accomplish this, we compute the score $r_{na}(s)$ for each sentence in the input D. Then we add sentences in decreasing order of their scores to the QA context E, until we have filled no more than 508 word-pieces (incl. question word-pieces). For every new paragraph considered, we also add its first sentence, and the title of the article (enclosed in `<t></t>`). This ensures that our span-prediction model has the right co-referential information from each paragraph. We arrange these paragraphs in the order of their highest-scoring sentence, so the most relevant sentences come earlier – a signal that could be exploited by our model. The final four tokens are a separator, plus the words `yes`, `no`, and `noans`. This allows the model to answer yes/no comparison questions, or give no answer at all.

3.3 Bringing it Together

Given a question along with 10 distractor paragraphs D, we use the $r_{na}(s)$ variant of our sentence scoring module to score each sentence s in D, again without looking at other paragraphs. In the second step, the selected sentences are fed as context E into the QA module (as described in Section 3.2) to choose an answer. In the final step, to find sentences supporting the chosen answer, we use $r_a(s)$ to score each sentence in D, this time with the chosen answer as part of the input.

We define the score $R_a(S)$ of a set of sentences $S \subset D$ to be the sum of the individual sentence scores; that is, $R_a(S) = \sum_{s \in S} r_a(s)$.[3] In HotpotQA, supporting sentences always come from exactly two paragraphs. We compute this score for all possible S satisfying this constraint and take the highest scoring set of sentences as our support.

---

[2] While we use the model fine-tuned on SQuAD, ablations show that this only adds 0.2% to the final score.

[3] Note that $r_a(s)$ is the logit score and can be negative, so adding a sentence may not always improve this score.

QA Model	Ans EM	Ans F1	Sup EM	Sup F1	Joint EM	Joint F1
Single-paragraph (Min et al., 2019a)	–	67.08	–	–	–	–

HGN + SR-MRS (Fang et al., 2020)	**56.71**	**69.16**	**49.97**	**76.39**	**35.36**	**59.86**

Table 2: HotpotQA's fullwiki setting, Test set. The bottom-most model uses a larger language model than Quark.

At first blush, the number of possible sentence subsets S to consider grows exponentially with the total number of sentences, making it impossible to evaluate them all. Fortunately, it is part of the task specification that the sentences in S always come from exactly two different paragraphs. This makes the problem exponential in the number of sentences in a single paragraph, not in the total number of sentences across paragraphs. The number of sets to consider is $\mathrm{O}(p^2 \times 2^{2s})$, where p is the number of paragraphs and s is the number of sentences per paragraph. In practice, this results in a median of 12000 sets evaluated per question. While evaluating this number of sets is feasible, we also use another trick to reduce the sets: For every paragraph, we only consider sentences with a positive score, plus the top two sentences with a negative score.

In the fullwiki setting, we use the paragraphs SR-MRS (Nie et al., 2019) as a starting point. SR-MRS assigns a score to individual paragraphs, so we determined a score cut-off of -7.0 for optimal performance on the dev set. The rest of the experimental setup is identical to the distractor setting.

4 Experiments

We evaluate on both the distractor and fullwiki settings of HotpotQA with the following goal: *Can a simple pipeline model outperform more complex approaches?* We present the EM (Exact Match) and F1 scores on (1) answer selection, (2) support selection, and (3) Joint score.

Table 1 shows that on the distractor setting, Quark outperforms previous models based on BERT. Moreover, we are within 1 point of models that use RoBERTa embeddings—a stronger language model that has shown big improvements in previous HotpotQA models. Quark also performs better than the recent single-paragraph approach for the QA subtask (Min et al., 2019a) by 14 points F1. While most of this gain comes from using a larger language model, Quark scores 2 points higher even with a language model of the same size.

We observe a similar trend in the fullwiki setting (Table 2). While we rely on retrieval from SR-MRS (Nie et al., 2019) for our initial paragraphs, we outperform the original work.[4] Even when we use the same language model as SR-MRS, BERT-Base, we achieve a joint F1 score of 51.8 on the Dev set compared to their joint F1 score of 49.2.

We attribute this improvement to two factors: our sentence selection capitalizing on the sentence's paragraph context leading to better support selection, and a better span selection model leading to improved QA.

4.1 Ablation

To evaluate the impact of context on our sentence selection model in isolation, we look at the number of sentences that score at least as high as the lowest-scoring annotated support sentence. In other words, this is the number of sentences we must send to the QA model to ensure all annotated support is included. Table 3 shows that providing the model

---

[4] Recent retrieval approaches outperform SR-MRS (Asai et al., 2020). Evaluating our system on their retrieval is a potential direction of future work.

	top-n	Sup F1	Ans F1
B-Base w/o context	10	74.45	78.59
B-Base w/ context	6	83.15	80.92
+ B-Large ($r_{na}(s)$)	**5**	85.35	**81.21**
w/ answers ($r_a(s)$)	5	**86.97**	–
Oracle	3	–	–

Table 3: Ablation study on sentence selection in the distractor setting. top-*n* is the number of sentences required to cover the annotated support sentences in 90% of the questions.

with the context from the paragraph gives a substantial boost on this metric, bringing it down from 10 to only 6 when using BERT-Base (an oracle would need 3 sentences). It further shows that this boost carries over to the downstream tasks of span selection and choosing support sentences (improving it by 9 points to 83%). Finally, the table shows the value of running the sentence selection model a second time: with BERT-Large, $r_a(s)$ outperforms $r_{na}(s)$ by 1.62% on the Support F1 metric.

5 Conclusion

Our work shows that on the HotpotQA tasks, a simple pipeline model can do as well as or better than more complex solutions, such as graph networks, cross-document attention, or NER. Powerful pre-trained models allow us to score sentences one at a time, without looking at other paragraphs. By operating jointly over these sentences chosen from multiple paragraphs, we arrive at answers and supporting sentences on par with state-of-the-art approaches. This result shows that supporting sentence identification in HotpotQA is itself not a multi-hop problem, and suggests focusing on other multi-hop datasets to demonstrate the value of more complex retrieval techniques.

A Appendix

A.1 Training the sentence scoring model

Both $r_{na}(s)$ and $r_a(s)$ are trained the same way. We use the 90447 questions from the HotpotQA training set, shuffle them, and train for three epochs. We construct positive and negative examples by choosing the two paragraphs containing the annotated support sentences, plus two more randomly chosen paragraphs. All sentences from the chosen paragraphs become instances for the model. If an instance contains more than 512 tokens, we truncate the paragraph until the question, special tokens, and paragraph tokens fit within the 512 token limit.

During training, we follow the fine-tuning advice from (Devlin et al., 2019), with two exceptions. We ramp up the learning rate from 0 to 10^{-5} over the first 10% of the batches, and then linearly decrease it again to 0.

Except where stated otherwise, we use *BERT-Large-Cased* model trained with whole-word masking as a starting point. Here, whole word masking refers to a BERT variant that masks entire words instead of word pieces during pre-training.

To avoid biasing the training towards questions with many context sentences, we create batches at the question level. Three questions make up one batch, regardless of how many sentences they contain. We cap the batch size at 5625 tokens for practical purposes. If a batch exceeds this size, we drop sentences at random until the batch is small enough. As is standard for BERT classifiers, we use a cross-entropy loss with two classes, one for positive examples, and one for negative examples.

Training one of these models takes about 55 hours on a single NVidia Quadro RTX 8000. Inference on the same model gets up to 1.1 questions per second on the same GPU. Since our model does not differ in architecture from the one described in Devlin et al. (2019), it has the same 340M parameters. Most of our experiments centered around the format of the input data instead of hyperparameters. We only varied the number of epochs from 1 to 4, choosing 3 as the one giving the best performance on the development set.

A.2 Training the span prediction model

We train the BERT span prediction model on the output paragraphs from $r_{na}(s)$. We use a batch size of 16 questions and maximum sequence length of 512 word-pieces. We use the same optimizer settings as the sentence selection model with an additional weight decay of 0.01. The model is trained for a fixed number of epochs (set to 3) and the final model is used for evaluation.

Under the hood, this model consists of two classifiers that run at the same time. One finds the first token of potential spans, and one finds the last token of potential spans. Each classifier uses a cross entropy loss. The final loss is the average loss of the two classifiers. We train one model on the output from our best $r_{na}(s)$ selection model and use it in all our experiments (and ablations).

Once again, this model differs from BERT only in the input and training data, and thus has the same 340M parameters. Our choice of hyperparameters is derived from the work in Clark et al. (2019). We did no further hyperparameter searches. Experiments with three different random seeds show a variation of QA F1 score of $\pm 0.2\%$. Training takes about 10 hours on a NVidia Quadro RTX 8000. During inference, the span prediction model can process 25 questions per second.

Is Multihop QA in DiRe Condition?
Measuring and Reducing Disconnected Reasoning

Abstract

Has there been real progress in multi-hop question-answering? Models often exploit dataset artifacts to produce correct answers, without connecting information across multiple supporting facts. This limits our ability to measure true progress and defeats the purpose of building multi-hop QA datasets. We make three contributions towards addressing this. First, we formalize such undesirable behavior as disconnected reasoning across subsets of supporting facts. This allows developing a model-agnostic probe for measuring how much any model can cheat via disconnected reasoning. Second, using a notion of *contrastive support sufficiency*, we introduce an automatic transformation of existing datasets that reduces the amount of disconnected reasoning. Third, our experiments[1] suggest that there hasn't been much progress in multifact QA in the reading comprehension setting. For a recent large-scale model (XLNet), we show that only 18 points out of its answer F1 score of 72 on HotpotQA are obtained through multifact reasoning, roughly the same as that of a simpler RNN baseline. Our transformation substantially reduces disconnected reasoning (19 points in answer F1). It is complementary to adversarial approaches, yielding further reductions in conjunction.

1 Introduction

Multi-hop question answering requires connecting and synthesizing information from multiple facts in the input text, a process we refer to as *multifact reasoning*. Prior work has, however, shown that bad reasoning models, ones that by design do not connect information from multiple facts, can achieve high scores because they can exploit specific types of biases and artifacts (e.g., answer type shortcuts) in existing datasets (Min et al., 2019; Chen and Durrett, 2019). While this demonstrates the existence of models that *can* cheat, what we do not know is the extent to which current models *do* cheat, and whether there has been real progress in building models for multifact reasoning.

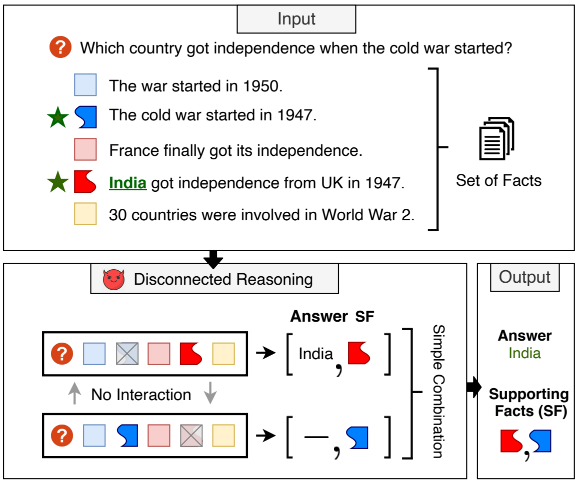

Figure 1: Example of *disconnected reasoning*, a form of bad multifact reasoning: Model arrives at the answer by simply combining its outputs from two subsets of the input, neither of which contains all supporting facts. From one subset, it identifies the blue supporting fact (🟦), the only one mentioning cold war. *Independently*, from the other subset, it finds the red fact (🟥) as the only one mentioning a country getting independence with associated time, and returns the correct answer (India). Further, it returns a simple union of the supporting facts it found over the input subsets.

We address this issue in the context of multi-hop reading comprehension. We introduce a general-purpose characterization of a form of bad multihop reasoning, namely *disconnected reasoning*. For datasets annotated with supporting facts, this allows devising a model-agnostic probe to estimate the extent of disconnected reasoning done by *any* model, and an automatic transformation of existing datasets that reduces such disconnected reasoning.

Measuring Disconnected Reasoning. Good multifact reasoning,[2] at a minimum, requires models to connect information from one or more facts when they select and use information from other facts to arrive at an answer. However, models can cheat, as illustrated in Figure 1, by independently assessing information in subsets of the input facts none of which contains all supporting facts, and taking a simple combination of outputs from these subsets (e.g., by taking a union) to produce the overall output. This entirely avoids meaningfully combining information across all supporting facts, a fundamental requirement of multifact reasoning. We refer to this type of reasoning as *disconnected reasoning* (DiRe in short) and provide a formal criterion, the DIRE condition, to catch cheating models. Informally, it checks whether for a given test of multifact reasoning (e.g., answer prediction or supporting fact identification), a model is able to trivially combine its outputs on subsets of the input context (none of which has all supporting facts) without any interaction between them.

Using the DIRE condition, we develop a systematic probe, involving an automatically generated probing dataset, that measures how much a model can score using disconnected reasoning.

Reducing Disconnected Reasoning. A key aspect of a disconnected reasoning model is that it does not change its behavior towards the selection and use of supporting facts that are in the input, whether or not the input contains all of the supporting facts the question requires. This suggests that the notion of sufficiency—whether all supporting facts are present in the input, which clearly matters to a good multifact model—does not matter to a bad model. We formalize this into a *constrastive support sufficiency* test (CSST) as an additional test of multifact reasoning that is harder to cheat. We introduce an automatic transformation that adds to each question in an original multi-hop dataset a group of *insufficient context* instances corresponding to different subsets of supporting facts. A model must recognize these as having insufficient context in order to receive any credit for the question.

Our **empirical evaluation** on the HotpotQA dataset (Yang et al., 2018) reveals three interesting findings: (i) A substantial amount of progress on multi-hop reading comprehension can be attributed to improvements in disconnected reasoning. E.g., XLNet (Yang et al., 2019), a recent large-scale langugage model, only achieves 17.5 F1 pts (of its total 71.9 answer F1) via multifact reasoning, roughly the same as a much simpler RNN model. (ii) Training on the transformed dataset with CSST results in a substantial reduction in disconnected reasoning (e.g., a 19 point drop in answer F1), demonstrating that it less cheatable, is a harder test of multifact reasoning, and gives a better picture of the current state of multifact reasoning. (iii) The transformed dataset is more effective at reducing disconnected reasoning than a previous adversarial augmentation method (Jiang and Bansal, 2019), and is also complementary, improving further in combination.

In summary, the DiRe probe serves as a simple yet effective tool for **model designers** to assess how much of their model's score can actually be attributed to multifact reasoning. Similarly, **dataset designers** can assess how cheatable is their dataset D (in terms of allowing disconnected reasoning) by training a strong model on the DiRe probe for D, and use our transform to reduce D's cheatability.

2 Related Work

Multi-hop Reasoning: Many multifact reasoning approaches have been proposed for HotpotQA and similar datasets (Mihaylov et al., 2018; Khot et al., 2020). These use iterative fact selection (Nishida et al., 2019; Tu et al., 2020; Asai et al., 2020; Das et al., 2019), graph neural networks (Xiao et al., 2019; Fang et al., 2020; Tu et al., 2020), or simply cross-document self-attention (Yang et al., 2019; Beltagy et al., 2020) to capture inter-paragraph interaction. While these approaches have pushed the state of the art, the extent of actual progress on multifact reasoning remains unclear.

Identifying Dataset Artifacts: Several works have identified dataset artifacts for tasks such as NLI (Gururangan et al., 2018), Reading Comprehension (Feng et al., 2018; Sugawara et al., 2020), and even multi-hop reasoning (Min et al., 2019; Chen and Durrett, 2019). These artifacts allow models to solve the dataset without actually solving the underlying task. On HotpotQA, prior work has shown *existence* of models that identify the support (Groeneveld et al., 2020) and answer (Min et al., 2019; Chen and Durrett, 2019) by operating on each paragraph or sentence independently. We, on the other hand, estimate the amount of disconnected reasoning in *any* model and quantify the cheatability of answer and support identification.

---

[2] We refer to desirable types of multifact reasoning as *good* and undesirable types as *bad*.

Mitigation of Dataset Artifacts: To deal with these artifacts, several adversarial methods have been proposed for reading comprehension (Jia and Liang, 2017; Rajpurkar et al., 2018) and multi-hop QA (Jiang and Bansal, 2019). These methods minimally perturb the input text to limit the effectiveness of the dataset artifacts. Our insufficient context instances that partition the context are complementary to these approaches (as we show in our experiments). Rajpurkar et al. (2018) used a mix of answerable and unanswerable questions to make the models avoid superficial reasoning. In a way, while these hand-authored unanswerable questions also provide insufficient context, we specifically focus on (automatically) creating unanswerable *multi-hop questions* by providing insufficient context.

Minimal Pairs: Recent works (Kaushik et al., 2019; Lin et al., 2019; Gardner et al., 2020) have proposed evaluating NLP systems by generating minimal pairs (or contrastive examples) that are similar but have different labels. Insufficient context instances in our sufficiency test can be thought of as automatically generated contrastive examples specifically for avoiding disconnected reasoning.

3 Measuring Disconnected Reasoning

This section formalizes the DiRe *condition*, which captures what it means for a model to employ disconnected reasoning, and describes how to use this condition to probe the amount of disconnected reasoning performed by a given model, and the extent of such reasoning possible on a dataset.

A good multifact reasoning is one where information from all the supporting facts is meaningfully synthesized to arrive at an answer. The precise definition for what constitutes meaningful synthesis is somewhat subjective; it depends on the semantics of the facts and the specific question at hand, making it challenging to devise a measurable test for the amount of multifact (or non-multifact) reasoning done by a model or needed by a dataset.

Previous works have used the Answer Prediction task (i.e., identifying the correct answer) and the Supporting Fact Identification task (identifying all facts supporting the answer) as approximate *tests* of multifact reasoning. We argue that, *at a minimum*, good multifact reasoning requires connected reasoning—one where information from at least one supporting fact is connected to the selection and use of information from other supporting facts. Consider the example question in Figure 1. A good multifact reasoning will look for a supporting fact that mentions when the cold war started (🟦) and use information from this fact (year 1947) to select the other supporting fact mentioning the country that got independence (🟥) (or vice versa).

A bad multifact reasoning model, however, can cheat on answer prediction by only looking for a fact that mentions a country getting independence at some time (mentioned in 🟥), without connecting this to when the cold war started (mentioned in 🟦). Similarly, the model can also cheat on supporting fact identification by treating it as two independent sub-tasks—one returning a fact mentioning the time when a country got independence, and another for a fact mentioning the time when cold war started. The result of at least one of the two sub-tasks should influence the result of the other sub-task, but here it does not. This results in *disconnected reasoning*, where *both* supporting facts are identified without reference to the other.[3] Even though the precise definition of a meaningful synthesis of information is unclear, it is clear that models performing this type of disconnected reasoning cannot be considered as doing valid multifact reasoning. Neither answer prediction nor support identification directly checks for such disconnected reasoning.

3.1 Disconnected Reasoning

We can formalize the notion of disconnected reasoning from the perspective of any multihop reasoning test. For the rest of this work, we assume a multifact reading comprehension setting, where we have a dataset D with instances of the form $q = (Q, C; A)$. Given a question Q along with a context C consisting of a set of facts, the task is to predict the answer A. C includes a subset F_s of at least two facts that together provide support for A.

Let τ denote a test of multifact reasoning and $\tau(q)$ the output a model should produce when tested on input q. Consider the Support Identification test, where $\tau(q) = F_s$. Let there be two proper subsets of the supporting facts F_{s1} and F_{s2} such that $F_s = F_{s1} \cup F_{s2}$. We argued above that a model performs disconnected reasoning if it does not use information in F_{s1} to select and use information in F_{s2} and vice versa. One way we can catch this behavior is by checking if the model is able to identify F_{s1} given $C \setminus F_{s2}$ and identify F_{s2}

---

[3] Identifying one of the facts in isolation is fine, as long as information from this fact is used to identify the other fact.

given $C \setminus F_{s1}$. To pass the test successfully the model only needs to trivially combine its outputs from the two subsets $C \setminus F_{s2}$ and $C \setminus F_{s1}$.

Concretely, we say M performs Disconnected Reasoning on q from the perspective of a test τ if the following condition holds:

DiRe condition: There exists a proper bi-partition[4] $\{F_{s1}, F_{s2}\}$ of F_s such that the two outputs of M with input q modified to have $C \setminus F_{s2}$ and $C \setminus F_{s1}$ as contexts, respectively, can be *trivially combined* to produce $\tau(q)$.

The need for considering all proper bi-partitions is further explained in Appendix A.2, using an example of 3-hop reasoning (Figure 8). The DiRe condition does not explicitly state what constitutes a trivial combination; this is defined below individually for each test. We note that it only captures disconnected reasoning, which is one manifestation of the lack of a meaningful synthesis of facts.

For Answer Prediction, trivial combination corresponds to producing answers (which we assume are associated confidence scores) independently for the two contexts, and choosing the answer with the highest score. Suppose M answers a_1 with score $s(a_1)$ on the first context in the DiRe condition; similarly a_2 for the second context. We say the condition is met if $A = \arg\max_{a \in \{a_1, a_2\}} s(a)$.

For the Support Identification test, as in the example discussed earlier, *set union* constitutes an effective trivial combination. Suppose M identifies G_1 and G_2 as the sets of supporting facts for the two inputs in the DiRe condition, respectively. We say the condition is met if $G_1 \cup G_2 = F_s$.

In the above discussion, we assumed the so called 'exact match' or EM metric for assessing whether the answer or supporting facts produced by the combination operator were correct. In general, let $m_\tau(q, \mu(q))$ be any metric for scoring the output $\mu(q)$ of a model against the true label $\tau(q)$ for a test τ on question q (e.g., answer EM, support F1, etc.). We can apply the same metric to the output of the combination operator (instead of $\mu(q)$) to assess the extent to which the DiRe condition is met for q under the metric m_τ.

3.2 Probing Disconnected Reasoning

The DiRe condition allows devising a probe for measuring how much can a model cheat on a test τ, i.e., how much can it score using disconnected reasoning. The probe for a dataset D comprises an *automatically generated* dataset $\mathbb{P}_\tau(D)$, on which the model is evaluated, with or without training.

For simplicity, consider the case where $F_s = \{f_1, f_2\}$. Here $\{\{f_1\}, \{f_2\}\}$ is the unique proper bi-partition of F_s. The DiRe condition checks whether a model M can arrive at the correct test output $\tau(q)$ for input $q = (Q, C; A)$ by trivially combining its outputs on contexts $C \setminus \{f_1\}$ and $C \setminus \{f_2\}$. Accordingly, for each $q \in D$, the probing dataset $\mathbb{P}_{\text{ans+supp}}(D)$ for Answer Prediction and Support Identification contains a *group of instances*:

$$(Q, C \setminus \{f_1\}; L_{\text{ans}}^{?}{=}A, L_{\text{supp}}{=}\{f_2\}) \tag{1}$$

$$(Q, C \setminus \{f_2\}; L_{\text{ans}}^{?}{=}A, L_{\text{supp}}{=}\{f_1\}) \tag{2}$$

where L_{supp} denotes the support identification label and $L_{\text{ans}}^{?}{=}A$ represents an optional answer label that is included only if A is present in the supporting facts retained in the context. These labels are only used if the model is trained on $\mathbb{P}_\tau(D)$.

Models operate independently over instances in $\mathbb{P}_\tau(D)$, whether or not they belong to a group. Probe performance, however, is measured via a **grouped probe metric**, denoted $m_\tau^{\mathbb{P}}$, that captures how well does the *trivial combination* of the two corresponding outputs match $\tau(q)$ according to metric m_τ, as per the DiRe condition for τ. Specifically, for Answer Prediction, we use the highest scoring answer (following the *argmax* operator in Section 3.1) across the two instances in the group, and evaluate it against A using a standard metric m_{ans} (EM, F1, etc.). For Support Identification, we take the *union* of the two sets of supporting facts identified (for the two instances), and evaluate it against $\{f_1, f_2\}$ using a standard metric m_{supp}.

General case of $|F_s| \geq 2$: We translate each $q \in D$ into a *collection* $\mathbb{P}_\tau(q)$ of $2^{|F_s|-1} - 1$ groups of instances, with $\mathbb{P}_\tau(q; s_1)$ denoting the group for the bi-partition $\{F_{s1}, F_{s2}\}$ of F_s. This group, for answer and support prediction tests, contains:

$$(Q, C \setminus F_{s1}; L_{\text{ans}}^{?}{=}A, L_{\text{supp}}{=}F_{s2}) \tag{3}$$

$$(Q, C \setminus F_{s2}; L_{\text{ans}}^{?}{=}A, L_{\text{supp}}{=}F_{s1}) \tag{4}$$

As per the DiRe condition, as long as the model cheats on any one bi-partition, it is considered to cheat on the test. Accordingly, the probe metric $m_\tau^{\mathbb{P}}$ uses a *disjunction* over the groups:

$$m_\tau^{\mathbb{P}}(q, \mu(\mathbb{P}_\tau(q))) = \max_{\{F_{s1}, \text{-}\}} m_\tau^{\mathbb{P}}(q, \mu(\mathbb{P}_\tau(q; s_1))) \tag{5}$$

---

[4] $\{X, Y\}$ is a proper bi-partition of a set Z if $X \cup Y = Z, X \cap Y = \phi, X \neq \phi$, and $Y \neq \phi$.

where $\mu(\mathbb{P}_\tau(q))$ denotes the model's prediction on the probe group $\mathbb{P}_\tau(q)$, the max is over all proper bi-partitions of F_s, and $m^{\mathbb{P}}_\tau(q, \mu(\mathbb{P}_\tau(q; s_1)))$ denotes the probe metric for the group $\mathbb{P}_\tau(q; s_1)$ which incorporates the trivial combination operator, denoted $\oplus$, associated with τ as follows:

$$m^{\mathbb{P}}_\tau(q, \mu(\mathbb{P}_\tau(q; s_1))) = m_\tau(q, \oplus_{q' \in \mathbb{P}(q; s_1)} \mu(q')) \quad (6)$$

For example, when τ is answer prediction, we view $\mu(q')$ as both the predicted answer and its score for q', $\oplus$ chooses the answer with the highest score, and m_{ans} evaluates it against A. When τ is support identification, $\mu(q')$ is the set of facts the model outputs for q', $\oplus$ is union, and m_{supp} is a standard evaluation of the result against the true label F_s.

3.3 Use Cases of DiRe Probe

The probing dataset $\mathbb{P}_\tau(D)$ can be used by **model designers** to assess what portion of their model M's performance on D can be achieved on a test τ via disconnected reasoning, by computing:

$$\text{DiRe}^\tau(M, D) = \text{S}^\tau_{\text{cond}}(M, \mathbb{P}_\tau(D) \mid D) \quad (7)$$

This is a zero-shot evaluation[5] where M is not trained on $\mathbb{P}_\tau(D)$. $\text{S}^\tau_{\text{cond}}$ represents M's score on $\mathbb{P}_\tau(D)$ conditioned on its score on D, computed as the question-wise minimum of M's score on D and $\mathbb{P}_\tau(D)$, in terms of metrics m_τ and $m^{\mathbb{P}}_\tau$, resp.[6]

Similarly, $\mathbb{P}_\tau(D)$ can be used by a **dataset designer** to assess how cheatable D is by computing:

$$\text{DiRe}^\tau(D) = \text{S}^\tau(M^*, \mathbb{P}_\tau(D)) \quad (8)$$

where M^* is the strongest available model architecture for τ that is trained on $\mathbb{P}_\tau(D)$ and S^τ is its score under metric $m^{\mathbb{P}}_\tau$.

4 Reducing Disconnected Reasoning

This section introduces an automatic transformation of a dataset to make it less cheatable by disconnected reasoning. It also defines a probe dataset for assessing how cheatable the transformed dataset is.

A disconnected reasoning model does not connect information across supporting facts. This has an important consequence: when a supporting fact is dropped from the context, the model's behavior on other supporting facts remains unchanged. Figure 2 illustrates this for the example in Figure 1.

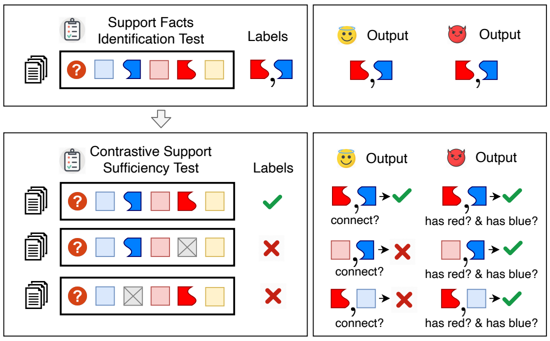

Figure 2: Transformation of a question for Contrastive Support Sufficiency evaluation. Top-Left: Original instance q labeled with red (🟥) and blue (🟦) supporting facts F_s. Bottom-Left: Its transformation into a group $\mathbb{T}(q)$ of 3 instances, one with sufficient and two with insufficient context, with labels denoting context sufficiency. Right: Behavior of good vs. bad models on q and $\mathbb{T}(q)$. A good multifact model would realize that the potentially relevant facts are not sufficient (do not connect) whereas a bad model would find potentially relevant facts and assume they are sufficient.

Suppose we create an insufficient context C' by removing the blue fact (🟦) from C (shown in the last row of Figure 2, with the removed fact crossed out). With the full context C, the cheating model discussed earlier did not use the information in the blue fact (🟦) to produce the answer or to identify the red fact (🟥). Therefore, the absence of the blue fact in C' will induce *no change* in this model's answer or its ability to select the red fact (🟥). Further, to return a second supporting fact, the model would choose the next best matching fact (□) that also indicates the start of a war and thus appears to be a reasonable choice (see bottom-right of Figure 2). Without considering interaction between the two identified facts, this model would not realize that the light blue fact (□) does not fit well with the red fact (🟥) because of the year mismatch (1950 vs. 1947), and the two together are thus insufficient to answer Q.

A good multifact model, on the other hand, connects information across different supporting facts. Thus, when evaluated on context C' with the blue fact (🟦) missing, its answer as well as behavior for selecting the other supporting facts *will* be affected.

4.1 Contrastive Support Sufficiency

The above example illustrates that *sufficiency of supporting facts* in the input context matters to a good multifact model (i.e., it behaves differently under C and C') but not to a disconnected reasoning model. This suggests that if we force models

---

[5] Our experiments also include inoculation (i.e., finetuning on a small fraction of the dataset) before evaluation.

[6] For answer prediction with exact-match, this corresponds to M getting 1 point for correctly answering a question group in $\mathbb{P}(\mathcal{D})$ only if it correctly answers the corresponding original question in $\mathcal{D}$ as well.

to pay attention to sufficiency, we can reduce disconnected reasoning. We formalize this idea and introduce the notion of *contrastive support sufficiency*. Informally, for each question, we consider several variants of the context that are contrastive: some contain sufficient information (i.e., $F_s \subseteq C$) while others don't. Evaluating models with these contrastive inputs allows discerning the difference in behavior between good and bad models. Figure 2 illustrates an example of contrastive contexts and the expected behavior of such models.

4.2 Transforming Existing Datasets

To operationalize this idea, we introduce an *automated* dataset transformation, Contrastive Support Sufficiency Transform ($\mathbb{T}$), applicable to any multifact reading comprehension dataset where each question is associated with a set of facts as context, of which a subset is annotated as supporting facts. Intuitively, given a context C, we want the model to identify whether C is sufficient to answer the question. If sufficient, we also want it to provide correct outputs for other tests (e.g., answer prediction).

Formally, $\mathbb{T}(D)$ transforms each instance $q = (Q, C; A)$ in a dataset D into a *group* $\mathbb{T}(q)$ of two types of instances, those with sufficient support and those without. For simplicity, consider the case of $F_s = \{f_1, f_2\}$ as in Section 3.2. The transformed instance group $\mathbb{T}(q)$ is illustrated in the bottom half of Figure 2. It includes two *insufficient context instances* corresponding to the two non-empty proper subsets of F_s, with the output label set to $L_{\text{suff}} = 0$ (illustrated as × in Figure 2):

$$(Q, C \setminus \{f_1\};\ L_{\text{suff}}{=}0), (Q, C \setminus \{f_2\};\ L_{\text{suff}}{=}0)$$

Since these contexts lack sufficient information, we omit labels for answer or supporting facts.

$\mathbb{T}(q)$ also includes a single *sufficient context instance*, but not with entire C as the context. To avoid introducing a context length bias relative to the above two instances, we remove from C a fixed, uniformly sampled non-supporting fact f_r chosen from $C \setminus F_s$ (we assume $|C| \geq 3$). The output label is set to $L_{\text{suff}} = 1$. Since the context is sufficient, the correct answer and supporting facts are included as additional labels, to use for Answer and Support tests if desired, resulting in the instance:

$$(Q, C \setminus \{f_r\};\ L_{\text{ans}}{=}A, L_{\text{supp}}{=}F_s, L_{\text{suff}}{=}1) \quad (9)$$

For any performance metric $m_\tau(q, \cdot)$ of interest in D (e.g., answer EM, support F1, etc.), the corresponding **transformed metric** $m^{\mathbb{T}}_{\tau+\text{suff}}(q, \cdot)$ operates in a conditional fashion: it equals 0 if any L_{suff} label in the group is predicted incorrectly, and equals $m_\tau(q_{\text{suff}}, \cdot)$ otherwise, where q_{suff} denotes the unique sufficient context instance in $\mathbb{T}(q)$. A model that predicts all instances to be insufficient (or sufficient) will get 0 pts under $m^{\mathbb{T}}_{\tau+\text{suff}}$.

The case of $|F_s| \geq 2$ is left to Appendix A.3. Intuitively, $m^{\mathbb{T}}_{\tau+\text{suff}}(q, \cdot) \neq 0$ suggests that when reasoning with any proper subset of F_s, the model relies on at least one supporting fact outside of that subset. High performance on $\mathbb{T}(D)$ thus suggests combining information from all facts.[7,8]

4.3 Probing Disconnected Reasoning in $\mathbb{T}(D)$

The sufficiency test (CSST) used in the transform discourages disconnected reasoning by encouraging models to track sufficiency. Much like other tests of multifact reasoning, we can apply the DiRe condition to probe models for how much they can cheat on CSST. As explained in Appendix A.4, the probe checks whether a model M can independently predict whether F_{s1} and F_{s2} are present in the input context, without relying on each other. If so, M can use disconnected reasoning to correctly predict sufficiency labels in $\mathbb{T}(D)$.

For $F_s = \{f_1, f_2\}$, if the transformed group $\mathbb{T}(q)$ uses fact f_r for context length normalization, the probing group $\mathbb{P}(\mathbb{T}(q))$ contains 3 instances:

$$(Q, C \setminus \{f_1, f_r\};\ L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}\{f_2\}, L^{*}_{\text{suff}}{=}0)$$

$$(Q, C \setminus \{f_2, f_r\};\ L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}\{f_1\}, L^{*}_{\text{suff}}{=}0)$$

$$(Q, C \setminus \{f_1, f_2\};\ L^{*}_{\text{suff}}{=}-1)$$

Metric $m^{\mathbb{PT}}_{\tau+\text{suff}}(q, \cdot)$ on this probing group equals 0 if the model predicts any of the L^{*}_{suff} labels incorrectly. Otherwise, we use the grouped probe metric $m^{\mathbb{P}}_{\tau}(q, \cdot)$ from Section 3.2 for the first two instances, ignoring their L^{*}_{suff} label. Details are deferred to Appendices A.4 and A.5

We can use $\mathbb{P}(\mathbb{T}(\mathcal{D}))$ to assess how cheatable $\mathbb{T}(\mathcal{D})$ is via disconnected reasoning by computing:

$$\text{DiRe}^{\tau+\text{suff}}(\mathbb{T}(\mathcal{D})) = \mathrm{S}^{\tau+\text{suff}}(M'^{*}, \mathbb{P}(\mathbb{T}(\mathcal{D}))) \quad (10)$$

where M'^{*} is the strongest available model architecture for τ + suff that is trained on $\mathbb{P}(\mathbb{T}(\mathcal{D}))$, and $\mathrm{S}^{\tau+\text{suff}}$ is its score under the metric $m^{\mathbb{PT}}_{\tau+\text{suff}}$.

---

[7] We say *suggests* rather than guarantees because the behavior of the model with partial context $C' \subset C$ may not be qualitatively identical to its behavior with full context C.

[8] The transformation encourages a model to combine information from all facts in F_s. Whether the information that is combined is semantically meaningful or how it is combined is interesting is beyond its scope.

Dataset	Definition	Purpose	How to measure	Metric
$\mathcal{D}$	HotpotQA	Measure state of multihop reasoning	Evaluate trained M on D	$S^{\tau}(M, D)$
$\mathbb{P}(\mathcal{D})$	Probing dataset of $\mathcal{D}$	Measure how much disconnected reasoning M does on τ test of D	Evaluate M on $\mathbb{P}_{\tau}(\mathcal{D})$ in zero-shot setting or with inoculation	DiRe$^{\tau}(M, \mathcal{D})$ [Equation 7]
		Measure how much cheatable τ test of $\mathcal{D}$ is via disconnected reasoning	Train and evaluate a strong NLP model on $\mathbb{P}_{\tau}(\mathcal{D})$	DiRe$^{\tau}(\mathcal{D})$ [Equation 8]
$\mathbb{T}(\mathcal{D})$	Transformed dataset of $\mathcal{D}$	Measure truer state of multi-hop reasoning, by reducing the amount of cheatability compared to D	Evaluate trained M' on $\mathbb{T}(\mathcal{D})$	$S^{\tau+\text{suff}}(M', \mathbb{T}(\mathcal{D}))$ [Section 4.2]
$\mathbb{P}(\mathbb{T}(\mathcal{D}))$	Probing dataset of $\mathbb{T}(\mathcal{D})$	Measure how much cheatable τ+suff test of $\mathbb{T}(\mathcal{D})$ is via disconnected reasoning	Train and evaluate a strong NLP model on $\mathbb{P}_{\tau+\text{suff}}(\mathbb{T}(\mathcal{D}))$	DiRe$^{\tau+\text{suff}}(\mathbb{T}(\mathcal{D}))$ [Equation 10]

Table 1: Summary of dataset variations we create, their purposes and how we use them. τ can be any test, but our experiments are with Ans + Supp. M and M' are models that can take τ and τ + suff tests respectively. In our experiments, they are trained on D and $T(D)$ respectively with supervision for τ and τ + suff respectively.

5 Experiments

To obtain a more realistic picture of the progress in multifact reasoning, we compare the performance of the original Glove-based baseline model (Yang et al., 2018) and a state-of-the-art transformer-based LM, XLNet (Yang et al., 2019) on the multi-hop QA dataset HotpotQA (Yang et al., 2018). While it may appear that the newer models are more capable of multifact reasoning (based on answer and support prediction tasks), we show most of these gains are from better exploitation of disconnected reasoning. Our proposed transformation reduces disconnected reasoning exploitable by these models and gives a more accurate picture of the state of multifact reasoning. To support these claims, we use our proposed dataset probes, transformations, and metrics summarized in Table 1.

Datasets $\mathcal{D}$ and $\mathbb{T}(\mathcal{D})$: HotpotQA is a popular multi-hop QA dataset with about 113K questions which has spurred many models (Nishida et al., 2019; Xiao et al., 2019; Tu et al., 2020; Fang et al., 2020). We use the *distractor* setting where each question has a *set* of 10 input paragraphs, of which two were used to create the multifact question. Apart from the answer span, each question is annotated with these two supporting paragraphs and the supporting sentences within them. As described in Sec. 4.2, we use these supporting paragraph annotations as F_s to create a transformed dataset $\mathbb{T}(\mathcal{D})$.[9]

Models: We evaluate two models: **(1) XLNet-Base:** Since HotpotQA contexts are 10 paragraphs long, we use XLNet, a model that can handle contexts longer than 1024 tokens. We train XLNet-Base to predict the answer, supporting sentences, supporting paragraphs, and the sufficiency label (only on transformed datasets). As shown in Table 2 of Appendix B.4, our model is comparable to other models of similar sizes on the HotpotQA dev set. **(2) Baseline:** We re-implement the baseline model from HotpotQA. It has similar answer scores and much better support scores than the original implementation (details in Appendix B).

Metrics: We report metrics for standard tests for HotpotQA: answer span prediction (Ans), support identification (paragraph-level: Supp$_\text{p}$, sentence-level: Supp$_\text{s}$), as well as *joint* tests Ans +Supp$_\text{p}$ and Ans +Supp$_\text{s}$. For each of these, we show F1 scores, but trends are similar for EM scores.[10] These metrics correspond to $m_\tau(q, \cdot)$ in Section 3 and to $S^{\tau}(M, D)$ in Table 1. When evaluating on the probing or transformed datasets, we use the corresponding metrics shown in Table 1.

Measuring Disconnected Reasoning

We first use our DiRe probe to estimate the amount of disconnected reasoning in **HotpotQA models** (Eqn. 7). For this, we train our models on $\mathcal{D}$ and evaluate them against $\mathbb{P}(\mathcal{D})$, the probe dataset, under three settings: (1) zero-shot evaluation (no training on $\mathbb{P}(\mathcal{D})$), (2) after fine-tuning on 1% of $\mathbb{P}(\mathcal{D})$, and (3) after fine-tuning on 5% of $\mathbb{P}(\mathcal{D})$. Since the model has never seen examples with the modified context used in the probe, the goal of fine-tuning or *inoculation* (Liu et al., 2019) is to allow the model to adapt to the new inputs, while not straying far from its original behavior on $\mathcal{D}$.

Figure 3 summarizes the results. The total heights of the bars depict overall scores of the baseline and XLNet models on $\mathcal{D}$. The upper,

---

[9] We do not use the sentence-level annotations as we found them to be too noisy for the purposes of transformation.

[10] See Appendix F for these metrics for all our results.

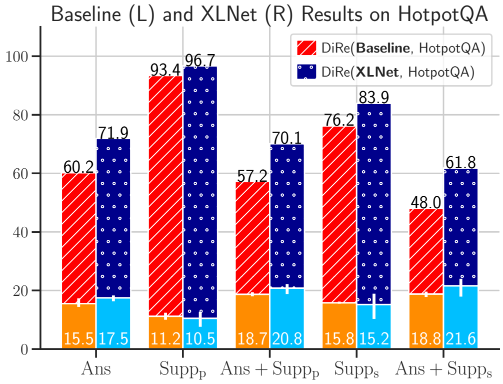

Figure 3: F1 scores for two models under various metrics. Progress on HotpotQA from Baseline model to XLNet (entire bars) is largely due to progress in disconnected reasoning (upper, darker regions), with little change in multifact reasoning (lower, lighter regions).

darker regions depict the portion of the overall score achieved via disconnected reasoning as estimated by the DiRe probe.[11] Their height is based on the average across the three fine-tuning settings, with white error margins depicting min/max. Importantly, results vary only marginally across the 3 settings. The lower, lighter regions show the remaining score, attributable to multifact reasoning.

First, the amount of multifact reasoning in XLNet is low—ranging from 10.5 to 21.6 F1 across the metrics. Second, even though the scores have improved going from the baseline model to XLNet, the amount of multifact reasoning (lighter regions at the bottom) has barely improved. Notably, while the XLNet model improves on the Ans + $\mathrm{Supp_p}$ metric by 14 pts, the amount of multifact reasoning has only increased by 3 pts! While existing metrics would suggest substantial progress in multifact reasoning for HotpotQA, the DiRe probe shows that this is likely not the case—empirical gains are mostly due to higher disconnected reasoning.

As a sanity check, we also train a Single-Fact XLNet model (Appendix B.2) that only reasons over one paragraph at a time—a model incapable of multifact reasoning. This model achieves nearly identical scores on $\mathcal{D}$ as $\mathbb{P}(\mathcal{D})$, demonstrating that our DiRe probe captures the extent of disconnected reasoning performed by a model (see Appendix E).

Next, we use the DiRe probe to estimate how cheatable is the **HotpotQA dataset** via disconnected reasoning (Eqn. 8). For this, we train and evaluate the powerful XLNet model on $\mathbb{P}(\mathcal{D})$.[12]

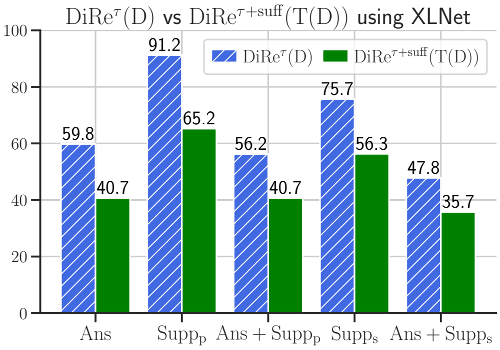

Figure 4: F1-based DiRe scores of $\mathcal{D}$ and $\mathbb{T}(\mathcal{D})$ using XLNet-Base. Dataset transformation reduces disconnected reasoning bias, demonstrated by DiRe scores being substantially lower on $\mathbb{T}(\mathcal{D})$ than on $\mathcal{D}$.

While the answer prediction test is known to be cheatable, we find that even the supporting fact (paragraph/sentence) identification test is highly cheatable (up to 91.2 and 75.7 F1, resp.).

Reducing Disconnected Reasoning

Our automatic transformation reduces disconnected reasoning bias in the dataset and gives a more realistic picture of the state of multifact reasoning. We show this by comparing how much score can a strong model (XLNet) achieve using disconnected reasoning on the original dataset, by training it on $\mathbb{P}(\mathcal{D})$ and computing $\mathrm{DiRe}^{\tau}(D)$ (Eqn. 8), and on the transformed dataset, by training it on $\mathbb{P}(\mathbb{T}(\mathcal{D}))$ and computing $\mathrm{DiRe}^{\tau+\mathrm{suff}}(\mathbb{T}(\mathcal{D}))$ (Equation 10). Training the model allows it to learn the kind of disconnected reasoning needed to do well on these probes, thus providing an upper estimate of the cheatability of $\mathcal{D}$ and $\mathbb{T}(\mathcal{D})$ via disconnected reasoning.

Figure 4 shows that the XLNet model's DiRe score on the Ans +Suff metric for $\mathbb{T}(\mathcal{D})$ is only 40.7, much lower compared to its DiRe score of 59.8 on Ans for $\mathcal{D}$. Across all metrics, $\mathbb{T}(\mathcal{D})$ is significantly less exploitable via disconnected reasoning than $\mathcal{D}$, drops ranging from 12 to 26 pts.

$\mathbb{T}(\mathcal{D})$ is a Harder Test of Multifact Reasoning

By reducing the amount of exploitable disconnected reasoning in $\mathbb{T}(\mathcal{D})$, we show that our transformed dataset is harder for models that have relied on disconnected reasoning. Figure 5 shows that the transformed dataset is harder for both models across all metrics. Since a true-multihop model would naturally detect insufficient data, the drops in performance on $\mathbb{T}(\mathcal{D})$ show that the current model architectures when trained on $\mathcal{D}$ are reliant on dis-

---

[11] This is a *conditional* score as explained in Eqn. (7).

[12] The use of even stronger models is left to future work.

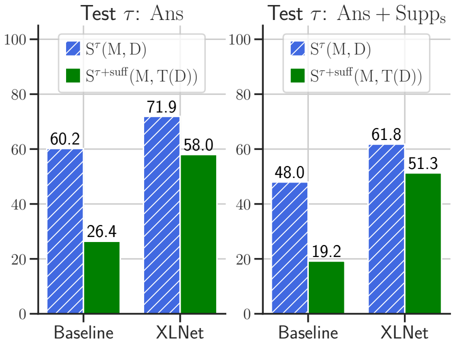

Figure 5: F1 scores of two models on $\mathcal{D}$ and $\mathbb{T}(\mathcal{D})$ under two common metrics. Transformed dataset is harder for both models since they rely on disconnected reasoning. The weaker, Baseline model drops more as it relies more heavily on disconnected reasoning.

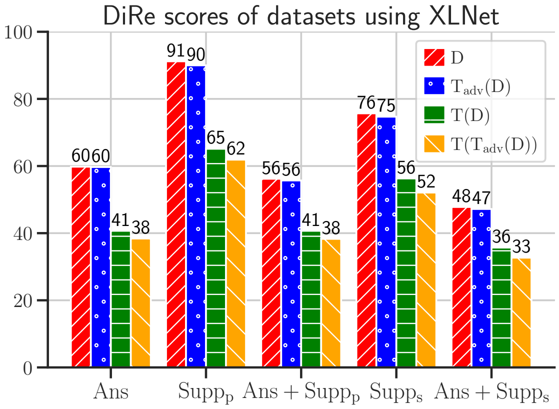

Figure 6: F1-based DiRe score on various metrics using XLNet-base for $\mathcal{D}$, adversarial $\mathbb{T}_{\text{adv}}(\mathcal{D})$, transformed $\mathbb{T}(\mathcal{D})$, and transformed adversarial $\mathbb{T}(\mathbb{T}_{\text{adv}}(\mathcal{D}))$. Transformation here is more effective than, and complementary to, adversarial augmentation.

connected reasoning. The weaker baseline model has substantially lower scores on $\mathbb{T}(\mathcal{D})$, suggesting that simple models cannot get high scores.

Single-Fact XLNet (the model incapable of multifact reasoning as described earlier) also sees a big drop (-23 F1 pts on Ans) going from $\mathcal{D}$ to $\mathbb{T}(\mathcal{D})$ – almost all of which was caught as disconnected reasoning by our DiRe probe (see Appendix E).

$\mathbb{T}(\mathcal{D})$ is Hard for the Right Reasons

Our transformation makes two key changes to the original dataset $\mathcal{D}$: (C1) adds a new *sufficiency test*, and (C2) uses a grouped metric over a set of *contrastive examples*. We argue that these changes by themselves do not result in a score drop independent of the model's ability to perform multifact reasoning (details in Appendices D and G).

Transformation vs. Adversarial Augmentation

An alternate approach to reduce disconnected reasoning is via adversarial examples for single-fact models. Jiang and Bansal (2019) proposed such an approach for HotpotQA. As shown in Figure 6, our transformation results in a larger reduction in disconnected reasoning across all metrics; e.g., the XLNet model only achieves a DiRe score (metric: Ans +$\mathrm{Supp_s}$) of 36 F1 on $\mathbb{T}(\mathcal{D})$ as compared to 47 F1 on $\mathbb{T}_{\text{adv}}(\mathcal{D})$, computed using Eqns. (10) and (8), resp. Moreover, since our approach can be applied to any dataset with supporting fact annotations, we can even transform the adversarial dataset, further reducing the DiRe score to 33 F1.

6 Conclusions

Progress in multi-hop QA under the reading comprehension setting relies on understanding and quantifying the types of undesirable reasoning current models may perform. This work introduced a formalization of disconnected reasoning, a form of bad reasoning prevalent in multi-hop models. It showed that a large portion of current progress in multifact reasoning can be attributed to disconnected reasoning. Using a notion of contrastive sufficiency, it showed how to automatically transform existing support-annotated multi-hop datasets to create a more difficult and less cheatable dataset that results in reduced disconnected reasoning.

Our probing and transformed dataset construction assumed that the context is an unordered set of facts. Extending it to a *sequence* of facts (e.g., as in MultiRC (Khashabi et al., 2018)) requires accounting for the potential of new artifacts by, for instance, carefully replacing rather than dropping facts. Additionally, for factual reading comprehension datasets where the correct answer can be arrived at without consulting all annotated facts in the input context, our probe will unfairly penalize a model that uses implicitly known facts, even if it correctly connects information across these facts. However, our transformation alleviates this issue: a model that connects information will have an edge in determining the sufficiency of the given context. We leave further exploration to future work.

It is difficult to create large-scale multihop QA datasets that do not have unintended artifacts, and it is also difficult to design models that do not exploit such shortcuts. Our results suggest that carefully devising tests that probe for desirable aspects of multifact reasoning is an effective way forward.

A Probe and Transformation Details

A.1 Probes and Transformation for $|F_s| = 2$

Figure 7 summarizes in a single place all probes and transformation discussed for the case of two supporting facts ($|F_s| = 2$).

A.2 Need for Considering All Bi-partitions

Figure 8 illustrates support bi-partitions and two examples of disconnected reasoning for a 3-hop reasoning question. It highlights the need for considering *every* bi-partition in the DiRe condition. For instance, if we only consider partitions that separate the purple (🟪) and yellow (🟨) facts, then the model performing the lower example of disconnected reasoning would not be able to output the correct labels in any partition and would thus appear to not satisfy the DiRe condition. We would therefore not be able to detect that it is doing disconnected reasoning.

A.3 Transformation for $|F_s| \geq 2$

The Contrastive Support Sufficiency Transform described in Section 4.2 for the case of two supporting facts can be generalized as follows for $|F_s| \geq 2$. There are two differences. First, there are $2^{|F_s|} - 2$ choices of proper subsets of F_s that can be removed to create insufficient context instances. Second, these subsets are of different sizes, potentially leading to unintended artifacts models can exploit. Hence, we use *context length normalization* to ensure every context has precisely $|C| - |F_s| + 1$ facts. To this end, let F_r be a fixed, uniformly sampled subset of $C \setminus F_s$ of size $|F_s| - 1$ that we will remove for the sufficient context instance.[13] Further, for each non-empty insufficient context $F_{s1} \subset F_s, F_{s1} \neq \phi$, let F_{r1} denote a fixed, uniformly sampled subset of F_r of size $|F_s| - |F_{s1}| - 1$. The transformed group $\mathbb{T}(q)$ contains the following $2^{|F_s|} - 1$ instances:

$$(Q, C \setminus F_r;\ L_{\text{ans}}{=}A, L_{\text{supp}}{=}F_s, L_{\text{suff}}{=}1) \quad (11)$$

$$(Q, C \setminus (F_{s1} \cup F_{r1});\ L_{\text{suff}}{=}0) \quad \text{for all } F_{s1} \quad (12)$$

Note that $|F_r| = |F_{s1}| + |F_{r1}| = |F_s| - 1$ by design, and therefore all instances have exactly $|C| - |F_s| + 1$ facts in their context.

Similar to the case of $|F_s| = 2$, for any performance metric $m_\tau(q, \cdot)$ of interest in D (e.g., answer EM, support F1, etc.), the corresponding *transformed metric* $m^{\mathbb{T}}_{\tau+\text{suff}}(q, \cdot)$ operates in a conditional fashion: it equals 0 if any L_{suff} label in the group is predicted incorrectly, and equals $m_\tau(q_{\text{suff}}, \cdot)$ otherwise, where q_{suff} denotes the unique sufficient context instance in $\mathbb{T}(q)$.

A.4 Probing $\mathbb{T}(D)$ for $|F_s| = 2$

A model M meets the DiRe condition for CSST when given an input context C', it can correctly predict whether: (i) C' contains F_{s1}, even when F_{s2} is not in C'; (ii) C' contains F_{s2}, even when F_{s1} is not in C'; and (iii) C' contains neither F_{s1} nor F_{s2}. Intuitively, if M can do this correctly, then it has the information needed to correctly identify support sufficiency for all instances in the transformed group $\mathbb{T}(q)$, without relying on interaction between F_{s1} and F_{s2}.

This leads to the following probe for $\mathbb{T}(D)$, denoted $\mathbb{P}_{\text{ans+supp+suff}}(\mathbb{T}(D))$ (sometimes simply $\mathbb{P}(\mathbb{T}(D))$ for brevity) and described here for the case of $F_s = \{f_1, f_2\}$.[14] Let f_r be the fact used for context length normalization in the transformed group $\mathbb{T}(q)$. Similar to Eqns. (1) and (2) in Section 3.2, the probing dataset contains a group $\mathbb{P}(\mathbb{T}(q))$ of instances corresponding to the unique bi-partition $\{\{f_1\}, \{f_2\}\}$ of F_s:

$$(Q, C \setminus \{f_1, f_r\}; L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}\{f_2\}, L^{*}_{\text{suff}}{=}0)$$

$$(Q, C \setminus \{f_2, f_r\}; L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}\{f_1\}, L^{*}_{\text{suff}}{=}0)$$

$$(Q, C \setminus \{f_1, f_2\}; L^{*}_{\text{suff}}{=}-1)$$

$L^{?}_{\text{ans}}$, as before, is an optional label that is included in the instance only if A is present in the supporting facts retained in the context of that instance.

We use the notation L^{*}_{suff} here to highlight that this label is semantically different from L_{suff} in $\mathbb{T}(D)$, in the sense that when $L^{*}_{\text{suff}} = 0$, the model during this probe is expected to produce the partial support and the answer (if present in the context). When not even partial support is there, the output label is $L^{*}_{\text{suff}} = -1$ and we don't care what the model outputs as the answer or supporting facts. Note that the label semantics being different is not an issue, as the probing method involves training models on the probe dataset.

The *joint* grouped metric here considers the sufficiency label, along with any standard test(s) of interest (answer prediction, support identification, or both). Denoted $m^{\mathbb{PT}}_{\tau+\text{suff}}(q, \cdot)$, it is defined as follows: similar to the conditional nature of the transformed metric $m^{\mathbb{T}}_{\tau+\text{suff}}(q, \cdot)$, a model receives

---

[13] We assume $|C| \geq 2|F_s| - 1$.

[14] Appendix A.5 describes the probe for $|F_s| \geq 2$.

Original Dataset D
⇒ Question $q = (Q, C; A)$ in D is assumed to be annotated with supporting facts $\{f_1, f_2\}$.

Probing Dataset $\mathbb{P}_{\text{ans+supp}}(D)$ for Answer Prediction and Support Identification tests:
⇒ Probing question collection $\mathbb{P}_{\text{ans+supp}}(q)$ has only one group, corresponding to the unique bi-partition $\{\{f_1\}, \{f_2\}\}$, containing:

1. $(Q, C \setminus \{f_1\}; L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}\{f_2\})$
2. $(Q, C \setminus \{f_2\}; L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}\{f_1\})$

Transformed Dataset $\mathbb{T}(D)$ for evaluating Constrastive Support Sufficiency:
⇒ Transformed question group $\mathbb{T}(q)$ in $\mathbb{T}(D)$ is defined using a single replacement fact $f_r \in C \setminus \{f_1, f_2\}$:

1. $(Q, C \setminus \{f_r\};\ L_{\text{ans}}{=}A, L_{\text{supp}}{=}F_s, L_{\text{suff}}{=}1)$
2. $(Q, C \setminus \{f_1\};\ L_{\text{suff}}{=}0)$
3. $(Q, C \setminus \{f_2\};\ L_{\text{suff}}{=}0)$

Probing Dataset $\mathbb{P}_{\text{ans+supp+suff}}(\mathbb{T}(D))$ for all three tests:
⇒ Probing question collection $\mathbb{P}_{\text{ans+supp+suff}}(\mathbb{T}(q))$ for the transformed question $\mathbb{T}(q)$ has only one group, corresponding to the unique bi-partition $\{\{f_1\}, \{f_2\}\}$, and is defined as:

1. $(Q, C \setminus \{f_1, f_r\};\ L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}\{f_2\}, L^{*}_{\text{suff}}{=}0)$
2. $(Q, C \setminus \{f_2, f_r\};\ L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}\{f_1\}, L^{*}_{\text{suff}}{=}0)$
3. $(Q, C \setminus \{f_1, f_2\};\ L^{*}_{\text{suff}}{=}-1)$

Figure 7: Proposed dataset transformation and probes for the case of $|F_s| = 2$ supporting facts.

a score of 0 on the above group if it predicts the L^{*}_{suff} label incorrectly for any instance in the group. Otherwise, we consider only the partial support instances (those with $L^{*}_{\text{suff}} = 0$) in the group, which we observe are identical to the un-transformed probe group $\mathbb{P}_{\text{ans+supp}}(q; \{f_1\})$ when ignoring the sufficiency label, and apply the grouped probe metric $m^{\mathbb{P}}_{\tau}$ from Section 3.2 to this subset of instances.

A.5 Probing $\mathbb{T}(D)$ for $|F_s| \geq 2$

The probe for disconnected reasoning in the transformed dataset $\mathbb{T}(D)$ described in Appendix A.4 for the case of two supporting facts can be generalized as follows for $|F_s| \geq 2$. For each proper bi-partition $\{F_{s1}, F_{s2}\}$ of F_s, we consider two partial contexts, $C \setminus F_{s1}$ and $C \setminus F_{s2}$, and one where not even partial support is present, $C \setminus (F_{s1} \cup F_{s2})$.

Recall that when constructing $\mathbb{T}(D)$, we had associated non-supporting facts F_{r1} and F_{r2} (both chosen from F_r) with supporting facts F_{s1} and F_{s2}, respectively, and had additionally removed them from the respective input contexts for length normalization. For the partial context instances in the probe, we choose another non-supporting fact $f_{r1} \in F_r \setminus \cup F_{r1}$, and combine it with F_{r1} to obtain $F'_{r1} = F_{r1} \cup \{f_{r1}\}$; similarly define F'_{r2}.

For each $q \in D$, the probing dataset contains a collection $\mathbb{P}(\mathbb{T}(q))$ of $2^{|F_s|-1} - 1$ groups of instances, where each group corresponds to one proper bi-partition of F_s. For the bi-partition $\{F_{s1}, F_{s2}\}$, the group, denoted $\mathbb{P}(\mathbb{T}(q); F_{s1})$, contains the following instances, each of which has exactly $|C| - |F_s|$ facts in its context:

1. $(Q, C \setminus (F_{s1} \cup F'_{r1});$
   $L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}F_{s2}, L^{*}_{\text{suff}}{=}0)$
2. $(Q, C \setminus (F_{s2} \cup F'_{r2});$
   $L^{?}_{\text{ans}}{=}A, L_{\text{supp}}{=}F_{s1}, L^{*}_{\text{suff}}{=}0)$
3. $(Q, C \setminus F_s;\ L^{*}_{\text{suff}}{=}-1)$

The semantics of $L^{?}_{\text{ans}}$ and L^{*}_{suff} remain the same as for the case of $|F_s| = 2$.

The grouped metric for this bi-partition, denoted $m^{\mathbb{P}\mathbb{T}}_{\tau+\text{suff}}(q, \mu(\mathbb{P}(\mathbb{T}(q); F_{s1})))$, captures whether the model exhibits correct behavior on the entire group (as discussed for the case of $|F_s| = 2$). The overall probe metric, $m^{\mathbb{P}\mathbb{T}}_{\tau+\text{suff}}(q, \cdot)$, continues to follow Eqn. (5) and captures the disjunction of undesirable behavior across all bi-partitions.

B XLNet QA Model Details

B.1 XLNet-Base (Full)

We concatenate all 10 paragraphs together into one long context with special paragraph marker token `[PP]` at the beginning of each paragraph and special sentence marker token at the beginning of each sentence in the paragraph. Lastly, the question is concatenated at the end of this long context.

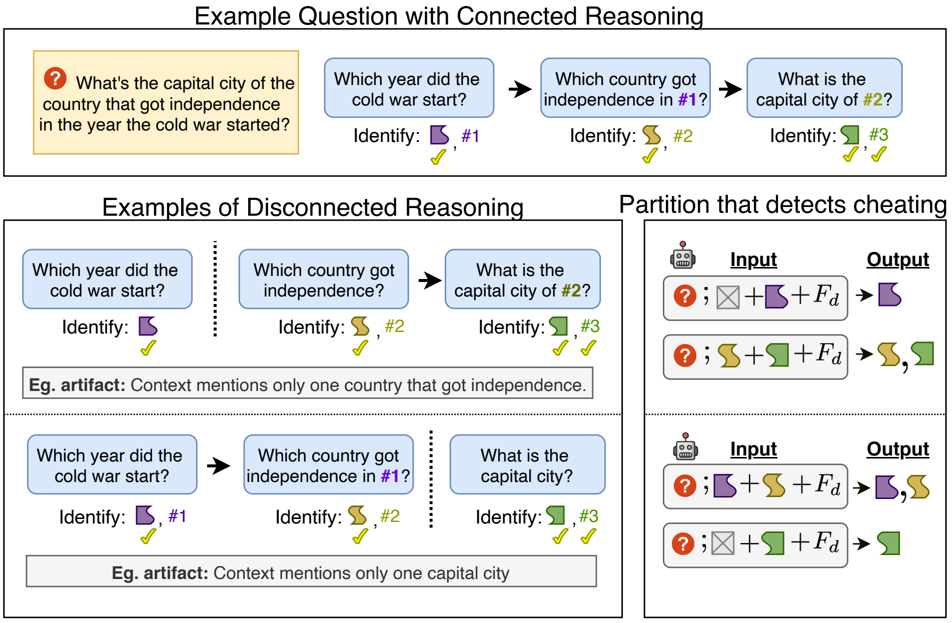

Figure 8: Generalization of disconnected reasoning to a 3-fact reasoning question. As shown in the bottom half, a model could perform multifact reasoning on two disjoint partitions to answer this question. We consider such a model to be performing disconnected reasoning as it does not use the entire chain of reasoning and relies on artifacts (specifically, it uses 1-fact and 2-fact reasoning, but not 3-fact reasoning). For each of the two examples, there exists a fact bi-partition (shown on the right) that we can use to detect such reasoning as the model would continue to produce all the expected labels even under this partition.

Apart of questions that have answer as a span in the context, HotpotQA also has comparison questions for which the answer is ”yes” or ”no” and it’s not contained in the context. So we also prepend text `"<yes> <no>"` to the context to deal with both types of questions directly by answer span extraction. Concretely, we have, `[CLS] <yes> <no> [PP] [SS] sent1,1 [SS] sent1,2 [PP] [SS] sent2,1 [QQ] q`.

We generate logits for each paragraph and sentence by passing marker tokens through feedforward network. Supporting paragraphs and sentences are supervised with binary cross entropy loss. Answer span extraction is using standard way (Devlin et al., 2019) where span start and span end logits are generated with feedforward on each token and it’s supervised with cross entropy loss. We use first answer occurrence among of the answer text among the supporting paragraphs as the correct span. This setting is very similar to recent work (Beltagy et al., 2020), and our results in Table 2, show that this model achieves comparable accuracy to other models with similar model complexity. We haven’t done any hyperparameter (learning rate, num epoch) tuning on the development set because of the expensive runs, which could explain the minor difference.

For predicting sufficiency classification, we use feedforward on `[CLS]` token and train it with cross entropy loss. In our transformed dataset, because HotpotQA has K=2, there are twice the number of instances with insufficient supporting information than the instances with insufficient supporting information. So during *training* we balance the number of insufficient instances by dropping half of them.

B.2 XLNet-Base (Single Fact)

To verify the validity of our tests, we also evaluate a variant of XLNet *incapable of Multifact reasoning*. Specifically, we train our XLNet model that makes predictions one paragraph at a time (similar to Min et al. (2019)). Although these previous works showed that answer prediction is hackable, we adapt it to predict supporting facts and sufficiency as well.

Specifically, we process the following through the XLNet transformer `[CLS] <yes> <no> [PP] [SS] sent1,1 [SS] sent1,2 [QQ] q` for each paragraph. We then supervise `[PP]` tokens for two tasks: identify if paragraph is a supporting paragraph and identify if paragraph has the answer span (for yes/no question both supporting paragraphs are supervised to be having the answer). We then select top ranked paragraph for having the answer and generate the best answer span. Similarly, select top two ranked paragraphs for having being supporting and predict the corresponding supporting sentences. The logits for answer span and supporting sentences are ignored when the paragraph doesn't have the answer and is not supporting respectively. We train for three losses jointly: (i) ranking answer containing paragraph, (ii) ranking supporting paragraphs (iii) predicting answer from answer containing paragraph (iv) predicting supporting sentences from supporting paragraphs. We use binary cross entropy for ranking of paragraphs, so there's absolutely no interaction the paragraphs in this model. To get the sufficiency label, we apply check if the sufficiency classification label based on the number of supporting paragraphs predicted[15]. For original dataset, if $|\text{predicted}(\text{Supp}_\text{p})| > 1$, then $C = 1$ otherwise $C = 0$. For probing dataset, if $|\text{predicted}(\text{Supp}_\text{p})| > 0$, then $C = 0$ otherwise $C = -1$.

B.3 Glove-based Baseline

We have re-implemented the baseline described in (Yang et al., 2018) in AllenNLP (Gardner et al., 2017) library. Unlike original implementation, which uses only answer and sentence support identification supervision, we also using paragraph supervision identification supervision. Additionally, we use explicit paragraph and sentence marker tokens as in our XLNet-based implementation, and supervise model to predict paragraph and sentences support logits via feedforward on these token marker representations. We train answer span identification by cross-entropy loss and both paragraph and sentence support identification with binary cross-entropy loss.

B.4 QA Model Results

Table 2 shows results for QA models. Our XLNet model is comparable to other models of similar sizes on the HotpotQA dev set. Our implementation of RNN baseline model has answer scores similar to the reported ones, and has much better support identification scores than the original implementation.

Model	Ans F1	Supp_s F1	Joint F1
Baseline (reported)	58.3	66.7	40.9
QFE (BERT-Base)	68.7	84.7	60.6
DFGN (BERT-Base)	69.3	82.2	59.9
RoBERTa-Base	73.5	83.4	63.5
LongFormer-Base	74.3	84.4	64.4
Baseline (our)	60.2	76.2	48.0
XLNet-Base	71.9	83.9	61.8

Table 2: Performance of XLNet-Base compared to other transformer models (of similar size) on HotpotQA. Our model scores higher than BERT-Base models QFE (Nishida et al., 2019) and DFGN (Xiao et al., 2019), and performs comparable to recent models using RoBERTa and Longformer (Beltagy et al., 2020).

C Implementation and Model Training

All our models are implemented using AllenNLP (Gardner et al., 2017) library. For XLNet-base, we have also used Huggingface Transformers (Wolf et al., 2019). For all XLNet-base experiments, we train for two epochs, checkpointing every 15K instances and early stopping after 3 checkpoints of no validation metric improvement. For Glove-based baseline model, we do the same but for 3 epochs. For both models, effective batch size were 32. For XLNet-based model, we used learning rate of 0.00005 and linear decay without any warmup. The hyper-parameters were chosen as the default parameters used by hugging-face transformers to reproduce BERT results on SQuAD dataset. Our experiments were done using V100 gpus from Google Cloud. On average XLNet training runs took 2 days on 1 gpu and baseline model took less than 1 day.

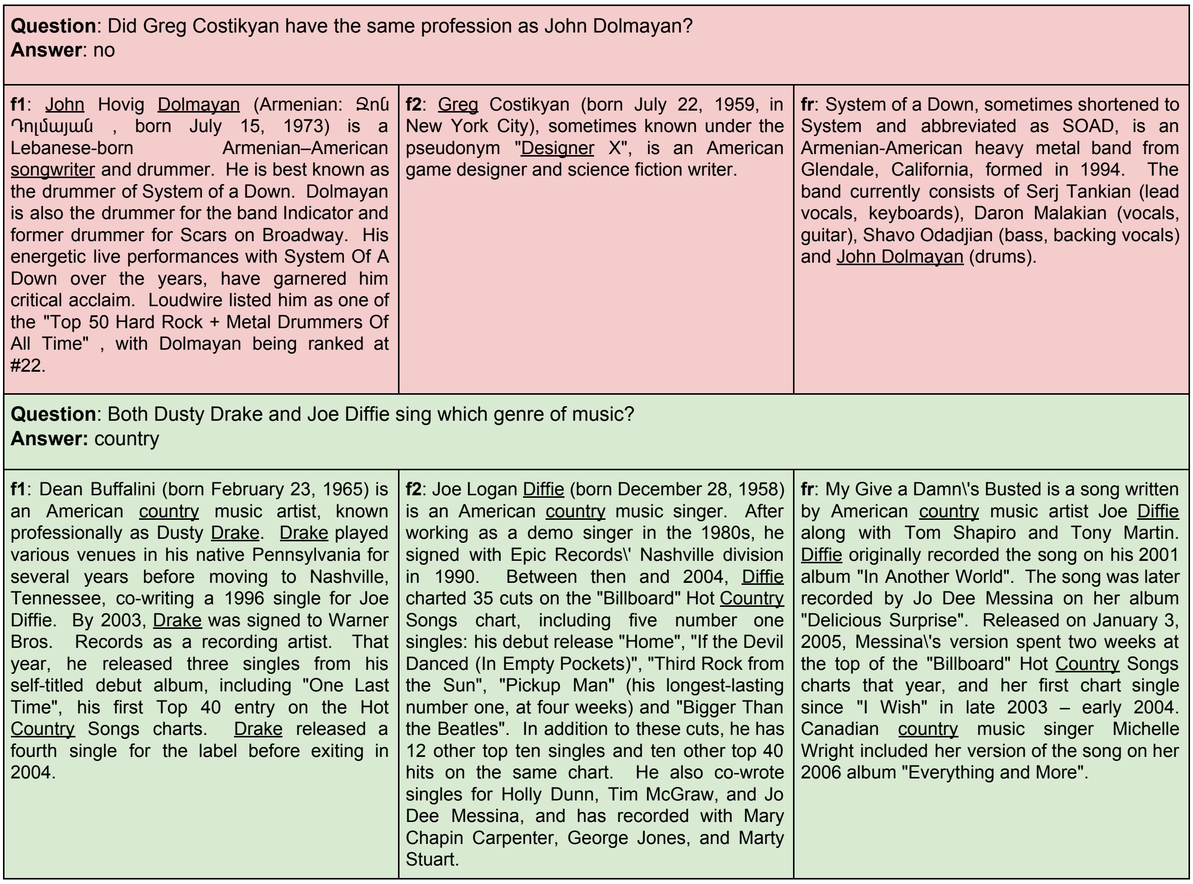
D Human Evaluation of Sufficiency Prediction

The sufficiency test can cause a spurious drop if sufficiency labels are incorrect, i.e., the context is sufficient even after f_1 or f_2 is removed. To rule this out, we randomly evaluated (using MTurk) 115 paragraphs from $C \setminus F_s$, and found only 2 (1.7%) could be used in place of f_1 or f_2 to answer the question. As we show below, this would result in only a marginal score drop compared to the roughly 20% observed drops.

To estimate this, we setup an annotation task on MTurk for turkers to annotate whether a pair of facts has sufficient information to arrive at an answer. For each question, we create three pair (f_1, f_2), (f_1, f_r) and (f_r, f_2), where f_1 and f_2 are annotated supporting paragraphs, and f_r is a

---

[15] This heuristic exploits the fixed number of hops=2 and doesn't need any training on the sufficiency label. We use this heuristic because we want to predict sufficiency label without interaction across *any* of the facts.



Question: Did Greg Costikyan have the same profession as John Dolmayan? **Answer**: no		
f1: John Hovig Dolmayan (Armenian: Ջոն Դոլմայան , born July 15, 1973) is a Lebanese-born Armenian–American songwriter and drummer. He is best known as the drummer of System of a Down. Dolmayan is also the drummer for the band Indicator and former drummer for Scars on Broadway. His energetic live performances with System Of A Down over the years, have garnered him critical acclaim. Loudwire listed him as one of the "Top 50 Hard Rock + Metal Drummers Of All Time" , with Dolmayan being ranked at #22.	**f2**: Greg Costikyan (born July 22, 1959, in New York City), sometimes known under the pseudonym "Designer X", is an American game designer and science fiction writer.	**fr**: System of a Down, sometimes shortened to System and abbreviated as SOAD, is an Armenian-American heavy metal band from Glendale, California, formed in 1994. The band currently consists of Serj Tankian (lead vocals, keyboards), Daron Malakian (vocals, guitar), Shavo Odadjian (bass, backing vocals) and John Dolmayan (drums).
Question: Both Dusty Drake and Joe Diffie sing which genre of music? **Answer:** country		
f1: Dean Buffalini (born February 23, 1965) is an American country music artist, known professionally as Dusty Drake. Drake played various venues in his native Pennsylvania for several years before moving to Nashville, Tennessee, co-writing a 1996 single for Joe Diffie. By 2003, Drake was signed to Warner Bros. Records as a recording artist. That year, he released three singles from his self-titled debut album, including "One Last Time", his first Top 40 entry on the Hot Country Songs charts. Drake released a fourth single for the label before exiting in 2004.	**f2**: Joe Logan Diffie (born December 28, 1958) is an American country music singer. After working as a demo singer in the 1980s, he signed with Epic Records\' Nashville division in 1990. Between then and 2004, Diffie charted 35 cuts on the "Billboard" Hot Country Songs chart, including five number one singles: his debut release "Home", "If the Devil Danced (In Empty Pockets)", "Third Rock from the Sun", "Pickup Man" (his longest-lasting number one, at four weeks) and "Bigger Than the Beatles". In addition to these cuts, he has 12 other top ten singles and ten other top 40 hits on the same chart. He also co-wrote singles for Holly Dunn, Tim McGraw, and Jo Dee Messina, and has recorded with Mary Chapin Carpenter, George Jones, and Marty Stuart.	**fr**: My Give a Damn\'s Busted is a song written by American country music artist Joe Diffie along with Tom Shapiro and Tony Martin. Diffie originally recorded the song on his 2001 album "In Another World". The song was later recorded by Jo Dee Messina on her album "Delicious Surprise". Released on January 3, 2005, Messina\'s version spent two weeks at the top of the "Billboard" Hot Country Songs charts that year, and her first chart single since "I Wish" in late 2003 – early 2004. Canadian country music singer Michelle Wright included her version of the song on her 2006 album "Everything and More".

Figure 9: Two examples where we found a non-supporting fact provides an alternative support for answering the question. **f1** and **f2** are annotated supporting facts, but **fr** in C and **f1** form alternative support.

randomly sample from total non-supporting paragraphs. The questions were taken from HotpotQA development set. If for a question, annotators agree that both (f_1, f_2) and (f_1, f_r) are sufficient, we assume f_r provides proxy (duplicate) information for f_2. Likewise for (f_1, f_2) and (f_r, f_2).

Out of 115 examples questions (with annotator agreement), we found only 2 (1.7%) of them to have a proxy fact in f_r. Figure 9 shows these 2 examples. This shows that such proxy information is very rare in HotpotQA. We next estimate the impact of these duplicates on the human score.

D.1 Human Score Estimate on $\mathbb{T}(\mathcal{D})$

Given the number of observed duplicates, we can now estimate the expected drop in human performance. For simplicity, lets consider only the Exact Match score where the human would get one point if they predict all the facts exactly. There are two scenarios where the sufficiency test in our transformed dataset would introduce more noise resulting in a drop in human score.

1. The original context was not actually sufficient: In this case the sufficiency label, $L_{\text{suff}} = 1$ would be incorrect and the human score on the sufficiency test for this example would be zero. However, in such a case, the human score on paragraph and sentence identification would also be zero. As a result, there would be no drop in human score relative to the original task

2. The constrastive examples are actually sufficient: Due to a potential proxies of f_1 in $C \setminus f_1$, it is possible that our contrastive examples would be considered sufficient. While this would also effect the original dataset, its impact would be more extreme on our test. We focus on this scenario in more detail next.

Lets assume that there are k such proxy paragraphs in any given context. In such a case, there is a $1/(k+1)$ chance that a human would select the annotated support paragraphs instead of these proxy paragraphs. So there is a $1/(k+1)$ chance

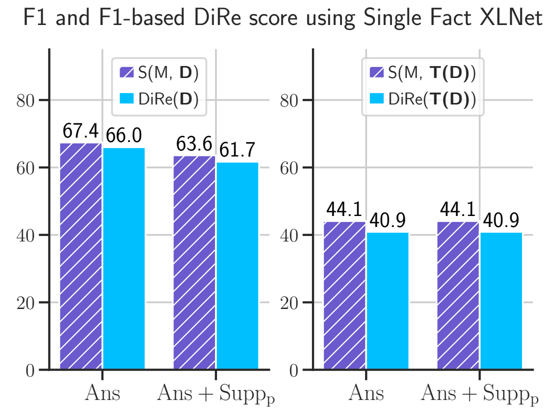


Figure 10: F1 and F1-based DiRe scores of $\mathcal{D}$ and $\mathbb{T}(\mathcal{D})$ using Single-Fact XLNet-base.

that they get one point on the original task, but they would always get 0 points on our transformation.

Given that we observed a proxy paragraph in 1.7% of our annotated paragraphs, we can model the likelihood of observing k proxy paragraphs with a binomial distribution. Specifically, since there are 8 distractor paragraphs in HotpotQA, the probability of observing k proxy paragraphs:

$$P(k) = \binom{8}{k} \times (0.017)^k \times (1 - 0.017)^{8-k}$$

So the expected drop in score would be given by:

$$\sum_{k=1}^{8} P(k) \times \frac{1}{k+1} = 0.0628$$

So the expected drop in human score is only 6.28% whereas we observed about 18% drop in EM scores as shown in Appendix F.

E XLNet (Single-Fact) Results

Figure 10 shows the results of our Single-Fact model on the original dataset $\mathcal{D}$ and the transformation $\mathbb{T}(\mathcal{D})$. On both the metrics, we can see that our DiRe probe gets the almost the same score as the Single-Fact model, i.e., our probe can detect the disconnected reasoning bias in the Single-Fact model. Additionally, we can see that score of this Single-Fact model drops from 67.4 to 44.1, a drop of 23 F1 pts, going from $\mathcal{D}$ to $\mathbb{T}(\mathcal{D})$ (on the Ans metric). This shows that our transformed dataset is less exploitable by a disconnected reasoning model.

F Exact Match Numbers

Figure 11 shows the EM scores of our models on the original dataset $\mathcal{D}$ and transformed dataset $\mathbb{T}(\mathcal{D})$. Consistent with our F1 metric, we can see large drops in model score going from $\mathcal{D}$ to $\mathbb{T}(\mathcal{D})$, showing that the transformation is harder for these models

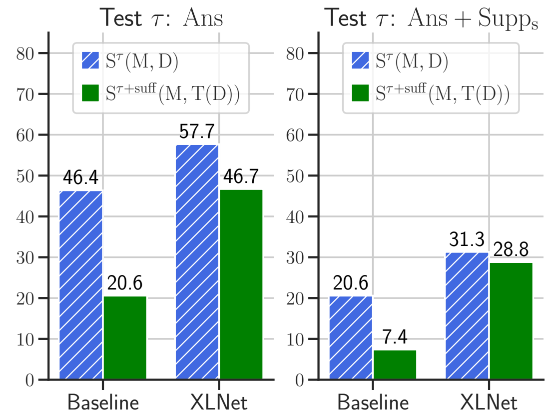

Figure 11: EM scores of two models on $\mathcal{D}$ and $\mathbb{T}(\mathcal{D})$ under two common metrics. Transformed dataset is harder for both models since they rely on disconnected reasoning. The weaker, Baseline model drops more as it relies more heavily on disconnected reasoning.

Figure 12 shows the disconnected reasoning bias in the XLNet-Base model trained on $\mathcal{D}$ and $\mathbb{T}(\mathcal{D})$ using the EM scores. Again, we see the same trend here – the transformed dataset has a reduced DiRe score indicating lower disconnected reasoning bias.

Finally, Figure 13 shows the impact of adversarial examples and the transformation on the EM scores. While the drops are lower due to the strictness of the EM scores, the trends are still the same – adversarial examples have a minor impact on the DiRe scores but transformation of the original dataset as well transformation of the adversarial examples results in a big drop in the disconnected reasoning bias.

G Grouped Metric on Trivial Transformation

The grouped metric combines decisions over a set of instances and, one can argue, is therefore inherently harder. However, one can show that unless the instances within a group test for qualitatively different information, the grouped metric will not be necessarily lower than the single instance metric.

To support this claim, we compute grouped metric over a trivial transform that is similar to $\mathbb{T}(\mathcal{D})$ but does not involve the contrastive sufficiency prediction test. This trivial transform, denoted $\mathbb{T}_{trv}$, creates 3 copies of each instance but drops at ran-

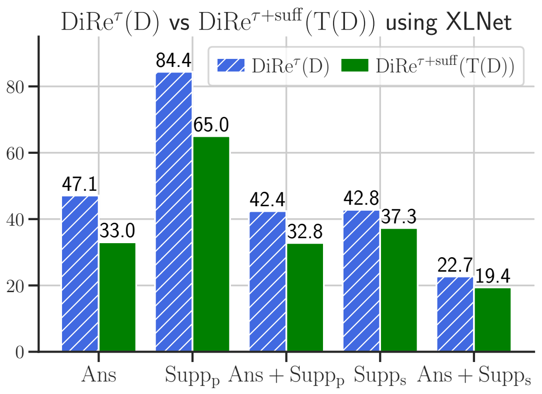

Figure 12: EM-based DiRe scores of $\mathcal{D}$ and $\mathbb{T}(\mathcal{D})$ using XLNet-Base. Dataset transformation reduces disconnected reasoning bias, demonstrated by DiRe scores being substantially lower on $\mathbb{T}(\mathcal{D})$ than on $\mathcal{D}$.

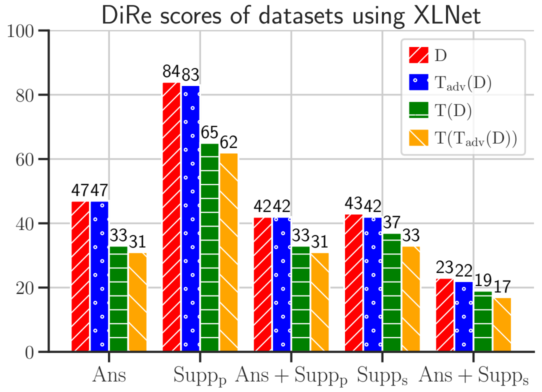

Figure 13: EM-based DiRe score on various metrics using XLNet-base for four datasets: original $\mathcal{D}$, adversarial $\mathbb{T}_{\text{adv}}(\mathcal{D})$, transformed $\mathbb{T}(\mathcal{D})$, and transformed adversarial $\mathbb{T}(\mathbb{T}_{\text{adv}}(\mathcal{D}))$. Transformation is more effective than, and complementary to, Adversarial Augmentation for reducing DiRe scores.

dom one non-supporting fact from each instance. Similar to $\mathbb{T}(\mathcal{D})$ in which we require the model to produce correct sufficiency labels for all 3 instances, here we require the model to produce correct answer and support on all 3 copies.[16]

1. $(Q, C \setminus \{f_{r_1}\};\ L_{\text{ans}}{=}A, L_{\text{supp}}{=}F_s)$
2. $(Q, C \setminus \{f_{r_2}\};\ L_{\text{ans}}{=}A, L_{\text{supp}}{=}F_s)$
3. $(Q, C \setminus \{f_{r_3}\};\ L_{\text{ans}}{=}A, L_{\text{supp}}{=}F_s)$

In Figure 14, we show the EM results corresponding to the respective grouped metrics for $\mathbb{T}_{trv}(\mathcal{D})$ and $\mathbb{T}(\mathcal{D})$). We see barely any drop of results from $\mathcal{D}$ to $\mathbb{T}_{trv}(\mathcal{D})$, but do see significant drop going from $\mathcal{D}$ to $\mathbb{T}(\mathcal{D})$. This shows that

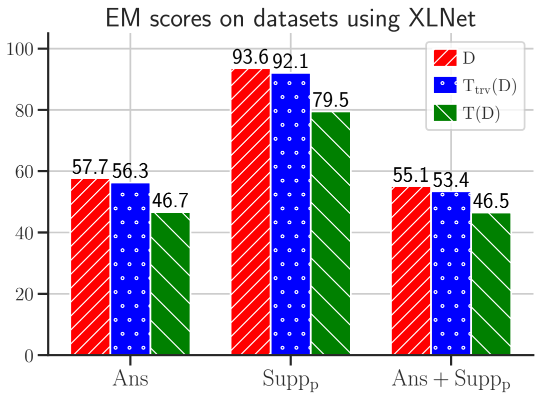

Figure 14: EM scores of XLNet-base on three metrics for original HotpotQA ($\mathcal{D}$), trivially transformed HotpotQA ($\mathbb{T}_{trv}(\mathcal{D})$) and our transformed HotpotQA ($\mathbb{T}(\mathcal{D})$). Model scores barely drop from $\mathcal{D}$ to $\mathbb{T}_{trv}(\mathcal{D})$ but significantly drop $\mathcal{D}$ to $\mathbb{T}(\mathcal{D})$ showing that drop of scores in $\mathbb{T}(\mathcal{D})$ is not simply a result of using a grouped metric

adding a grouped metric over an arbitrary set of decisions would not make $\mathbb{T}(\mathcal{D})$ harder. Hence, the drop in scores from $\mathcal{D}$ to $\mathbb{T}(\mathcal{D})$ is not simply a result of using a grouped metric.

---

[16] Note that our transformed dataset does not even require the answer and support labels on all the examples, making $\mathbb{T}(\mathcal{D})$, in some ways, easier than this dataset.

Unsupervised Question Decomposition for Question Answering

Abstract

We aim to improve question answering (QA) by decomposing hard questions into simpler sub-questions that existing QA systems are capable of answering. Since labeling questions with decompositions is cumbersome, we take an unsupervised approach to produce sub-questions, also enabling us to leverage millions of questions from the internet. Specifically, we propose an algorithm for One-to-N Unsupervised Sequence transduction (ONUS) that learns to map one hard, multi-hop question to many simpler, single-hop sub-questions. We answer sub-questions with an off-the-shelf QA model and give the resulting answers to a recomposition model that combines them into a final answer. We show large QA improvements on HOTPOTQA over a strong baseline on the original, out-of-domain, and multi-hop dev sets. ONUS automatically learns to decompose different kinds of questions, while matching the utility of supervised and heuristic decomposition methods for QA and exceeding those methods in fluency. Qualitatively, we find that using sub-questions is promising for shedding light on why a QA system makes a prediction.[1]

1 Introduction

It has been a long-standing challenge in AI to answer questions of any level of difficulty (Winograd, 1991). Question answering (QA) systems struggle to answer complex questions such as *"What profession do H. L. Mencken and Albert Camus have in common?"* since the required information is scattered in different places (Yang et al., 2018). However, QA systems accurately answer simpler, related questions such as *"What profession does H. L. Mencken have?"* and *"Who was Albert Camus?"* (Petrochuk and Zettlemoyer, 2018). Thus, a promising strategy to answer hard questions is divide-and-conquer: decompose a hard question into simpler sub-questions, answer the sub-questions with a QA system, and recompose the resulting answers into a final answer, as shown in Figure 1. This approach leverages strong performance on simple questions to help answer harder questions (Christiano et al., 2018).

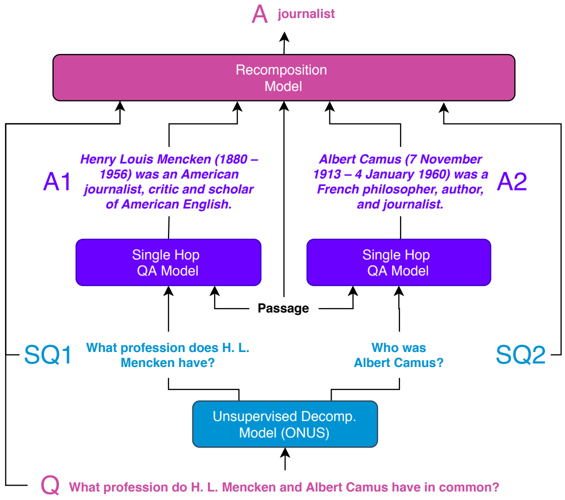

Figure 1: *Overview*: Using unsupervised learning, we decompose a multi-hop question into single-hop sub-questions, whose predicted answers are given to a recomposition model to predict the final answer.

Existing work decomposes questions using a combination of hand-crafted heuristics, rule-based algorithms, and learning from supervised decompositions (Talmor and Berant, 2018; Min et al., 2019b), which each require significant human effort. For example, DECOMPRC (Min et al., 2019b) decomposes some questions using supervision and other questions using a heuristic algorithm with fine-grained, special case handling based on part-

November 16–20, 2020.

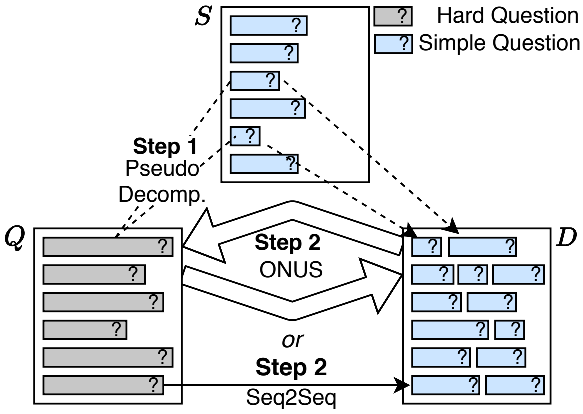

Figure 2: *One-to-N Unsupervised Sequence transduction (ONUS)*: **Step 1**: We create a corpus of pseudo-decompositions D by finding candidate sub-questions from a simple question corpus S which are similar to a multi-hop question in Q. **Step 2**: We learn to map multi-hop questions to decompositions using Q and D as training data, via either standard sequence-to-sequence learning (Seq2Seq) or unsupervised sequence-to-sequence learning (for ONUS).

of-speech tags and over 50 keywords. Prior work also assumes that sub-questions only consist of words from the question, which is not always true. Decomposing arbitrary questions requires sophisticated natural language generation, which often relies on many, high-quality supervised examples. Instead of using supervision, we find it possible to decompose questions in a *fully unsupervised* way.

We propose an algorithm for One-to-N Unsupervised Sequence transduction (ONUS) that learns to map from the distribution of hard questions to that of *many* simple questions. First, we automatically create a noisy "pseudo-decomposition" for each hard question by using embedding similarity to retrieve sub-question candidates. We mine over 10M possible sub-questions from Common Crawl with a classifier, showcasing the effectiveness of parallel corpus mining, a common approach in machine translation (Xu and Koehn, 2017; Artetxe and Schwenk, 2019), for QA. Second, we train a decomposition model on the mined data with unsupervised sequence-to-sequence learning, allowing ONUS to improve over pseudo-decompositions. As a result, we are able to train a large transformer model to generate decompositions, surpassing the fluency of heuristic/extractive decompositions. Figure 2 overviews our approach to decomposition.

We validate ONUS on multi-hop QA, where questions require reasoning over multiple pieces of evidence. We use an off-the-shelf single-hop QA model to answer decomposed sub-questions. Then, we give sub-questions and their answers to a recomposition model to combine into a final answer. We evaluate on three dev sets for HOTPOTQA, a standard benchmark for multi-hop QA (Yang et al., 2018), including two challenge sets.

ONUS proves to be a powerful tool for QA in the following ways. First, QA models that use decompositions outperform a strong RoBERTa baseline (Liu et al., 2019; Min et al., 2019a) by 3.1 points in F1 on the original dev set, 10 points on the out-of-domain dev set from Min et al. (2019b), and 11 points on the multi-hop dev set from Jiang and Bansal (2019a). Our method is competitive with state-of-the-art methods SAE (Tu et al., 2020) and HGN (Fang et al., 2019) that use additional, strong supervision on which sentences are relevant to the question. Second, our analysis shows that sub-questions improve multi-hop QA by using the single-hop QA model to retrieve question-relevant text. Qualitative examples illustrate how the retrieved text adds a level of interpretability to otherwise black-box, neural QA models. Third, ONUS automatically learns to generate useful decompositions for all four question types in HOTPOTQA, highlighting the general nature of ONUS over prior work, such as IBM Watson (Ferrucci et al., 2010) and DECOMPRC (Min et al., 2019b), which decompose different question types separately. Without finetuning, our trained ONUS model can even decompose some questions in visual QA (Johnson et al., 2017b) and knowledge-base QA (Talmor and Berant, 2018), as well as claims in fact verification (Thorne et al., 2018), suggesting promising future avenues in other domains.

2 Method

We now formulate the problem and describe our high-level approach, with further details in §3. The goal of this work is to leverage a QA model that is accurate on simple questions for answering hard questions, without using annotated question decompositions. Here, we consider simple questions to be "single-hop" questions that require reasoning over one paragraph or piece of evidence, and we consider hard questions to be "multi-hop." Our aim is to train a multi-hop QA model M to provide the correct answer a to a multi-hop question q about a given context c (e.g., several paragraphs). Normally, we would train M to maximize $\log p_M(a|c, q)$. To facilitate learning, we leverage a single-hop QA model that may be queried with sub-questions $s_1, \dots, s_N$, whose "sub-answers" $a_1, \dots, a_N$ may be given to M. M may then maximize the potentially easier objective $\log p_M(a|c, q, [s_1, a_1], \dots, [a_N, s_N])$.

Supervised decomposition models learn to map each question $q \in Q$ to a decomposition $d = [s_1; \dots; s_N]$ of N sub-questions $s_n \in S$ using annotated (q, d) examples. In this work, we do not assume access to strong (q, d) supervision. To leverage the single-hop QA model without supervision, we follow a three-stage approach: 1) map a question q into sub-questions $s_1, \dots, s_N$ via unsupervised techniques, 2) find sub-answers $a_1, \dots, a_N$ with the single-hop QA model, and 3) use $s_1, \dots, s_N$ and $a_1, \dots, a_N$ to predict a.

2.1 Unsupervised Question Decomposition

To train an unsupervised decomposition model, we need suitable data. We assume access to a hard question corpus Q and simple question corpus S. Instead of using supervised (q, d) examples, we design an algorithm that creates pseudo-decompositions d' to form (q, d') pairs from Q and S using an unsupervised method (§2.1.1). We then train a model to map q to a decomposition. We explore learning to decompose with standard and unsupervised sequence-to-sequence learning (§2.1.2).

2.1.1 Creating Pseudo-Decompositions

Inspired by Zhou et al. (2015) in question retrieval, we create a pseudo-decomposition set $d' = \{s_1; \dots; s_N\}$ for each $q \in Q$ by retrieving simple question s_i from S. We concatenate $s_1; \dots; s_N$ to form d' used downstream. N may potentially vary based on q. To retrieve useful simple questions for answering q, we face a joint optimization problem. We want sub-questions that are both (i) similar to q according to a metric f (first term) and (ii) maximally diverse (second term), so our objective is:

$$\operatorname*{argmax}_{d' \subset S} \sum_{s_i \in d'} f(q, s_i) - \sum_{s_i, s_j \in d', i \neq j} f(s_i, s_j) \quad (1)$$

2.1.2 Learning to Decompose

With the above pseudo-decompositions, we explore various decomposition methods (details in §3.2.3):

PseudoD We use sub-questions from pseudo-decompositions directly in downstream QA.

Sequence-to-Sequence (Seq2Seq) We train a Seq2Seq model p_θ to maximize $\log p_\theta(d'|q)$.

One-to-N Unsupervised Sequence transduction (ONUS) We use unsupervised learning to map one question to N sub-questions. We start with paired (q, d') but do not learn from the pairing because it is noisy. Instead, we use unsupervised Seq2Seq methods to learn a $q \rightarrow d$ mapping.

2.2 Answering Sub-Questions

To answer the generated sub-questions, we use an off-the-shelf QA model. The QA model may answer sub-questions using any free-form text (i.e., a word, phrase, sentence, etc.). Any QA model is suitable, so long as it can accurately answer simple questions in S. We thus leverage good accuracy on questions in S to help answer questions in Q.

2.3 Learning to Recompose

Downstream QA systems may use sub-questions and sub-answers in various ways. We train a recomposition model to combine the decomposed sub-questions/answers into a final answer, when also given the original input (context+question).

3 Experimental Setup

We now detail the implementation of our approach.

3.1 Question Answering Task

We test ONUS on HotpotQA, a standard multi-hop QA benchmark. Questions require information from two distinct Wikipedia paragraphs to answer (*"Who is older, Annie Morton or Terry Richardson?"*). For each question, HotpotQA provides 10 context paragraphs from Wikipedia. Two paragraphs contain question-relevant sentences called "supporting facts," and the remaining paragraphs are irrelevant, "distractor paragraphs." Answers in HotpotQA are either `yes`, `no`, or a text span in an input paragraph. Accuracy is measured with F1 word overlap and Exact Match (EM) between predicted and gold spans.

3.2 Unsupervised Decomposition

3.2.1 Training Data and Question Mining

Supervised decomposition methods are limited by the amount of available human annotation, but our unsupervised method faces no such limitation, similar to unsupervised QA (Lewis et al., 2019). Since we need to train data-hungry Seq2Seq models, we would benefit from large training corpora. A larger simple question corpus will also improve the relevance of retrieved simple questions to the hard question. Thus, we take inspiration from parallel corpus mining in machine translation (Xu and Koehn, 2017; Artetxe and Schwenk, 2019). We use questions from SQUAD 2 and HOTPOTQA to form our initial corpora S (single-hop questions) and Q (multi-hop questions), respectively, and we augment Q and S by mining more questions from Common Crawl. First, we select sentences that start with "wh"-words or end in "?" Next, we train an efficient, FastText classifier (Joulin et al., 2017) to classify between questions sampled from Common Crawl, SQUAD 2, and HOTPOTQA (60K in total). Then, we classify our Common Crawl questions, adding those classified as SQUAD 2 questions to S and those classified as HOTPOTQA questions to Q. Mining greatly increases the number of single-hop questions (130K $\rightarrow$ 10.1M) and multi-hop questions (90K $\rightarrow$ 2.4M), showing the power of parallel corpus mining in QA. [2]

3.2.2 Creating Pseudo-Decompositions

To create pseudo-decompositions (retrieval-based sub-questions for a given question), we experimented with using a variable number of sub-questions N per question (Appendix §A.1), but we found similar QA results with a fixed $N = 2$, which we use in the remainder for simplicity.

Similarity-based Retrieval To retrieve relevant sub-questions, we embed any text t into a vector $\mathbf{v}_t$ by summing the FastText vectors (Bojanowski et al., 2017)[3] for words in t and use cosine as our similarity metric f.[4] Let q be a multi-hop question with a pseudo-decomposition (s_1^*, s_2^*) and $\hat{\mathbf{v}}$ be the unit vector of $\mathbf{v}$. Since $N = 2$, Eq. 1 simplifies to:

$$(s_1^*, s_2^*) = \underset{\{s_1, s_2\} \in S}{\operatorname{argmax}} \left[\hat{\mathbf{v}}_q^\top \hat{\mathbf{v}}_{s_1} + \hat{\mathbf{v}}_q^\top \hat{\mathbf{v}}_{s_2} - \hat{\mathbf{v}}_{s_1}^\top \hat{\mathbf{v}}_{s_2} \right]$$

The last term requires $O(|S|^2)$ comparisons, which is expensive as $|S| > 10\text{M}$. Instead of solving the above equation exactly, we find an approximate pseudo-decomposition (s_1', s_2') by computing over $S' = \text{topK}_{\{s \in S\}} \left[\hat{\mathbf{v}}_q^\top \hat{\mathbf{v}}_s \right]$ with $K = 1000$. We efficiently build S' with FAISS (Johnson et al., 2017a).

Random Retrieval For comparison, we test a random pseudo-decomposition baseline, where we retrieve $s_1, \ldots, s_N$ by sampling uniformly from S.

Editing Pseudo-Decompositions Since sub-questions are retrieval-based, they are often not about the same entities as q. Inspired by retrieve-and-edit methods (e.g., Guu et al., 2018), we replace each sub-question entity not in q with an entity from q of the same type (e.g., "Date" or "Location") if possible.[5] This step is important for PseudoD and Seq2Seq (which would learn to hallucinate entities) but not ONUS (which must reconstruct entities in q from its own decomposition, as discussed next).

3.2.3 Unsupervised Decomposition Models

Pretraining Pretraining is crucial for unsupervised Seq2Seq methods (Artetxe et al., 2018; Lample et al., 2018), so we initialize all decomposition models (Seq2Seq or ONUS) with the same pretrained weights. We warm-start our pretraining with the pretrained, English Masked Language Model (MLM) from Lample and Conneau (2019), a 12-block transformer (Vaswani et al., 2017). We do MLM finetuning for one epoch on Q and pseudo-decompositions D formed via random retrieval, using the final weights to initialize a pretrained encoder-decoder. See Appendix §B.2 for details.

Seq2Seq We finetune the pretrained encoder-decoder using maximum likelihood. We stop training based on validation BLEU between generated decompositions and pseudo-decompositions.

ONUS We finetune the pretrained encoder-decoder with back-translation (Sennrich et al., 2016) and denoising objectives simultaneously, similar to Lample and Conneau (2019) in unsupervised one-to-one translation.[6] For denoising, we produce a noisy input d' by randomly masking, dropping, and locally shuffling tokens in $d \sim D$, and we train a model with parameters θ to maximize $\log p_\theta(d|d')$. We likewise maximize $\log p_\theta(q|q')$ for a noised version q' of $q \sim Q$. For back-translation, we generate a multi-hop question $\hat{q}$ for a decomposition $d \sim D$, and we maximize $\log p_\theta(d|\hat{q})$. Similarly, we maximize $\log p_\theta(q|\hat{d})$ for a model-generated decomposition $\hat{d}$ of $q \sim Q$. To stop training without supervision, we use a modified version of round-trip BLEU (Lample et al., 2018) (see Appendix §B.1 for details). We train on HOTPOTQA questions Q and their pseudo-decompositions D.[7]

---

[2] See Appendix §A.3 for details on question classifier.

[3] 300-dim. English Common Crawl vectors: `https://fasttext.cc/docs/en/english-vectors.html`

[4] We also tried TFIDF and BERT representations but did not see improvements over FastText (see Appendix §A.4).

[5] Entities found with spaCy (Honnibal and Montani, 2017).

[6] `www.github.com/facebookresearch/XLM`

[7] Using the augmented corpora here did not improve QA.

3.3 Single-hop Question Answering Model

We finetune a pretrained model for single-hop QA following prior work from Min et al. (2019b) on HOTPOTQA, as described below.[8]

Model Architecture Our model takes in a question and several paragraphs to predict the answer. We compute a separate forward pass on each paragraph (with the question). For each paragraph, the model learns to predict the answer span if the paragraph contains the answer and to predict "no answer" otherwise. We treat `yes` or `no` predictions as spans within the passage (prepended to each paragraph), as in Nie et al. (2019) on HOTPOTQA. During inference, for the final softmax, we consider all paragraphs as a single chunk. Similar to Clark and Gardner (2018), we subtract a paragraph's "no answer" logit from the logits of all spans in that paragraph, to reduce or increase span probabilities accordingly. In other words, we compute the probability $p(s_p)$ of each span s_p in a paragraph $p \in \{1, \dots, P\}$ using the predicted span logit $l(s_p)$ and "no answer" paragraph logit $n(p)$ with $p(s_p) \propto e^{l(s_p)-n(p)}$. ROBERTA$_{\text{LARGE}}$ (Liu et al., 2019) is used as our pretrained model.

Training Data and Ensembling Similar to Min et al. (2019b), we train an ensemble of 2 single-hop QA models on SQUAD 2 and the "easy" (single-hop) subset of HOTPOTQA (see Appendix §C for training details). We average model logits before predicting the answer. We use the single-hop QA ensemble as a black-box model once trained, never training the model on multi-hop questions.

Returned Text Instead of returning only the predicted sub-answer span to the recomposition model, we return the sentence that contains the predicted sub-answer, which is more informative.

3.4 Recomposition Model

Our recomposition model architecture is identical to the single-hop QA model, but the recomposition model also uses sub-questions and sub-answers as input. We append each (sub-question, sub-answer) pair to the question with separator tokens. We train one recomposition model on all of HOTPOTQA, also including SQUAD 2 examples used to train the single-hop QA model. All reported error margins show the mean and std. dev. across 5 recomposition training runs using the same decompositions.

Decomp. Method	Pseudo-Decomps.	HOTPOTQA Dev F1 Orig	Multi	OOD
✗	✗ (1hop)	66.7	63.7	66.5
✗	✗ (Baseline)	77.0$_{\pm.2}$	65.2$_{\pm.2}$	67.1$_{\pm.5}$
PseudoD	Random	78.4$_{\pm.2}$	70.9$_{\pm.2}$	70.7$_{\pm.4}$
	FastText	78.9$_{\pm.2}$	72.4$_{\pm.1}$	72.0$_{\pm.1}$
Seq2Seq	Random	77.7$_{\pm.2}$	69.4$_{\pm.3}$	70.0$_{\pm.7}$
	FastText	78.9$_{\pm.2}$	73.1$_{\pm.2}$	73.0$_{\pm.3}$
ONUS	Random	79.8$_{\pm.1}$	76.0$_{\pm.2}$	76.5$_{\pm.2}$
	FastText	**80.1**$_{\pm.2}$	**76.2**$_{\pm.1}$	**77.1**$_{\pm.1}$
DecompRC*		79.8$_{\pm.2}$	76.3$_{\pm.4}$	77.7$_{\pm.2}$
SAE (Tu et al., 2020) †		80.2	61.1	62.6
HGN (Fang et al., 2019) †		82.2	78.9‡	76.1‡

	Ours	SAE†	HGN†
Test (EM/F1)	66.33/79.34	66.92/79.62	69.22/82.19

Table 1: Unsupervised decompositions significantly improve F1 on HOTPOTQA over the baseline and single-hop QA model used to answer sub-questions ("1hop"). On all dev sets and the test set, we achieve similar F1 to methods that use supporting fact supervision (†). (*) We test supervised/heuristic decompositions from Min et al. (2019b). (‡) Scores are approximate due to mismatched Wikipedia dumps.

4 Results on Question Answering

We compare variants of our approach that use different learning methods and different pseudo-decomposition training sets. As a baseline, we compare ROBERTA with decompositions to ROBERTA without decompositions. We use the best hyperparameters for the baseline to train our ROBERTA models with decompositions (see Appendix §D.3 for hyperparameters).

We report results on 3 dev set versions: (1) the original version,[9] (2) the multi-hop version from Jiang and Bansal (2019a) who created some distractor paragraphs adversarially to test multi-hop reasoning, and (3) the out-of-domain (OOD) version from Min et al. (2019b) who retrieved distractor paragraphs with the same procedure as the original version but excluded the original paragraphs.

Main Results Table 1 shows how unsupervised decompositions affect QA. Our ROBERTA baseline does quite well on HOTPOTQA (77.0 F1), in line with Min et al. (2019a) who achieved strong results using a BERT-based version of the model (Devlin et al., 2019). We achieve large gains over the ROBERTA baseline by simply adding sub-questions and sub-answers to the input. Using decompositions from ONUS trained on FastText

---

[9] Test set is private, so we randomly halve the dev set to form validation/held-out dev sets. Our codebase has our splits.

Q-Type	Using Decomps. ✗	Using Decomps. ✓
Bridge	$80.1_{\pm .2}$	**81.7**$_{\pm .4}$
Comp.	$73.8_{\pm .4}$	**80.1**$_{\pm .3}$
Inters.	$79.4_{\pm .6}$	**82.3**$_{\pm .5}$
1-hop	$73.9_{\pm .6}$	**76.9**$_{\pm .6}$

SQs	SAs	QA F1
✗	✗	$77.0_{\pm .2}$
✓	Sent.	$80.1_{\pm .2}$
✓	Span	$77.8_{\pm .3}$
✓	Rand.	$76.9_{\pm .2}$
✓	✗	$76.9_{\pm .2}$
✗	Sent.	$80.2_{\pm .1}$

Table 2: **Left**: Decompositions improve QA F1 for all 4 HOTPOTQA types. **Right (Ablation)**: QA model F1 when trained with various sub-answers: the sentence of the predicted sub-answer, predicted sub-answer span, or random entity from the context. We also train models with (✓) or without (✗) sub-questions/sub-answers.

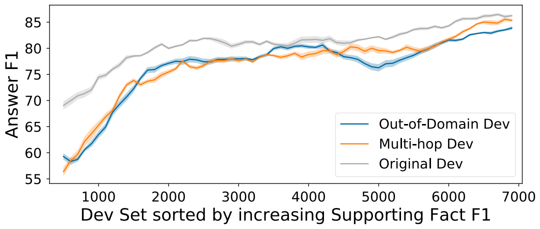

Figure 3: Multi-hop QA is better when the single-hop QA model answers with the ground truth "supporting fact" sentences. We plot mean and std. over 5 QA runs.

pseudo-decompositions, we find a gain of 3.1 F1 on the original dev set, 11 F1 on multi-hop dev, and 10 F1 on OOD dev. ONUS decompositions even match the performance of using supervised and heuristic decompositions from DECOMPRC (i.e., 80.1 vs. 79.8 F1 on the original dev set).

Pseudo-decomposition and ONUS training both contribute to decomposition quality. FastText pseudo-decompositions themselves provide an improvement in QA over the baseline (e.g., 72.0 vs. 67.1 F1 on OOD dev) and over random pseudo-decompositions (70.7 F1), validating our retrieval-based algorithm for creating pseudo-decompositions. Seq2Seq trained on FastText pseudo-decompositions achieves comparable gains to FastText pseudo-decompositions (73.0 F1 on OOD dev), validating the quality of pseudo-decompositions as training data. As hypothesized, ONUS improves over PseudoD and Seq2Seq by learning to align hard questions and pseudo-decompositions while ignoring the noisy pairing (77.1 F1 on OOD dev). ONUS is relatively robust to the training data used but still improves further by using FastText vs. Random pseudo-decompositions (77.1 vs. 76.5 F1 on OOD dev).

We submitted the best QA approach based on dev evaluation (using ONUS trained on FastText pseudo-decompositions) for hidden test evaluation. We achieved a test F1 of 79.34 and Exact Match (EM) of 66.33. Our approach is competitive with state-of-the-art systems SAE (Tu et al., 2020) and HGN (Fang et al., 2019), which both (unlike us) learn from strong, supporting-fact supervision about which sentences are relevant to the question.

4.1 Question Type Breakdown

To understand where decompositions help, we break down QA accuracy across 4 question types from Min et al. (2019b). "Bridge" questions ask about an entity not explicitly mentioned (*"When was Erik Watts' father born?"*). "Intersection" questions ask to find an entity that satisfies multiple separate conditions (*"Who was on CNBC and Fox News?"*). "Comparison" questions ask to compare a property of two entities (*"Which is taller, Momhil Sar or K2?"*). "Single-hop" questions are answerable using single-hop shortcuts or single-paragraph reasoning (*"Where is Electric Six from?"*). We split the original dev set into the 4 types using the supervised type classifier from Min et al. (2019b). Table 2 (left) shows F1 scores for ROBERTA with and without decompositions across the 4 types.

ONUS decompositions improve QA across all types. Our single decomposition model does not need to be tailored to the question type, unlike Min et al. (2019b) who use a different model per question type. For single-hop questions, our QA approach does not require falling back to a single-hop QA model and instead learns to leverage decompositions in that case also (76.9 vs. 73.9 F1).

4.2 Answers to Sub-Questions are Crucial

To measure the usefulness of sub-questions and sub-answers, we train the recomposition model with various, ablated inputs, as shown in Table 2 (right). Sub-answers are crucial to improving QA, as sub-questions with no answers or random answers do not help (76.9 vs. 77.0 F1 for the baseline). Only when sub-answers are provided do we see improved QA, with or without sub-questions (80.1 and 80.2 F1, respectively). It is important to provide the sentence containing the predicted answer span instead of the answer span alone (80.1 vs. 77.8 F1, respectively), though the answer span alone still improves over the baseline (77.0 F1).

4.3 How Do Decompositions Help?

Decompositions help by retrieving important supporting evidence to answer questions. Fig. 3 shows

Q1: Who is older, Annie Morton or Terry Richardson?
SQ$_1$: Who is Annie Morton?
∟ Annie Morton (born October 8, 1970) is an American model born in Pennsylvania.
SQ$_2$: When was Terry Richardson born?
∟ Kenton Terry Richardson (born 26 July 1999) is an English professional footballer who plays as a defender for League Two side Hartlepool United.
Â: Annie Morton

Q2: How many copies of Roald Dahl's variation on a popular anecdote sold?
SQ$_1$: How many copies of Roald Dahl's?
∟ His books have sold more than 250 million copies worldwide.
SQ$_2$ What is the name of the variation on a popular anecdote?
∟ "Mrs. Bixby and the Colonel's Coat" is a short story by Roald Dahl that first appeared in the 1959 issue of Nugget.
Â: more than 250 million

Q3: Are both Coldplay and Pierre Bouvier from the same country?
SQ$_1$: Where are Coldplay and Coldplay from?
∟ Coldplay are a British rock band formed in 1996 by lead vocalist and keyboardist Chris Martin and lead guitarist Jonny Buckland at University College London (UCL).
SQ$_2$: What country is Pierre Bouvier from?
∟ Pierre Charles Bouvier (born 9 May 1979) is a Canadian singer, songwriter, musician, composer and actor who is best known as the lead singer and guitarist of the rock band Simple Plan.
Â: No

Table 3: Example sub-questions generated by our model, along with predicted sub-answer sentences (answer span underlined) and final predicted answer.

that QA improves when the sub-answer sentences are gold "supporting facts." We retrieve these without relying on strong, supporting fact supervision, unlike many state-of-the-art models (Tu et al., 2020; Fang et al., 2019; Nie et al., 2019).[10]

4.4 Example Decompositions

To illustrate how decompositions help, Table 3 shows example sub-questions from ONUS with predicted sub-answers. Sub-questions are single-hop questions relevant to the multi-hop question. The single-hop QA model returns relevant sub-answers, sometimes despite under-specified (**Q2, SQ$_1$**) or otherwise imperfect sub-questions (**Q3, SQ$_1$**). The recomposition model returns an answer consistent with the sub-answers. Furthermore, the sub-answers used for QA are in natural language, adding a level of interpretability to otherwise black-box, neural QA models. Decompositions are largely extractive, copying from the multi-hop question rather than hallucinating new entities, which helps generate relevant sub-questions. Appendix Table 7 shows decompositions from our trained ONUS model, without further finetuning, on image-based questions (CLEVR; Johnson et al., 2017b), knowledge-base questions (ComplexWebQuestions; Talmor and Berant, 2018), and even claims in fact verification (FEVER; Thorne et al., 2018), which suggests promising future avenues for our approach in other domains and highlights the general nature of the proposed method.

Decomp. Method	GPT2 NLL	% Well-Formed	Edit Dist.	Length Ratio
ONUS	5.56	60.9	5.96	1.08
DecompRC	6.04	32.6	7.08	1.22

Table 4: Analysis of sub-questions produced by our method vs. the supervised+heuristic method of Min et al. (2019b). Left-to-right: Negative Log-Likelihood according to GPT2 (lower is better), % classified as Well-Formed, Edit Distance between decomposition and multi-hop question, and token-wise Length Ratio between decomposition and multi-hop question.

5 Analysis

To better understand our system, we now analyze our pipeline by examining the model for each stage: decomposition, single-hop QA, and recomposition.

5.1 Unsupervised Decomposition Model

Intrinsic Evaluation of Decompositions We evaluate the quality of decompositions on other metrics aside from downstream QA. To measure the fluency of decompositions, we compute the likelihood of decompositions using the pretrained GPT-2 language model (Radford et al., 2019). We train a BERT$_{\text{BASE}}$ classifier on the question-wellformedness dataset of Faruqui and Das (2018), and we use the classifier to estimate the proportion of sub-questions that are well-formed. We measure how abstractive decompositions are by computing (i) the token Levenstein distance between the multi-hop question and its generated decomposition and (ii) the ratio between the length of the decomposition and the length of the multi-hop question. We compare ONUS to DECOMPRC (Min et al., 2019b), a supervised+heuristic decomposition method.

As shown in Table 4, ONUS decompositions are more natural and well-formed than DECOMPRC decompositions. As an example, for Table 3 **Q3**, DECOMPRC produces the sub-questions "Is Coldplay from which country?" and "Is Pierre Bouvier

---

[10] See Appendix §B.3 for supporting fact scores.

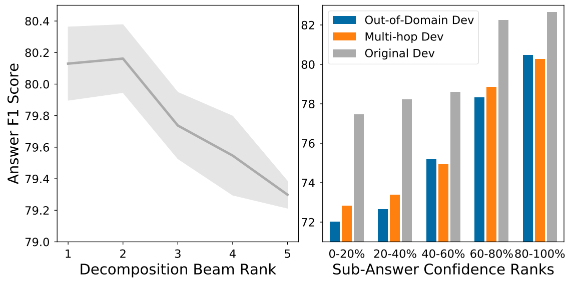

Figure 4: **Left**: We decode decompositions with beam search and use n$^{\text{th}}$-ranked hypothesis as a question decomposition. We plot the F1 of a recomposition model trained to use the n$^{\text{th}}$-ranked decomposition. **Right**: Multi-hop QA is better when the single-hop QA model places high probability on its sub-answer.

from which country?" ONUS decompositions are also closer in edit distance and length to the multi-hop question, consistent with our observation that our decomposition model is largely extractive.

Quality of Decomposition Model A well-trained decomposition model should place higher probability on decompositions that are more helpful for QA. We generate $N = 5$ hypotheses from our best decomposition model using beam search, and we train a recomposition model to use the n^{th}-ranked hypothesis as a question decomposition (Figure 4, left). QA accuracy decreases as we use lower probability decompositions, but accuracy remains relatively robust, at most decreasing from 80.1 to 79.3 F1. The limited drop suggests that decompositions are still useful if they are among the model's top hypotheses, another indication that ONUS is trained well for decomposition.

5.2 Single-hop Question Answering Model

Sub-Answer Confidence Figure 4 (right) shows that the single-hop model's sub-answer confidence correlates with downstream multi-hop QA accuracy on all dev sets. A low confidence sub-answer may be indicative of (i) an unanswerable or ill-formed sub-question or (ii) a sub-answer that is more likely to be incorrect. In both cases, the single-hop QA model is less likely to retrieve useful supporting evidence for answering the multi-hop question.

Changing the Single-hop QA Model We find that our approach is robust to the single-hop QA model used. We test the BERT$_{\text{BASE}}$ ensemble from Min et al. (2019b) as the single-hop QA model. The model performs much worse compared to our RoBERTa$_{\text{LARGE}}$ single-hop ensemble on HotpotQA itself (56.3 vs. 66.7 F1). However, the model results in similar QA when used to answer single-hop sub-questions within our larger system (79.9 vs. 80.1 F1 for our ensemble).

Recomposition Model	QA F1 (w/o → w/ Decomps.)
BERT$_{\text{BASE}}$	71.8±.4 → 73.0±.4
BERT$_{\text{LARGE}}$	76.4±.2 → 79.0±.1
RoBERTa$_{\text{LARGE}}$	77.0±.3 → 80.1±.2

Table 5: Better models gain more from decomposition.

5.3 Recomposition Model

Varying the Base Model To understand how decompositions impact performance as the recomposition model gets stronger, we vary the base pre-trained model. Table 5 shows the impact of adding decompositions to BERT$_{\text{BASE}}$, BERT$_{\text{LARGE}}$, and finally RoBERTa$_{\text{LARGE}}$ (see Appendix §D.3 for hyperparameters). The gain from using decompositions grows with strength of the recomposition model. Decompositions improve QA by 1.2 F1 for a BERT$_{\text{BASE}}$ model, by 2.6 F1 for the stronger BERT$_{\text{LARGE}}$ model, and by 3.1 F1 for our best RoBERTa$_{\text{LARGE}}$ model.

6 Related Work

Answering complex questions has been a long-standing challenge in natural language processing. Prior work explored decomposing questions with supervision and heuristic algorithms. IBM Watson (Ferrucci et al., 2010) decomposes questions into sub-questions in multiple ways or not at all. DecompRC (Min et al., 2019b) largely frames sub-questions as extractive spans of a question, learning to predict span-based sub-questions via supervised learning on human annotations. In other cases, DecompRC decomposes a multi-hop question using a heuristic algorithm or not at all. Watson and DecompRC use special case handling to decompose different questions, while our algorithm is fully automated and requires little hand-engineering.

More traditional, semantic parsing methods map questions to compositional programs, whose sub-programs can be viewed as question decompositions in a formal language (Talmor and Berant, 2018; Wolfson et al., 2020). Examples include classical QA systems like SHRDLU (Winograd, 1972) and LUNAR (Woods et al., 1974), as well as neural Seq2Seq semantic parsers (Dong and Lapata, 2016) and neural module networks (Andreas et al., 2015, 2016). Such methods usually require strong, program-level supervision to generate programs, as in visual QA (Johnson et al., 2017c) and on HOTPOTQA (Jiang and Bansal, 2019b). Some models use other forms of strong supervision, e.g., the sentences needed to answer a question, as annotated by HOTPOTQA. Such an approach is taken by SAE (Tu et al., 2020) and HGN (Fang et al., 2019), whose methods may be combined with ours.

Unsupervised decomposition complements strongly and weakly supervised decomposition approaches. Our unsupervised approach enables methods to leverage millions of otherwise unusable questions, similar to work on unsupervised QA (Lewis et al., 2019). When decomposition examples exist, supervised and unsupervised learning can be used in tandem to learn from both labeled and unlabeled examples. Such semi-supervised methods outperform supervised learning for tasks like machine translation (Sennrich et al., 2016). Other work on weakly supervised question generation uses a downstream QA model's accuracy as a signal for learning to generate useful questions. Weakly supervised question generation often uses reinforcement learning (Nogueira and Cho, 2017; Wang and Lake, 2019; Strub et al., 2017; Das et al., 2017; Liang et al., 2018), where an unsupervised initialization can greatly mitigate the issues of exploring from scratch (Jaderberg et al., 2017).

7 Conclusion

We proposed a QA system that answers a question via decomposition, without supervised question decompositions, using three stages: (1) decompose a question into many sub-questions using One-to-N Unsupervised Sequence transduction (ONUS), (2) answer sub-questions with an off-the-shelf QA system, and (3) recompose sub-answers into a final answer. When evaluated on three HOTPOTQA dev sets, our approach significantly improved QA over an equivalent model that did not use decompositions. Our approach relies only on the final answer as supervision but works as effectively as state-of-the-art methods that rely on much stronger supervision, such as supporting fact labels or example decompositions. We found that ONUS generates fluent sub-questions whose answers often match the gold-annotated, question-relevant text. Overall, this work opens up exciting avenues for leveraging methods in unsupervised learning and natural language generation to improve the interpretability and generalization of machine learning systems.

A Pseudo-Decompositions

Tables 8-10 show examples of pseudo-decompositions and learned decompositions from various models.

A.1 Variable-Length Pseudo-Decompositions

A general algorithm for creating pseudo-decompositions should find a suitable number of sub-questions N for each question. To this end, we compare the objective in Eq. 1 for creating pseudo-decompositions with an alternate objective based on Euclidean distance. This alternate objective has the advantage that the regularization term that encourages sub-question diversity grows more slowly N, disencouraging larger N less:

$$d'^{*} = \operatorname*{argmin}_{d' \subset S} \left\| \mathbf{v}_q - \sum_{s \in d'} \mathbf{v}_s \right\|_2 \tag{2}$$

We create pseudo-decompositions in an similar way as with Eq. 1, first finding a set of candidate sub-questions $S' \subset S$ with high cosine similarity to $\mathbf{v}_q$. Then, we perform beam search to sequentially choose sub-questions up to a maximum of N sub-questions.

We test pseudo-decomposition objectives by creating synthetic, compositional questions by combining 2-3 single-hop questions with "and." Then, we measure rank of the correct decomposition (a concatenation of the single-hop questions), according to each objective. For $N = 2$, both objectives perform well. For $N = 3$, Eq. 2 achieves a mean reciprocal rank of 30%, while Eq. 1 gets ∼0%. In practice, few questions appear to require $N > 2$ on HotpotQA, as we find similar QA accuracy with Eq. 1 (which consistently uses $N = 2$ sub-questions) and Eq. 2 (which mostly uses $N = 2$ but sometimes uses $N = 3$). For example, with Eq. 1 vs. Eq. 2, we find 79.9 vs. 79.4 dev F1 when using the BERT$_{\text{BASE}}$ ensemble from Min et al. (2019b) to answer sub-questions. Thus, we use Eq. 1 in our main experiments, as it is simpler and faster to compute. Table 8 contains an example where the variable-length decomposition method discussed above (Eq. 2) generates three sub-questions while other methods produce two.

A.2 Impact of Question Corpus Size

In addition to our previous results on FastText vs. Random pseudo-decompositions, we found it important to use a large question corpus to create pseudo-decompositions. QA F1 increased from 79.2 to 80.1 when we trained decomposition models on pseudo-decompositions comprised of questions retrieved from Common Crawl (>10M questions) rather than only SQuAD 2 (∼130K questions), using an appropriately larger beam size for pseudo-decomposition (100 → 1000).

Decomp. Method	Pseudo-Decomps.	HotpotQA F1 Dev	Advers.	OOD
✗	✗ (1hop)	66.7	63.7	66.5
✗	✗ (Baseline)	77.0±$_{.2}$	65.2±$_{.2}$	67.1±$_{.5}$
PseudoD	Random	78.4±$_{.2}$	70.9±$_{.2}$	70.7±$_{.4}$
	BERT	78.9±$_{.4}$	71.5±$_{.3}$	71.5±$_{.2}$
	TFIDF	79.2±$_{.3}$	72.2±$_{.3}$	72.0±$_{.5}$
	FastText	78.9±$_{.2}$	72.4±$_{.1}$	72.0±$_{.1}$
Seq2Seq	Random	77.7±$_{.2}$	69.4±$_{.3}$	70.0±$_{.7}$
	BERT	79.1±$_{.3}$	72.6±$_{.3}$	73.1±$_{.3}$
	TFIDF	79.2±$_{.1}$	73.0±$_{.3}$	72.9±$_{.3}$
	FastText	78.9±$_{.2}$	73.1±$_{.2}$	73.0±$_{.3}$
CONUS	Random	79.4±$_{.2}$	75.1±$_{.2}$	75.2±$_{.4}$
	BERT	78.9±$_{.2}$	74.9±$_{.1}$	75.2±$_{.2}$
	TFIDF	78.6±$_{.3}$	72.4±$_{.4}$	72.8±$_{.2}$
	FastText	79.9±$_{.2}$	76.0±$_{.1}$	76.9±$_{.1}$
ONUS	Random	79.8±$_{.1}$	76.0±$_{.2}$	76.5±$_{.2}$
	BERT	79.8±$_{.3}$	**76.2**±$_{.3}$	76.7±$_{.3}$
	TFIDF	79.6±$_{.2}$	75.5±$_{.2}$	76.0±$_{.2}$
	FastText	**80.1**±$_{.2}$	**76.2**±$_{.1}$	**77.1**±$_{.1}$
DecompRC		79.8±$_{.2}$	76.3±$_{.4}$	77.7±$_{.2}$
SAE (Tu et al., 2020)		80.2	61.1	62.6
HGN (Fang et al., 2019)		82.2	78.9	76.1

Table 6: QA F1 scores for all combinations of learning methods and pseudo-decomposition retrieval methods that we tried.

A.3 Question Mining Details

We train a 4-way FastText, bag-of-words classifier to classifier between (1) HotpotQA "Bridge"/"Intersection" questions (See §4.1 for definitions), (2) HotpotQA "Comparison" questions (See §4.1 for definition), (3) SQuAD 2.0 questions, (4) and Common Crawl questions. We randomly sample 15K examples from each of the above four groups of questions to form our training data. The trained classifier performs well, achieving 95.5% accuracy for HotpotQA vs. SQuAD question classification on held-out questions. Questions in Common Crawl that were classified as from HotpotQA by the classifier often had more words, conjunctions ("or," "and"), and comparison words ("older," "earlier"), and were generally complex questions.

A.4 Pseudo-Decomposition Retrieval Method

Table 6 shows QA results with pseudo-decompositions retrieved using sum-bag-of-

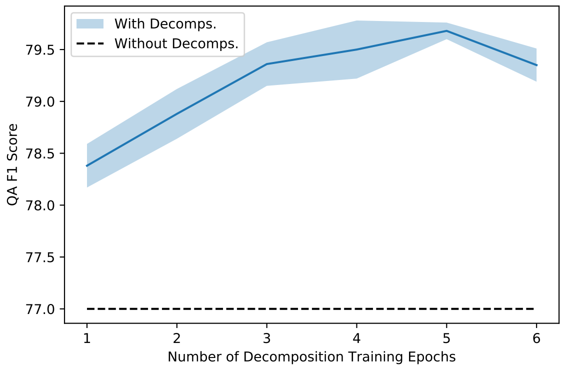

Figure 5: How multi-hop QA accuracy varies over the course of decomposition model training, for one training run of ONUS on FastText pseudo-decompositions. Our unsupervised stopping criterion selects the epoch 3 checkpoint, which performs roughly as well as the best checkpoint (epoch 5).

word representations from FastText, TFIDF, BERT$_{\text{LARGE}}$ first layer hidden states. We also vary the learning method and include results Curriculum ONUS (CONUS), where we initialize the ONUS approach with the Seq2Seq model trained on the same data.

B Unsupervised Decomposition Model

B.1 Training Procedure

Unsupervised Stopping Criterion To stop ONUS training, we use an unsupervised stopping criterion to avoid relying on a supervised validation set of decompositions. We generate a decomposition $\hat{d}$ for a multi-hop question q, and we measure BLEU between q and the model-generated question $\hat{q}$ for $\hat{d}$, similar to round-trip BLEU in unsupervised one-to-one translation (Lample et al., 2018). We scale round-trip BLEU score by the fraction of "good" decompositions, where a good decomposition has (1) two sub-questions (question marks), (2) no sub-question which contains all words in the multi-hop question, and (3) no sub-question longer than the multi-hop question. We chose these criteria to detect a failure mode; without scaling, decomposition models can achieve perfect round-trip BLEU by copying the multi-hop question as the decomposition. We measure scaled BLEU across multi-hop questions in HotpotQA dev, and we stop training when the metric does not increase for 3 consecutive epochs.

It is possible to stop training the decomposition model based on downstream QA accuracy. However, training a QA model on each decomposition model checkpoint (1) is computationally expensive and (2) ties decompositions to a specific, downstream QA model. In Figure 5, we show downstream QA results across various ONUS checkpoints when using the BERT$_{\text{BASE}}$ single-hop QA ensemble from Min et al. (2019b). The unsupervised stopping criterion does not significantly hurt downstream QA compared to using a weakly-supervised stopping criterion based on multi-hop QA accuracy.

B.2 Training Hyperparameters

MLM Pretraining We warm-start our pretraining with the 340M parameter, pretrained, English Masked Language Model (MLM) from Lample and Conneau (2019), a 12-block *encoder-only* transformer (Vaswani et al., 2017) trained on Toronto Books Corpus (Zhu et al., 2015) and Wikipedia. We pretrain our encoder for 26 hours (one full epoch on Q) with 8 DGX-1 machines, each with 8, 32GB NVIDIA V100 GPUs interconnected by Infiniband. We use the largest possible batch size (1536), and we choose the best learning rate (3×10^{-5}) based on training loss after a small number of iterations. We chose a maximum sequence length of 128. Other hyperparameters are identical to those from Lample and Conneau (2019) used in unsupervised one-to-one translation. To initialize a pretrained *encoder-decoder* from the encoder-only MLM, we initialize a 6-block encoder with the first 6 MLM blocks, and we initialize a 6-block decoder with the last 6 MLM blocks, randomly initializing the remaining weights as in Lample and Conneau (2019).

ONUS We train each decomposition model with distributed training over 8, 32GB NVIDIA V100 GPUs, lasting roughly 8 hours. We chose the largest batch size that fit in GPU memory (256) and then the largest learning rate that resulted in stable learning early in training (3×10^{-5}). Other hyperparameters are the same as Lample and Conneau (2019).

Seq2Seq We again train each decomposition model with distributed training over 8, 32GB NVIDIA V100 GPUs, lasting roughly 8 hours. We use a large batch size (1024) and chose the largest learning rate which resulted in stable training across the various pseudo-decomposition training corpora from Appendix §A.4 (1×10^{-4}). We keep other training settings and hyperparameters the same as for ONUS.

B.3 Unsupervised Fact Retrieval

Our unsupervised supporting fact retrieval (described in §4.3) achieves 15.7 EM and 55.2 F1 for retrieving the gold supporting facts (sentences) needed to answer HotpotQA questions. To our knowledge, there is no prior work on unsupervised fact retrieval on HotpotQA to compare against, but our performance approaches early, supervised fact-retrieval methods on HotpotQA from Yang et al. (2018) which achieve 59.0 F1.

B.4 Decomposing Questions in Other Tasks

As shown in Table 7, we decompose queries from several other datasets, using our decomposition model trained on only questions in HotpotQAand Common Crawl. In particular, we generate subquestions for (1) questions in ComplexWebQuestions (Talmor and Berant, 2018), which are multi-hop questions about knowledge-bases, (2) questions in CLEVR (Johnson et al., 2017b), which are multi-hop questions about images, and (3) claims (statements) in fact-verification challenges, FEVER 1.0 (Thorne et al., 2018) and 2.0 (Thorne et al., 2019). These queries differ significantly from questions in HotpotQA in topic, syntactic structure, and/or modality being asked about. Despite such differences, our trained ONUS model often (though not always) generates reasonable subquestions without any further finetuning, providing further evidence of the general nature of our approach and potential for applicability to other domains.

C Single-hop QA Model

To train the single-hop QA model, we largely follow Min et al. (2019b) as described below. We use an ensemble of two models trained on SQuAD 2 and examples from HotpotQA labeled as “easy” (single-hop). SQuAD is a single-paragraph QA task, so we adapt it to the multi-paragraph setting by retrieving and appending distractor paragraphs from Wikipedia for each question. We use the TFIDF retriever from DrQA (Chen et al., 2017) to retrieve two distractor paragraphs, which we add to the input for one model in the ensemble. We drop words from the question with a 5% probability to help the model handle any ill-formed subquestions.

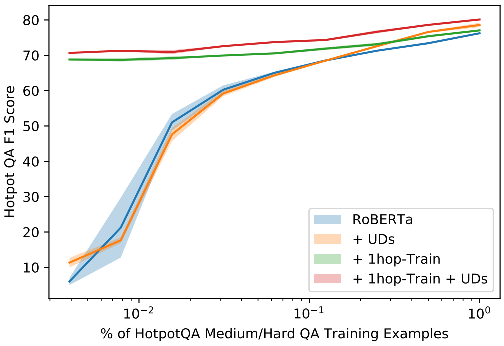

Figure 6: QA F1 of the downstream, recomposition model, with and without unsupervised decompositions (UDs), when varying the amount of training data. We also assess the impact of removing single-hop training data (SQuAD 2.0 and HotpotQA“easy” questions).

D Recomposition Model

D.1 Varying Training Set Size

To understand how decompositions impact performance given different amounts of QA training data, we vary the number of multi-hop training examples. We use the “medium” and “hard” level labels in HotpotQA to determine which examples are multi-hop. We consider training setups where the recomposition model does or does not use data augmentation via training on hotpot “easy”/single-hop questions and SQuAD 2 questions. Fig. 6 shows the results. Decompositions improve QA, so long as the recomposition model has enough training data to achieve a minimum level of performance (here, roughly 68 F1).

D.2 Improvements across Question Types

To better understand where decompositions improve QA, we examined the improvement over the baseline across various fine-grained splits of our three evaluation sets. Decompositions were roughly as helpful for `yes`/`no` questions as for questions with a span-based answer. Across our evaluation sets, we did not find a consistent pattern regarding what questions, stratified by “wh-” question-starting words, benefited the most from decompositions. Intuitively, we found larger QA improvements when using decompositions when a sub-answer sentence contained a gold, final answer, as shown in Figure 7.

D.3 Training Hyperparameters

To train RoBERTa$_{\text{LARGE}}$, we fix the number of training epochs to 2, as training longer did not help.

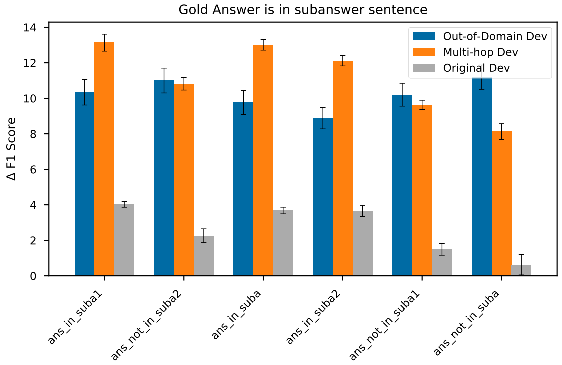

Figure 7: Performance difference between a QA model that does vs. does not use ONUS decompositions, stratified by whether the gold final answer is in a subanswer sentence. We find a larger gain when the subanswer sentence contains the gold, final answer.

We sweep over batch size $\in \{64, 128\}$, learning rate $\in \{1\times10^{-5}, 1.5\times10^{-5}, 2\times10^{-5}, 3\times10^{-5}\}$, and weight decay $\in \{0, 0.1, 0.01, 0.001\}$, similar to the ranges used in the original paper (Liu et al., 2019). We chose the hyperparameters that did best for the baseline QA model (without decompositions) on our dev set: batch size 64, learning rate 1.5×10^{-5}, and weight decay 0.01. Similarly, for BERT experiments, we fix the number of epochs to 2 and choose hyperparameters by sweeping over the recommended ranges from Devlin et al. (2019) for learning rate ($\{2 \times 10^{-5}, 3 \times 10^{-5}, 5 \times 10^{-5}\}$) and batch size ($\{16, 32\}$). For BERT$_{\text{BASE}}$, we thus choose learning rate 2×10^{-5} and batch size 16, and for BERT$_{\text{LARGE}}$, we use the whole-word masking model with learning rate 2×10^{-5} and batch size 32. RoBERTa$_{\text{LARGE}}$ and BERT$_{\text{LARGE}}$ have 340M parameters, while BERT$_{\text{BASE}}$ has 110M parameters. We train all QA models with mixed precision floating point arithmetic (Micikevicius et al., 2018), distributing training across 8, 32GB NVIDIA V100 GPUs, lasting roughly 6 hours.

Dataset	Question and ONUS Decomposition
FEVER 1.0	**Q1**: The highest point of the Hindu Kush is Everest.
	SQ$_1$: The highest point of the Hindu Kush?
	SQ$_2$: Where is Everest?
	Q2: John Dolmayan was born on July 15, 1873.
	SQ$_1$: When was John Dolmayan born?
	SQ$_2$: Who was born on July 15, 1873.?
	Q3: Colin Kaepernick became a starter during the 49ers 63rd season in the Republican party.
	SQ$_1$: When did Colin Kaepernick become a starter?

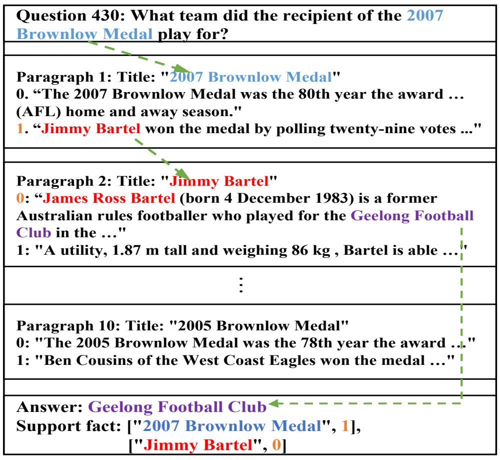
Abstract

This work deals with the challenge of learning and reasoning over multi-hop question answering (QA). We propose a graph reasoning network based on the semantic structure of the sentences to learn cross paragraph reasoning paths and find the supporting facts and the answer jointly. The proposed graph is a heterogeneous document-level graph that contains nodes of type sentence (question, title, and other sentences), and semantic role labeling sub-graphs per sentence that contain arguments as nodes and predicates as edges. Incorporating the argument types, the argument phrases, and the semantics of the edges originated from SRL predicates into the graph encoder helps in finding and also the explainability of the reasoning paths. Our proposed approach shows competitive performance on the HotpotQA distractor setting benchmark compared to the recent state-of-the-art models.

1 Introduction

Understanding and reasoning over natural language plays a significant role in artificial intelligence tasks such as Machine Reading Comprehension (MRC) and Question Answering (QA). Several QA tasks have been proposed in recent years to evaluate the language understanding capabilities of machines (Rajpurkar et al., 2016; Joshi et al., 2017; Dunn et al., 2017). These tasks are single-hop QA tasks and consider answering a question given only one single paragraph. Many existing neural models rely on learning context and type-matching heuristics (Weissenborn et al., 2017). Those rarely build reasoning modules but achieve promising performance on single-hop QA tasks. The main reason is that these single-hop QA tasks are lacking a realistic evaluation of reasoning capabilities because they do not require complex reasoning.



Question 430: What team did the recipient of the 2007 Brownlow Medal play for?

Paragraph 1: Title: "2007 Brownlow Medal"
0. "The 2007 Brownlow Medal was the 80th year the award ... (AFL) home and away season."
1. "Jimmy Bartel won the medal by polling twenty-nine votes ..."

Paragraph 2: Title: "Jimmy Bartel"
0: "James Ross Bartel (born 4 December 1983) is a former Australian rules footballer who played for the Geelong Football Club in the ..."
1: "A utility, 1.87 m tall and weighing 86 kg , Bartel is able ..."

⋮

Paragraph 10: Title: "2005 Brownlow Medal"
0: "The 2005 Brownlow Medal was the 78th year the award ..."
1: "Ben Cousins of the West Coast Eagles won the medal ..."

Answer: Geelong Football Club
Support fact: ["2007 Brownlow Medal", 1],
["Jimmy Bartel", 0]

Figure 1: An example of HotpotQA data.

Recently multi-hop QA tasks, such as HotpotQA (Yang et al., 2018) and WikiHop (Welbl et al., 2018), have been proposed to assess multi-hop reasoning ability. HotpotQA task provides annotations to evaluate document level question answering and finding supporting facts. Providing supervision for supporting facts improves explainabilty of the predicted answer because they clarify the cross paragraph reasoning path. Due to the requirement of multi-hop reasoning over multiple documents with strong distraction, multi-hop QA tasks are challenging. Figure 1 shows an example of HotpotQA. Given a question and 10 paragraphs, only paragraph 1 and paragraph 2 are relevant. The second sentence in paragraph 1 and the first sentence in paragraph 2 are the supporting facts. The answer is "Geelong Football Club".

Primary studies in HotpotQA task prefer to use a reading comprehension neural model (Min et al., 2019; Zhong et al., 2019; Yang et al., 2018). First, they use a neural retriever model to find the relevant paragraphs to the question. After that, a neural reader model is applied to the selected paragraphs for answer prediction. Although these approaches obtain promising results, the performance of evaluating multi-hop reasoning capability is unsatisfac-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8881–8891,

tory (Min et al., 2019).

To solve the multi-hop reasoning problem, some models tried to construct an entity graph using Spacy[1] or Stanford CoreNLP (Manning et al., 2014) and then applied a graph model to infer the entity path from question to the answer (Chen et al., 2019; Xiao et al., 2019; Clark and Gardner, 2018; Fang et al., 2019). However, these models ignore the importance of the semantic structure of the sentences and the edge information and entity types in the entity graph. To take the in-depth semantic roles and semantic edges between words into account here we use semantic role labeling (SRL) graph as the backbone of a graph convolutional network. Semantic role labeling provides the semantic structure of the sentence in terms of argument-predicate relationships (He et al., 2018). The argument-predicate relationship graph can significantly improve the multi-hop reasoning results. Our experiments show that SRL is effective in finding the cross paragraph reasoning path and answering the question.

Our proposed semantic role labeling graph reasoning network (SRLGRN) jointly learns to find cross paragraph reasoning paths and answers questions on multi-hop QA. In SRLGRN model, firstly, we train a paragraph selection module to retrieve gold documents and minimize distractor. Second, we build a heterogeneous document-level graph that contains sentences as nodes (question, title and sentence), and SRL sub-graphs including semantic role labeling arguments as nodes and predicates as edges. Third, we train a graph encoder to obtain the graph node representations that incorporate the argument types and the semantics of the predicate edges in the learned representations. Finally, we jointly train a multi-hop supporting fact prediction module that finds the cross paragraph reasoning path, and answer prediction module that obtains the final answer. Notice that both supporting fact prediction and answer prediction are based on contextual semantics graph representations as well as token-level BERT pre-trained representations. The contributions of this work are as follows:

1) We propose the SRLGRN framework that considers the semantic structure of the sentences in building a reasoning graph network. Not only the semantics roles of nodes but also the semantics of edges are exploited in the model.

2) We evaluate and analyse the reasoning capabilities of the semantic role labeling graph compared to usual entity graphs. The fine-grained semantics of SRL graph help in both finding the answer and the explainability of the reasoning path.

3) Our proposed model obtains competitive results on both HotpotQA (Distractor setting) and the SQuAD benchmarks.

2 Related Work

2.1 Graph Models for Multi-Hop Reasoning

Previous QA datasets, such as TriviaQA (Joshi et al., 2017) and SearchQA (Dunn et al., 2017), and MRC datasets, like SQuAD (Rajpurkar et al., 2016), rarely require sophisticated reasoning (such as cross paragraph reasoning) to answer the question and fail to provide ground-truth explanations for answers. Recently, WikiHop (Welbl et al., 2018) and HotpotQA (Yang et al., 2018) are two published multi-hop QA datasets that provide multiple paragraphs. Those QA datasets require a multi-hop reasoning model to learn the cross paragraph reasoning paths and predict the correct answer.

Most of the existing multi-hop QA models (Tu et al., 2019; Xiao et al., 2019; Fang et al., 2019) utilize graph based neural networks, such as graph attention network (Velickovic et al., 2018), graph recurrent network (Song et al., 2018b), and graph convolutional network (Kipf and Welling, 2017). Moreover, multi-hop QA models use different ways to construct entity graphs. Coref-GRN (Dhingra et al., 2018) utilize co-reference resolution to build the entity graph. MHQA-GRN (Song et al., 2018a) is an updated version of Coref-GRN that adds sliding windows. Entity-GCN (Cao et al., 2019) builds the graph using entities and different types of edges called match edges and complement edges. DFGN (Xiao et al., 2019) and SAE (Tu et al., 2019) construct entity graph through named entity recognition (NER).

In contrast to the above mentioned models, our SRLGRN builds a heterogeneous graph that contains a document-level graph of various sentences and replaces the entity-based graphs with argument-predicate based sub-graphs using SRL.

2.2 Semantic Role Labeling

The goal of semantic role labeling is to capture argument and predicate relationships given a sentence, such as "who did what to whom." Several deep SRL models achieve highly accurate results in

---

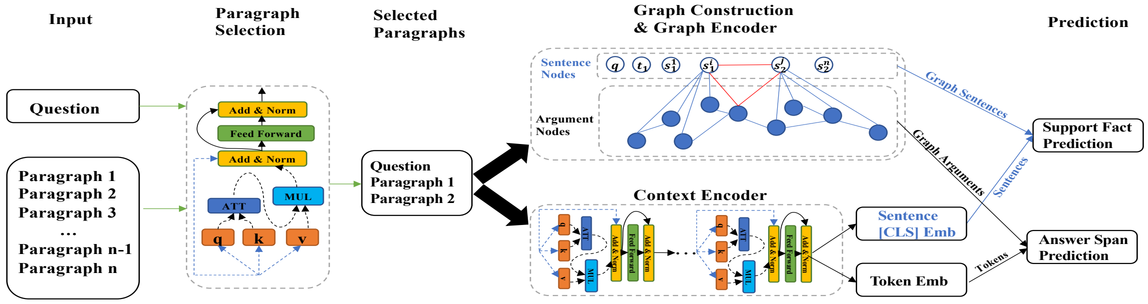

Figure 2: Our proposed SRLGRN model is composed of Paragraph Selection, Graph Construction, Graph Encoder, Supporting Fact prediction, and Answer Span prediction.

finding argument spans (Zhou and Xu, 2015; Tan et al., 2018; Marcheggiani et al., 2017; He et al., 2017). However, those models are evaluated based on given gold predicates. Therefore, some deep models (He et al., 2018; Guan et al., 2019) are proposed to recognize all argument-predicate pairs. Recently, Shi and Lin proposed a BERT Model for SRL and Relation Extraction.

3 Model Description

Our proposed SRLGRN approach is composed of Paragraph Selection, Graph Construction, Graph encoder, Supporting Fact prediction, and Answer Span prediction modules. Figure 2 shows the proposed architecture. In this section, we introduce our approach in detail and then explain how to train it with an efficient algorithm.

3.1 Problem Formulation

Formally, the problem is to predict supporting fact y_{SF} and answer span y_{ans} given input question q and candidate paragraphs. Each paragraph content $\mathcal{C} = \{t, s_1, \ldots, s_n\}$ includes title t and several sentences $\{s_1, \ldots, s_n\}$.

3.2 Paragraph Selection

Most of the paragraphs are distractors in the HotpotQA task (Yang et al., 2018). SRLGRN can select gold documents and minimize distractors from given N documents by a Paragraph Selection module. The Paragraph Selection is based on the pre-trained BERT model (Devlin et al., 2018). Our Paragraph Selection module has two rounds explained in section 3.2.1 and section 3.2.2.

3.2.1 First Round Paragraph Selection

For every candidate paragraph, we take the question q and the paragraph content $\mathcal{C}$ as input:

$$Q_1 = [[CLS]; q; [SEP]; \mathcal{C}], \qquad (1)$$

where Q_1 represents the input, [CLS] and [SEP] are the same as BERT tokenizer process (Devlin et al., 2018). We feed input Q_1 to a pre-trained BERT encoder to obtain token representations. Then we use $BERT_{[CLS]}$ token representation as the summary representation of the paragraph. Meanwhile, we utilize a two-layer MLP to output the relevance score, y_{sel}. The paragraph which obtains the highest relevance score is selected as the first relevant context. We concatenate q to the selected paragraph as q_{new} for the next round of paragraph selection.

3.2.2 Second Round Paragraph Selection

For the remaining $N-1$ candidate paragraphs, we use the same model as first round paragraph selection to generate a relevance score that takes q_{new} and paragraph content as input. We call this process as second round paragraph selection. Similar to section 3.2.1, one of the remaining candidate paragraphs with the highest score is selected. Afterwards, we concatenate the question and the two selected paragraphs to form a new context used as the input text for graph construction.

3.3 Heterogeneous SRL Graph Construction

We build a heterogeneous graph that contains document-level sub-graph $\mathcal{S}$ and argument-predicate SRL sub-graph Arg for each data instance. In the graph construction process, the document level sub-graph $\mathcal{S}$ includes question q, title t_1 and sentences $s_1^{1,\ldots,n}$ from first round selected paragraph, and title t_2 and sentences $s_2^{1,\ldots,n}$ from the second round selected paragraph, that is $\{q, t_1, s_1^1, \ldots, s_1^n, t_2, s_2^1, \ldots, s_2^n\} \in \mathcal{S}$. The argument-predicate SRL sub-graphs Arg, including arguments as nodes and the predicates as edges, are generated using AllenNLP-SRL model (Shi and Lin, 2019). Each argument node is the concatenation of argument phrase and argument type,

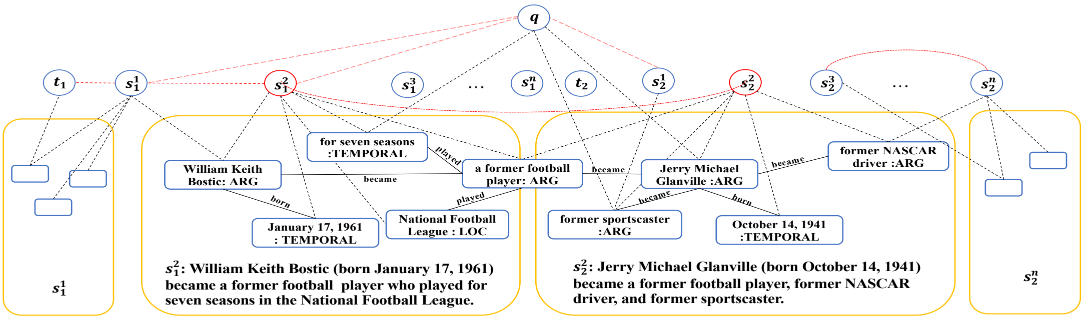

Figure 3: An example of Heterogeneous SRL Graph. The question is "Who is younger Keith Bostic or Jerry Glanville?" The circles show the document-level nodes, i.e., sentences. The blue squares show the argument nodes. The argument nodes include argument phrase and argument type information. The solid black lines are semantic edges between two arguments carrying the predicate information. The black dashed lines show the edges between sentence nodes and argument nodes. The red dashed lines show the edges between two sentences if there exists a shared argument (based on exact string match). The orange blocks are the SRL argument-predicate sub-graphs for sentences. s_i^j means the j-th sentence from the i-th paragraph.

including "TEMPORAL", "LOC", etc.

Figure 3 describes the construction of the heterogeneous graph. The heterogeneous graph's edges are added as follows: **1)** There will be an edge between a sentence and an argument if an argument appears in this sentence (the black dashed lines in Figure 3); **2)** Two sentences s_i and s_j will have an edge if they share an argument by exact matching (the red dashed lines); **3)** Two argument nodes Arg_i and Arg_j will have an edge if a predicate exists between Arg_i and Arg_j (the black solid lines); **4)** There will be an edge between the question and sentence if they share an argument (the red dashed lines).

Figure 3 shows an example of a heterogeneous SRL graph. s_1^2 and s_2^2 are connected because of a shared argument node "a former football player: ARG". Besides, the shared argument node has several semantic edges, such as "played" and "became". In this way, the shared argument node and other connected argument nodes have argument-predicate relationships.

We create two matrices based on the constructed graph that we will use in section 3.4. We build a predicate-based semantic edge matrix K and a heterogeneous edge weight matrix A. The semantic edge matrix K is a matrix that stores the word index of the predicates. We initialize all the elements of K with empty, $\emptyset$. If two argument nodes Arg_i and Arg_j related to the same predicate, we add that predicate word index to $K_{(Arg_i,Arg_j)}$. Sometimes, Arg_i and Arg_j are related to more than one predicate.

In the meantime, the heterogeneous edge weight matrix A is a matrix that stores different types of edge weights. We divide the edges into three types: sentence-argument edges, argument-argument edges, and sentence-sentence edges.

The weight of a sentence-sentence edge is 1 when two sentences share an argument. Meanwhile, the weight of a sentence-argument edge is 1 if there exists an edge between a sentence and an argument. If two argument nodes have an edge, the weight can be calculated by point-wise mutual information (PMI) (Bouma, 2009). The reason we use PMI is that it can better explain associations between nodes compared to the traditional co-occurrence count method (Yao et al., 2019).

3.4 Graph Encoder

Section 3.3 introduces the detailed process of building a heterogeneous graph. Next, we introduce the Graph Convolution Network (Kipf and Welling, 2017) to obtain the graph embeddings. Graph Convolution Network (GCN) is a multi-layer network that uses the graph input directly and generates embedding vectors of the graph.

Besides, GCN plays an essential role in incorporating higher-order neighborhood nodes and helps in capturing the structural graph information. The SRL graph uses the semantic structure of the sentence to form the graph nodes and semantic edges, making the GCN's representation more explainable. For instance, the GCN node vectors of document level sub-graph help in finding the supporting fact path, while GCN node vectors of argument-predicate level sub-graph help in identifying the text span of the potential answers. In this work, we consider a two-layer GCN to allow message passing operations and learn the graph embeddings. The graph embeddings are computed as follows:

$$E_1 = (D^{-\frac{1}{2}} A D^{-\frac{1}{2}})[X_{Arg}; X_{\mathcal{S}}]W_1, \quad (2)$$

$$G = (D^{-\frac{1}{2}} A D^{-\frac{1}{2}}) f(E_1) W_2, \quad (3)$$

where E_1 and G are graph embedding outputs of two GCN layers that incorporate higher-order neighborhood nodes by stacking GCN layers. $f(x)$ is an activation function, D is the degree matrix of the graph (Kipf and Welling, 2017), A is the heterogeneous edge weight matrix, and W_1 and W_2 are the learned parameters. X represents node embeddings, including argument-predicate embedding X_{Arg} and sentence embedding $X_{\mathcal{S}}$. Notice that each argument embedding X^i_{Arg} is the concatenation of the argument node Arg^i embedding and the average embedding of K^i_{Arg}. Given G, we use $G_{\mathcal{S}}$ to represent document level node embeddings, and G_{Arg} to represent argument-predicate level node embeddings.

3.5 Supporting Fact Prediction

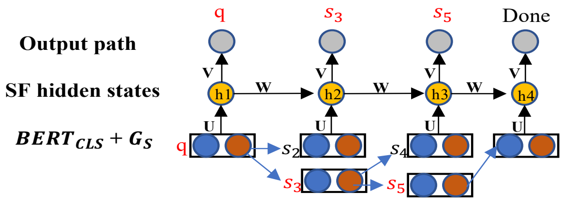

Figure 4: An example of Supporting Fact Prediction.

The goal of supporting fact (SF) prediction is to find the SF that is necessary to arrive at the answer. Inspired by Asai et al., we utilize RNN with a beam search to find the best document-level SF path. This approach turns out to be effective for selecting the SF reasoning path. Notice that, our supporting fact prediction is not only based on BERT and RNN, but also incorporates document level graph node embeddings $G_{\mathcal{S}}$.

Formally, we use the concatenation of the graph sentence embedding, $G_{\mathcal{S}}$ (blue circles in Figure 4), and BERT's [CLS] token representation (orange circles) to represent the candidate sentence $X^{cand}_{\mathcal{S}}$:

$$X^{cand}_{\mathcal{S}} = [G^{cand}_{\mathcal{S}}; BERT_{[CLS]}(q, \mathcal{S}_{cand})], \quad (4)$$

where $\mathcal{S}_{cand}$ represents the neighbors of the candidate sentence. Afterwards, two feed-forward fully connected layers with activation functions determine whether s_{cand} is an actual SF. The process of selecting an SF is shown as follows:

$$h_t = \sigma(W h_{t-1} + U X^{cand}_{\mathcal{S}} + b_h), \quad (5)$$

$$o_t = V h_t + b_o, \quad (6)$$

where h_t is the hidden state of the RNN at the t-th SF reasoning step, σ is the activation function. W, U, V, b_h and b_o are the parameters.

Finally, we use the beam search to output SF paths, choosing the highest scored path as our final supporting fact answer y_{SF}:

$$y_{\text{SF}} = \arg\max_{1 \le t \le T} \prod o_t, \quad (7)$$

where T is the maximum number of reasoning hops. We penalize with the cross-entropy loss. More details are described in section 3.7.

Figure 4 shows an example of the predicted SF process. Based on the constructed heterogeneous graph, two sentence nodes have an edge if they share an argument. We start from question node q as the first input sentence. Since q is a unique input, we select q as the first SF candidate. In the second step, two candidate sentence nodes, s_2 and s_3 that are neighbor nodes of q, are chosen as the input. We separately feed s_2 and s_3 to the RNN layers. The sentence s_3 that obtains a larger logit score is selected as the second SF candidate of the reasoning path. In the third step, s_4 and s_5 are neighbor nodes of the second SF, s_3. Then the model chooses s_5 as the third SF. In the end, s_1, s_3, and s_5 are the supporting facts.

3.6 Answer Span Prediction

The goal of the answer span prediction module is to output "yes", "no", or answer span for the final answer. We firstly design an answer type classification based on BERT and an additional two fully connected feed-forward layers. If the highest probability of type classification is "yes" or "no", we directly output the answer. The input of type classification is $BERT_{[CLS]}$. The answer type y_{type} can be calculated as

$$y_{\text{type}} = MLP_{\text{type}}([BERT_{[CLS]}]).$$

If the answer is not "yes" or "no", we compute the logit of every token to find the start position i and end position j for answer span. The logit is calculated using BERT as the input given to two fully connected layers. The input token representation is the concatenation of BERT token representation $BERT_{tok}$ and graph embedding G_{Arg}. The answer span y_{ans} can be computed as

$$y_{\text{ans}} = \arg\max_{i,j,\ i\leq j} y^i_{start} y^j_{end}, \tag{8}$$

$$y^i_{\text{start}} = MLP_{\text{start}}([BERT^i_{tok}; G^i_{Arg}]), \tag{9}$$

$$y^i_{\text{end}} = MLP_{\text{end}}([BERT^i_{tok}; G^i_{Arg}]), \tag{10}$$

where y_{ans} is the index pair of (start position, end position), y^i_{start} represents the logit score of the i-th word as the start position, and y^i_{end} represents the logit score of the i-th word as the end position.

3.7 Objective Function

Inspired by Xiao et al. and Tu et al., the joint objective function includes the sum of cross-entropy losses for the span prediction L_{ans}, answer type classification L_{type}, and supporting fact prediction L_{SF}. The loss function is computed as follows:

$$\begin{aligned} L_{\text{joint}} &= L_{\text{ans}} + L_{\text{SF}} + L_{\text{type}} \\ &= \lambda_1(-y_{\text{start}} \log y_{\text{start}} - y_{\text{end}} \log y_{\text{end}}) \\ &\quad - \lambda_2 y_{\text{SF}} \log y_{\text{SF}} - \lambda_3 y_{\text{type}} \log y_{\text{type}}, \end{aligned}$$

where λ_1, λ_2, and λ_3 are weighting factors.

4 Experiments and Results

4.1 Dataset

We use the HotpotQA dataset (Yang et al., 2018), a popular benchmark for multi-hop QA task, for the main evaluation of the SRLGRN. Specifically, two sub-tasks are included in this dataset: Answer prediction and Supporting facts prediction. For each sub-task, exact match (EM) and partial match (F1) are two official evaluations that follow the work of Rajpurkar et al.. A joint EM and F1 score are used to measure the final performance of both answer and supporting fact prediction. We evaluate the model on the Distractor Setting. For each question in the Distractor Setting, two gold paragraphs and 8 distractor paragraphs, which are collected by a high-quality TF-IDF retriever from Wikipedia, are provided. Only gold paragraphs include ground-truth answers and supporting facts. In addition, we use MRC datasets, Stanford Question-Answering Dataset (SQuAD) v1.1 (Rajpurkar et al., 2016) and v2.0 (Rajpurkar et al., 2018), to demonstrate the language understanding ability of our model.

4.2 Implementation Details

We implemented SRLGRN using PyTorch[2]. We use a pre-trained BERT-base language model with 12 layers, 768-dimensional hidden size, 12 self-attention heads, and around $110M$ parameters (Devlin et al., 2018). We keep 256 words as the maximum number of words for each paragraph. For the graph construction module, we utilize a semantic role labeling model (Shi and Lin, 2019) from AllenNLP[3] to extract the predicate-argument structure. For the graph encoder module, we use 300-dimensional GloVe (Pennington et al., 2014) pre-trained word embedding. The model is optimized using Adam optimizer (Kingma and Ba, 2015).

4.3 Baselines

Baseline Model (Yang et al., 2018) makes use of Clark and Gardner approach. The model includes some neural modules that are based on self-attention and bi-attention (Seo et al., 2017).

DFGN (Xiao et al., 2019) is a strong baseline method for the HotpotQA task. DFGN builds an entity graph from the text. Moreover, DFGN includes a dynamic fusion layer that helps in finding relevant supporting facts.

SAE (Tu et al., 2019) is an effective Select, Answer and Explain system for multi-hop QA. SAE is a pipeline system that first selects the relevant paragraph and uses the selected paragraph to predict the answer and the supporting fact.

4.4 Results

Table 1 shows the results of HotpotQA (Distractor setting). We can observe the SRLGRN model exceeds most published results. Our model obtains a Joint Exact Matching (EM) score of 39.41% and Partial Matching (F1) score of 66.37% on joint performance. Our SRLGRN model has a significant improvement, about 28.58% on Joint EM and 26.21% on F1, over the Baseline Model (Yang et al., 2018). Compared to the current published state of the art, SAE model (Tu et al., 2019), our model improves EM about 2.29% and F1 about 2.56% on Answer performance and 1.41% of F1 on Joint performance. We can observe that F1 of answer span prediction is better than the current SOTA. The reason is that our model not only

uses token-level BERT representation, but also uses graph-level SRL node representations.

Our framework provides an effective way for multi-hop reasoning taking the advantages of the SRL graph model and powerful pre-trained language models. In the following section, we give a detailed analysis of the SRLGRN model.

5 Analysis

Effect of SRL Graph. The SRL graph extracts argument-predicate relationships, including in-depth semantic roles and semantic edges. The constructed graph is the basis of reasoning as the inputs of each hop are directly selected from the SRL graph, as shown in Figure 4. The SRL graph significantly improves the completeness of the graph network, that is, providing sufficient semantic edges to cover reasoning paths, see Figure 3.

Compared to the NER graph in the previous models (Xiao et al., 2019), the proposed SRL graph covers the 86.5% of complete reasoning paths for the data samples. The NER graph of DFGN is incomplete and can only cover 68.7% of the reasoning paths (Xiao et al., 2019). The graph completeness is one major reason that the SRLGRN model has higher accuracy than other published models. As shown in Table 1, the SRLGRN improves 5.79% on joint EM and 6.55% on joint F1 over DFGN, which is based on the NER graph.

Ablation	**Model**	**Ans**(%)	
		EM	F1
Graph	w/o graph	53.06	67.68
	w/o Argument type and Semantic edge	60.10	73.24
Joint	w/o joint training	58.50	71.58
Language	ALBERT-base	59.87	74.20
	BERT-base	62.65	76.14

Table 2: SRLGRN ablation study on HotpotQA.

To evaluate the effectiveness of the types of semantic roles and the edge types, we perform an ablation study. First, we removed the whole SRL graph. Second, we removed the predicate based edge information from the SRL graph. Table 2 shows the results. The complete SRLGRN improves 8.46% on F1 score compared to the model without the SRL graph. The model loses the connections used for multi-hop reasoning if we remove the SRL graph and only use BERT for answer prediction.

We also observe that the F1 score of answer span prediction decreases 2.9% if we did not incorporate semantic edge information and argument types. The reason is that removing predicate edges and argument types will destroy the argument-predicate relationships in the SRL graph and breaks the chain of reasoning. For example, in Figure 3, the main arguments of the two supporting facts in s_1^2 and s_2^2 (William and Jerry) are connected with a predicate edge, "born", to the temporal information necessary for finding the answer. Both "born" edge and the adjunct temporal roles are the key information in the two sentences to find the final answer to this question. The shared ARG node, "football player", also helps to connect the line of reasoning between the two sentences. These two results indicate that both semantic roles and semantic edges in the SRL graph are essential for the SRLGRN performance.

In a different experiment, we tested the influence of the joint training of the supporting facts and answer-prediction. As shown in Table 2, the performance will decrease by 4.56% when we did not train the model jointly.

Effect of Language Models. We use two recent and widely-used pre-trained language representation models, BERT and ALBERT (Lan et al., 2020). The last two lines of Table 2 show the results. Although BERT achieves relatively better performance, ALBERT architecture has significantly fewer parameters (18x) and is faster (about 1.7x running time) than BERT. In other words, ALBERT reduces memory consumption by cross-layer parameter sharing, increases the speed, and obtains a satisfactory performance.

Effect of SRLGRN on Single-hop QA. We evaluate the SRLGRN (excluding the paragraph selection module) on SQuAD (Rajpurkar et al., 2016) to demonstrate its reading comprehension ability. We evaluate the performance on both SQuAD v1.1 and SQuAD v2.0. Table 3 describes the comparison results with several baseline methods on SQuAD v1.1. Our model obtains a 1.8% improvement over BERT-large, and a 1.6% improvement over BERT-large+TriviaQA (Devlin et al., 2018).

Model	**Ans**(%)	
	EM	F1
Human	82.3	91.2
BERT-base	80.8	88.5
BERT-large	84.1	90.9
BERT-large+TriviaQA	84.2	91.1
BERT-large+SRLGRN	85.4	92.7

Table 3: SQuAD v1.1 performance.

We further test the SRLGRN on SQuAD v2.0. The main difference is that SQuAD v2.0 combines answerable questions (like SQuAD v1.1) with unanswerable questions (Rajpurkar et al., 2018). Table 4 shows that our proposed approach improves the performance for SQuAD benchmark compared to several recent strong baselines.

Model	**Ans**(%)	
	EM	F1
Human	86.3	89.0
ELMo+DocQA (Rajpurkar et al., 2018)	65.1	67.6
BERT-large (Devlin et al., 2018)	78.7	81.9
SemBERT (Zhang et al., 2019)	84.8	87.6
BERT-large+SRLGRN	85.8	87.9

Table 4: SQuAD v2.0 performance.

We recognize that our SRLGRN improves 7.1% on EM compared to the robust BERT-large model and improves 1.0% on EM compared to SemBERT (Zhang et al., 2019). The two experiments on SQuAD v1.1 and SQuAD v2.0 demonstrate the significance of SRL graph and the graph encoder.

Error Type	Model Prediction	Label
Synonyms	washington dc	district of columbia
	sars	severe acute respiratory syndrome
	ey	ernst young
	writer	author
MLV	australian	australia
	hessian	hessians
	mcdonald's, co	mcdonalds
Month-Year	1946	1945
	25, november, 2015	3, december
	10, july, 1873	1, september, 1864
Number	11	10
	fourth	4

Other	taylor, swift	usher
	film	documentary
	fourteenth	500th episode

Table 5: Error types on HotpotQA dev set.

6 Error Analysis

Synonyms are the most frequent cause of the reported errors in many cases where the predicted answer is semantically correct. As shown in the first row of the Table 5, our predicted answer and gold label have the same meaning. For example, SRLGRN predicts "sars", while the label is "severe acute respiratory syndrome." We know that "sars" is the abbreviation of the gold label.

Minor Lexical Variation (MLV) is another major cause of mistakes in the SRLGRN model. As shown in the second row of Table 5, our model's predicted answer is "australian", while the gold label is "australia". Many wrong predictions occur in the singular noun versus plural noun selection.

Paragraph Selection is a small portion of errors in the SRLGRN model. As shown in Figure 5, the model chooses a wrong paragraph "43rd Battalion". The reason is that "43rd Battalion" is a distractor although "43rd" appears in the question. The paragraph "Saturday Night Live" is the correct relevant paragraph that includes "forty-third season" and the answer. To resolve this issue in the future, we will try to combine our model with an IR system designed for multi-hopQA similar to the Multi-step entity-centric model for multi-hop QA in (Godbole et al., 2019).

Comparison and Bridge are two types of reasoning that are needed for answering HotpotQA questions. "Bridge" reasoning predicts the answer by connecting arguments to the line of reasoning that leads to the final answer. "Comparison" reasoning predicts the answer (that is, yes, no, or a text span) by comparing two arguments.

SRLGRN sometimes obtains wrong predictions in the "Comparison" reasoning when the questions

Wrong Paragraph Selection	Question: Luke Null is an actor who was on the program that premiered its 43rd season on which date? Wrong Paragraph Selection: 1. Luke Null 2. 43rd Battalion (Australia) Label Paragraphs Selection: 1. Luke Null 2. Saturday Night Live Supporting Facts: 1. Luke Null is an American actor, comedian, and singer, who currently works as a cast member on "Saturday Night Live", having joined the show at the start of its forty-third season. 2. The forty-third season of the NBC comedy series "Saturday Night Live" premiered on September 30, 2017 with host Ryan Gosling and musical guest Jay-Z during the 2017-2018 television season. Answer: September 30, 2017
Comparison	Question: Who is younger, Wayne Coyne or Toshiko Koshijima? Supporting Facts: 1. Wayne Michael Coyne (born January 13, 1961) is an American musician. 2. Toshiko Koshijima (こしじま としこ , Koshijima Toshiko , born March 3, 1980 in Kanazawa, Ishikawa) is a Japanese singer. Wrong Answer: Wayne Coyne Answer: Toshiko Koshijima
Bridge	Question: What Division was the college football team that fired their head coach on November 24, 2006? Supporting Facts: 1. The 2006 Miami Hurricanes football team represented the University of Miami during the 2006 NCAA I FBS football season. 2. Coker was fired by Miami on November 24, 2006 following his sixth loss that season. Wrong Answer: Coker Label Answer: NCAA I FBS football

Figure 5: Failing cases on our proposed SRLGRN framework.

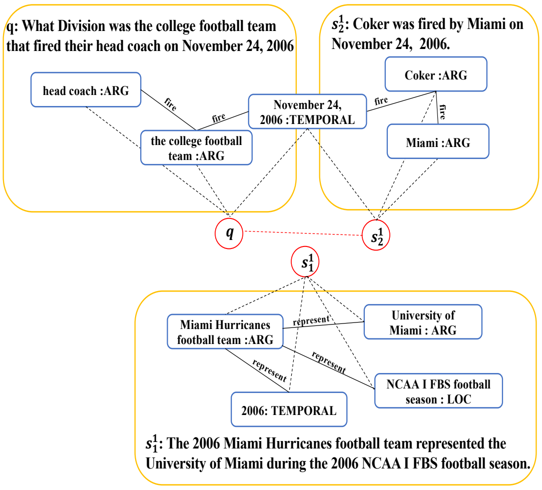

Figure 6: The "Bridge" failing case that SRL fails to lead to the correct answer. The meaning of different lines and node colors are the same as Figure 3.

are related to "Month-year" and "Number". Our qualitative error analysis showed that SRLGRN graph leads to a wrong answer when two or more argument nodes of a same type, such as "TEMPORAL" type, are connected to one node in the graph. Moreover, We notice that the SRLGRN sometimes makes inconsistent errors. For example, in the "Comparison" failing cases of Figure 5, we predict the wrong answer "Wayne Coyne". However, we received the correct answer after replacing the word "younger" with "older".

Moreover, the "Bridge" type needs external knowledge in the HotpotQA task. As is shown in "Bridge" failing cases of Figure 5, the selected paragraphs do not show the relation between "Coker" and "Miami Hurricanes football team". Figure 6 describes the SRL construction based on this failing case. The second supporting fact and the question have the same temporal argument node "November 24, 2006". However, there is no chain between the first supporting fact and the second supporting fact due to the lack of the external knowledge that can connect "Coker", "coach" and "Miami Hurricanes football team". Therefore, the isolated reasoning chain leads to a wrong answer.

7 Conclusion

We proposed a novel semantic role labeling graph reasoning network (SRLGRN) to deal with multi-hop QA. The backbone graph of our proposed graph convolutional network (GCN) is created based on the semantic structure of the sentences. In creating the edges and nodes of the graph, we exploit a semantic role labeling sub-graph for each sentence and connect the candidate supporting facts. The cross paragraph argument-predicate structure of the sentences expressed in the graph provides an explicit representation of the reasoning path and helps in both finding and explaining the multiple hops of reasoning that lead to the final answer. SRLGRN exceeds most of the SOTA results on the HotpotQA benchmark. Moreover, we evaluate the model (excluding the paragraph selection module) on other reading comprehension benchmarks. Our approach achieves competitive performance on SQuAD v1.1 and v2.0.

CancerEmo ♥: A Dataset for Fine-Grained Emotion Detection

Tiberiu Sosea and Cornelia Caragea
Computer Science Department
University of Illinois at Chicago
`tsosea2@uic.edu`, `cornelia@uic.edu`,

Abstract

Emotions are an important element of human nature, often affecting the overall wellbeing of a person. Therefore, it is no surprise that the health domain is a valuable area of interest for emotion detection, as it can provide medical staff or caregivers with essential information about patients. However, progress on this task has been hampered by the absence of large labeled datasets. To this end, we introduce CancerEmo ♥, an emotion dataset created from an online health community and annotated with eight fine-grained emotions. We perform a comprehensive analysis of these emotions and develop deep learning models on the newly created dataset. Our best BERT model achieves an average F1 of 71%, which we improve further using domain-specific pre-training.

1 Introduction

Life-threatening diseases such as cancer and AIDS make people extremely vulnerable and stir a diverse range of feelings and emotions in them, e.g., from fear to trust or joy and from anger to surprise or sadness. These feelings and emotions shape a person's behavior, beliefs, and actions, and many turn to online health communities to share their health concerns and emotions. Recent research shows that this form of sharing is very beneficial to a patient's progress and well-being. For example, Qiu et al. (2011) show that cancer patients feel better and change to positive attitudes when they interact with others during or after the disease. Pollak et al. (2007) show that less anxiety and depression lead to better adherence to cancer care therapies.

The online sharing of emotions in online health communities on topics such as treatment, medication, side effects, moods, and the disease itself, has resulted into a large amount of user-generated content in the form of discussions. This together with the fact that people find it easier to express themselves and reveal personal details in health forums, rather than in a face-to-face context (Kummervold et al., 2002), make online health communities a great place to examine and study patients' emotions at a large scale using computational models.

However, despite that emotion detection has started to emerge in the health domain, the lack of large annotated datasets in the field greatly hinders the capabilities of supervised techniques and limits an understanding of fine-grained expressions of emotions at a large scale. For example, available datasets contain only about $1,000$ sentences annotated with Ekman's six basic emotions. Since some emotions appear very rarely in the annotated set, only the most frequent ones joy and sadness are analyzed (Khanpour and Caragea, 2018).

In this paper, we explore fine-grained emotion detection in online health communities and present a large dataset for this task. Specifically, we introduce CancerEmo ♥, a health-related dataset, composed of $8,500$ sentences annotated with emotions taken out of $25,000$ sentences sampled from an online cancer survivors network. This network, which is designed for patients suffering from cancer, and their caregivers, friends, and families, contains several discussion boards grouped by cancer type, where users can start a discussion thread or comment to messages in an existing thread. We construct our dataset from the breast, lung, and prostate cancer discussion boards, since there are higher stakes involved for patients with this type of disease. For example, breast cancer is the most common women cancer with about 18% of all women's cancers (McPherson et al., 2000); lung cancer is the leading cause of death among men and second among women (Torre et al., 2016), while prostate cancer is the third leading cause of cancer deaths in the United States (Haas et al., 2008). Our dataset is fine-grained, being annotated with

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8892–8904,
November 16–20, 2020.

SADNESS	I just cant stand seeing her like this.
ANTICIPATION TRUST	If they get better, they can opt out of the program.
JOY	Could I get spoiled YES...LOL Love to all of you Kay.
FEAR	Guess I am more scared cause this has been very speedy.
SURPRISE	It is so awesome to hear news like yours!
DISGUST ANGER	I hate cancer and I sure hate what it has done to good people, like you.
SADNESS FEAR	My cancer was very rare, non invasive Mucusom Cancer.
JOY FEAR	Yesterday they told me they didnt see anything which brought tears of joy, but also a wave of fear.

Table 1: Examples from our dataset.

Plutchick-8 basic emotions (Plutchik, 1980), composed of anger, fear, disgust, sadness, surprise, anticipation, trust, and joy. We use crowd-sourcing and ensure quality control measures to exclude spurious annotations.

Detecting emotions is inherently challenging, requiring a deep understanding of the writer's beliefs and reasoning, especially when dealing with health-related data. To illustrate some of these challenges, we present examples from our dataset in Table 1, and discuss a few patterns. For example, in the sentence *I just cant stand seeing her like this*, we can easily notice the writer's discontent, regardless of the absence of emotion-rich words in its content. Our data also includes a great deal of medical terminology, which adds another layer of complexity to the language used across the discussion boards. For example, in *My cancer was very rare, non invasive Mucusom Cancer*, in order to predict the perceived conveyed emotions - fear and sadness, computational models must distinguish whether *Mucusom Cancer* is a dangerous or harmless disease. In addition, a sentence may be the expression of a mixture of emotions, not just one. We further speculate that distantly supervised techniques focusing on lexical information to collect emotion-rich data (Abdul-Mageed and Ungar, 2017) are unable to capture these subtleties in a health domain, and we reinforce this idea in §3.

Our contributions in this paper are as follows: **(1)** We create CANCEREMO ♥, a novel health-related dataset for fine-grained emotion detection composed of $8,500$ sentences. We study how emotions are distributed in our dataset and how they co-occur with each other. We further analyze emotions associations with topics such as medical procedures, side effects, and drugs, and with events or activities that happen in the past, present, and future; **(2)** We experiment on the fine-grained emotion detection task and establish strong baselines based on BERT and variants; **(3)** We study different supervised and unsupervised pre-training techniques and reveal the importance of choosing the *right* pre-training domain.

2 Related Work

Emotion detection has been studied in computational linguistics for a long time, with researchers exploring domains ranging from music (Strapparava et al., 2012; Mihalcea and Strapparava, 2012) and classic literature (Liu et al., 2019a) to social networks (Mohammad, 2012; Islam et al., 2019; Desai et al., 2020) and online news (Bao et al., 2009). Most studies focus on two main emotion categorizations: Ekman's (Ekman, 1992) 6 basic emotions (Katz et al., 2007; Strapparava et al., 2012; Aman and Szpakowicz, 2007; Mohammad, 2012) and Plutchik's (Plutchik, 1980) 8 emotions (Abdul-Mageed and Ungar, 2017; Mohammad and Turney, 2010). Emotion detection remains a challenging task, mainly due to the limited availability of labeled data (Abdul-Mageed and Ungar, 2017). In an effort to minimize this drawback, several studies created high quality data annotated with fine-grained emotions. For example, general Twitter data was automatically annotated with emotions using corpus-specific cues (i.e., hashtags expressing emotions) (Wang et al., 2012a; Abdul-Mageed and Ungar, 2017). Other studies turned to human annotators to manually label data (Aman and Szpakowicz, 2007; Poria et al., 2018; Liu et al., 2019a).

Interestingly, despite the importance of emotion detection in the health domain, computational studies for this task are limited. Specifically, most of these studies focus mainly on identifying two types of social support from online health communities (OHCs): emotional (Eysenbach et al., 2004) or informational (Boon et al., 2007). Along the same lines, Wang et al. (2012b) used Linear Regression to predict the degree of emotional or informational support from an OHC related to breast cancer, while Biyani et al. (2014) studied the presence of such support from breast and lung cancer data using models such as Naïve Bayes, Support Vector Machines, and Logistic Regression with part-of-speech tags and bag-of-words. Wang et al. (2014) studied social support using lexical and sentiment features, and analyzed user engagement in OHCs. Yang et al. (2019a), on the other hand, modeled social roles in OHCs. They used a Gaussian mixture model to identify coherent roles such as *emotional support provider*, *informational support provider*, *newcomer*, or *all-round expert*. The types of features they used range from linguistic behaviors or network (i.e., relationship with other users) to features regarding the context of communication (i.e., public or private). Khanpour and Caragea (2018) highlighted the need to examine emotions from health-related posts at a finer granularity and used annotators to label two datasets with the Ekman's six basic emotion set (Ekman, 1992). The authors trained a hybrid neural model composed of a word-level Convolutional Neural Network followed by a Long Short Term Memory network. However, given the limited size of the annotated datasets (~$1,000$ sentences each) and the fact that most emotions were extremely infrequent, the analysis could only be performed on the most frequent emotions: joy and sadness. In contrast to the above works, we study Plutchick-8 basic emotions and present CANCEREMO ♥, which, to our knowledge, is the first large health dataset for the fine-grained emotion detection task, being more than eight times larger than the currently available datasets of Khanpour and Caragea (2018).

CANCEREMO ♥ enables complex explorations of deep learning models including pre-trained language models, such as BERT (Devlin et al., 2018), XLNet (Yang et al., 2019b) and RoBERTa (Liu et al., 2019b), which achieve state-of-the-art performance on several NLP tasks. We use the aforementioned pre-trained language models, fine-tune the models on our dataset, then compare these approaches with baselines from Traditional and Deep Natural Language Processing.

3 Dataset

3.1 Task Structure

Corpus We choose an online cancer network as the basis of our data, which we will call *CancerNet*[1] throughout the paper. CancerNet was founded in 2002 and represents a platform for people suffering from cancer as well as for their caregivers, friends, and families to socialize, share experiences and emotions, and feel supported. We collected the data from the beginning until the year of 2018. The network consists of multiple discussion boards, corresponding to different types of cancer. To create our dataset, we randomly sampled sentences from the discussion boards corresponding to three frequent types of cancer: breast, lung and prostate (BLP). We model the emotion detection task at *sentence level* since longer messages usually contain multiple topics and could possibly switch between many emotions from one sentence to another (Biyani et al., 2014).

Objective Given a predefined set of emotions - Plutchik-8 basic emotions, the goal is to classify a sentence with all emotions contained in it, i.e., identify all emotions conveyed in a piece of text.

3.2 Task Construction

Sampling Strategy Current datasets for emotion detection usually utilize some type of sampling bias, e.g., using emotion words as a proxy for sampling. For example, Abdul-Mageed and Ungar (2017) used cues in the data (i.e., emotion hashtags) to collect and further annotate a large Twitter dataset with emotions, while making the strong assumption that a sentence can only express one emotion. We argue that a sentence can not only express emotions even in the absence of emotion words but also convey multiple emotions, as shown in Table 1 in §1. Thus, we sample at random $25,000$ sentences from the BLP boards and annotate them using crowd-sourcing. This sampling strategy also helps us analyze how many sentences convey emotions out of all sampled sentences and how many sentences that do not contain emotion words (i.e., do not have surface lexical patterns) in fact appear to convey emotions.

Annotation To annotate our data, we use the Amazon Mechanical Turk (AMT) crowd-sourcing platform. The emotion definitions provided to the annotators are shown in Appendix A. We ran the annotation task in several iterations in order to develop our quality control steps. Initially, we internally annotated a batch of 100 sentences using all emotions that apply from all 8 Plutchik's emotions, in a multi-class setting. Then, we explored two settings with the AMT annotators: First, we designed a form that asked annotators to select all emotions that apply for a sentence and used the same batch of 100 sentences for analysis. We noticed that the task was very difficult and resulted in a low

---

[1] https://csn.cancer.org/

inter-agreement. Second, we created a separate annotation form for each emotion: for an emotion x, a form asks the annotators to annotate a sentence with *true* or *false*, i.e., if a sentence contains x, the label is *true*, otherwise it is *false*. We used again the same batch of 100 sentences for analysis. We noticed that this task was much easier and resulted in a higher inter-agreement among the AMT annotators, as well as a much higher agreement with our internal annotations. Thus, for our final annotation, we chose the latter approach over creating a single annotation form for all eight emotions, in order to leverage annotation ease and prevent any implicit associations annotators might make - one might refrain from assigning both fear and joy to the same sentence, which could in fact appear together; such an example is shown in Table 1.

We use three annotators for each sentence, and the final label for a specific emotion is computed through majority vote. We avoid spamming by ruling out the annotators that are inconsistent with the majority vote in more than 25% of the cases. We compute the inter-annotator agreement using Krippendorff Alpha, and obtain an average value of $\alpha = 0.69$ on all emotions. We also studied the per-emotion inter-agreement, and observed lower inter-annotator agreement on the emotion *anticipation*, which, in line with our beliefs, was the hardest emotion to distinguish, with $\alpha = 0.5$. Emotions such as joy, sadness, and fear produced a higher agreement, with $\alpha = 0.75$.

3.3 Analysis

Emotion Distribution Table 2 shows the number of sentences annotated with no emotions and with 1-4 emotions. Interestingly, out of the 25,000 sampled sentences, 16,500 sentences (66%) do not contain any emotions at all, and only 8,500 contain at least one emotion, out of which 16% contain two or more emotions. Figure 1 shows the distribution of our 8 emotions in the 8,500 sentences. We can notice that the distribution is very unbalanced: joy, fear and sadness appear most frequently, amounting for about 75% of the data, while anticipation, anger, surprise, disgust, and trust appear rarely, a few orders of magnitude less than the frequent ones. It is interesting to see that joy is the most prevalent, despite dealing with a cancer forum.

Table 3 shows the number of sentences annotated with no emotions (EMOSENT$^-$) and with one or more emotions (EMOSENT$^+$) and for each category the number of sentences that contain at least one emotion word from EmoLex (Mohammad and Turney, 2013). EmoLex is a word-emotion lexicon composed of a list of English emotion rich words and their associations with Plutchik's eight basic emotions. As an example, the sentence *"He is always in pain .. (chest and back pain) and has trouble swallowing pills."* contains an emotion word *pain* from EmoLex, which is associated with sadness in EmoLex. The sentence is annotated with sadness by our annotators as well. In contrast, the sentence *"I just miss him so much.....we would hold hands every night"*, does not contain any emotion word from EmoLex and is annotated with sadness by our annotators. Moreover, the sentence *"So get a second opinion and don't be afraid to change doctors."* contains the emotion rich word *afraid* from EmoLex, which is associated with fear in EmoLex, whereas the sentence conveys no emotion at all (and is annotated with no emotion by our annotators). Notably, 10% of the sentences annotated with emotions do not contain EmoLex words, while 23% of sentences with EmoLex words, do not convey any emotion.

We further use EmoLex to compare sentences

	0E	1E	2E	3E	4E
#SENT	16,500	7,098	1,292	96	14

Table 2: Number (#) of sentences with 0 to 4 emotions.

	EMOWORD$^+$	EMOWORD$^-$
EMOSENT$^+$	7,659	841
EMOSENT$^-$	2,220	14,661

Table 3: Number (#) of sentences with and without emotions and emotion words. $^+$ means an emotion or emotion word is present; $^-$ means otherwise.

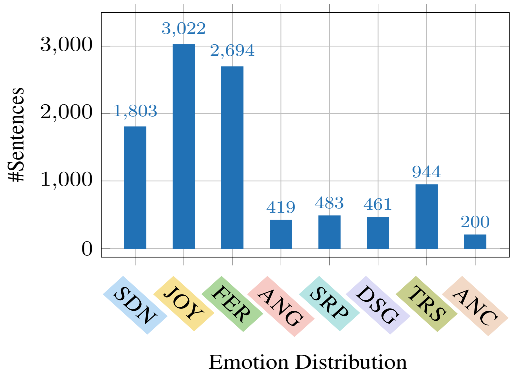

Figure 1: Emotion distribution in the dataset, including sadness (SDN), joy (JOY), fear (FER), anger (ANG), surprise (SRP), disgust (DSG), trust (TRS), and anticipation (ANC).

with and without EmoLex emotion words with respect to the difficulty to distinguish the emotions present in them. For each of the eight emotions, we separate sentences with EmoLex emotion words from those without EmoLex emotion words and calculate the AMT inter-annotator agreement. Interestingly, we find that the agreement is higher for sentences with EmoLex words only for anger, anticipation, fear, joy, and trust, and is lower on sadness, surprise, and disgust.

Emotion co-occurrence Since each sentence can be annotated with multiple emotions, we study what emotions tend to appear in the same context with others through a co-occurrence heatmap, shown in Figure 2. We use a logarithmic scale for a better visualization of the less frequent emotions. As expected, emotion pairs like fear-sadness or trust-joy are commonly used together. However, we observe quite a few unusual co-occurrences (of even opposing emotions) such as fear-joy or joy-sadness. For example, in the sentence *"Yesterday they told me they didnt see anything which brought tears of joy, but also a wave of fear."*, we speculate that the writer is expressing *joy* because of recent good medical analysis results, but at the same time *fear*, facing the possibility of the disease reappearing. When humans become emotional, they may indeed experience a mixture of emotions (not just one). We allow multi-labels for the same text to capture this mixture of emotions.

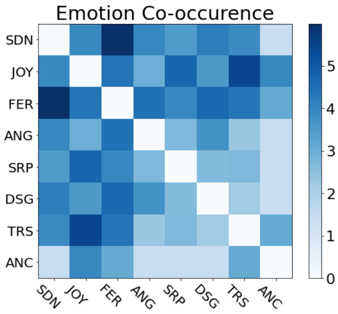

Figure 2: Emotion co-occurrence.

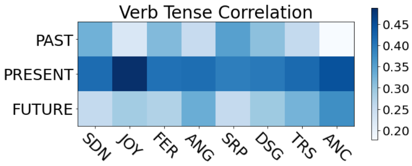

Figure 3: Emotion-Verb Tense Association. The results are normalized along the vertical axis.

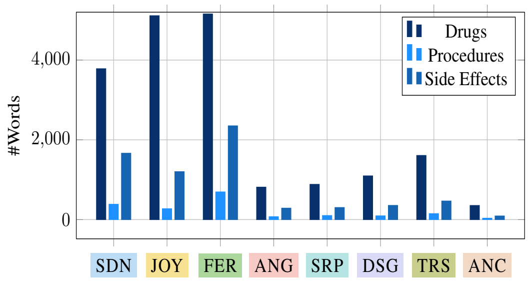

Figure 4: Emotions across Topics.

Emotion Associations with Past, Present, or Future Events or Activities We investigate whether user posts are more emotional about events or activities that happen in the past, present, or future, and how these emotions are distributed along these three dimensions. For example, in the sentence *"I just cant stand seeing her like this"*, the writer's discontent is expressed towards an event in the present, while in *"I have been through the worst fear when I started to have the pain."*, the expressed emotions are relative to an event in the past. We study this using Stanford CoreNLP Natural Language Software (Manning et al., 2014) in three steps: first, we perform a dependency parsing to extract the verb phrase in a sentence, then we take the POS tag of the verb in the verb phrase to get the sentence tense, followed by investigating the emotion conveyed in the sentence and how it relates to the identified verb tense of the sentence. Figure 3 shows the results obtained. We observe that events or activities in the present are frequently discussed across all emotions. Anticipation is, as expected, rarely discussed in the past, as well as anger and trust. Surprise, sadness, and fear on the other hand are conveyed more frequently towards past events or activities. We can also notice that emotions are associated most often with events or activities in the present.

Topics Recognizing how patients feel about different medical topics can provide information into potential causes for the conveyed emotions. These topics are frequently discussed in OHCs and range from prescribed drugs to side effects of medication and medical procedures. We study how these medical topics relate to patient's emotions by using three medical lexicons specifically created for our cancer domain, which contain words and phrases associated with medical procedures, side effects of medication, and drugs. We collected these lexicons from online resources such as Wikipedia and WebMD.[2] These medical topics are extremely important from

---

[2] https://www.webmd.com/

a practical point of view, as can provide insight into how patients react to their medication, or what side-effects they may be experiencing. We match words from the three lexicons to our dataset, then study how emotions correlate with these topics. We report our findings in Figure 4. As we can see from the figure, interestingly, the topic on *Drugs* is discussed most frequently (across all emotions), while the topics on *Side Effects* and *Medical Procedures* appear more often in sentences conveying fear or sadness as compared to joy.

Benchmark Dataset To enable development on the fine-grained emotion detection task in health related posts, we construct a benchmark dataset. We group the positive examples (sentences conveying one or more emotions) into eight pools - one for each emotion; a sentence is part of a pool if the sentence is annotated with the respective emotion. We remind that a sentence can convey more than one emotion, so it can be part of two different pools at the same time. Next, we sample an equal amount of negative examples for each pool using the following strategy: $\frac{1}{3}$ are sampled from the sentences that convey no emotions, while the other $\frac{2}{3}$ are sampled from all the positive examples from the other pools. We followed this strategy in order to create a challenging negative set for each emotion. We sample an equal number of positives and negatives because of the imbalanced emotion distribution, which would lead to an extremely skewed ratio of positive to negative samples. Next, we randomly create an 80/10/10 split to create the train, validation and test split. We present specific details about each split in Appendix B.

To facilitate future research, we make our code available[3] along with all other resources of this project (for research purposes).

4 Baseline Modeling

We model the Plutchik-8 basic set of emotions in CancerEmo ♥ using the following methods:

Statistical and Machine Learning Methods We experiment with **(1) EmoLex** - a simple annotation scheme based on EmoLex words' emotions: we label a sentence with the union of the emotion labels of the EmoLex words (Mohammad and Turney, 2013) contained in the sentence, or no emotion if no EmoLex words appear in the sentence. **(2) Naïve Bayes** using a tf*idf weighting scheme, computed after stemming and stop-word removal; and **(3) Logistic Regression** using averaged pre-trained FastText (Bojanowski et al., 2017) word embeddings.

Standard Neural Methods We experiment with **(1) Bi-LSTM** (Hochreiter and Schmidhuber, 1997) **(2) CNN** (Kim, 2014) and **(3) Conv-Bi-LSTM**, a mix of the two used in prior work on the fine-grained emotion detection task (Khanpour and Caragea, 2018).

Pre-Trained Language Models Recently, pre-trained language models have risen in popularity, because they use transfer learning, the process of storing information learned from a task and applying it to another task. The process usually involves unsupervised pre-training on a large corpus, followed by a less computationally expensive fine-tuning, performed on the task at hand. We experiment with three models: **(1) BERT** (Devlin et al., 2018) **(2) RoBERTa** (Liu et al., 2019b), a variant of BERT, which underwent significantly more pre-training, and **(3) XLNet** (Yang et al., 2019b), which has a different language modeling objective than BERT called *Permutation Language Modeling*.

5 Experiments and Results

In this section, we present the set of experiments performed on the fine-grained emotion detection task on CancerEmo ♥, as well as show the results obtained using the aforementioned baselines.

Experimental Setting All the traditional neural network models were tested with pre-trained FastText (Bojanowski et al., 2017) word embeddings. The LSTM-based models have 300 hidden units and a dropout rate of 0.5. For the CNN, we follow the best hyper-parameters presented by Kim (2014). For the pre-trained language models, we start from the best reported hyper-parameters and perform a bi-directional linear sweep. More details on the fine-tuning techniques and the hyper-parameter values used for the best models can be found in Appendix C. The reported results represent the average of five independent runs. All experiments were carried out on an NVIDIA V100 GPU.

Results Table 4 shows the results in terms of F1-score, obtained using BERT-like models compared with the other weaker baselines. We can observe that EmoLex performs very poorly, reinforcing our premise that lexical level information in the form of

In order from top to bottom: **(1)** BERT, which corresponds to BERT with no intermediate pre-training (top) **(2)** Unsupervised Pre-training (middle block) **(3)** Supervised Pre-training (bottom block). An improvement over the BERT model is marked with PURPLE, while a decrease in performance is signaled using RED. The best performing model F1s are underlined.

emotion words does not necessarily reveal the emotion conveyed. Interestingly, the Conv-Bi-LSTM model manages to improve upon the other statistical and standard neural network methods by as much as 5%. The BERT base model is extremely successful across all emotions, greatly outperforming all the other baselines by 4% F1 on average.

Next, we explore intermediate task pre-training to understand if this improves the performance of our BERT models further (Pruksachatkun et al., 2020; Han and Eisenstein, 2019).

6 Intermediate Pre-Training

CANCEREMO ♥ is created from a health forum, i.e., a network of cancer survivors that we call CancerNet (or CNet for short). Thus, our data differs substantially from the pre-training domain of BERT (Devlin et al., 2018) (Wikipedia and Bookcorpus). As Xia and Ding (2019) noted, domain-adaptive fine-tuning (i.e., adapting the contextualized embeddings to the target domain) might implicitly incorporate inductive biases and improve the performance of the models. To investigate this, we perform an additional set of comprehensive experiments with the best performing model from the previous experiment: BERT. The experimental pipeline consists of two steps: starting from a pre-trained BERT model, we **(1)** perform an unsupervised or supervised pre-training on an *intermediate pre-training task*, followed by **(2)** fine-tuning on the *target task*, which is always the fine-grained emotion detection on CANCEREMO ♥.

Intermediate Tasks The unsupervised pre-training is performed using the Masked Language Modeling objective, while the supervised pre-training is carried out by adding a linear layer, followed by fine-tuning on the emotion detection task. The intermediate tasks are as follows: **(1) Unsupervised EmoNet** EmoNet (Abdul-Mageed and Ungar, 2017) is a Twitter dataset composed of tweets automatically annotated using distant supervision with Plutchik-24 emotion set. We obtained a smaller version of the dataset from the authors which contains the Plutchik-8 basic emotions. We pre-train the BERT model on all EmoNet sentences. **(2) Unsupervised CNet** We pre-train the BERT model on all CancerNet sentences, hoping to implicitly learn information specific to the health domain. **(3) Unsupervised Filtered CNet** We use lexical features to filter CancerNet. To this end, we implicitly induce both health and emotion specific biases, by only pre-training on CancerNet sen-

	SDN	JOY	FER	ANG	SRP	DSG	TRS	ANC	AVERAGE

EMOWORDS^{-} FLTR CNET	0.64	0.76	0.76	0.68	0.67	0.50	0.65	0.67	0.66

Table 6: F1 performance of BERT (top two lines) and FLTR CNET BERT (last two lines) F1 performance on sentences **with** (EMOWORDS^{+}) and **without** (EMOWORDS^{-}) emotion words.

tences that contain at least one emotion word from EmoLex (Mohammad and Turney, 2013). **(4) Unsupervised Clinical** We observe that sentences in our data contain terms from medical specialty vocabulary. We present some examples of this phenomenon: *"I too had Adenocarcinoma in the very top of my left lung in 1987, they removed the top half of the lung."*; *"My wife, 68, was recently diagnosed with Stage IV lung cancer with K-RAS mutation."* These examples illustrate some uses of medical terminology in the forum. We explore whether pre-training on a medical speciality corpus improves the performance of the models. To this end, we use the publicly available Clinical BERT (Alsentzer et al., 2019) medical specific contextual embeddings. **(5) Unsupervised Clinical Filtered CNet** We investigate if additional emotion guided pre-training helps Clinical BERT. Following **Unsupervised Filtered CNet** method, we pre-train Clinical BERT on CancerNet sentences that contain at least an emotion word. **(6) Supervised EmoNet** For the supervised setting, we pre-train on a multi-class emotion classification task on EmoNet (Abdul-Mageed and Ungar, 2017). We use a linear layer to perform the fine-grained emotion classification task on EmoNet, and after achieving an F1 of 0.83%, we drop this layer. Next, the target fine-tuning on CANCEREMO ♥ is performed using a freshly initialized linear layer.

Results The results in terms of F1-score obtained are compared with the BERT models in Table 5. In the unsupervised setting, we observe a few patterns. First, unsupervised pre-training on EmoNet (Abdul-Mageed and Ungar, 2017) largely hurts downstream performance. Second, approaches inducing health specific biases from **CNet** and **Clinical** perform better than BERT on sadness, joy and anticipation. Third, **Clinical Filtered CNet** consistently outperforms all the other models by as much as 5% on sadness, joy, fear and anticipation, while keeping the same overall F1-score on the other 4 emotions. We speculate that this happens because the pre-training corpus used is very close to the task domain, and we manage to implicitly induce both emotion-specific and health-specific biases. Last, interestingly, the supervised intermediate task pre-training on EmoNet improves the performance on emotions like sadness, joy, and anticipation, but performs similarly or degrades the performance on the other emotions. Still, the **Supervised EmoNet** performs much better compared with the **Unsupervised EmoNet**.

Takeaways One should pay close attention when dealing with very narrow domains like emotion or health, where the pre-training corpus greatly influences the performance of the models, and the *right* pre-training can improve the performance.

7 Emotion Word Testing

A good amount of sentences annotated with emotions by our annotators in CANCEREMO ♥ do not contain any emotion words from EmoLex (§3.3). Thus, we now investigate if the absence of emotion words affects the model performance. To this end, to depict a real scenario, we keep the train set unchanged and divide the test set in two: one set contains only sentences that have at least an emotion word, while the other contains only sentences without emotion words. As Table 6 shows, testing on sentences with emotion words provides a considerable 8% average F1 increase over sentences with no emotion words. Next, we perform the same experiment using the **Unsupervised Filtered CNet** method. Surprisingly, the performance improves on both test sets (with and without emotion words) on several emotions, e.g., sadness, joy and fear.

8 Significance Test and Error Analysis

We investigate if our results are statistically significant. To this end, we perform paired t-tests to test significant differences between model results. We reject the null hypothesis if $p < 0.05$. Our significance tests show the following: First, the improvement of BERT over the statistical and standard neural baselines is statistically significant on

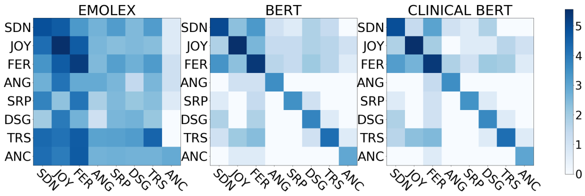

Figure 5: Predicted Lables (vertical axis) vs Actual Lables (horizontal axis).

all emotions. Second, the improvement of our best performing model (**Clinical Filtered CNet**) over the BERT model with no additional pre-training is statistically significant on sadness, joy and anticipation, but not on fear.

Next, using our best **Clinical Filtered CNet** BERT model, we manually investigate test errors to understand potential drawbacks of the model. We observe the following: First, the model often performs poorly on sentences with abbreviations or writing errors. For example, in the sentence *"As i will have alot of time, cuz i cant really sleep any significant amount of sleep."*, although the expressed emotion is sadness, the model assigns no emotion to it. Next, some errors arise from antithetic emotions in the same sentence. For example, the model assigns sadness to the following sentence: *"Still get tired but it's better every day."* Although the first part of the sentence could convey sadness, the overall emotion expressed is joy.

Finally, we construct confusion matrices to visualize commonly mislabeled classes, shown in Figure 5. We use a logarithmic scale to be able to better picture less frequent classes such as surprise, disgust, trust and anticipation. The EmoLex (Mohammad and Turney, 2013) visualization shows the poor performance of the lexicon approach, and reflects the results reported in Table 4. Next, we investigate commonly mislabeled classes by BERT and Clinical BERT, and observe a few patterns. For example, the most common mislabeling for the fear emotion is sadness and vice-versa, while quite a few sentences conveying disgust are annotated with sadness and fear.

9 Conclusion and Future Work

We introduced CancerEmo ♥, a cancer-related health dataset for perceived emotion detection, which is an order of magnitude larger and more fine-grained compared with previous datasets for health-related emotion detection. Composed of 8,500 sentences that convey at least one emotion, and 16,500 sentences that convey no emotion at all, CancerEmo ♥ is a challenging benchmark for fine-grained emotion detection, as shown by our results. We believe that CancerEmo ♥ is novel and has unique characteristics: 1) covers a large spectrum of emotions - being annotated with the Plutchik-8 fine-grained emotions; 2) has a large dataset size for exploring deep learning models; and 3) provides an invaluable context - cancer - for dealing with emotions. The value of our dataset arises also from: the expressions of emotions even in the absence of emotion words and the expressions of mixtures of (sometimes opposing) emotions in the same text. We believe that these characteristics add interestingness and challenges to our dataset and we hope that our work will spur future research in emotion detection from health data, especially in the context of life-threatening diseases such as cancer. Our dataset, which is anonymized and follows ethical considerations, can be used as a benchmark for both multi-class and multi-label emotion detection.

In the future, we plan to study how contextual information (i.e., different aspects of people's interactions captured through contiguous posts in a discussion thread) affects the perceived emotions. We also plan to perform a cross-corpus analysis to investigate if emotions are expressed differently in the health domain compared to other domains. Finally, we will carry out a thorough investigation into emotion-cause pairs (Xia and Ding, 2019). Specifically, in the health domain, the cause that leads to an emotion expressed in text can be just as important as the emotion itself. A deeper understanding of emotion causes can potentially help make people feel better.

SADNESS	The condition or quality of being sad.
JOY	A feeling of great pleasure and happiness.
FEAR	An unpleasant emotion caused by the belief that someone or something is dangerous, likely to cause pain, or a threat
ANGER	A strong feeling of annoyance, displeasure, or hostility.
SURPRISE	An unexpected or astonishing event, fact, or thing.
DISGUST	A feeling of revulsion or strong disapproval aroused by something unpleasant or offensive.
TRUST	Firm belief in the reliability, truth, ability, or strength of someone or something.
ANTICIPATION	The action of anticipating something; expectation or prediction. Similarly, anticipation is a feeling of excitement about something pleasant or exciting that you know is going to happen.

Table 7: Emotion Definitions given to the annotators.

A Emotions Definition

Table 7 shows the emotion definitions provided in the task instructions, which annotators have to read before starting to label the data.

B Split Details

We present the emotion counts in every train/val/test split through Table 8. We color the emotion counts of the split in question. For instance, the first train/val/test line corresponds to the sadness split, as the column corresponding to sadness is colored.

C Hyperparameters

We present the hyperparameters obtained by tuning in Table 9 and 10. The highest variance in the results is obtained by varying the learning rate, which we tune the most. For each emotion, we start from an initial value of 5e-05, then search for 5 iterations forward and backwards in steps of 1e-05. This type of tuning is performed for each emotion, and took in total 2 days on our V100 GPU. We use a batch size of 64 for the traditional baselines, while only 16 for BERT and RoBERTA and 8 for XLNet due to GPU ram restrictions.

Abstract

Online debate forums provide users a platform to express their opinions on controversial topics while being exposed to opinions from diverse set of viewpoints. Existing work in Natural Language Processing (NLP) has shown that linguistic features extracted from the debate text and features encoding the characteristics of the audience are both critical in persuasion studies. In this paper, we aim to further investigate the role of discourse structure of the arguments from online debates in their persuasiveness. In particular, we use the factor graph model to obtain features for the argument structure of debates from an online debating platform and incorporate these features to an LSTM-based model to predict the debater that makes the most convincing arguments. We find that incorporating argument structure features play an essential role in achieving the better predictive performance in assessing the persuasiveness of the arguments in online debates.

1 Introduction

The increase in availability of online argumentation platforms has provided opportunity for researchers to develop computational methods at a larger scale studying the important factors of persuasiveness such as the language use (Hidey et al., 2017; Tan et al., 2016; Zhang et al., 2016), characteristics of audience (i.e. prior beliefs, demographics) (Durmus and Cardie, 2019a, 2018) and social interactions (Durmus and Cardie, 2019b).

Prior work has showed incorporating argument structure features is important in assessing the quality of monological persuasive essays (Klebanov et al., 2016; Wachsmuth et al., 2016). Hidey et al. (2017) and Egawa et al. (2019) further collected annotations for semantic types of argument components and studied the relationship between the semantic types and persuasiveness of the arguments from online argumentative platform ChangeMyView (CMV) (Tan et al., 2016). CMV consists of discussion trees where the users interact with the original poster to change their opinion on a given topic. Although the discussion trees are of a high quality since they are monitored by moderators (Tan et al., 2016), they are not as structured since any user in the subreddit can participate in the discussions once the original post is posted. Furthermore, the persuasiveness of the posts in CMV is evaluated only by the original poster (i.e. whether they change their stance or not). In this paper, we aim to investigate the effect of argument structure in persuasion on online debates. We focus on debates from DDO corpus (Durmus and Cardie, 2019a) where debaters from two diverging sides of an issue express their opinions on a controversial topic in turns since these debates are more structured and the persuasiveness of the arguments in debates are evaluated by a larger set of audience. Moreover, this setup allows us to account for the audience characteristics when studying the effect of the argument structure on persuasion.

We first generate argument structure on DDO dataset (Durmus and Cardie, 2019a) using the model proposed by Niculae et al. (2017). We then incorporate the features extracted from argument structure to an LSTM-based model that encodes the sequence of turns from two sides (i.e. PRO vs. CON). We compare our results with the baselines proposed in (Durmus and Cardie, 2018) which extracts linguistics features from the debate text as well as features that encode characteristics of the audience. We find that incorporating argument structure features achieves significantly better results than the baselines. Our analysis further shows that argument structure features encode important strategies of persuasion, for example, we find that more convincing arguments are more likely to in-

Sent No.	Debate text
1	Parents should not send their children to preschool for several reasons.
2	First and foremost, the year is better spent with a full-time parent.
3	In addition, most children will learn very little at preschool.
4	Contrary to claims made by preschool advocates, children are not better equipped because of preschool.
5	They may develop social skills and hand painting skills sooner, however children that miss preschool will quickly catch up before they finish the first grade.

Figure 1: An example of argument structure extracted from the debate text in one round from one side.

clude personal experiences of the debater and appeal to audience emotion.

2 Related Work

Analysis of discourse structure There has been a lot effort to understand the role of discourse structure in argumentation. Jiang et al. (2019) applied RST to essays written by students in K-12 schools and demonstrated its potential to provide automated feedback for essay quality. Argument structures, which can be considered as a special kind of discourse structure, have been widely analyzed in the task of automatic essay scoring and feedback (Klebanov et al., 2016; Ghosh et al., 2016; Wachsmuth et al., 2016). Furthermore, Duthie and Budzynska (2018) has studied the relationship between ethos, a specific kind of argument unit, and the dynamics of governments from the UK parliamentary debates. The role of argument structure in persuasion on online debates is much less explored, which is the main focus of this paper.

Analysis of Persuasion Prior studies on persuasion has mainly focused on understanding the role of linguistic factors (Petty et al., 1983; Chaiken, 1987; Dillard and Pfau, 2002; Gold et al., 2015). Besides, the interaction between debaters has shown to be an important cue in persuasion studies (Zhang et al., 2016; Tan et al., 2016; Wang et al., 2017). Luu et al. (2019) further found that the debater's skill estimated from debate text history is also predictive of convincing the audience. User factors are explored in previous papers (Durmus and Cardie, 2019a, 2018; Longpre et al., 2019), demonstrating the importance of characteristics and beliefs of the audience. Furthermore, Potash and Rumshisky (2017) proposed a recurrent neural network architecture with attention and annotated audience favorability to predict the winner of the debate. Villata et al. (2018) and Benlamine et al. (2017) studied the correlation of the engagement index in brain hemispheres with the persuasion strategies. Argument structures have been used to understand argumentative strategies in dialogues and news editorials (Al Khatib et al., 2017; Wang et al., 2019). A few studies have explored the impact of argument structures in predicting persuasion on CMV dataset based on statistical analysis of proposition types (Hidey et al., 2017; Egawa et al., 2019; Morio et al., 2019). In this paper, we particularly study persuasion in online debates. We propose novel argument structure features based on n-grams of the supporting relations in argument structure graph of the debate text and experiment with these using both linear and neural models.

3 Dataset

We experiment with DDO dataset (Durmus and Cardie, 2019a) which includes 77,655 debates covering 23 different topic categories. Each debate consists of multiple rounds with each round containing one utterance from the PRO side and one utterance from the CON side. Besides the text information for debates, the dataset also contains user information and votes provided by the audience on six different criteria of evaluating both the debaters. We use the criterion *"Made more convincing arguments"* as an overall signal to study the role of argument structure in predicting more convincing arguments.

4 Prediction Task

Task. We aim to predict which side (i.e. PRO vs. CON) makes more convincing arguments during a debate, and thus is more persuasive.

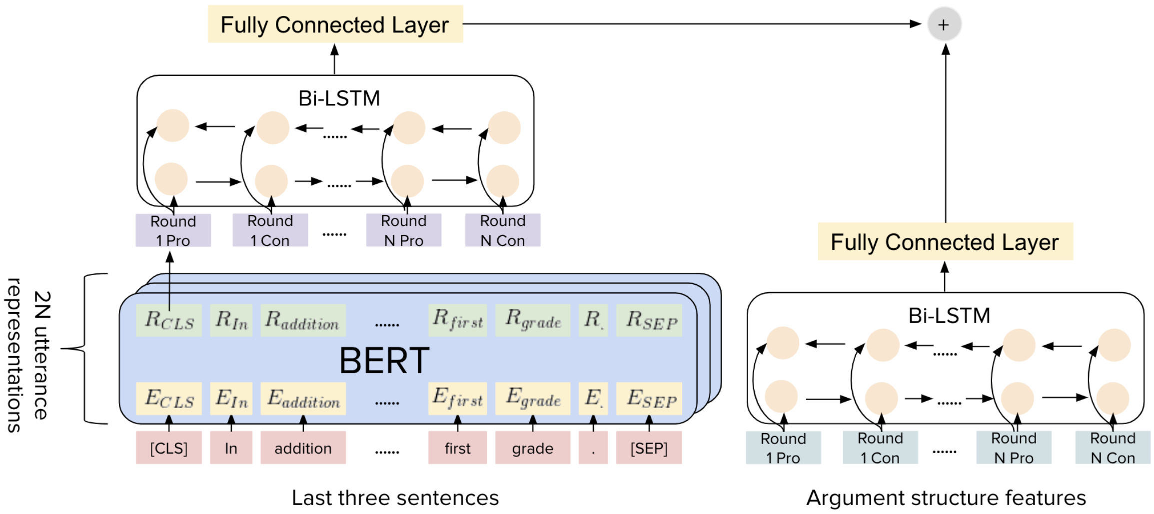

Figure 2: Model for predicting which side makes more convincing arguments

Data preprocessing. We count which side of the debate gets more votes for the criterion *"Made more convincing arguments"*. We eliminate debates if they are tied or the difference in votes is only 1.[1] The final dataset contains 2,606 debates.

4.1 Argument structure features

We apply the pre-trained model (Niculae et al., 2017) on DDO dataset to get the stucture of the arguments. We select this method since we can predict argumentative relations and classify proposition type at the same time, while the method proposed by Chakrabarty et al. (2020) mainly focuses on predicting argumentative relations. Besides, this model can model argumentative relations that do not necessarily form a tree structure which is more suitable to argumentation in the wild comparing to the models proposed in Stab and Gurevych (2017) and Peldszus and Stede (2015). We generate argument structures for the selected 2,606 debates.[2] The argument structure model outputs the proposition type for each sentence (i.e. REFERENCE, TESTIMONY, FACT, VALUE, POLICY) as well as the supporting relationship between the propositions. An example of argument structure generated on the text from one side in one round of the debate *'Preschool Is A Waste Of Time'* is shown in Figure 1. We use *Amazon Mechanical Turk* (AMT) to further evaluate the quality of the argument structure on debates by asking Turkers to classify each argument from randomly picked 30 debates into five categories: POLICY, VALUE, FACT, TESTIMONY, REFERENCE. In total, we get annotations for 1,098 sentences, and each sentence is annotated by two annotators. We find that around 64% of the output generated from the pre-trained model is consistent with either of the annotations from the Turkers. We then extract three sets of argument structure features to capture the proposition types and link between propositions:

Proposition n-gram frequency Similar to Wachsmuth et al. (2016), we obtain the frequencies of proposition unigrams, bigrams, and trigrams from the sequence of propositions. For example, (POLICY,VALUE) and (VALUE,VALUE) bigram features in Figure 1 has values 0.25,0.75 respectively.

Link n-gram frequency We extract the n-gram information from the supporting relations in argument structure graph. For example, we represent two propositions connected with a link as a bigram (i.e $a \rightarrow b$ in the graph is represented with bigram (a,b)).

Graphical representation Rahwan (2008) has found that there are five common argument structures in online environment: basic argument, convergent argument, serial argument, divergent argument, and linked argument. A typical basic argument is $a \rightarrow b$[3], while serial argument is $a \rightarrow b \,\&\, b \rightarrow c$. The simplest convergent argument

---

[1] Since the average number of total votes in one debate is 8, we consider difference of two or more votes as significant.

[2] Since the model takes relatively long inference time and performs worse for long debates, we eliminate all the debates with more than 40 sentences in one round from one side. We also eliminate debates where one of the debaters forfeit during the debate.

[3] a, b, c denotes propositions and $a \rightarrow b$ denotes the directed link between a and b.

Pro	Con
[...] One of the quotes I remembered clearly was, “God will give us whatever we want, as long as we don’t screw up.” [...] I haven’t committed genocide or anything bad like that. But I’ve made my mistakes, and everyone has. [...] I’m not dead.	[...] If cheating on test made someone happy, that doesn’t make up for their unfair advantage. [...] Multiple times it is mentioned in the bible that homosexuality is wrong, it’s a sin. “You shall not lie with a male as one lies with a female; it is an abomination.” [...]

Table 1: Example debate “GAY MARRIAGE” that is classified correctly after adding argument structure features.

Model	Accuracy
Majority baseline	62.62%
Linguistic+User LR	67.41%
Arg-Struct LR	69.52%
Linguistic+Arg-Struct LR	70.48%
Linguistic+User+Arg-Struct LR	70.44%
Our Model	**77.28%**
Our Model w/o All Arg-Struct	75.29%
Our Model w/o Proposition N-gram	76.21%
Our Model w/o Link N-gram	76.86%
Our Model w/o Graphical	76.95%

Table 2: Comparison with feature based Logistic Regression (LR). Arg-Struct denotes the argument structure features.

is in the form of $a \rightarrow b$ & $c \rightarrow b$, and a divergent argument is in the form of $a \rightarrow b$ & $a \rightarrow c$. Similarly, a linked argument is in the form of $a, c \rightarrow b$. We extract features to represent which of these types of arguments are used in the text of the debaters. We further classify the convergent arguments into two categories – where two propositions support one proposition (regular convergent argument) and more than two propositions support one proposition (multi convergent argument). Similarly, we classify divergent argument into regular divergent argument and multi divergent argument.

4.2 Model Architecture

We employ two separate bidirectional LSTM (Hochreiter and Schmidhuber, 1997) models to encode the argument structure features and features encoding the debate text derived from pre-trained BERT model (Devlin et al., 2019) as shown in Figure 2. LSTM modeling the debate text takes BERT representation (Devlin et al., 2019) while LSTM encoding argument structure features takes three set of argument structure features of an utterance in a round at each time step. Two fully connected layers with softmax are used to predict the output probabilities over both of these LSTM models separately. The model learns weights during training to combine these probabilities.

5 Experiments and Analysis

We compare our model with the baseline proposed by Durmus and Cardie (2019a) employing linguistic features and features encoding audience characteristics. The prediction accuracy is evaluated using 5-fold cross-validation, and the model parameters for each split are picked with 3-fold cross-validation on the training set. As shown in Table 2, incorporating argument structure features to Logistic Regression achieves significantly better performance than the baseline with linguistic and user-based features. LSTM with argument structure features achieves the best predicive performance since LSTM can better represent context and the interplay between debaters. We perform t-test over 10 runs between the model with and without argument structure features, the p-value is 0.0038, indicating a statistically significant result. Furthermore, we do ablation over different sets of argument structure features. The results show that using the sequential flow of arguments is more effective than using argumentative relations in our setting.

We further analyze what type of argument structure is more correlated with making more convincing arguments. Comparing the unigram, bigram and trigram frequencies of the propositions by more convincing vs. less convincing debaters, we find that unigram TESTIMONY ($p < 0.0001$)[4], bigram (VALUE,TESTIMONY) ($p < 0.001$), and trigram (VALUE,TESTIMONY,VALUE) ($p < 0.0001$) appear more frequently in the more convincing side. This result suggests that justifying the objective claims with personal experiences is an effective strategy as also shown in previous work (Villata et al., 2018).

---

[4] The p-values are calculated using the Wilcoxon signed-rank test.

Table 1 shows an example that is predicted classified by the model correctly after adding argument structure features. We observe that the side referring to their personal experiences (PRO) is voted as the side making more convincing arguments. Besides, we find that unigram POLICY ($p < 0.0001$), bigram (POLICY,VALUE) ($p < 0.005$) appear more frequently in the less convincing side suggesting that using propositions with type POLICY – which is used to specify a specific course of action to be taken – may not be a very effective strategy in online debating. Analyzing the link n-gram frequency features, we have further found that propositions with type VALUE from more convincing side are supported by a FACT ($p < 0.05$) more often. This suggests that the more convincing debaters may be using logos to support their views as also shown in previous work (Hidey et al., 2017). Finally, we observe that more convincing side tends to have more divergent arguments ($p = 0.052$). Divergent arguments involves three or more consecutive sentences most of the time. In the case of three consecutive sentences, the middle sentence supports both the other two sentences by giving explanations or evidence, and serves as a transition between two similar ideas.

We also look into some examples that are classified wrong by the model. A typical error is caused by wrong proposition type classification. For example, in the debate "Driving on public roads is a right not a privilege", sentences from PRO side "In addition, in purchasing our vehicles, we have the right to drive said vehicle." and "I appreciate the insight given by my opponent but he/she has failed to address the issue at hand." are classified as "Testimony" wrongly, which makes the model prefer PRO as the more convincing side. We believe that incorporating more accurate argument structure generation models can further improve the performance on persuasion prediction.

6 Conclusion

In this work, we explore the role of argument structure in online debate persuasion and find that incorporating argument structure features along with the linguistic features achieves the best predictive performance models. Moreover, we observe that argument structure features provide important cues about effective persuasion strategies in online debates.

A Appendix

A.1 Argument Structure Features Used

Proposition n-gram frequency When we eliminate proposition bigram and trigram that occur less than 3% in all training debates, five types of unigrams, eight types of bigrams and ten types of trigrams remain.

Unigram types: policy, value, fact, testimony, reference.

Bigram types: (value, value), (testimony, value), (value, testimony), (value, policy), (policy, value), (fact, value), (value, fact), (testimony, testimony).

Trigram types: (value, value, value), (testimony, value, value), (value, value, policy), (value, value, testimony), (value, testimony, value), (fact, value, value), (policy, value, value), (value, fact, value), (value, policy, value), (value, value, fact).

Link n-gram frequency When we eliminate all link bigrams that occur less than 3% of all training data, four types of link bigrams remain (i.e. (value, value), (value, policy), (fact, value), (testimony, value)).

Graphical representation There are 5 types of features for graphical representation: basic argument, regular convergent argument, regular divergent argument, multi convergent argument, multi divergent argument.

In total, the argument structure features are 32-dimensional.

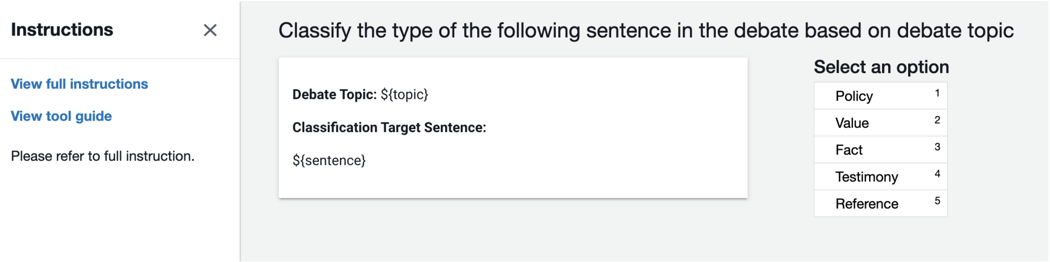
A.2 Linguistic Features and User Features

The linguistic features and user features we use for the Logistic Regression based baseline is the same as the features used by Durmus and Cardie (2019a). They include hedge words (Tan and Lee, 2016), evidence words (e.g. "according to"), positive words, negative words, swear words, personal pronouns, tf-idf, argument lexicon features (Somasundaran et al., 2007), politeness marks (Danescu-Niculescu-Mizil et al., 2013), sentiment, connotation (Feng and Hirst, 2011), subjectivity (Wilson et al., 2005), modal verbs, type-token ratio (diverse word usage), and punctuation.

The user features include opinion similarity for big issues, religious and political ideology match and persuadability score (how likely a person will be persuaded) (Longpre et al., 2019).

A.3 BERT Representation Generation

We input the utterance in one round for one debater. The segment embedding for each word in the utter-



Please refer to full instruction.

Classify the type of the following sentence in the debate based on debate topic

Debate Topic: ${topic}

Classification Target Sentence:

${sentence}

Figure 3: AMT annotation example

ance is the same, though one utterance will contain multiple sentences. Due to the maximum sequence length of 128 tokens of BERT [5], which is much shorter than the average length of utterance in one round for one debater, we truncate the debate text input and only preserve the last three sentences[6] in each round for each debater. The truncate method of choosing the first three sentences of the utterance has also been tested, but the performance of the model was around 3% lower.

A.4 Implementation Details

We use grid search to pick the hyperparameter. For the model that encodes linguistic information, we use a one-layer bidirectional LSTM with 768 dimension BERT representation input and 32 dimension hidden states. (We search in [16, 32, 64] for hidden dimension.) For the model that encodes argument structure information, we use a one-layer bidirectional LSTM with 32 dimension argument features input and 4 dimension hidden states. (We search in [16, 8, 4] for hidden dimension). We have a 0.5 dropout rate for both fully connected layers. Total number of parameters is around 100k. We use Adagrad (Duchi et al., 2011) with initial learning rate 0.005 and weight decay 0.01 to optimize the cross-entropy loss. (We also experiment with Adam with default setting, Adagrad without weight decay, learning rate between [0.001, 0.005, 0.01]). 2200 debates are used for training, 200 for validation and 206 for test set. We use early stopping to avoid overfitting, the model is trained for around 15 epochs on average. It takes less than 15 minutes to run the model on a CPU (2.7 GHz Intel Core i7). To test the stability of our results, we train and evaluate our model 10 times and take the average accuracy.

Type	# Proposition	Consistency
Policy	97	56.70%
Value	834	65.47%
Fact	85	84.71%
Testimony	79	37.97%
Reference	3	33.33%
All	1,098	64.12%

Table 3: Annotation results from Amazon Mechanical Turker.

A.5 Details on AMT result

Figure 3 shows the screenshot for a typical HIT for the Turkers. For each HIT, the turkers are given the debate topic and the sentence to be classified. They need to choose between 5 categories: Policy, Value, Fact, Testimony, Reference. The definition of these proposition types and the corresponding example are included in the full instruction.

In total, we get annotations for 1,098 sentences from seventeen annotators. The detailed results are listed in Table 3. Consistency means the generated annotations is consistent with either of the annotations from the Turkers. We also compute Inter-Annotator Agreement (IAA) using Kripendorff's alpha (Krippendorff, 1970). The Kripendorff's alpha is 0.2, indicating that annotating argument structure is still a hard task for Turkers.

---

[5] We use BERT-base with uncased input as the pretrained model.

[6] We also experimented using more sentences (e.g. last five sentences) in cases where the sequence length has not been maxed out has also been tested, but it doesn't show significant improvement.

Zero-Shot Stance Detection:
A Dataset and Model using Generalized Topic Representations

Abstract

Stance detection is an important component of understanding hidden influences in everyday life. Since there are thousands of potential topics to take a stance on, most with little to no training data, we focus on zero-shot stance detection: classifying stance from no training examples. In this paper, we present a new dataset for zero-shot stance detection that captures a wider range of topics and lexical variation than in previous datasets. Additionally, we propose a new model for stance detection that implicitly captures relationships between topics using generalized topic representations and show that this model improves performance on a number of challenging linguistic phenomena.

1 Introduction

Stance detection, automatically identifying positions on a specific topic in text (Mohammad et al., 2017), is crucial for understanding how information is presented in everyday life. For example, a news article on crime may also implicitly take a position on immigration (see Table 1).

Topic: immigration **Stance:** against

Text: The jury's verdict will ensure that another violent criminal alien will be removed from our community for a very long period . . .

Table 1: Example snippet from Fox News describing a crime but taking a stance *against* immigration. Phrases indicating stance are highlighted.

There are two typical approaches to stance detection: *topic-specific* stance (developing topic-specific classifiers, e.g., Hasan and Ng (2014)) and *cross-target* stance (adapting classifiers from a related topic to a single new topic detection, e.g., Augenstein et al. (2016)). Topic-specific stance requires the existence of numerous, well-labeled training examples in order to build a classifier for a new topic, an unrealistic expectation when there are thousands of possible topics for which data collection and annotation are both time-consuming and expensive. While cross-target stance does not require training examples for a new topic, it does require human knowledge about any new topic and how it is related to the training topics. As a result, models developed for this variation are still limited in their ability to generalize to a wide variety of topics.

In this work, we propose two additional variations of stance detection: zero-shot stance detection (a classifier is evaluated on a large number of completely new topics) and few-shot stance detection (a classifier is evaluated on a large number of topics for which it has very few training examples). Neither variation requires any human knowledge about the new topics or their relation to training topics. Zero-shot stance detection, in particular, is a more accurate evaluation of a model's ability to generalize to the range of topics in the real world.

Existing stance datasets typically have a small number of topics (e.g., 6) that are described in only one way (e.g., 'gun control'). This is not ideal for zero-shot or few-shot stance detection because there is little linguistic variation in how topics are expressed (e.g., 'anti second amendment') and limited topics. Therefore, to facilitate evaluation of zero-shot and few-shot stance detection, we create a new dataset, **VA**ried **S**tance **T**opics (VAST). VAST consists of a large range of topics covering broad themes, such as politics (e.g., 'a Palestinian state'), education (e.g., 'charter schools'), and public health (e.g., 'childhood vaccination'). In addition, the data includes a wide range of similar expressions (e.g., 'guns on campus' versus 'firearms on campus'). This variation captures how humans might realistically describe the same topic and con-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8913–8931,
November 16–20, 2020. ©2020 Association for Computational Linguistics

trasts with the lack of variation in existing datasets.

We also develop a model for zero-shot stance detection that exploits information about topic similarity through generalized topic representations obtained through contextualized clustering. These topic representations are unsupervised and therefore represent information about topic relationships without requiring explicit human knowledge.

Our contributions are as follows: (1) we develop a new dataset, VAST, for zero-shot and few-shot stance detection and (2) we propose a new model for stance detection that improves performance on a number of challenging linguistic phenomena (e.g., sarcasm) and relies less on sentiment cues (which often lead to errors in stance classification). We make our dataset and models available for use: `https://github.com/emilyallaway/zero-shot-stance`.

2 Related Work

Previous datasets for stance detection have centered on two definitions of the task (Küçük and Can, 2020). In the most common definition (*topic-phrase* stance), stance (pro, con, neutral) of a text is detected towards a topic that is usually a noun-phrase (e.g., 'gun control'). In the second definition (*topic-position* stance), stance (agree, disagree, discuss, unrelated) is detected between a text and a topic that is an entire position statement (e.g., 'We should disband NATO').

A number of datasets exist using the *topic-phrase* definition with texts from online debate forums (Walker et al., 2012; Abbott et al., 2016; Hasan and Ng, 2014), information platforms (Lin et al., 2006; Murakami and Putra, 2010), student essays (Faulkner, 2014), news comments (Krejzl et al., 2017; Lozhnikov et al., 2018) and Twitter (Küçük, 2017; Tsakalidis et al., 2018; Taulé et al., 2017; Mohammad et al., 2016). These datasets generally have a very small number of topics (e.g., Abbott et al. (2016) has 16) and the few with larger numbers of topics (Bar-Haim et al., 2017; Gottipati et al., 2013; Vamvas and Sennrich, 2020) still have limited topic coverage (ranging from 55 to 194 topics). The data used by Gottipati et al. (2013), articles and comments from an online debate site, has the potential to cover the widest range of topics, relative to previous work. However, their dataset is not explicitly labeled for topics, does not have clear pro/con labels, and does not exhibit linguistic variation in the topic expressions. Furthermore, all of these stance datasets are not used for zero-shot stance detection due to the small number of topics, with the exception of the SemEval2016 Task-6 (TwitterStance) data, which is used for cross-target stance detection with a single unseen topic (Mohammad et al., 2016). In constrast to the TwitterStance data, which has only one new topic in the test set, our dataset for zero-shot stance detection has a large number of new topics for both development and testing.

For *topic-position* stance, datasets primarily use text from news articles with headlines as topics (Thorne et al., 2018; Ferreira and Vlachos, 2016). In a similar vein, Habernal et al. (2018) use comments from news articles and manually construct position statements. These datasets, however, do not include clear, individuated topics and so we focus on the topic-phrase definition in our work.

Many previous models for stance detection trained an individual classifier for each topic (Lin et al., 2006; Beigman Klebanov et al., 2010; Sridhar et al., 2015; Somasundaran and Wiebe, 2010; Hasan and Ng, 2013; Li et al., 2018; Hasan and Ng, 2014) or for a small number of topics common to both the training and evaluation sets (Faulkner, 2014; Du et al., 2017). In addition, a handful of models for the TwitterStance dataset have been designed for cross-target stance detection (Augenstein et al., 2016; Xu et al., 2018), including a number of weakly supervised methods using unlabeled data related to the test topic (Zarrella and Marsh, 2016; Wei et al., 2016; Dias and Becker, 2016). In contrast, our models are trained jointly for all topics and are evaluated for zero-shot stance detection on a large number of new test topics (i.e., none of the zero-shot test topics occur in the training data).

3 VAST Dataset

We collect a new dataset, VAST, for zero-shot stance detection that includes a large number of specific topics. Our annotations are done on comments collected from *The New York Times* 'Room for Debate' section, part of the Argument Reasoning Comprehension (ARC) Corpus (Habernal et al., 2018). Although the ARC corpus provides stance annotations, they follow the *topic-position* definition of stance, as in §2. This format makes it difficult to determine stance in the typical *topic-phrase* (pro/con/neutral) setting with respect to a single topic, as opposed to a position statement (see *Topic* and *ARC Stance* columns respectively, Table 2).

Therefore, we collect annotations on both topic and stance, using the ARC data as a starting point.

3.1 Data Collection

3.1.1 Topic Selection

To collect stance annotations, we first heuristically extract specific topics from the stance positions provided by the ARC corpus. We define a candidate topic as a noun-phrase in the constituency parse, generated using Spacy[1], of the ARC stance position (as in (1) and (5) Table 2). To reduce noisy topics, we filter candidates to include only noun-phrases in the subject and object position of the main verb in the sentence. If no candidates remain for a comment after filtering, we select topics from the categories assigned by *The New York Times* to the original article the comment is on (e.g., the categories assigned for (3) in Table 2 are 'Business', 'restaurants', and 'workplace'). From these categories, we remove proper nouns as these are over-general topics (e.g., 'Caribbean', 'Business'). From these heuristics we extract 304 unique topics from 3365 unique comments (see examples in Table 2).

Although we can extract topics heuristically, they are sometimes noisy. For example, in (2) in Table 2, 'a problem' is extracted as a topic, despite being overly vague. Therefore, we use crowdsourcing to collect stance labels and additional topics from annotators.

3.1.2 Crowdsourcing

We use Amazon Mechanical Turk to collect crowdsourced annotations. We present each worker with a comment and first ask them to list topics related to the comment, to avoid biasing workers toward finding a stance on a topic not relevant to the comment. We then provide the worker with the automatically generated topic for the comment and ask for the stance, or, if the topic does not make sense, to correct it. Workers are asked to provide stance on a 5-point scale (see task snapshot in Appendix A.0.1) which we map to 3-point pro/con/neutral. Each topic-comment pair is annotated by three workers. We remove work by poor quality annotators, determined by manually examining the topics listed for a comment and using MACE (Hovy et al., 2013) on the stance labels. For all examples, we select the majority vote as the final label. When annotators correct the provided topic, we take the majority vote of stance labels on corrections to the same new topic.

Our resulting dataset includes annotations of three types (see Table 2): **Heur** stance labels on the heuristically extracted topics provided to annotators (see (1) and (5)), **Corr** labels on corrected topics provided by annotators (see (3)), **List** labels on the topics listed by annotators as related to the comment (see (2) and (4)). We include the noisy type **List**, because we find that the stance provided by the annotator for the given topic also generally applies to the topics the annotator listed and these provide additional learning signal (see A.0.2 for full examples). We clean the final topics to remove noise by lemmatizing and removing stopwords using NLTK[2] and running automatic spelling correction[3].

3.1.3 Neutral Examples

Every comment will not convey a stance on every topic. Therefore, it is important to be able to detect when the stance is, in fact, neutral or neither. Since the original ARC data does not include neutral stance, our crowdsourced annotations yield only 350 neutral examples. Therefore, we add additional examples to the neutral class that are *neither* pro nor con. These examples are constructed automatically by permuting existing topics and comments.

We convert each entry of type **Heur** or **Corr** in the dataset to a neutral example for a different topic with probability 0.5. We do not convert type noisy **List** entries into neither examples. If a comment d_i and topic t_i pair is to be converted, we randomly sample a new topic $\tilde{t_i}$ for the comment from topics in the dataset. To ensure $\tilde{t_i}$ is semantically distinct from t_i, we check that $\tilde{t_i}$ does not overlap lexically with t_i or any of the topics provided to or by annotators for d_i (see (6) Table 2).

3.2 Data Analysis

The final statistics of our data are shown in Table 3. We use Krippendorff α to compute interannotator agreement, yielding 0.427, and percentage agreement (75%), which indicate stronger than random agreement. We compute agreement only on the annotated stance labels for the topic provided, since few topic corrections result in identical new topics. We see that while the task is challenging, annotators agree the majority of the time.

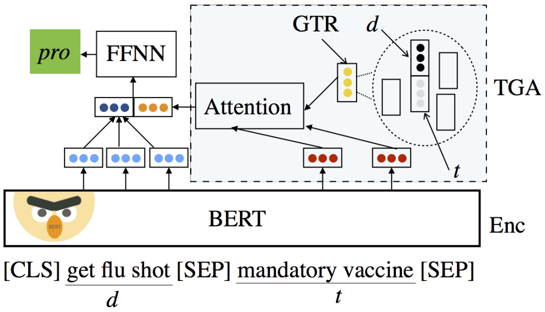

Figure 1: Architecture of TGA Net. Enc indicates contextual conditional encoding (§4.2), GTR indicates Generalized Topic Representation (§4.3), TGA indicates Topic-grouped Attention (4.4).

We observe the most common cause of disagreement is annotator inference about stance relative to an overly general or semi-relevant topic. For example, annotators are inclined to select a stance for the provided topic (correcting the topic only 30% of the time), even when it does not make sense or is too general (e.g., 'everyone' is overly general).

The inferences and corrections by annotators provide a wide range of stance labels for each comment. For example, for a single comment our annotations may include multiple examples, each with different topic and potentially different stance labels, all correct (see (3) and (4) Table 2). That is, our annotations capture semantic and stance complexity in the comments and are not limited to a single topic per text. This increases the difficulty of predicting and annotating stance for this data.

In addition to stance complexity, the annotations provide great variety in how topics are expressed, with a median of 4 unique topics per comment. While many of these are slight variations on the same idea (e.g., 'prison privatization' vs. 'privatization'), this more accurately captures how humans might discuss a topic, compared to restricting themselves to a single phrase (e.g., 'gun control'). The variety of topics per comment makes our dataset challenging and the large number of topics with few examples each (the median number of examples per topic is 1 and the mean is 2.4) makes our dataset well suited to developing models for zero-shot and few-shot stance detection.

4 Methods

We develop **T**opic-**G**rouped **A**ttention (TGA) Net: a model to implicitly construct and use relationships between the training and evaluation topics without supervision. The model consists of a contextual conditional encoding layer (§4.2), followed by topic-grouped attention (§4.4) using generalized topic representations (§4.3) and a feed-forward neural network (see Figure 1).

4.1 Definitions

Let $D = \{x_i = (d_i, t_i, y_i)\}_{i=1}^{N}$ be a dataset with N examples, each consisting of a document d_i (a comment), a topic t_i, and a stance label y_i. Recall that for each unique document d, the data may contain examples with different topics. For example (1) and (2) (Table 2) have the same document but different topics. The task is to predict a stance label $\hat{y} \in \{\text{pro, con, neutral}\}$ for each x_i, based on the *topic-phrase* definition of stance (see §2).

4.2 Contextual Conditional Encoding

Since computing the stance of a document is dependent on the topic, prior methods for cross-target stance have found that bidirectional conditional encoding (conditioning the document representation on the topic) provides large improvements (Augenstein et al., 2016). However, prior work used static word embeddings and we want to take advantage of contextual emebddings. Therefore, we embed a document and topic jointly using BERT (Devlin et al., 2019). That is, we treat the document and topic as a sentence pair, and obtain two sequences of token embeddings $\bar{t} = t^{(1)}, \ldots, t^{(m)}$ for the topic t and $\bar{d} = d^{(1)}, \ldots, d^{(n)}$ for the document d. As a result, the text embeddings are implicitly conditioned on the topic, and vice versa.

4.3 Generalized Topic Representations (GTR)

For each example $x = (d, t, y)$ in the data, we compute a generalized topic representation r_{dt}: the centroid of the nearest cluster to x in euclidean space, after clustering the training data. We use hierarchical clustering on $v_{dt} = [v_d; v_t]$, a representation of the document d and text t, to obtain clusters. We use one $v_d \in \mathbb{R}^E$ and one $v_t \in \mathbb{R}^E$ (where E is the embedding dimension) for each unique document d and unique topic t.

To obtain v_d and v_t, we first embed the document and topic separately using BERT (i.e., [CLS] <text> [SEP] and [CLS] <topic> [SEP]) then compute a weighted average over the token embeddings $\bar{d}$ (and similarly $\bar{t}$). In this way, v_d (v_t) is independent of all topics (comments) and so v_d and v_t can share information across examples. That is, for examples $x_i, x_j, x_k \in D$ we may have that $d_i = d_j$ but $d_j \neq d_k$ and $t_j = t_k$ but $t_i \neq t_j$. The token embeddings are weighted in v_d by tf-idf, in order to downplay the impact of common content words (e.g., pronouns or adverbs) in the average. In v_t, the token embeddings are weighted uniformly.

	Train	Dev	Test
# Examples	13477	2062	3006
# Unique Comments	1845	682	786
# Few-shot Topics	638	114	159
# Zero-shot Topics	4003	383	600

Table 4: Data split statistics for VAST.

4.4 Topic-Grouped Attention

We use the generalized topic representation r_{dt} for example x to compute the similarity between t and other topics in the dataset. Using learned scaled dot-product attention (Vaswani et al., 2017), we compute similarity scores s_i and use these to weigh the importance of the current topic tokens $t^{(i)}$, obtaining a representation c_{dt} that captures the relationship between t and related topics and documents. That is, we compute

$$c_{dt} = \sum_i s_i t^{(i)}, \; s_i = \text{softmax}\Big(\lambda t^{(i)} \cdot (W_a r_{dt})\Big)$$

where $W_a \in \mathbb{R}^{E \times 2E}$ are learned parameters and $\lambda = 1/\sqrt{E}$ is the scaling value.

4.5 Label Prediction

To predict the stance label, we combine the output of our topic-grouped attention with the document token embeddings and pass the result through a feed-forward neural network to compute the output probabilities $p \in \mathbb{R}^3$. That is,

$$p = \text{softmax}(W_2(\tanh(W_1[\tilde{d}; c_{dt}] + b_1) + b_2))$$

where $\tilde{d} = \frac{1}{n}\sum_i d^{(i)}$ and $W_1 \in \mathbb{R}^{h \times 2E}, W_2 \in \mathbb{R}^{3 \times h}, b_1 \in \mathbb{R}^h, b_2 \in \mathbb{R}^3$ are learned parameters and h is the hidden size of the network. We minimize cross-entropy loss.

5 Experiments

5.1 Data

We split VAST such that all examples $x_i = (d_i, t_i, y_i)$ where $d_i = d$, for a particular document d, are in exactly one partition. That is, we randomly assign each unique d to one partition of the data. We assign 70% of unique documents to the training set and split the remainder evenly between development and test. In the development and test sets we only include examples of types *Heur* and *Corr* (we exclude all noisy *List* examples).

We create separate zero-shot and few-shot development and test sets. The zero-shot development and test sets consist of topics (and documents) that are not in the training set. The few-shot development and test sets consist of topics in the training set (see Table 4). For example, there are 600 unique topics in the zero-shot test set (*none* of which are in the training set) and 159 unique topics in the few-shot test set (which *are* in the training set). This design ensures that there is no overlap of topics between the training set and the zero-shot development and test sets both for pro/con and neutral examples. We preprocess the data by tokenizing and removing stopwords and punctuation using NLTK.

Due to the linguistic variation in the topic expressions (§3.2), we examine the prevalence of lexically similar topics, *LexSimTopics*, (e.g., 'taxation policy' vs. 'tax policy') between the training and zero-shot test sets. Specifically, we represent each topic in the zero-shot test set and the training set using pre-trained GloVe (Pennington et al., 2014) word embeddings. Then, test topic $t_i^{(t)}$ is a *LexSimTopic* if there is at least one training topic $t_j^{(r)}$ such that $\text{cosine\_sim}(t_i^{(t)}, t_j^{(r)}) \geq \theta$ for fixed $\theta \in \mathbb{R}$. We manually examine a random sample of zero-shot dev topics to determine an appropriate threshold θ. Using the manually determined threshold $\theta = 0.9$, we find that only 16% (96 unique topics) of the topics in the entire zero-shot test set are *LexSimTopics*.

5.2 Baselines and Models

We experiment with the following models:

- `CMaj`: the majority class computed from each cluster in the training data.
- `BoWV`: we construct separate BoW vectors for the text and topic and pass their concatenation to a logistic regression classifier.
- `C-FFNN`: a feed-forward network trained on the generalized topic representations.
- `BiCond`: a model for cross-target stance that uses bidirectional encoding, whereby the topic is encoded using a BiLSTM as h_t and the text is then encoded using a second BiLSTM conditioned on h_t (Augenstein et al., 2016). This model uses fixed pre-trained word embeddings. A weakly supervised version of BiCond is currently state-of-the-art on cross-target TwitterStance.
- `CrossNet`: a model for cross-target stance that encodes the text and topic using the same bidirectional encoding as BiCond and adds an aspect-specific attention layer before classification (Xu et al., 2018). Cross-Net improves over BiCond in many cross-target settings.
- `BERT-sep`: encodes the text and topic separately, using BERT, and then classification with a two-layer feed-forward neural network.
- `BERT-joint`: contextual conditional encoding followed by a two-layer feed-forward neural network.
- `TGA Net`: our model using contextual conditional encoding and topic-grouped attention.

5.2.1 Hyperparameters

We tune all models using uniform hyperparameter sampling on the development set. All models are optimized using Adam (Kingma and Ba, 2015), maximum text length of 200 tokens (since $< 5\%$ of documents are longer) and maximum topic length of 5 tokens. Excess tokens are discarded

For `BoWV` we use all topic words and a comment vocabulary of $10,000$ words. We optimize using using L-BFGS and L2 penalty. For `BiCond` and `Cross-Net` we use fixed pre-trained 100 dimensional GloVe (Pennington et al., 2014) embeddings and train for 50 epochs with early stopping on the development set. For BERT-based models, we fix BERT, train for 20 epochs with early stopping and use a learning rate of 0.001. We include complete hyperparameter information in Appendix A.1.1.

We cluster generalized topic representations using Ward hierarchical clustering (Ward, 1963), which minimizes the sum of squared distances within a cluster while allowing for variable sized clusters. To select the optimal number of clusters k, we randomly sample 20 values for k in the range $[50, 300]$ and minimize the sum of squared distances for cluster assignments in the development set. We select 197 as the optimal k.

5.3 Results

We evaluate our models using macro-average F1 calculated on three subsets of VAST (see Table 5): all topics, topics only in the test data (zero-shot), and topics in the train or development sets (few-shot). We do this because we want models that perform well on both zero-shot topics and training/development topics.

	F1 All			F1 Zero-Shot			F1 Few-Shot		
	pro	con	all	pro	con	all	pro	con	all
`CMaj`	.382	.441	.274	.389	.469	.286	.375	.413	.263
`BoWV`	.457	.402	.372	.429	.409	.349	.486	.395	.393
`C-FFNN`	.410	.434	.300	.408	.463	.417	.413	.405	.282
`BiCond`	.469	.470	.415	.446	.474	.428	.489	.466	.400
`Cross-Net`	.486	.471	.455	.462	.434	.434	.508	.505	.474
`BERT-sep`	.4734	.522	.5014	.414	.506	.454	.524	.539	.544
`BERT-joint`	.545	**.591**	.653	.546	.584	.661	.544	**.597**	.646
`TGA Net`	**.573***	.590	**.665**	**.554**	**.585**	**.666**	**.589***	.595	**.663**

Table 5: Macro-averaged F1 on the test set. * indicates significance of `TGA Net` over `BERT-joint`, $p < 0.05$.

Test Topic	**Cluster Topics**
drug addicts	war drug, cannabis, legalization, marijuana popularity, social effect, pot, colorado, american lower class, gateway drug, addiction, smoking marijauana, social drug
oil drilling	natural resource, international cooperation, renewable energy, alternative energy, petroleum age, electric car, solar use, offshore drilling, offshore exploration, planet
free college education	tax break home schooling, public school system, education tax, funding education, public service, school tax, homeschool tax credit, community, home schooling parent

Table 6: Topics from test examples and training examples in their assigned cluster.

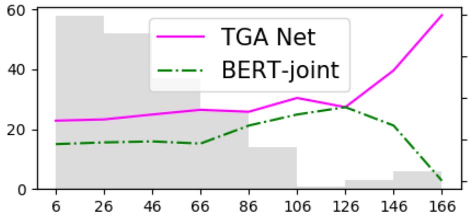

Figure 2: Percentage (right y-axis) each model is best on the test set as a function of the number of *unique topics in each cluster*. Histogram (left y-axis) of unique topics shown in gray.

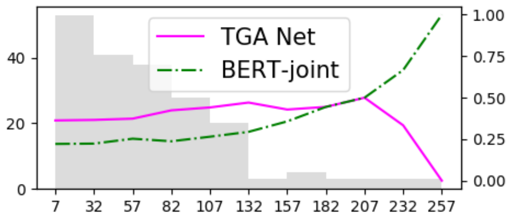

Figure 3: Percentage (right y-axis) each model is best on the test set as a function of the number of *examples per cluster*. Histogram of cluster sizes (left y-axis) shown in gray.

We first observe that `CMaj` and `BoWV` are strong baselines for zero-shot topics. Next, we observe that `BiCond` and `Cross-Net` both perform poorly on our data. Although these were designed for cross-target stance, a more limited version of zero-shot stance, they suffer in their ability to generalize across a large number of targets when few examples are available for each.

We see that while `TGA Net` and `BERT-joint` are statistically indistinguishable on all topics, the topic-grouped attention provides a statistically significant improvement for few-shot learning on 'pro' examples (with $p < 0.05$). Note that conditional encoding is a crucial part of the model, as this provides a large improvement over embedding the comment and topic separately (`BERT-sep`).

Additionally, we compare the performance of `TGA Net` and `BERT-joint` on both zero-shot *LexSimTopics* and non-*LexSimTopics*. We find that while both models exhibit higher performance on zero-shot *LexSimTopics* (.70 and .72 F1 respectively), these topics are such a small fraction of the zero-shot test topics that zero-shot evaluation primarily reflects model performance on the non-*LexSimTopics*. Additionally, the difference between performance on zero-shot *LexSimTopics* and non-*LexSimTopics* is less for `TGA Net` (only 0.04 F1) than for `BERT-joint` (0.06 F1), showing our model is better able to generalize to lexically distinct topics.

To better understand the effect of topic-grouped attention, we examine the clusters generated in §4.3 (see Table 6). The clusters range in size from 7 to 257 examples (median 62) with the number

		Imp	*mlT*	*mlS*	*Qte*	*Sarc*
BERT	I	.600	.610	.541	.625	.587
joint	O	.710	.748	.713	.657	.662
TGA	I	.623	.624	.547	.661	.637
Net	O	.713	.752	.725	.663	.667

Table 7: Accuracy on varying phenomena in the test set. I indicates examples with the phenomenon, O indicates examples without.

of unique topics per cluster ranging from 6 to 166 (median 43). We see that the generalized representations are able to capture relationships between zero-shot test topics and training topics.

We also evaluate the percentage of times each of our best performing models (`BERT-joint` and `TGA Net`) is the best performing model on a cluster as a function of the number of unique topics (Figure 2) and cluster size (Figure 3). To smooth outliers, we first bin the cluster statistic and calculate each percent for clusters with at least that value (e.g., clusters with at least 82 examples). We see that as the number of topics per cluster increases, `TGA Net` increasingly outperforms `BERT-joint`. This shows that the model is able to benefit from diverse numbers of topics being represented in the same manner. On the other hand, when the number of examples per cluster becomes too large ($>$ 182), `TGA NET`'s performance suffers. This suggests that when cluster size is very large, the stance signal within a cluster becomes too diverse for topic-grouped attention to use.

5.4 Error Analysis

5.4.1 Challenging Phenomena

We examine the performance of `TGA Net` and `BERT-joint` on five challenging phenomena in the data: **i)** *Imp* – the topic phrase is not contained in the document and the label is not neutral (1231 cases), **ii)** *mlT* – a document is in examples with multiple topics (1802 cases), **iii)** *mlS* – a document is in examples with different, non-neutral, stance labels (as in (3) and (4) Table 2) (952 cases), **iv)** *Qte* – a document with quotations, and **v)** *Sarc* – sarcasm, as annotated by Habernal et al. (2018).

We choose these phenomena to cover a range of challenges for the model. First, *Imp* examples require the model to recognize concepts related to the unmentioned topic in the document (e.g., recognizing that computers are related to the topic '3d printing'). Second, to do well on *mlT* and *mlS* examples, the model must learn more than global topic-to-stance or document-to-stance patterns (e.g., it cannot predict a single stance label for all examples with a particular document). Finally, quotes are challenging because they may repeat text with the opposite stance to what the author expresses themselves (see Appendix Table 20 for examples).

Overall, we find the `TGA Net` performs better on these difficult phenomena (see Table 7). These phenomena are challenging for both models, as indicated by the generally lower performance on examples with the phenomena compared to those without, with the *mlS* especially difficult. We observe that `TGA Net` has particularly large improvements on the rhetorical devices (*Qte* and *Sarc*), suggesting that topic-grouped attention allows the model to learn more complex semantic information in the documents.

5.4.2 Stance and Sentiment

Finally, we investigate the connection between stance and sentiment vocabulary. Specifically, we use the MPQA sentiment lexicon (Wilson et al., 2017) to identify positive and negative sentiment words in texts. We observe that in the test set, the majority (80%) of pro examples have more positive than negative sentiment words, while only 41% of con examples have more negative than positive sentiment words. That is, con stance is often expressed using positive sentiment words but pro stance is rarely expressed using negative sentiment words and therefore there is not a direct mapping between sentiment and stance.

We use $M+$ to denote majority positive sentiment polarity and similarity for $M-$ and negative. We find that on pro examples with $M-$, `TGA Net` outperforms `BERT-joint`, while the reverse is true for con examples with $M+$. For both stance labels and models, performance increases when the majority sentiment polarity agrees with the stance label ($M+$ for pro, $M-$ for con). Therefore, we investigate how susceptible both models are to changes in sentiment.

To test model susceptibility to sentiment polarity, we generate swapped examples. For examples with majority polarity p, we randomly replace sentiment words with a WordNet[4] synonym of opposite polarity until the majority polarity for the example is $-p$ (see Table 8). We then evaluate our models on

	$M-$	.79	.80
	$M+ \to M-$ ($\uparrow$)	.76→.80	.70→.74
	$M- \to M+$ ($\downarrow$)	.75→.71	.75→.74

Table 9: F1 on the test set for examples with a majority sentiment polarity (M) and conversion between sentiment polarities (e.g., $M+ \to M-$). The direction the score a sentiment-susceptible model is expected to change is indicated with $\uparrow$ or $\downarrow$.

the examples before and after the replacements.

When examples are changed from the opposite polarity ($- \to +$ for pro, $+ \to -$ for con), a model that relies too heavily on sentiment should increase performance. Conversely, when converting *to* the opposite polarity ($+ \to -$ for pro, $- \to +$ for con) an overly reliant model's performance should decrease. Although the examples contain noise, we find that both models are reliant on sentiment cues, particularly when adding negative sentiment words to a pro stance text. This suggests the models are learning strong associations between negative sentiment and con stance.

Our results also show `TGA Net` is less susceptible to replacements than `BERT-joint`. On pro $- \to +$, performance actually decreases by one point (`BERT-joint` increases by three points) and on con $- \to +$ performance only decreases by one point (compared to four for `BERT-joint`). `TGA Net` is better able to distinguish when positive sentiment words are actually indicative of a pro stance, which may contribute to its significantly higher performance on pro. Overall, `TGA Net` relies less on sentiment cues than other models.

6 Conclusion

We find that our model `TGA Net`, which uses generalized topic representations to implicitly capture relationships between topics, performs significantly better than BERT for stance detection on pro labels, and performs similarly on other labels. In addition, extensive analysis shows our model provides substantial improvement on a number of challenging phenomena (e.g., sarcasm) and is less reliant on sentiment cues that tend to mislead the models. Our models are evaluated on a new dataset, VAST, that has a large number of topics with wide linguistic variation and that we create and make available.

In future work we plan to investigate additional methods to represent and use generalized topic information, such as topic modeling. In addition, we will study more explicitly how to decouple stance models from sentiment, and how to improve performance further on difficult phenomena.

A Appendices

A.0.1 Crowdsourcing

We show a snap shot of one 'HIT' of the data annotation task in Figure 4. We paid annotators \$0.13 per HIT. We had a total of 696, of which we removed 183 as a result of quality control.

A.0.2 Data

We show complete examples from the dataset in Table 10. These show the topics extracted from the original ARC stance position, potential annotations and corrections, and the topics listed by annotators as relevant to each comment.

In (a), (d), (i), (j), and (l) the topic make sense to take a position on (based on the comment) and annotators do not correct the topics and provide a stance label for that topic directly. In contrast, the annotators correct the provided topics in (b), (c), (e), (f), (g), (h), and (k). The corrections are because the topic is not possible to take a position on (e.g., 'trouble'), or not specific enough (e.g, 'california', 'a tax break'). In one instance, we can see that one annotator chose to correct the topic (k) whereas another annotator for the same topic and comment chose not to (j). This shows how complex the process of stance annotation is.

We also can see from the examples the variations in how similar topics are expressed (e.g., 'public education' vs. 'public schools') and the relationship between the stance label assigned for the extracted (or corrected topic) and the listed topic. In most instances, the same label applies to the listed topics. However, we show two instances where this is not the case: (d) – the comment actually supports 'public schools' and (i) – the comment is actually against 'airline'). This shows that this type of example (ListTopic, see §3.1.2), although somewhat noisy, is generally correctly labeled using the provided annotations.

We also show neutral examples from the dataset in Table 11. Examples 1 and 2 were constructed using the process described in §3.1.3. We can see that the new topics are distinct from the semantic content of the comment. Example 3 shows an annotator provided neutral label since the comment is neither in support of or against the topic 'women's colleges'. This type of neutral example is less common than the other (in 1 and 2) and is harder, since the comment *is* semantically related to the topic.

A.1 Experiments

A.1.1 Hyperparameters

All neural models are implemented in Pytorch[5] and tuned on the developement. Our logistic regression model is implemented with scikit-learn[6]. The number of trials and training time are shown in Table 12. Hyperparameters are selected through uniform sampling. We also show the hyperparameter search space and best configuration for `C-FFNN` (Table 13), `BiCond` (Table 14), `Cross-Net` (Table 15), `BERT-sep` (Table 16), `BERT-joint` (Table 17) and `TGA Net` (Table 18). We use one TITAN Xp GPU.

We calculate expected validation performance (Dodge et al., 2019) for F1 in all three cases and additionally show the performance of the best model on the development set (Tale 19). Models are tuned on the development set and we use macro-averaged F1 of all classes for zero-shot examples to select the best hyperparameter configuration for each model. We use the scikit-learn implementation of F1. We see that the improvement of `TGA Net` over `BERT-joint` is high on the development set.

A.1.2 Results

A.1.3 Error Analysis

We investigate the performance of our two best models (`TGA Net` and `BERT-joint`) on five challenging phenomena, as discussed in §5.4.1. The phenomena are:

- Implicit (*Imp*): the topic is not contained in the document.
- Multiple Topics (*mlT*): document has more than one topic.
- Multiple Stance (*mlS*): a document has examples with different, non-neutral, stance labels.
- Quote (*Qte*): the document contains quotations.
- Sarcasm (*Sarc*): the document contains sarcasm, as annotated by Habernal et al. (2018).

We show examples of each of these phenomena in Table 20.

A.1.4 Stance and Sentiment

To construct examples with swapped sentiment words we use the MPQA lexicon (Wilson et al.,

---

[5] `https://pytorch.org/`

[6] `https://scikit-learn.org/stable/`

2017) for sentiment words. We use WordNet to select synonyms with opposite polarity, ignoring word sense and part of speech. We show examples from each set type of swap, $+ \rightarrow -$ (Table 22) and $- \rightarrow +$ (Table 21). In total there are 1158 positive sentiment words and 1727 negative sentiment words from the lexicon in our data. Of these, 218 positive words have synonyms with negative sentiment, and 224 negative words have synonyms with positive sentiment.

Abstract

Sentiment classification on tweets often needs to deal with the problems of under-specificity, noise, and multilingual content. This study proposes a heterogeneous multi-layer network-based representation of tweets to generate multiple representations of a tweet and address the above issues. The generated representations are further ensembled and classified using a neural-based early fusion approach. Further, we propose a centrality aware random-walk for node embedding and tweet representations suitable for the multi-layer network. From various experimental analysis, it is evident that the proposed method can address the problem of under-specificity, noisy text, and multilingual content present in a tweet and provides better classification performance than the text-based counterparts. Further, the proposed centrality aware based random walk provides better representations than unbiased and other biased counterparts.

1 Introduction

With the growing popularity of Twitter, sentiment analysis of tweets has drawn the attention of several researchers from both academia and industry in recent times. Unlike other regular texts, sentiment analysis on Twitter text poses plenty of challenges because of various characteristics such as (i) under-specificity due to text limits, (ii) free-form writing such as the presence of user-defined hashtags, mentions, emoticons, (iii) noisy texts due to the presence of short-form, long-form, multilingual, transliterated text, misspelling. Researchers try to address these problems by adopting various methods like task-specific representation learning (Singh et al., 2020; Pham and Le, 2018; Fu et al., 2018; Tang et al., 2016; Kim, 2014), incorporating additional information such as hashtags (Alfina et al., 2017; Qadir and Riloff, 2014), relationship between users (Zhao et al., 2017), multi-source information (Zhou and Huang, 2017), ensembling (Al-Twairesh and Al-Negheimish, 2019; Araque et al., 2017; Wang et al., 2014), etc.

This paper proposes a novel approach to handle the above issues using a heterogeneous multi-layer network representation of a tweet. A multi-layer network is a network formulated by connecting different layers of networks. For example, a heterogeneous multi-layer network can be formed by connecting layers of networks of mentions, hashtags, and keywords. Multi-layer networks have shown to provide promising performance in other tasks like community detection and clustering (Hanteer and Rossi, 2019; Luo et al., 2020), node classification (Li et al., 2018; Zitnik and Leskovec, 2017; Ghorbani et al., 2019), representation learning in graphs (Cen et al., 2019; Zhang et al., 2018; Ni et al., 2018). A tweet or a collection of tweets can be represented by a multi-layer network. An advantage of using network-based representation is that a network can be expanded by adding nodes or shrunk by removing nodes. The motivations of using a multi-layer network in this paper are as follows. (i) The semantic relation between keywords, hashtags, and mentions can be captured by applying an effective network embedding method. (ii) The noise and under-specificity can be reduced by expanding the network with related nodes or by shrinking the network after removing the unrelated nodes. Further, the co-occurring keywords, hashtags, and mentions often share semantic relationships (Wang et al., 2016; Weston et al., 2014; Qadir and Riloff, 2013; Wang et al., 2011).

This paper has four major contributions. First, it transforms a tweet into a multi-layer network. Second, it proposes a centrality[1] aware random

---

*Equal contributions.

[1] Prominence of a node in a network

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8932–8946,
November 16–20, 2020.

walk over the multi-layer network. Third, it generates multiple representations of a tweet using the proposed centrality aware random walk and builds an early-fusion based neural sentiment classifier. Fourth, it also addresses under-specificity and noisy text for sentiment classification by expanding or shrinking the network representing the tweets. As such, sentiment classification is a domain-dependent task (Karamibekr and Ghorbani, 2012). Therefore, we evaluate the proposed method over datasets in different domains. From extensive experimental evaluations, the proposed method is found to outperform its counterparts in the majority of the cases. To the best of our knowledge, this study is the first of its kind to investigate sentiment classification task by transforming tweet into a heterogeneous multi-layer network.

The rest part of the paper is organized as follows. Section 2 presents the literature related to this study. Section 3 presents the proposed framework. The experimental setup is described in Section 4. The results and observations are analyzed in Section 5. Finally, Section 6 concludes the study of this paper.

2 Related studies

Sentiment analysis is an old research area. Initial work on sentiment classification can be traced back as early as 2000 (Turney, 2002; Pang et al., 2002; Turney and Littman, 2003). There have been several paradigm shifts in sentiment analysis methods from statistical methods (Turney, 2002; Pang et al., 2002; Turney and Littman, 2003) to rule-based (Prabowo and Thelwall, 2009), to lexicon-based (Taboada et al., 2011; Balamurali et al., 2011; Mohammad et al., 2009), to feature-based (Kouloumpis et al., 2011; Barbosa and Feng, 2010), to deep neural network (Kim, 2014; Severyn and Moschitti, 2015). Majority of the recent studies focus on the application of neural network models. Therefore, this section briefly reviews a few of the recent and related studies which have exploited graph and neural models.

Authors in (Violos et al., 2016) use a homogeneous network known as *word graph* to represent a document by connecting co-occurring words in the document. Three different networks are created for positive, negative, and neutral classes using the documents in respective classes. Using these networks, a document is represented by a three-dimensional vector defined by the three sentiment classes. The elements of the vector correspond to the similarity of the word graph of the document and the word graph of the respective sentiment class. The vector thus obtained is used for classifying the document. Similarly, authors in (Bijari et al., 2020) construct co-occurrence word-graph of a document collection and generate word embedding using Node2Vec (Grover and Leskovec, 2016). The embeddings thus obtained are used to represent words in the text and build a classifier using the Convolution Neural Network (CNN) model. Further, in the studies (Gui et al., 2017; Zhao et al., 2017), the advantages of exploiting the relationship between keywords, sentiment, products and users have also been evident in sentiment analysis.

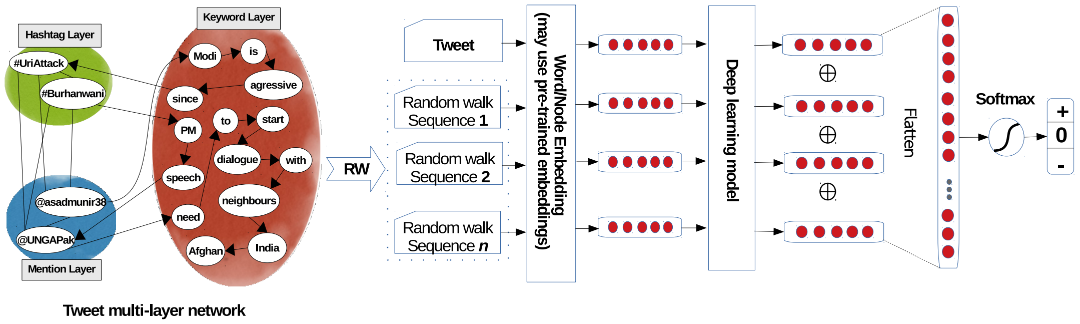
In recent times, deep learning based models are extensively used for sentiment classification. To mention few of them, authors in (Jianqiang et al., 2018; Dahou et al., 2016; Severyn and Moschitti, 2015; dos Santos and Gatti, 2014; Kim, 2014) use CNN, (Xu et al., 2019; Liu and Zhang, 2017) use Long Short Term Memory (LSTM), Bidirectional LSTM (Bi-LSTM), (Nguyen and Nguyen, 2018; Chen et al., 2017) use a combination of convolution and recurrent based neural network models. Further, studies (Al-Twairesh and Al-Negheimish, 2019; Araque et al., 2017) use neural ensemble models to combine different representation of text.

3 Proposed framework

As mentioned earlier, the proposed method has four distinct components; (i) representation of a tweet or collection of a tweet using a multi-layer network, (ii) centrality aware random walk over the multi-layer network, (iii) tweet classification using multiple representations generated from the multi-layer network of a tweet, and (iv) reduction of noise in a tweet by expanding or shrinking network. This section discusses the details of these components. Figure 1 shows a high-level schematic diagram of the proposed model using a heterogeneous multi-layer network.

3.1 Representation of tweets using multi-layer network

A L-layer network $\mathbf{G}$ is defined by $(\mathbf{V}, \mathbf{E}, \mathcal{L})$ where $\mathcal{L}$ denotes the set of layer indices $\{1, 2, ..., L\}$, $\mathbf{V} = \{\mathbf{V}^1 \cup \mathbf{V}^2 \cup ... \cup \mathbf{V}^L\}$, $\mathbf{V}^i$ denotes the set of vertices in layer i of the network, $\mathbf{E}$ denotes the set of edges. Considering three important components of a tweet, the proposed multi-layer network is formed with three layers



Tweet:*@asadmunir38 Modi is agressive since #UriAttack, #BurhanWani & PM speech @UNGAPak needs to start dialogue with neighbours India, Afghan*

Figure 1: Proposed heterogeneous multi-layer network based tweet sentiment classification framework

i.e., *hashtag, mention* and *keyword* as $\{H, M, K\}$. To capture both the co-occurrence and sequential characteristics of keywords, hashtags and mentions in a tweet, the proposed network consists of both directed and undirected edges. An edge $e_{x,y} \in \mathbf{E}$ is directed if x and y occur sequentially next to other in a tweet where, i) $x, y \in V^K$ or ii) $x \in V^K$ and $y \in \{V^H \cup V^M\}$ or iii) $x \in \{V^H \cup V^M\}$ and $y \in V^K$. Whereas, an edge $e_{x,y} \in \mathbf{E}$ is undirected if $x, y \in \{V^H \cup V^M\}$ co-occur in a tweet. An example of the proposed multi layer network for the tweet *"@asadmunir38 Modi is agressive since #UriAttack, #BurhanWani & PM speech @UNGAPak needs to start dialogue with neighbours India, Afghan"* is shown in Figure 1. Edge set $\mathbf{E} = \{\mathbf{A} \cup \mathbf{B}\}$ which comprises of a set of intra-layer adjacency matrices $\mathbf{A} = \{\mathbf{A}^1, \mathbf{A}^2, ..., \mathbf{A}^L\}$ with matrix $\mathbf{A}^i \in \mathcal{R}^{N^i \times N^i}$ in each layer i. A set of bipartite matrices $\mathbf{B}^{i,j} \in \mathcal{R}^{N^i \times N^j}$ represents cross-layer association between layer i and layer j. For our tweet multi-layer network, we have three layers $\mathbf{A} = \{\mathbf{A}^H, \mathbf{A}^M, \mathbf{A}^K\}$ and five types of bipartite associations $\mathbf{B} = \{\mathbf{B}^{HM}, \mathbf{B}^{MK}, \mathbf{B}^{HK}, \mathbf{B}^{KM}, \mathbf{B}^{KH}\}$. This kind of complex networks can also be viewed as one flattened representation in form of supra-adjacency matrix S, with total nodes $N = |\mathbf{V}^H| + |\mathbf{V}^M| + |\mathbf{V}^K|$,

$$\mathbf{S}_{N \times N} = \begin{bmatrix} \mathbf{A}^H & \mathbf{B}^{HM} & \mathbf{B}^{HK} \\ \mathbf{B}^{MH} & \mathbf{A}^M & \mathbf{B}^{MK} \\ \mathbf{B}^{KH} & \mathbf{B}^{KM} & \mathbf{A}^K \end{bmatrix} \quad (1)$$

The intra-layer associations $\mathbf{A}$s are on the main-diagonal, and the cross-layer connections $\mathbf{B}$ are on the off-diagonal elements of $\mathbf{S}$. Further, $\mathbf{A}^K, \mathbf{B}^{HK}, \mathbf{B}^{KH}, \mathbf{B}^{MK}, \mathbf{B}^{KM}$ are asymmetric matrices and other matrices of $\mathbf{S}$ are symmetric. A tweet or a collection of tweets can be represented as a multi-layer network, as discussed above.

3.2 Centrality aware random-walk with restart for heterogeneous multi-layer network

To generate random walk sequences from the proposed multi-layer tweet network, we extend the random walk followed in PageRank (Brin and Page, 1998) algorithm. Given a row stochastic adjacency matrix $\mathbf{A}$ of a network, the PageRank of the nodes in the network can be defined as the following vector.

$$\vec{\pi}_{t+1} = (1 - \delta)\mathbf{A}\vec{\pi}_t + \delta\vec{\pi}_0 \quad (2)$$

where $\vec{\pi}_t$ is the stationary probability distribution vector that depicts the probability with which a random walker would stay in a particular node at time t. The restart probability $\delta \in [0, 1]$ denotes the probability of jumping to a random node and $\vec{\pi}_0$ is the initial stationary probability vector.

As in (Li and Patra, 2010), the above random-walk can be extended to our tweet multi-layer heterogeneous network in the following manner. If $\lambda \in (0, 1)$ is the probability that a random-walker jumps to a different layer while surfing, in presence of L number of layers and considering jumping to any of the remaining layers is equiprobable, the transition probability $\mathbf{M}$ aka column-normalized supra-adjacency matrix $\mathbf{S}$ in Equation 1, is modified as,

$$\mathbf{M} = \begin{bmatrix} (1-\lambda)A^H & \frac{\lambda}{L-1}B^{HM} & \frac{\lambda}{L-1}B^{HK} \\ \frac{\lambda}{L-1}B^{MH} & (1-\lambda)A^M & \frac{\lambda}{L-1}B^{MK} \\ \frac{\lambda}{L-1}B^{KH} & \frac{\lambda}{L-1}B^{KM} & (1-\lambda)A^K \end{bmatrix} \quad (3)$$

That is, for a node, if its bipartite association exists, a random-surfer can stay in the same layer with probability $(1 - \lambda)$ or transit to a different layer with probability $(\frac{\lambda}{L-1})$. Now, Equation 2 can be re-written as follows,

$$\vec{\pi}_{t+1} = (1 - \delta)\mathbf{M}\vec{\pi}_t + \delta\vec{\pi}_{rs} \quad (4)$$

where $\vec{\pi}_{rs} = \begin{bmatrix} \eta_H.\vec{\pi}_0^H \\ \eta_M.\vec{\pi}_0^M \\ \eta_K.\vec{\pi}_0^K \end{bmatrix}$, η_i denotes the importance of layer i, $\vec{\pi}_0^i$ denotes the initial stationary distribution of nodes in layer i and $\sum_{i \in \{H,M,K\}} \eta_i = 1$. And, $\vec{\pi}_t \in \mathcal{R}^{(N^H+N^M+N^K)}$ is the stationary probability distribution of a random surfer on the heterogeneous multi-layer network at time t.

In this study, we propose to personalize the above PageRank algorithm using the global importance of nodes in the proposed heterogeneous multi-layer network. In Equation 4, $\vec{\pi}_{rs}$ the restart probability vector is interpreted as layer importance weighted over the centrality based initial stationary probabilities of nodes. This interpretation needs not only the node centrality scores but also the layer importances. MultiRank (Rahmede et al., 2018), a centrality estimate for multiplex networks[2] formulated using a modified version of PageRank algorithm, can estimate both the node centrality scores as well as the layer influences. MultiRank uses a layer-influence weighted aggregated adjacency matrix and a weighted bipartite matrix that relates nodes with layers to determine the node and layer centrality scores simultaneously. We specifically change the definition of these two matrices to customize the MultiRank algorithm for estimating the centrality scores over the heterogeneous multi-layer network representation of tweets. As we calculate the centrality scores, we modify $\vec{\pi}_{rs}$ of Equation 4 by replacing each η_i with respective influence score of layer i and each initial stationary vector $\vec{\pi}_0^i$ with node centrality scores in layer i.

In the customized MultiRank algorithm, we have tuned free-parameters (as described in the original paper) while calculating the centrality scores – i) to suppress or enhance the contribution of low-centrality nodes, ii) to take into account the elite layers that contain a few highly central nodes, iii) to or not to normalize layer influences by weighted layer in-strength. We have tuned the restart parameter in MultiRank and multi-layer random walks in the range $\in [0.5, 0.85]$. In this study, the MultiRank algorithm and multi-layer random walks gave the best performance by setting the restart parameter to 0.5 and 0.85, respectively. Furthermore, the average number of tokens per tweet present in our training dataset is 29, so we have hypothetically set the walk-length at 30. We set the number of walks at 10. All the free parameters are tuned based on end-task performance.

Node embedding methods
FastText Embedding (FT) (Bojanowski et al., 2017)
Multi-View Embedding (MVE) (Qu et al., 2017)

Table 1: Different embedding and neural methods

3.3 Classification of tweets represented with a multi-layer network

Let G_i be the multi-layer network representing a tweet T_i. Over this network, we generate n number of node sequences $\mathcal{S} = \{\mathcal{S}_1, \mathcal{S}_2, ..., \mathcal{S}_n\}$ by using the above proposed random walk. Each node sequence is maintained to have a length of m nodes. With n number of random sequences and the original tweet, we have $(n+1)$ sentences to represent the tweet T_i. Each word in these sentences can be represented using a vector obtained from an appropriate embedding method. This paper has considered different embedding methods, as listed in Table 1, trained over a large collection of tweets.

For each node sequence $\mathcal{S}_i$, we apply a neural model (Bi-LSTM (Chen et al., 2017) and CNN (Kim, 2014)) to generate a representation of the sequence $\mathcal{S}_i$. The last hidden state output obtained after passing the node sequences to Bi-LSTM represents the sequence $\mathcal{S}_i$. While, the vector obtained after applying the pooling step in CNN represents the sequence $\mathcal{S}_i$. Thus, we obtained $(n+1)$ vectors for each tweet. We concatenate these $(n+1)$ vectors and feed it to a feed-forward dense layer with three neurons (each for positive, negative, and neutral) and classify the sentiment of the tweet using softmax activation function in the output layer as shown in Figure 1. We use Keras[3] deep learning framework for building our proposed model.

We calculate the error loss (Δ) for the classifier using the well-known cross-entropy loss as,

$$\Delta = -\frac{1}{l}\sum_{i=1}^{l}\sum_{c}\mathbf{t}_{ic}log(s_{ic}) \qquad (5)$$

---

[2] Multiplex network (Kivelä et al., 2014) is a special case of a multi-layer network that has the same set of nodes exhibiting distinct relations in different layers.

[3] `https://keras.io`

where c is the number of sentiment classes, $\mathbf{t}_{ic}$ is the c^{th} ground truth class for the tweet, *l* is the total number of training samples, and $\mathbf{s}_{ic}$ is the predicted probability on sample i for the c^{th} class.

3.4 Network expansion and shrinking

One of the motivations of using the multi-layer network for representing a tweet lies in its flexibility to expand or shrink the network. Given a set of existing nodes in a tweet-network as query nodes, the idea is to identify the most related nodes or most noisy nodes by exploiting a multi-layer network of a global tweet collection. We consider the most central and most similar neighboring nodes of the query nodes as potential expansion candidates. To reduce the search space, we first select the top *k* query nodes ranked by the nodes' centrality scores in the tweet network view. The centrality scores of the nodes are calculated from the whole tweets collection. We then find neighbors of the selected nodes and ranked them using a weighted combination of similarity and centrality score using the scoring function defined below: $Score(v) = \sum_{u \in N_v} \alpha.sim(v,u) + (1-\alpha).centrality(u)$ where N_v denotes neighbouring nodes of v, $sim(v,u)$ denotes cosine similarity using node embeddings of v and u, and $centrality(u)$ denotes centrality score of node u in global network. In this study, we take equal weights of cosine and centrality score by setting $\alpha = 0.5$. Top neighbouring nodes are selected using the above scoring function and added to the network in their respective layers using the edge policy discussed in Section 3.1.

The above node expansion method finds new nodes having semantic relation with the query nodes. However, for the sentiment analysis task, we are interested in adding only sentiment bearing nodes by selecting only those nodes having the dominant sentiment class among the selected nodes for expansion. While, the rest of the nodes with less dominating sentiment classes are removed from the tweet network. The Sentiment Hashtag Embedding (SHE) method proposed in (Singh et al., 2020) is used to estimate the sentiment orientation of a node. We have used the same experimental setup as described in the literature.

Heterogeneous Multi-layer Tweet Network			
Relation	**#Nodes**	**#Edges***	**Edge-type**
Hashtag-Hashtag, A^H	3552	10776	Undirected

Table 2: Statistical characteristics of the dataset

4 Experimental Setup

4.1 Dataset

This paper considers a locally annotated dataset named as *Societal*. We have collected $50,300$ tweets using Twitter Streaming API[4] over four events that happened in India during August-December 2016, namely *Uri Attack, Surgical Strike, GST Amendment Bill, and Demonetization*. Two annotators with strong command on English and Hindi are engaged to annotate the tweets with *positive, negative,* and *neutral* sentiments. We have selected $42,422$ tweets where the two annotators have agreed on the same sentiment, which is of 85% agreement having 82.35 Kappa coefficient scores. The majority of the disagreements among the annotators are on the tweets with stance and sarcastic natures. A similar observation is also reported in (Karamibekr and Ghorbani, 2012). The `Societal` dataset contains 18% non-English tweets (i.e., Hindi and code-mix with English), of which $1,626$ code-mix tweets and $1,505$ tweets with less than five keywords are kept unseen for evaluation of our proposed model. Meanwhile, the hashtags and mentions cover 11% and 15% of the total $39,428$ unique vocabulary of the `Societal` dataset. This dataset is used to build sentiment classifiers and construct a multi-layer network to generate node embeddings. Details of the dataset is shown in Table 2.

4.2 Embedding method

We investigate the efficacy of our proposed multi-layer network using four different types of node embedding methods namely Multiplex Network Embedding (MNE) (Zhang et al., 2018), Multi-View Embedding (MVE) (Qu et al., 2017), FastText (FT) (Bojanowski et al., 2017), and Sentiment Hashtag Embedding (SHE) (Singh et al., 2020)

Table 3: Performance of sentiment classifiers across different embedding and representations. Blue: Embedding method that performs best for each tweet representations. Red: Best performing tweet representation for each embedding models. Purple: Best performing classifier across different representation of tweet and embedding models. **Purple bold**: Overall best.

(listed in Table 1). These embedding methods need a collection of node sequences. This study represents the tweet corpus into an expanded multi-layer network by combining the whole tweet networks to generate node sequences via a random walk method. For experimental comparison, we investigate three random walk methods to generate the node sequences, namely *Unbiased* random walk used in MNE, biased random walk used in Node2Vec (*N2V*) (Grover and Leskovec, 2016) and the proposed centrality aware *Biased* random walk. Moreover, to investigate the efficacy of our proposed random walk (RW), we modeled the generated *Biased* RW sequences using the FastText embedding model – which we refer to as *Biased* FT (BFT) in Table 3.

4.3 Selection of n random walks

A random walker can generate various node sequences starting from a node in the given network. However, all of the sequences are not useful. To identify the node sequences of our interest, we consider a simple second-order Markov chain based language model (Lafferty and Zhai, 2001) by calculating the probability of generating a node sequence given a tweet network. This study considers the top three random-walk sequences.[5]

5 Results and observations

In Table 3, we show the performance of two sentiment classifiers CNN (Nguyen and Nguyen, 2018) and Bi-LSTM (Xu et al., 2019) in terms of accuracy and F-Macro scores over the *Societal* dataset using 10-fold cross validation approach for four embedding models of our choice namely Multiplex Network Embedding (MNE) (Zhang et al., 2018), Multi-View Embedding (MVE) (Qu et al., 2017), FastText (FT) (Bojanowski et al., 2017), and Sentiment Hashtag Embedding (SHE) (Singh et al., 2020). We consider the work of (Nguyen and Nguyen, 2018; Xu et al., 2019) as the baseline models for text-based sentiment classification of tweet. Along the rows of Table 3, we have three groups namely [A], [B] and [C] pertaining to the three types of tweet-network representations, where we compare three different types of Random-Walks (RWs) – *Unbiased*, Node2Vec (*N2V*) and the proposed *Biased* RW to generate node sequences required as inputs for the above embedding methods. From the table, we can see that the network representation of tweets helps the sentiment classification task. Though the tweet-text only classification (in the first row) is hard to beat using the multi-layer network representation of a tweet without node expansion, but for Bi-LSTM based classifier, the classifiers using *Biased* RW in the group [A] beats text only prediction in 75% of the cases with a maximum of 1.13% difference in terms of F-macro using *Biased* FT embeddings. For CNN classifier, the *Biased* RW in [A] beats original tweet prediction using SHE embeddings. Although the classifiers in [B] gave a competitive performance as compared to text-only classifiers in [A], sentiment polarized node expansion (SNE) method in [C] beats tweet-text based prediction by a margin of 1.4%, and 1.9% (on average) for CNN and Bi-LSTM classifiers respectively – indicating the network representation of tweets, especially when augmented with informative nodes, are useful and complements the text in tweets. Among the RW based methods for node sequence generation, the proposed *Biased* RW performs the best followed by *Unbiased* and *N2V*. The proposed *Biased* RW outperforms *Unbiased* RW decently – can be seen with prominence in [A] *Biased* vs *Unbiased* RWs

---

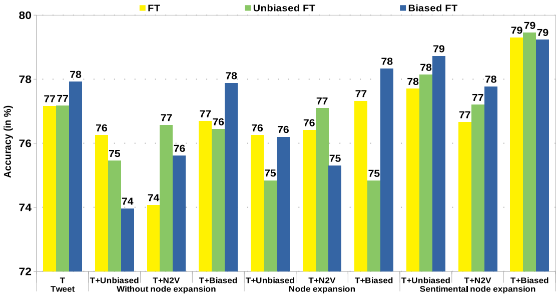
[5] We have considered only the top few walks (3, 5, and 7) with the highest probability. Experiments show that considering the top 3 walks provide the best results. The codes for this paper are available at: `https://github.com/gloitongbam/SA_Hetero_Net`

for CNN classifiers using *Biased* FT embedding. Even the best performances in both the metrics pertain to [C] *Biased* RW with SHE embedding using both the classifiers. We feel the *N2V* style global topology-based biasing is not that useful for sentiment prediction than our biased approach, which uses centrality scores intuitively. Among the embedding models, we observe that *Biased* FT and SHE give competitive performances. We believe *Biased* FT performs competitively as it is trained on centrality-aware random-walks, additionally augmented with sentiment polarized nodes. Whereas, SHE systematically embeds sentiment information and also aided by biased tweet graph view – this makes it an unbeatable performer for sentiment classification.

To realize the importance of generating node sequences with an effective RW method over the proposed network, we investigate another experimental setup by randomly shuffling the selected nodes for expansion (both sentiment polarized and non-polarized nodes) with the tweet text. We call it as T+Shuffle–*Filtered* and *Unfiltered* methods for shuffling of sentiment polarized and non-polarized node expansions respectively in [D]. For Bi-LSTM, we can see [D] *Unfiltered* beats text-only prediction, which signifies that the list of selected nodes, though randomly shuffled, but are informative enough. For both the classifiers in [D] *Filtered* outperforms text-only prediction on average by $0.8\%, 2.4\%$, respectively, signifying selected nodes by sentiment polarized node expansion method aids in performance. Here we shall also showcase the novelty of node sequences over a randomly shuffled list of the same nodes. [D] *Unfiltered* is comparable with [B] view – *Biased* RWs are seen to improve upon the prior. Whereas walks in the [C] view, which is comparable to [D] *Filtered* are seen to improve the performance of the latter. [C] *Biased* RW beats [D] *Filtered* by $1.6\%, 1.5\%$ points on average for CNN and Bi-LSTM.

5.1 Novelty of centrality-aware walks

It is evident from the already-shown results that our proposed biased random-walks are useful for the effective representation of tweets. One may be further interested in knowing how far these *Biased* RW sequences can improve any embedding models' performance. We conduct a pilot study by creating three versions of the FastText algorithm – a word embedding based original version (FT), an *Unbiased* RW sequence-based version (*Unbiased* FT), and a *Biased* RW sequence-based version (*Biased* FT) as summarized in Figure 2. *Biased* FT beats tweet-based FT in 6 out of 10 cases by an average of 1.11%. *Biased* FT also beats *Unbiased* FT in $6/10$ cases by an average of 1.37%. Although *Unbiased* FT seems to perform poorer as compared to the original FT in general, in the case of sentiment polarized node expansion, it consistently outperformed the FT – which again proves the effectiveness of the sentiment polarized node expansion method.



* The plot shows different scale but of same value due to round-off error.

Figure 2: Performance of CNN classifier using different types of node embedding generated via FastText algorithm

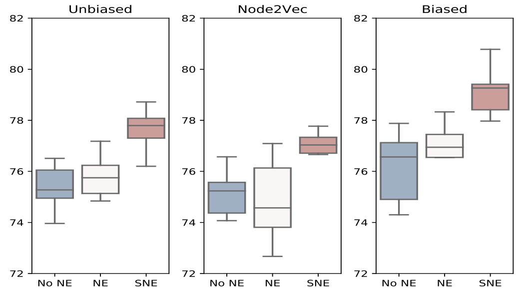


Figure 3: Effectiveness of (sentiment polarized) node expansion in tweet-network representations. A:Unbiased, B:Node2Vec, C:Biased representation of tweet-network for No Node Expansion (No NE), Node Expansion (NE), sentiment polarized node expansion (SNE) methods. Accuracy(%) of sentiment prediction is in Y-axis.

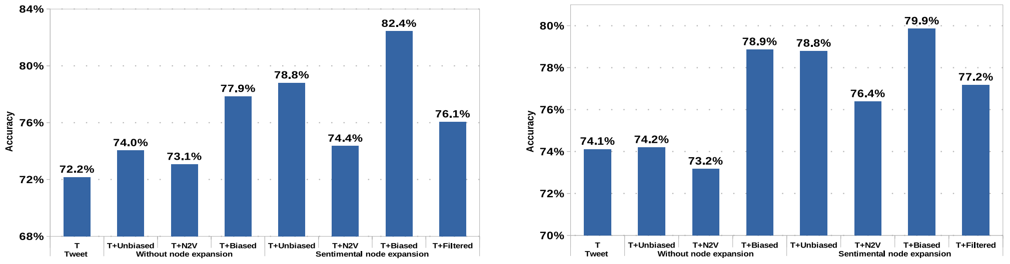
5.2 Novelty of sentiment polarized node expansion

In this section, we further analyzed the effectiveness of node expansion for the sentiment classification task. We summarize using box-plot in Figure 3, the performances of the tweet-network representations (shown in Table 3) for sentiment polarized and non-polarized node expansion, and without node expansion over different RW algorithms (i.e. *Unbiased*, Node2Vec, *Biased*). From the figure, it is observed that for each RW methods, the node ex-



(a) Tweets with keywords < 5

(b) Multilingual tweets

Figure 4: Performance of CNN classifier for different under-specified and multi-lingual tweet categories. Inputs to classifier are 5 different tweet representations; i.e. (i) tweet-text only, and node expansion over the actual tweet using random walkers based on (ii) MNE (Unbiased), (iii) Node2Vec (N2V), and (iv) centrality biased node expansions (Biased), and (v) random shuffled of the selected sentiment polarized nodes (Filtered).

pansion based representation beats the performance of the tweet representation without any node expansion. Precisely, the sentiment polarized node expansion beats the performance of classifiers with and without non-polarized node expansion by an average margin of 9.19% and 10.57%, respectively. Further, the non-polarized node expansion beats the performance of the classifiers without node expansion by 1.38%. From Figure 3, we observe two aspects; – i) the expansion of semantically related nodes in tweet-network makes the performance of centrality based biasing algorithm more reliable, ii) the box-plot of sentiment polarized node expansion methods has a small variance, indicating that it is a pretty stable, reliable method to enhance the tweet network view. Hence we can conclude that extending the networked-view of a tweet by including a few semantically similar, central nodes serves our purpose decently. Further, the performance is enhanced in a considerable margin by adding only the sentiment polarized nodes related to the tweet.

5.3 Response on under-specified Tweets

We consider tweets having less than five keywords[6] as an under-specified tweet. Tweets with fewer keywords, although informative, can pose challenges to sentiment classifiers due to under-specificity. We considered the CNN-based classifiers trained using *Biased* FT embedding to classify the under-specified tweets for this study. Figure 4(a) shows the CNN-based classifiers' performance based on the different types of tweet representations. From the figure, we observed that the sentiment classifier trained without any node expansion performs better than the classifier trained with tweet-text only. This observation shows the power of optimally selected n random-walk sequences as an alternative representation of tweets. Among no expansion methods, *Biased* RW sequences give the best performance – beat tweet-text only prediction by 5.7% and *Unbiased* RW by 3.82%. We can see similar trends of performance for RW based sequences in case of sentiment polarized node expansion also. However, sentiment polarized node expansion strategically mitigates the problem of under-specified tweets by extending the tweet-network view to include less-noisy informative nodes so that the generated walks are more diverse and discriminating. The last pair of columns is one special scenario where we give the original tweet-text + list of randomly-shuffled sentiment polarized nodes to the sentiment classifier. This combination (T+*Filtered*) outperforms the tweet only prediction by 3.9% – depicting nodes selected for expansion are important for inference. However, as T+*Biased* without node expansion, T+*Unbiased* and T+*Biased* with sentiment polarized node expansion beat this T+*Filtered* by a margin of $1.8\%, 2.7\%$ & 6.4% accuracy respectively. This proves the veracity of this fact that random-walk sequences are a stronger representation of tweets as compared to mere inclusion of a shuffled-list of semantically related words to the tweet-text.

5.4 Response on Multilingual tweet

Figure 4(b) shows sentiment classification performance over the multilingual tweets – tweet-text written in the code-mixed language. This plot also follows similar trends, as reflected in Figure 4(a), but we have two striking observations this time. In the case of multilingual tweets, since the co-occurrence of multilingual words is rare, our proposed node expansion methods are useful to retrieve semantically related co-occurred English

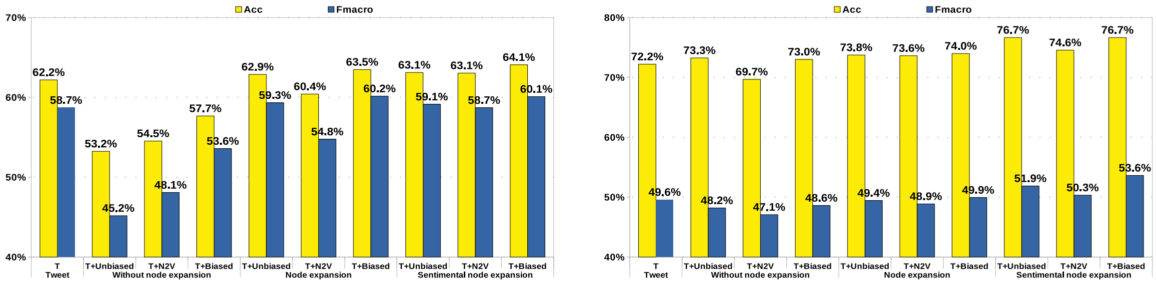
[6] Including hashtags and mentions



(a) SemEval-2013

(b) SemEval-2016

Figure 5: Performance of CNN classifiers across SemEval challenge datasets

words that can aid in inference. We verify the same intuition with this plot. We can see the jump in prediction results for sentiment polarized node expansion for T+*Unbiased*, T+*N2V*, and T+*Biased* over their counterparts in the previous group (without node expansion) with a margin of $4.6\%, 3.2\%$ and 0.1% accuracy respectively. It is interesting to see the huge performance improvement of T+*Biased* without node expansion over tweet only prediction by a margin of 4.75% accuracy – which we believe is due to the power of interpretable, centrality-score aided, optimally the *Biased* RW sequences of multilingual words.

5.5 Evaluation on SemEval datasets

We further investigate the performance of the proposed method with two popular Twitter datasets used in SemEval challenges for sentiment analysis; SemEval-2013[7] and SemEval-2016[8]. For this study, we consider the train and test split provided in the datasets. Figure 5 (a) and (b) shows the performance of the CNN classifier trained over different types of tweet representation using the SemEval-2013 and SemEval-2016 datasets, respectively. For training the CNN classifier, we use *Biased* FT embeddings trained using the challenge datasets. Our proposed centrality aware-based biased random walker through sentiment polarized node expansion has achieved best performance up to 64% accuracy and 60% F-macro score on SemEval-2013 and up to 77% accuracy and 54% F-macro score for SemEval-2016. Further, on comparing the performance of tweet representation between text-based and network-based without node expansion, it is observed that for both datasets, the representation without node expansion could hardly beat text-based representation in F-macro measure. However, for the SemEval-2016 dataset, our proposed method outperforms text-based representation in both the evaluation measures. We see substantial performance gain for *N2V* RW in both the datasets when augmented with any node expansion. For SemEval-2016, a fascinating thing to observe is – *Unbiased* and *Biased* RW-based sequences almost give a comparable performance in terms of accuracy. However, the *Biased* RW view consistently outperformed the *Unbiased* view in F-macro measure in both datasets for each of the cases of node expansion. This points to the fact that our method consistently performs better than its counterpart methods.

6 Conclusion

This study investigates the efficacy of transforming tweets to heterogeneous multi-layer network for the sentiment classification task. Our proposed centrality aware random-walk method can generate walk sequences that capture better semantic relations than its unbiased and biased random walk based counterparts. From various experimental observations, it is evident that sentiment-oriented node expansion can reduce under-specificity, noise in a tweet, and enhance the representation. The proposed method outperforms its text-based counterpart in a majority of the cases.

A Appendix

Here, we show some additional experiment results and their implications in support of our proposed framework for sentiment classification.

A.1 Interpretation of node centrality scores and layer influences

In Table 4 and Figure 8, we precisely show three example tweets and their ranked centrality scores calculated by our proposed method. The first example is all about a terrorist attack in India and India's Prime Minister Modi's reaction to it. In simple multi-layer view of a tweet, we see *india, pm, modi, speech* - keywords related to how India reacts have more centrality than the attack *#uriattack* and one terrorist named *#burhanwani*. It is interesting to look at the list of nodes selected by our plain and sentiment polarized node expansion methods in Table 4. The list of nodes for expansion related to *#uriattack* talk about the surgical strike, home minister, defense minister, soldiers killed in this attack, and have higher ranks. The second tweet is one under-specified tweet where India's Prime Minister greets soldiers. Here, our node expansion methods beautifully guess that this greeting is related to India's success in #surgicalstrike as India's reaction to *#uriattack*. Keywords related to the war, causalities and related emotions like *army, pak, loc, diplomatic, refute, lose, collateral, pray, roar* come higher in centrality-score based ranking. Example 3 is one multilingual tweet whose main theme is *Goods & Services Tax (GST)* (a bill related to tax payment adopted by the Indian government in 2017). Although the original tweet mentions @*narendramodi* PM of India and uses Hindi keywords, but the nodes selected for expansion rightfully capture about finance ministry (@*arunjaitley*, @*finminindia*), home ministry (@*amitshah*), economic transformation and mostly positive sentiments about it. Also, as we create one large multi-layer heterogeneous network from the tweet corpus to train node embedding methods, the layer influence calculated by our method ranks the hashtag layer higher than the mention layer followed by the keyword layer ($H > M > K$). This ranking is pretty intuitive as we have most of the influential nodes in the hashtag (trending topics) and mention (Twitter handles of important personalities) networks. Whereas, the keyword layer has a large number of keywords, among them, the entire population of the less frequently used keywords brings down the overall influence score of this layer.

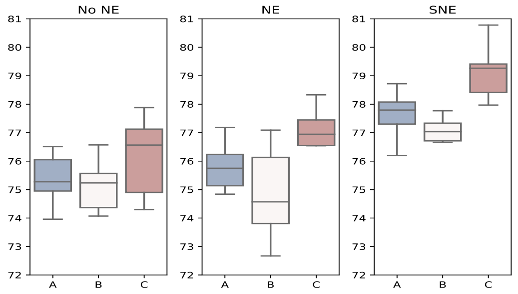

Figure 6: Effectiveness of centrality score-based biased representation of tweets A:Unbiased, B:Node2Vec, C:Biased representation of networked-tweets for No Node Expansion(No NE), Node Expansion(NE), sentiment polarized node expansion (SNE) methods. Accuracy(%) of sentiment prediction in Y-axis.

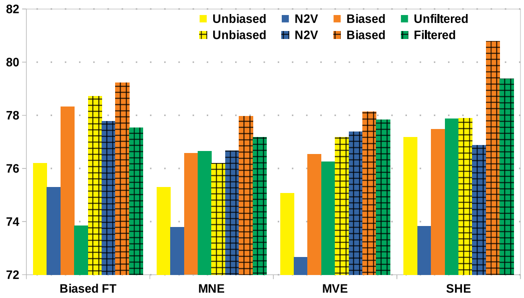

Figure 7: Effectiveness of (sentiment polarized) node expansion in tweet-networks. Patterned and plain colored bars shows the performance with and without sentiment polarized node expansion respectively.

A.2 Novelty of centrality score-based tweet network representation

We created boxplots of aggregated performances of three competing methods (*Unbiased*, *Node2Vec* and *Biased* as in Table 3) for tweet network representation and generation of RW sequences. From Figure 6, for each networked view of tweets (NE, No NE, SNE), it is evident that our centrality score-based RW sequences provide better tweet representations than unbiased and Node2Vec biasing based RW sequences. Node2Vec biasing does not seem to be an intuitive tweet networked view for tweet sentiment classification. Our proposed centrality aware RW sequences beat Node2Vec by 3.1% and unbiased RWs by 1.7% on average.

A.3 Novelty of (sentiment polarized) node expansion: more insights

In Figure 7, we compare two node expansion methods that we propose as part of our framework. The

Tweet	**New nodes for expansion**	**sentiment polarized nodes**
Tweet 1	#pakistanarmy, @amitshah, @rajnathsingh, @finminindia, @pmoindia, ji, pls, request, indiansoldiers, takesover, frmindia, pakintensifies, brave, aftrstrikes, surgstrikes, soldiers, killed	@pmoindia, @amitshah, @finminindia, request, takesover, aftrstrikes, indiansoldiers, pakintensifies, frmindia, soldiers, killed
Tweet 2	#surgicalstrike, #surgical, #surgicalstrikes, @saikatd, initiative, detailed, nomura, indian, clai, outstrip, lic, operational, offenders, collateral, initiative, lose, pakistani, roar, claims, pray, remembered, diplomatic, write, refute, army, indian, pak, loc	#surgicalstrikes, offenders, collateral, pray, remembered, diplomatic, roar, write, pak, army, pakistan
Tweet 3	#gstbill, #gst, @arunjaitley, @finminindia, @adhia, @amitshah, @pmoindia, transformation, congratulation, request, cgstate, lagu, ke, wishes, nahi, hind, liye, didi, pls, ji, taxation, finance	@pmoindia, @amitshah, @arunjaitley, @finminindia, didi, nahi, request, cgstate, transformation, congratulation

Table 4: Nodes selected for tweet view expansion. **Tweet 1:** *@asadmunir38 Modi is agressive since #UriAttack, #BurhanWani & PM speech @UNGAPak needs to start dialogue with neighbours India, Afghan*; **Tweet 2:** *@narendramodi #GreetingsToSoldiers*; **Tweet 3:** *@narendramodi Thank you Sir GST laagu karne ke liye is India great*

patterned and plain colored bars show the performance with and without sentiment polarized node expansion, respectively. Evidently, sentiment polarized node expansion offers a performance improvement of 8.4% over non-polarized node expansion on average across all four embedding methods. Even sentiment polarized node expansion improves the tweet representation with a list of unfiltered nodes without any network structure by an accuracy improvement of 1.8% on average – which clearly shows that list of nodes selected for sentiment polarized node expansion are less-noisy and informative in the context of tweet sentiment classification.

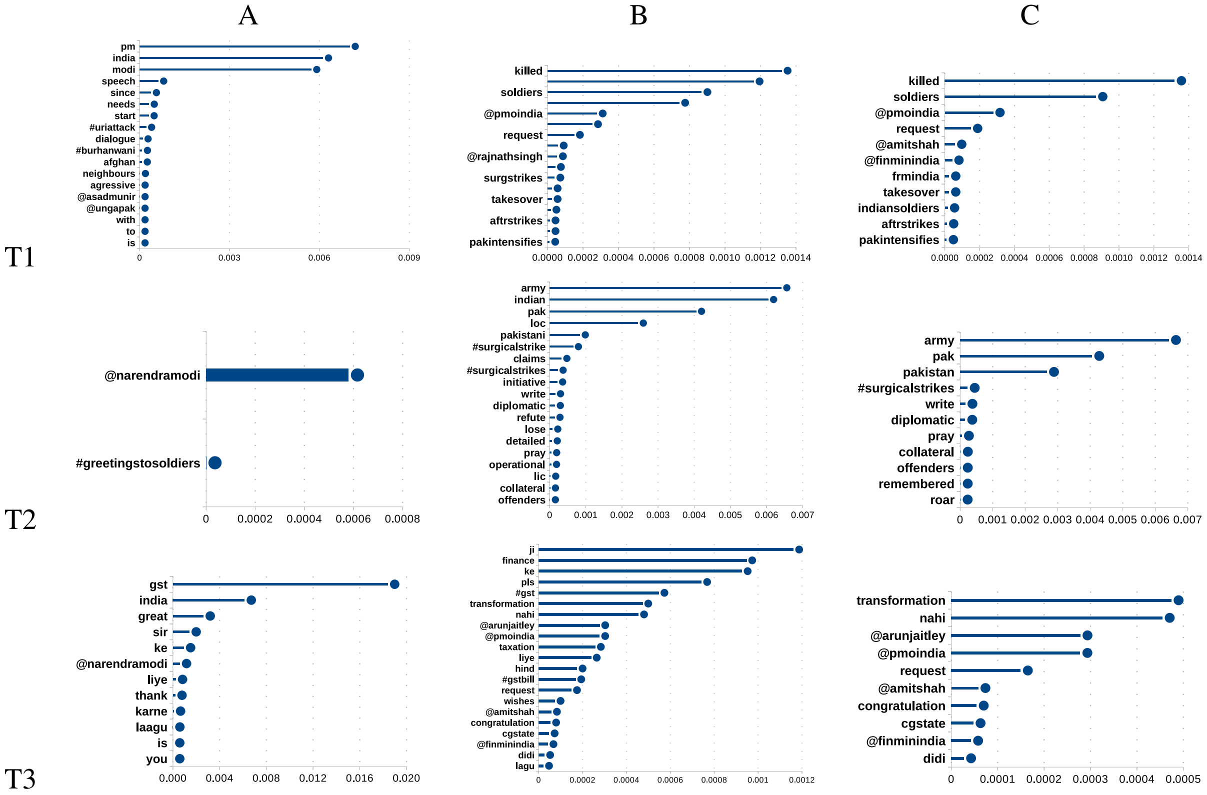

Figure 8: Tweet component centrality rankings A: without node expansion, B: plain node expansion, C: sentiment polarized node expansion. **T1:** *@asadmunir38 Modi is agressive since #UriAttack, #BurhanWani & PM speech @UNGAPak needs to start dialogue with neighbours India, Afghan*; **T2:** *@narendramodi #GreetingsToSoldiers*; **T3:** *@narendramodi Thank you Sir GST laagu karne ke liye is India great*.

Introducing Syntactic Structures into Target Opinion Word Extraction with Deep Learning

Abstract

Targeted opinion word extraction (TOWE) is a sub-task of aspect based sentiment analysis (ABSA) which aims to find the opinion words for a given aspect-term in a sentence. Despite their success for TOWE, the current deep learning models fail to exploit the syntactic information of the sentences that have been proved to be useful for TOWE in the prior research. In this work, we propose to incorporate the syntactic structures of the sentences into the deep learning models for TOWE, leveraging the syntax-based opinion possibility scores and the syntactic connections between the words. We also introduce a novel regularization technique to improve the performance of the deep learning models based on the representation distinctions between the words in TOWE. The proposed model is extensively analyzed and achieves the state-of-the-art performance on four benchmark datasets.

1 Introduction

Targeted Opinion Word Extraction (TOWE) is an important task in aspect based sentiment analysis (ABSA) of sentiment analysis (SA). Given a target word (also called aspect term) in the input sentence, the goal of TOWE is to identify the words in the sentence (called the target-oriented opinion words) that help to express the attitude of the author toward the aspect represented by the target word. For instance, as a running example, in the sentence "*All warranties honored by XYZ (what I thought was a reputable company) are disappointing.*", "*disappointing*" is the opinion word for the target word "*warranties*" while the opinion words for the target word "*company*" would involve "*reputable*". Among others, TOWE finds its applications in target-oriented sentiment analysis (Tang et al., 2016; Xue and Li, 2018; Veyseh et al., 2020) and opinion summarization (Wu et al., 2020).

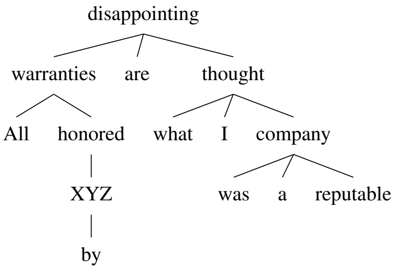

Figure 1: The dependency tree of the example sentence.

The early approach for TOWE has involved the rule-based and lexicon-based methods (Hu and Liu, 2004; Zhuang et al., 2006) while the recent work has focused on deep learning models for this problem (Fan et al., 2019; Wu et al., 2020). One of the insights from the rule-based methods is that the syntactic structures (i.e., the parsing trees) of the sentences can provide useful information to improve the performance for TOWE (Zhuang et al., 2006). However, these syntactic structures have not been exploited in the current deep learning models for TOWE (Fan et al., 2019; Wu et al., 2020). Consequently, in this work, we seek to fill in this gap by extracting useful knowledge from the syntactic structures to help the deep learning models learn better representations for TOWE. In particular, based on the dependency parsing trees, we envision two major syntactic information that can be complementarily beneficial for the deep learning models for TOWE, i.e., the syntax-based opinion possibility scores and syntactic word connections for representation learning. First, for the syntax-based possibility scores, our intuition is that the closer words to the target word in the dependency tree of the input sentence tend to have better chance for being the opinion words for the target in TOWE. For instance, in our running example, the opinion word "*disappointing*" is sequentially far from its target word "*warranties*". However, in the de-

---

November 16–20, 2020. ©2020 Association for Computational Linguistics

pendency tree shown in Figure 1, "*disappointing*" is directly connected to "*warranties*", promoting the distance between "*disappointing*" and "*warranties*" (i.e., the length of the connecting path) in the dependency tree as an useful feature for TOWE. Consequently, in this work, we propose to use the distances between the words and the target word in the dependency trees to obtain a score to represent how likely a word is an opinion word for TOWE (called syntax-based possibility scores). These possibility scores would then be introduced into the deep learning models to improve the representation learning for TOWE.

In order to achieve such possibility score incorporation, we propose to employ the representation vectors for the words in the deep learning models to compute a model-based possibility score for each word in the sentence. The model-based possibility scores also aim to quantify the likelihood of being an opinion word for each word in the sentence; however, they are based on the internal representation learning mechanism of the deep learning models for TOWE. To this end, we propose to inject the information from the syntax-based possibility scores into the models for TOWE by enforcing the similarity/consistency between the syntax-based and model-based possibility scores for the words in the sentence. The rationale is to leverage the possibility score consistency to guide the representation learning process of the deep learning models (using the extracted syntactic information) to generate more effective representations for TOWE. In this work, we employ the Ordered-Neuron Long Short-Term Memory Networks (ON-LSTM) (Shen et al., 2019) to obtain the model-based possibility scores for the words in the sentences for TOWE. ON-LSTM introduces two additional gates into the original Long Short-Term Memory Network (LSTM) cells that facilitate the computation of the model-based possibility scores via the numbers of active neurons in the hidden vectors for each word.

For the second type of syntactic information in this work, the main motivation is to further improve the representation vector computation for each word by leveraging the dependency connections between the words to infer the effective context words for each word in the sentence. In particular, motivated by our running example, we argue that the effective context words for the representation vector of a current word in TOWE involve the neighboring words of the current word and the target word in the dependency tree. For instance, consider the running example with "*warranties*" as the target word and "*reputable*" as the word we need to compute the representation vector. On the one hand, it is important to include the information of the neighboring words of "*reputable*" (i.e., "*company*") in the representation so the models can know the context for the current word (e.g., which object "*reputable*" is modifying). On the other hand, the information about the target word (i.e., "*warranties*" and possibly its neighboring words) should also be encoded in the representation vector for "*reputable*" so the models can be aware of the context of the target word and make appropriate comparison in the representation to decide the label (i.e., non-opinion word) for "*reputable*" in this case. Note that this syntactic connection mechanism allows the models to de-emphasize the context information of "*I*" in the representation for "*reputable*" to improve the representation quality. Consequently, in this work, we propose to formulate these intuitions into an importance score matrix whose cells quantify the contextual importance that a word would contribute to the representation vector of another word, given a target word for TOWE. These importance scores will be conditioned on the distances between the target word and the other words in the dependency tree. Afterward, the score matrix will be consumed by a Graph Convolutional Neural Network (GCN) model (Kipf and Welling, 2017) to produce the final representation vectors for opinion word prediction.

Finally, in order to further improve the induced representation vectors for TOWE, we introduce a novel inductive bias that seeks to explicitly distinguish the representation vectors of the target-oriented opinion words and those for the other words in the sentence. We conduct extensive experiments to demonstrate the benefits of the proposed model, leading to the state-of-the-art performance for TOWE in several benchmark datasets.

2 Related Work

Comparing to the related tasks, TOWE has been relatively less explored in the literature. In particular, the most related task of TOWE is opinion word extraction (OWE) that aims to locate the terms used to express attitude in the sentences (Htay and Lynn, 2013; Shamshurin, 2012). A key difference between OWE and TOWE is that OWE does not require the opinion words to tie to any target words in the sentence while the opinion words in TOWE should be explicitly paired with a given target word. Another related task for TOWE is opinion target extraction (OTE) that attempts to identify the target words in the sentences (Qiu et al., 2011; Liu et al., 2015; Poria et al., 2016; Yin et al., 2016; Xu et al., 2018). Note that some previous works have also attempted to jointly predict the target and opinion words (Qiu et al., 2011; Liu et al., 2013; Wang et al., 2016, 2017; Li and Lam, 2017); however, the target words are still not paired with their corresponding opinion words in these studies.

As mentioned in the introduction, among a few previous work on TOWE, the main approaches include the rule-based methods (i.e., based on word distances or syntactic patterns) (Zhuang et al., 2006; Hu and Liu, 2004) and the recent deep learning models (Fan et al., 2019; Wu et al., 2020). Our model is different from the previous deep learning models as we exploit the syntactic information (i.e., dependency trees) for TOWE with deep learning.

3 Model

The TOWE problem can be formulated as a sequence labeling task. Formally, given a sentence W of N words: $W = w_1, w_2, \ldots, w_N$ with w_t as the target word ($1 \leq t \leq N$), the goal is to assign a label l_i to each word w_i so the label sequence $L = l_1, l_2, ..., l_N$ for W can capture the target-oriented opinion words for w_t. Following the previous work (Fan et al., 2019), we use the BIO tagging schema to encode the label l_i for TOWE (i.e., $l_i \in \{B, I, O\}$ for being at the **B**eginning, **I**nside or **O**utside of the opinion words respectively). Our model for TOWE consists of four components that would be described in the following: (i) Sentence Encoding, (ii) Syntax-Model Consistency, (iii) Graph Convolutional Neural Networks, and (iv) Representation Regularization.

3.1 Sentence Encoding

In order to represent the input sentence W, we encode each word w_i into a real-valued vector x_i based on the concatenation of the two following vectors: (1) the hidden vector of the first wordpiece of w_i from the last layer of the BERT$_{base}$ model (Devlin et al., 2019), and (2) the position embedding for w_i. For this vector, we first compute the relative distance d_i from w_i to the target word w_t (i.e., $r_i = i - t$). Afterward, we retrieve the position embedding for w_i by looking up r_i in a position embedding table (initialized randomly). The position embeddings are fine-tuned during training in this work. The resulting vector sequence $X = x_1, x_2, \ldots, x_N$ for W will be then sent to the next computation step.

3.2 Syntax-Model Consistency

As presented in the introduction, the goal of this component is to employ the dependency tree of W to obtain the syntax-based opinion possibility scores for the words. These scores would be used to guide the representation learning of the models via the consistency with the model-based possibility scores. In particular, as we consider the closer words to the target word w_t in the dependency tree of W as being more likely to be the target-oriented opinion words, we first compute the distance d_i^{syn} between each word w_i to the target word w_t in the dependency tree (i.e., the number of words along the shortest path between w_i and w_t). Afterward, we obtain the syntax-based possibility score s_i^{syn} for w_i based on: $s_i^{syn} = \frac{\exp(-d_i^{syn})}{\sum_{j=1..N} \exp(-d_j^{syn})}$.

In order to implement the possibility score consistency, our deep learning model needs to produce $s_1^{syn}, s_2^{syn}, \ldots, s_N^{syn}$ as the model-based possibility scores the words $w_1, w_2, \ldots, w_N$ in W respectively. While the model-based score computation would be explained later, given the model-based scores, the syntax-model consistency for possibility scores would be enforced by introducing the KL divergence L_{const} between the syntax-based and model-based scores into the overall loss function to minimize:

$$L_{KL} = -\sum_i s_i^{model} \frac{s_i^{model}}{s_i^{syn}} \tag{1}$$

As mentioned in the introduction, in this work, we propose to obtain the model-based possibility scores for TOWE using the Ordered-Neuron Long Short-Term Memory Networks (ON-LSTM) (Shen et al., 2019). ON-LSTM is an extension of the popular Long Short-Term Memory Networks (LSTM) that have been used extensively in Natural Language Processing (NLP). Concretely, given the vector sequence $X = x_1, x_2, \ldots, x_N$ as the input, a LSTM layer would produce a sequence of hidden vectors $H = h_1, h_2, \ldots, h_N$ via:

$$\begin{aligned} f_i &= \sigma(W_f x_i + U_f h_{i-1} + b_f) \\ i_i &= \sigma(W_i x_i + U_i h_{i-1} + b_i) \\ o_i &= \sigma(W_o x_i + U_o h_{i-1} + b_o) \\ \hat{c}_i &= tanh(W_c x_i + U_c h_{i-1} + b_c) \\ c_i &= f_i \circ c_{i-1} + i_i \circ \hat{c}_i, h_i = o_i \circ tanh(c_i) \end{aligned} \tag{2}$$

in which h_0 is set to zero vector, $\circ$ is the element-wise multiplication, and f_t, i_t and o_t are called the forget, input, and output gates respectively.

A major problem with the LSTM cell is that all the dimensions/neurons of the hidden vectors (for the gates) are equally important as these neurons are active/used for all the step/word i in W. In other words, the words in W have the same permission to access to all the available neurons in the hidden vectors of the gates in LSTM. This might not be desirable as given a NLP task, the words in a sentence might have different levels of contextual contribution/information for solving the task. It thus suggests a mechanism where the words in the sentences have different access to the neurons in the hidden vectors depending on their informativeness. To this end, ON-LSTM introduces two additional gates $\bar{f}_i$ and $\bar{i}_i$ (the master forget and input gates) into the original LSTM mechanism using the $cummax$ activation function (i.e., $cumax(x) = cumsum(softmax(x)))$[1]:

$$\begin{aligned}
\hat{f}_i &= cummax(W_{\hat{f}} x_i + U_{\hat{f}} h_{i-1} + b_{\hat{f}}) \\
\hat{i}_i &= 1 - cummax(W_{\hat{i}} x_i + U_{\hat{i}} h_{t-1} + b_{\hat{i}}) \\
\bar{f}_i &= \hat{f}_i \circ (f_i \hat{i}_i + 1 - \hat{i}_i), \bar{i}_i = \hat{i}_i \circ (i_t \hat{f}_i + 1 - \hat{f}_i) \\
c_i &= \bar{f}_i \circ c_{i-1} + \bar{i}_i \circ \hat{c}_i
\end{aligned} \tag{3}$$

The benefit of $cummax$ is to introduce a hierarchy over the neurons in the hidden vectors of the master gates so the higher-ranking neurons would be active for more words in the sentence and vice verse (i.e., the activity of the neurons is limited to only a portion of the words in the sentence in this case). In particular, as $cummax$ applies the softmax function on the input vector whose outputs are aggregated over the dimensions, the result of $cummax(x)$ represents the expectation of a binary vector of the form $(0, \ldots, 0, 1, \ldots, 1)$ (i.e., two consecutive segments of 0's and 1's). The 1's segment in this binary vector determines the neurons/dimensions activated for the current step/word w_i, thus enabling the different access of the words to the neurons. In ON-LSTM, a word is considered as more informative or important for the task if it has more active neurons (or a larger size for its 1's segment) in the master gates' hidden vectors than the other words in the sentence. As such, ON-LSTM introduces a mechanism to estimate an informativeness score s_i^{imp} for each word w_i in the sentence based on the number of active neurons in the master gates. Following (Shen et al., 2019), we approximate s_i^{imp} via the sum of the weights of the neurons in the master forget gates, i.e., $s_i^{imp} = 1 - \sum_{j=1..D} \hat{f}_{ij}$. Here, D is the number of dimensions/neurons in the hidden vectors of the ON-LSTM gates and $\hat{f}_{ij}$ is the weight of the j-th dimension for the master forget gate $\hat{f}_i$ at w_i.

An important property of the target-oriented opinion words in our TOWE problem is that they tend to be more informative than the other words in the sentence (i.e., for understanding the sentiment of the target words). To this end, we propose to compute the model-based opinion possibility scores s_i^{model} for w_i based on the informativeness scores s_i^{imp} from ON-LSTM via: $s_i^{model} = \frac{\exp(s_i^{imp})}{\sum_{j=1..N} \exp(s_j^{imp})}$. Consequently, by promoting the syntax-model consistency as in Equation 1, we expect that the syntactic information from the syntax-based possibility scores can directly interfere with the internal computation/structure of the ON-LSTM cell (via the neurons of the master gates) to potentially produce better representation vectors for TOWE. For convenience, we also use $H = h_1, h_2, \ldots, h_N$ to denote the hidden vectors returned by running ON-LSTM over the input sequence vector X in the following.

3.3 Graph Convolutional Networks

This component seeks to extract effective context words to further improve the representation vectors H for the words in W based on the dependency connections between the words for TOWE. As discussed in the introduction, given the current word $w_i \in W$, there are two groups of important context words in W that should be explicitly encoded in the representation vector for w_i to enable effective opinion word prediction: (i) the neighboring words of w_i, and (ii) the neighboring words of the target word w_t in the dependency tree (i.e., these words should receive higher weights than the others in the representation computation for w_i). Consequently, in order to capture such important context words for all the words in the sentence for TOWE, we propose to obtain two importance score matrices of size $N \times N$ for which the scores at cells (i, j) are expected to weight the importance of the contextual information from w_j with respect to the representation vector computation for w_i in W. In particular, one score matrix would be used to capture the syntactic neighboring words of the current words (i.e., w_i) while the other score matrix would

---

[1] $cumsum(u_1, u_2, \ldots, u_n) = (u'_1, u'_2, \ldots, u'_n)$ where $u'_i = \sum_{j=1..i} u_j$.

be reserved for the neighboring words of the target word w_t. These two matrices would then be combined and consumed by a GCN model (Kipf and Welling, 2017) for representation learning.

Specifically, for the syntactic neighbors of the current words, following the previous GCN models for NLP (Marcheggiani and Titov, 2017; Nguyen and Grishman, 2018; Veyseh et al., 2019), we directly use the adjacency binary matrix $A^d = \{a^d_{i,j}\}_{i,j=1..N}$ of the dependency tree for W as the importance score matrix for this group of words. Note that $a^d_{i,j}$ is only set to 1 if w_i is directly connected to w_j in the dependency tree or $i = j$ in this case. In the next step for the neighboring words of the target word w_t, as we expect the closer words to the target word w_t to have larger contributions for the representation vectors of the words in W for TOWE, we propose to use the syntactic distances (to the target word) d^{syn}_i and d^{syn}_j of w_i and w_j as the features to learn the importance score matrix $A^t = \{a^t_{i,j}\}_{i,j=1..N}$ for the words in this case. In particular, $a^t_{i,j}$ would be computed by: $a^t_{i,j} = \sigma(FF([d^{syn}_i, d^{syn}_j, d^{syn}_i + d^{syn}_j, |d^{syn}_i - d^{syn}_j|, d^{syn}_i * d^{syn}_j]))$ where FF is a feed-forward network to convert a vector input with five dimensions into a scalar score and σ is the *sigmoid* function. Given the importance score matrices A^d and A^t, we seek to integrate them into a single importance score matrix A to simultaneously capture the two groups of important context words for representation learning in TOWE via the weighted sum: $A = \gamma A^d + (1 - \gamma)A^t = \{a_{i,j}\}_{i,j=1..N}$ where γ is a trade-off parameter[2].

In the next step for this component, we run a GCN model over the ON-LSTM hidden vectors H to learn more abstract representation vectors for the words in W. This step will leverage A as the adjacency matrix to enrich the representation vector for each word w_i with the information from its effective context words (i.e., the syntactic neighboring words of w_i and w_t), potentially improving the opinion word prediction for w_i. In particular, the GCN model in this work involves several layers (i.e., G layers in our case). The representation vector $\bar{h}^k_i$ for the word w_i at the k-the layer of the GCN model would be computed by:

$$\bar{h}^k_i = ReLU\left(\frac{\Sigma_{j=1..N} a_{i,j}(W_k \bar{h}^{k-1}_j + b_k)}{\sum_{j=1..N} a_{i,j}}\right) \quad (4)$$

where W_k and b_k are the weight matrix and bias for the k-th GCN layer. The input vector h^0_i for GCN is set to the hidden vector h_i from ON-LSTM (i.e., $h^0_i = h_i$) for all i in this case. For convenience, we denote $\bar{h}_i$ as the hidden vector for w_i in the last layer of GCN (i.e., $\bar{h}_i = \bar{h}^G_i$ for all $1 \leq i \leq N$). We also write $\bar{h}_1, \bar{h}_2, \ldots, \bar{h}_N = GCN(H, A)$ to indicate that $\bar{h}_1, \bar{h}_2, \ldots, \bar{h}_N$ are the hidden vectors in the last layer of the GCN model run over the input H and the adjacency matrix A for simplicity.

Finally, given the syntax-enriched representation vectors h_i from ON-LSTM and $\bar{h}_i$ from the last layer of GCN, we form the vector $V_i = [h_i, \bar{h}_i]$ to serve as the feature to perform opinion word prediction for w_i. In particular, V_i would be sent to a two-layer feed-forward network with the softmax function in the end to produce a probability distribution $P(.|W, t, i)$ over the possible opinion labels for w_i (i.e., B, I, and O). The negative log-likelihood function L_{pred} would then be used as the objective function to train the overall model: $L_{pred} = -\sum_{i=1}^{N} P(l_i|W, t, i)$.

3.4 Representation Regularization

There are three groups of words in the input sentence W for our TOWE problem, i.e., the target word w_t, the target-oriented opinion words (i.e., the words we want to identify) (called $W^{opinion}$), and the other words (called W^{other}). After the input sentence W has been processed by several abstraction layers (i.e., ON-LSTM and GCN), we expect that the resulting representation vectors for the target word and the target-oriented opinion words would capture the sentiment polarity information for the target word while the representation vectors for the other words might encode some other context information in W. We thus argue that the representation vector for the target word should be more similar to the representations for the words in $W^{opinion}$ (in term of the sentiment polarity) than those for W^{other}. To this end, we introduce an explicit loss term to encourage such representation distinction between these groups of words to potentially promote better representation vectors for TOWE. In particular, let R^{tar}, R^{opn}, and R^{oth} be some representation vectors for the target word w_t, the target-oriented opinion words (i.e., $W^{opinion}$),

---

[2] Note that we tried to directly learn A from the available information from A^d and A^t (i.e., $a_{i,j} = \sigma(FF([a^d_{i,j}, d^{syn}_i, d^{syn}_j, d^{syn}_i + d^{syn}_j, |d^{syn}_i - d^{syn}_j|, d^{syn}_i * d^{syn}_j])))$. However, the performance of this model was worse than the linear combination of A^d and A^t in our experiments.

and the other words (i.e., W^{other}) in W. The loss term for the representation distinction based on our intuition (i.e., to encourage R^{tar} to be more similar to R^{opn} than R^{oth}) can be captured via the following triplet loss for minimization:

$$L_{reg} = 1 - cosine(R^{tar}, R^{opn}) + cosine(R^{tar}, R^{oth}) \quad (5)$$

In this work, the representation vector for the target word is simply taken from last GCN layer, i.e., $R^{tar} = \bar{h}_t$. However, as $W^{opinion}$ and W^{other} might involve sets of words, we need to aggregate the representation vectors for the individual words in these sets to produce the single representation vectors R^{opn} and R^{oth}. The simple and popular aggregation method in this case involves performing the max-pooling operation over the representation vectors (i.e., from GCN) for the individual words in each set (i.e., our baseline). However, this approach ignores the structures/orders of the individual words in $W^{opinion}$ and W^{other}, and fails to recognize the target word for better customized representation for regularization. To this end, we propose to preserve the syntactic structures among the words in $W^{opinion}$ and W^{other} in the representation computation for regularization for these sets. This is done by generating the target-oriented pruned trees from the original dependency tree for W that are customized for the words in $W^{opinion}$ and W^{other}. These pruned trees would then be consumed by the GCN model in the previous section to produce the representation vectors for $W^{opinion}$ and W^{other} in this part. In particular, we obtain the pruned tree for the target-oriented opinion words $W^{opinion}$ by forming the adjacency matrix $A^{opinion} = \{a^{opinion}_{i,j}\}_{i,j=1..N}$ where $a^{opinion}_{i,j} = a_{i,j}$ if both w_i and w_j belong to some shortest dependency paths between w_t and some words in $W^{opinion}$, and 0 otherwise. This helps to maintain the syntactic structures of the words in $W^{opinion}$ and also introduce the target word w_t as the center of the pruned tree for representation learning. We apply the similar procedure to obtain the adjacency matrix $A^{other} = \{a^{other}_{i,j}\}_{i,j=1..N}$ for the pruned tree for W^{other}. Given the two adjacency matrices for the pruned trees, the GCN model in the previous section is run over the ON-LSTM vectors H, resulting in two sequences of hidden vectors for $W^{opinion}$ and W^{other}, i.e., $h'_1, h'_2, \ldots, h'_N = GCN(H, A^{opinion})$ and $h''_1, h''_2, \ldots, h''_N = GCN(H, A^{other})$. Afterward, we compute the representation vectors R^{opn} and R^{oth} for the sets $W^{opinion}$ and W^{other} by retrieving the hidden vectors for the target word returned by the GCN model with the corresponding adjacency matrices, i.e., $R^{opn} = h'_t$ and $R^{oth} = h''_t$. Note that the application of GCN over the pruned trees and the ON-LSTM vectors makes R^{opn} and R^{oth} more comparable with R^{tar} in our case. This completes the description for the representation regularizer in this work. The overall loss function in this work would be: $L = L_{pred} + \alpha L_{KL} + \beta L_{reg}$ where α and β are the trade-off parameters.

4 Experiments

4.1 Datasets & Parameters

We use four benchmark datasets presented in (Fan et al., 2019) to evaluate the effectiveness of the proposed TOWE model. These datasets contain reviews for restaurants (i.e., the datasets **14res**, **15res** and **16res**) and laptops, (i.e., the dataset **14lap**). They are created from the widely used ABSA datasets from the SemEval challenges (i.e., SemEval 2014 Task 4 (14res and 14lap), SemEval 2015 Task 12 (15res) and SemEval 2016 Task 5 (16res)). Each example in these datasets involves a target word in a sentence where the opinion words have been manually annotated.

As none of the datasets provides the development data, for each dataset, we sample 20% of the training instances for the development sets. Note that we use the same samples for the development data as in (Fan et al., 2019) to achieve a fair comparison. We use the 14res development set for hyper-parameter fine-tuning, leading to the following values for the proposed model (used for all the datasets): 30 dimensions for the position embeddings, 200 dimensions for the layers of the feed-forward networks and GCN (with $G = 2$ layers), 300 hidden units for one layer of ON-LSTM, 0.2 for γ in A, and 0.1 for the parameters α and β.

4.2 Comparing to the State of the Art

We compare the TOWE model in this work (called **ONG** for ON-LSTM and GCN) with the recent models in (Fan et al., 2019; Wu et al., 2020) and their baselines. More specifically, the following baselines are considered in our experiments:

1. **Rule-based**: These baselines employ predefined patterns to extract the opinion-target pairs that could be either **dependency-based** (Zhuang et al., 2006) or **distance-based** (Hu and Liu, 2004).

	14res			14lap			15res			16res		
Model	P	R	F1	P	R	F1	P	R	F1	P	R	F1
Distance-rule (2004)	58.39	43.59	49.92	50.13	33.86	40.42	54.12	39.96	45.97	61.90	44.57	51.83

IOG (2019)	82.85	77.38	80.02	73.24	69.63	71.35	76.06	70.71	73.25	82.25	78.51	81.69
LOTN (Wu et al., 2020)	84.00	80.52	82.21	77.08	67.62	72.02	76.61	70.29	73.29	86.57	80.89	83.62
ONG (Ours)	83.23	81.46	**82.33**	73.87	77.78	**75.77**	76.63	81.14	**78.81**	87.72	84.38	**86.01**

Table 1: Test set performance (i.e., Precision (P), Recall (R) and F1 scores) of the models.

2. **Sequence-based Deep Learning**: These approaches apply some deep learning model over the input sentences following the sequential order of the words to predict the opinion words (i.e., **LSTM/BiLSTM** (Liu et al., 2015), **TC-BiLSTM** (Fan et al., 2019) and **IOG** (Fan et al., 2019)).

3. **Pipeline with Deep Learning**: This method utilizes a recurrent neural network to predict the opinion words. The distance-based rules are then introduced to select the target-oriented opinion words (i.e., **Pipeline**) (Fan et al., 2019).

4. **Multitask Learning**: These methods seek to jointly solve TOWE and another related task (i.e., sentiment classification). In particular, the **LOTN** model in (Wu et al., 2020) uses a pre-trained SA model to obtain an auxiliary label for each word in the sentence using distance-based rules. A bidirectional LSTM model is then trained to make prediction for both TOWE and the auxiliary labels[3].

Table 1 shows the performance of the models on the test sets of the four datasets. It is clear from the table that the proposed ONG model outperforms all the other baseline methods in this work. The performance gap between ONG and the other models are large and significant (with $p < 0.01$) over all the four benchmark datasets (except for LOTN on 14res), clearly testifying to the effectiveness of the proposed model for TOWE. Among different factors, we attribute this better performance of ONG to the use of syntactic information (i.e., the dependency trees) to guide the representation learning of the models (i.e., with ON-LSTM and GCN) that is not considered in the previous deep learning models for TOWE.

4.3 Model Analysis and Ablation Study

There are three main components in the proposed ONG model, including the ON-LSTM component, the GCN component and the representation regularization component. This section studies different variations and ablated versions of such components to highlight their importance for ONG.

ON-LSTM: First, we evaluate the following variations for the ON-LSTM component: (i) **ONG - KL**: this model is similar to ONG, except that the syntax-model consistency loss based on KL L_{KL} is not included in the overall loss function, (ii) **ONG - ON-LSTM**: this model completely removes the ON-LSTM component in ONG (so the KL-based syntax-model consistency loss is not used and the input vector sequence X is directly sent to the GCN model), and (iii) **ONG_wLSTM**: this model replaces the ON-LSTM model with the traditional LSTM model in ONG (so the syntax-model consistency loss is also not employed in this case as LSTM does not support the neuron hierarchy for model-based possibility scores). The performance for these models on the test sets (i.e., F1 scores) are presented in Table 2.

Model	14res	14lap	15res	16res
ONG	82.33	75.77	78.81	86.01
ONG - KL	80.91	73.34	76.21	83.78
ONG - ON-LSTM	78.99	70.28	71.39	81.13
ONG_wLSTM	81.03	73.98	74.43	82.81

Table 2: Performance of the ON-LSTM's variations.

As we can see from the table, the syntax-model consistency loss with KL divergence is important for ONG as removing it would significantly hurt the model's performance on different datasets. The model also becomes significantly worse when the ON-LSTM component is eliminated or replaced by the LSTM model. These evidences altogether confirm the benefits of the ON-LSTM model with the

---

[3] Note that (Peng et al., 2020) also proposes a related model for TOWE based on multitask deep learning. However, the models in this work actually predict general opinion words that are not necessary tied to any target word. As we focus on target-oriented opinion words, the models in (Peng et al., 2020) are not comparable with us.

syntax-model consistency proposed in this work.

GCN Structures: There are two types of importance score matrices in the GCN model, i.e., the adjacency binary matrices A^d for the syntactic neighbors of the current words and A^t for the syntactic neighbors of the target word. This part evaluates the effectiveness of these score matrices by removing each of them from the GCN model, leading to the two ablated models **ONG -** A^d and **ONG -** A^t for evaluation. Table 3 provides the performance on the test sets for these models (i.e., F1 scores). It is clear from the table that the absence of any importance score matrices (i.e., A^d or A^t) would decrease the performance over all the four datasets and both matrices are necessary for ONG to achieve its highest performance.

Model	14res	14lap	15res	16res
ONG	82.33	75.77	78.81	86.01
ONG - A^d	80.98	73.05	75.51	83.72
ONG - A^t	81.23	74.18	76.32	85.20

Table 3: Ablation study on the GCN structures.

GCN and Representation Regularization: As the representation regularization component relies on the GCN model to obtain the representation vectors, we jointly perform analysis for the GCN and representation regularization components in this part. In particular, we consider the following variations for these two components: (i) **ONG - REG**: this model is similar to ONG except that the representation regularization loss L_{reg} is not applied in the overall loss function, (ii) **ONG_REG_wMP-GCN**: this is also similar to ONG; however, it does not apply the GCN model to compute the representation vectors R^{opn} and R^{oth} for regularization. Instead, it uses the simple max-pooling operation over the GCN-produced vectors $\bar{h}_1, \bar{h}_2, \ldots, \bar{h}_N$ of the target-oriented words $W^{opinion}$ and the other words W^{other} for R^{opn} and R^{oth}: $R^{opn} = max\_pool(\bar{h}_i|w_i \in W^{opinion})$ and $R^{oth} = max\_pool(\bar{h}_i|w_i \in W^{other})$, (iii) **ONG - GCN**: this model eliminates the GCN model from ONG, but still applies the representation regularization over the representation vectors obtained from the ON-LSTM hidden vectors. In particular, the ON-LSTM hidden vectors $H = h_1, h_2, \ldots, h_N$ would be employed for both opinion word prediction (i.e., $V = [h_i]$ only) and the computation of R^{target}, R^{opn} and R^{oth} for representation regularization with max-pooling (i.e., $R^{target} = h_t$, $R^{opn} = max\_pool(h_i|w_i \in W^{opinion})$ and $R^{oth} = max\_pool(h_i|w_i \in W^{other})$) in this case, and (iv) **ONG - GCN - REG**: this model completely excludes both the GCN and the representation regularization models from ONG (so the ON-LSTM hidden vectors $H = h_1, h_2, \ldots, h_N$ are used directly for opinion word prediction (i.e., $V = [h_i]$ as in ONG - GCN) and the regularization loss L_{reg} is not included in the overall loss function). Table 4 shows the performance of the models on the test datasets (i.e., F1 scores).

Model	14res	14lap	15res	16res
ONG	82.33	75.77	78.81	86.01
ONG - REG	80.88	73.89	75.92	84.03
ONG_REG_wMP-GCN	80.72	72.44	74.28	84.29
ONG - GCN	81.01	70.88	72.98	82.58
ONG - GCN - REG	79.23	71.04	72.53	82.13

Table 4: Performance of the variations of the GCN and representation regularization components.

There are several important observations from this table. First, as ONG - REG is significantly worse than the full model ONG over different datasets, it demonstrates the benefits of the representation regularization component in this work. Second, the better performance of ONG over ONG_REG_wMP-GCN (also over all the four datasets) highlights the advantages of the GCN-based representation vectors R^{opn} and R^{oth} over the max-pooled vectors for representation regularization. We attribute this to the ability of ONG to exploit the syntactic structures among the words in $W^{opinion}$ and W^{other} for regularization in this case. Finally, we also see that the GCN model is crucial for the operation of the proposed model as removing it significantly degrades ONG's performance (whether the representation regularization is used (i.e., in ONG - GCN) or not (i.e., in ONG - GCN - REG). The performance become the worst when both the GCN and the regularization components are eliminated in ONG, eventually confirming the effectiveness of our model for TOWE in this work.

Regularization Analysis: This section aims to further investigate the effect of the dependency structures R^{opn} and R^{oth} (i.e., among the words in $W^{opinion}$ and W^{other}) to gain a better insight into their importance for the representation regularization in this work. Concretely, we again compare the performance of the full proposed model ONG (with the graph-based representations for R^{opn} and R^{oth}) and the baseline model ONG_REG_wMP-GCN (with the direct max-pooling over the word representations,

Distance	14res		14lap	
	ONG	ONG_REG_wMP-GCN	ONG	ONG_REG_wMP-GCN

2	83.18	78.43	75.03	73.12
3	81.56	75.41	74.21	70.69
>3	80.97	73.77	73.92	66.23
Distance	15res		16res	
	ONG	ONG_REG_wMP-GCN	ONG	ONG_REG_wMP-GCN
1	79.92	74.29	86.52	83.33
2	78.04	73.33	87.31	83.27
3	77.71	70.91	84.77	78.63
>3	76.98	68.88	84.05	77.13

Table 5: The performance (i.e., F1 scores) of ONG and ONG_REG_wMP-GCN on the four data folds of the development sets for 14res, 14lap, 15res, and 16res. The data folds are based on the target-opinion distances of the examples (called Distance in this table).

i.e., $R^{opn} = max\_pool(\bar{h}_i | w_i \in W^{opinion})$ and $R^{oth} = max\_pool(\bar{h}_i | w_i \in W^{other})$). However, in this analysis, we further divide the sentences in the development sets into four folds and observe the models' performance on those fold. As such, for each sentence, we rely on the longest distance between the target word and some target-oriented opinion word in $W^{opinion}$ in the dependency tree to perform this data split (called the target-opinion distance). In particular, the four data folds for the development sets (of each dataset) correspond to the sentences with the target-opinion distances of 1, 2, 3 or greater than 3. Intuitively, the higher target-opinion distances amount to more complicated dependency structures among the target-oriented opinion word in $W^{opinion}$ (as more words are involved in the structures). The four data folds are thus ordered in the increasing complexity levels of the dependency structures in $W^{opinion}$.

Table 5 presents the performance of the models on the four data folds for the development sets of the datasets in this work. First, it is clear from the table that ONG significantly outperforms the baseline model ONG_REG_wMP-GCN over all the datasets and structure complexity levels of $W^{opinion}$. Second, we see that as the structure complexity (i.e., the target-opinion distance) increases, the performance of both ONG and ONG_REG_wMP-GCN decreases, demonstrating the more challenges presented by the sentences with more complicated dependency structures in $W^{opinion}$ for TOWE. However, comparing ONG and ONG_REG_wMP-GCN, we find that ONG's performance decreases slower than those for ONG_REG_wMP-GCN when the target-opinion distance increases (for all the four datasets considered in this work). This implies that the complicated dependency structures in $W^{opinion}$ have more detrimental effect on the model's performance for ONG_REG_wMP-GCN than those for ONG, leading to the larger performance gaps between ONG and ONG_REG_wMP-GCN. Overall, these evidences suggest that the sentences with complicated dependency structures for the words in $W^{opinion}$ are more challenging for the TOWE models and modeling such dependency structures to compute the representation vectors R^{opn} and R^{oth} for regularization (as in ONG) can help the models to better perform on these cases.

5 Conclusion

We propose a novel deep learning model for TOWE that seeks to incorporate the syntactic structures of the sentences into the model computation. Two types of syntactic information are introduced in this work, i.e., the syntax-based possibility scores for words (integrated with the ON-LSTM model) and the syntactic connections between the words (applied with the GCN model with novel adjacency matrices). We also present a novel inductive bias to improve the model, leveraging the representation distinction between the words in TOWE. Comprehensive analysis is done to demonstrate the effectiveness of the proposed model over four datasets.

Abstract

Given the growing ubiquity of emojis in language, there is a need for methods and resources that shed light on their meaning and communicative role. One conspicuous aspect of emojis is their use to convey affect in ways that may otherwise be non-trivial to achieve. In this paper, we seek to explore the connection between emojis and emotions by means of a new dataset consisting of human-solicited association ratings. We additionally conduct experiments to assess to what extent such associations can be inferred from existing data in an unsupervised manner. Our experiments show that this succeeds when high-quality word-level information is available.

1 Introduction

People increasingly rely on digital channels such as mobile instant messaging apps to communicate with their friends, families, colleagues, and communities. Along with this rapid shift in medium, there have been concomitant changes in the way people express themselves in written language (McCulloch, 2019). One notable development has been the emergence of emojis as a new modality, presenting rich possibilities for representation and interaction. Emojis have become ubiquitous in social media and in instant messaging, owing in part to their visual appeal and their ease of use compared to typing out full words on mobile devices.

However, the rise of emojis also substantially appears to stem from their ability to convey affect (Vidal et al., 2016; Zhou et al., 2017). This is evinced by the fact that the most frequently used emojis are smileys and other facial expression symbols that exhibit a direct connection to emotional expression (Ekman and Friesen, 1986). These largely displaced traditional *emoticons* such as ":-)" and ":)", which as well were chiefly used to convey humor and emotion (Derks et al., 2008), as also reflected in their name, a portmanteau of the words *emotion* and *icon*.

This mandates additional analysis of the nexus between emojis and emotion. Past work has compiled a list of sentiment polarity scores for a set of emojis (Novak et al., 2015). Rakhmetullina et al. (2018) categorized a set of 15 emojis into 4 different emotion classes, while Li et al. (2019) used a lexicon-based heuristic to compare connections between emojis and emotions in social media data. Several studies have explored the linguistic connection between words and emojis (Cappallo et al., 2019; Barbieri et al., 2017; Na'aman et al., 2017; Shoeb et al., 2019). However, previous work has not assessed to what extent humans associate particular emotions with different emojis.

In this work, we present EmoTag1200, a dataset of human ratings of association for a set of 150 popular emojis with regard to 8 different emotions. Each of the resulting 1,200 pairs of emojis and emotions has been annotated by 9 human raters on a 5-point scale. The purpose of this endeavor is to measure the degree of emotion that people associate with the use of a given emoji in written expression. As the set of emotions, we consider the eight basic ones in the Wheel of Emotions by Plutchik (1980), i.e., *anger*, *anticipation*, *disgust*, *fear*, *joy*, *sadness*, *surprise*, and *trust*. The EmoTag1200 dataset as well as additional emoji-related resources are available online[1].

We assess the emotion scores of this set of emojis and subsequently study a series of simple unsupervised models to predict such emotion intensity scores automatically. For this, we investigate standard pre-trained vector embedding models, but also consider an emoji-centric corpus consisting of 20.8M tweets to study how it can expose semantic relationships between emotion words and

November 16–20, 2020.

emojis, drawing on additional lexical resources. The results suggest that models drawing on word-level emotion intensity information as background knowledge fare better than vanilla vector embedding models.

2 Background and Related Work

Emotion and Communication. Darwin (1872) was among the first to consider the connection between emotions and their expression in substantial detail. He remarked for instance, that for both animals and humans, anger coincides with eye muscle contractions and teeth exposure, and commented on the fact that humans lift their eyebrows in moments of surprise. His work then goes on to study the role of such forms of facial expression in conveying to others how an animal feels, studying primates as well as human infants and adults.

In light of this important role, humans continue to rely extensively on such nonverbal cues in oral forms of linguistic communication. Although a person's emotion and mood can to some extent be conveyed by means of suitable content words (e.g., "I am happy to hear that!") or interjections ("Wow!"), face-to-face communication has important properties that written communication tends to lack (Bordia, 1997). These include facial expressions of the aforementioned sort, but also gesture and intonation. In certain problem-solving settings, for instance, face-to-face communication may hence prove more efficient and effective (Bordia, 1997).

Accordingly, throughout the history of writing, humans have resorted to surrogate mechanisms to convey emotive signals, attempting to push the boundaries and overcome some of the inherent restrictions of plain written language as a medium, e.g., by means of illustrative embellishments and ornaments (Voronova and Sterligov, 1997). User studies have shown that images (Lang et al., 1999), color (Bartram et al., 2017; Kulahcioglu and de Melo, 2019), and typography (Kulahcioglu and de Melo, 2018, 2020) contribute to conveying affect.

Emoticons. Emoticons such as ":-)" and Japanese 顔文字 (*kaomoji*) such as "(^_^)", both composed from regular symbols, have been in use for several decades. Early studies focused on the use of emoticons in social media. Go et al. (2009) proposed a form of distant supervision by using emoticons as noisy labels for Twitter sentiment classification. Davidov et al. (2010) adopted a similar approach by handpicking smileys and hashtags as tweet labels to train a supervised model to classify the sentiment of tweets.

Emojis. Emoji characters are pictorial, similar to earlier dingbat characters, but also colorful. Despite the lexicographic similarity between the two words *emoji* and *emotion*, etymologically, the former stems from the Japanese words 絵 (*e*, picture) and 文字 (*moji*, character). Emojis originated in Japan in the 1990s and have only recently spread globally. Historically, the spread of emojis has been driven in large part by their adoption in popular messaging and social media platforms, which led, among other things, to their inclusion in Shift JIS, and, subsequently, the Unicode standard. Nowadays, they are ubiquitous in social media and chat applications, but increasingly also in emails and other digital correspondence.

Emojis have a number of different roles. Kaye et al. (2017) explained how emojis may aid the interlocutor in disambiguating utterances that would otherwise remain ambiguous.

One of their principal uses has been to convey emotion, particularly via facial expression emojis, as explained in Section 1. In 2015, Oxford Dictionaries declared the *Face with Tears of Joy* emoji its Word of the Year 2015. Emojis may also be useful as a more instantaneously and widely recognized form of communicating degrees of satisfaction. Kaye et al. (2017) go as far as suggesting them for consideration as possible alternatives to regular Likert scales.

Emoji Semantics. The MIT DeepMoji project (Felbo et al., 2017) developed a model that recommends emojis given a natural language sentence as input. A deep neural architecture was trained on a collection of 1.2B tweets to learn the sentiment, emotions, and the use of sarcasm in short text.

Barbieri et al. (2016b) proposed a method to learn vector space embeddings of emojis using the standard word2vec skip-gram approach, applied to a large collection of tweets. In contrast, Eisner et al. (2016) attempted to learn vector embeddings of emojis based on their short descriptions in the Unicode standard. EmojiNet (Wijeratne et al., 2017) provides a sense inventory to distinguish different senses of an emoji, drawing on Web-crawled emoji definitions and connecting them to word senses from a lexical resource, along with vector representations of context words.

The first paper to thoroughly investigate the sentiment of emojis (Novak et al., 2015) proposed a sentiment ranking of 715 emojis on a corpus of 70,000 tweets. This work provides a basis for future research on the logographic usage of emojis in social media. Rakhmetullina et al. (2018) classify 15 emojis with regard to their sentiment polarity and with regard to 4 emotion classes. For this, they applied a distant supervision technique for a reliable mapping based on manually annotated data. Li et al. (2019) used a heuristic to observe ties between emojis and emotions in social media data and compared emoji usage on Twitter and Weibo. Their heuristic involves training word vector models and then invoking a word–emotion lexicon to obtain average vectors for 8 emotions. Finally, EmoTag (Shoeb et al., 2019) provides interpretable word vectors that describe words in terms of their association with emojis. These vectors were found to be useful for emotion prediction.

Zhou and Wang (2017) trained a natural language conversation model that accounts for the underlying emotion of utterances by exploiting the existence of emojis as a signal.

3 Annotation Task

In order to better study the connection between emojis and emotions, we proceeded to compile a dataset of ratings quantifying the perceived strength of association between emojis and emotions.

3.1 Task Setup and Guidelines

Target Emoji Set. We considered a set of 150 most frequently used emojis, based on frequencies reported by the Emoji Tracker service[2], a platform that visualizes the real-time use of emojis on Twitter. The counters on Emoji Tracker indicate how many times an emoji has been used on Twitter since July 4, 2013. We rank all emojis based on their reported total frequency counts as of July 3, 2019 and pick the top 150 emojis for our annotation task. While their frequencies are based on global data, the ranking remains useful because of the large proportion of English tweets (Vicinitas, 2018) and the fact that emoji use is broadly similar across languages (Barbieri et al., 2016a), despite certain language-specific differences.

Emotion Set. While numerous emotion models and affective classification schemes have been put forth, for this study we consider the 8 basic emotions proposed in the Wheel of Emotions model by Plutchik (1980), i.e., *anger*, *anticipation*, *disgust*, *fear*, *joy*, *sadness*, *surprise*, and *trust*.

Linguistic Context. In this study, we focus on emoji use within the English language. A previous study found that the meaning of an emoji remains relatively stable across different languages and media (Barbieri et al., 2016a). In part, this may stem from the language-independent visual nature of emojis. However, different concepts may have different associations in different cultures, so our results cannot be taken as being universal.

Ratings. For a given emoji, the participants were asked to assess to what extent said emoji is associated with a given emotion, for each of the 8 different target emotions.

Association is a broad notion that not only covers emojis that are directly invoked to express an emotion, as in the case of certain facial expression emojis, but also encompasses mere conceptual association. For instance, the wrapped gift emoji may be associated with *joy*, although the semantics of the emoji itself correspond to a *present* or *gift* rather than directly conveying *joy*.

Note also that this notion of association reflects a general, abstract form of connection, much like a prior. Clearly, embedded in a specific utterance, the specific emotions that are evoked may differ quite substantially, due to the complex ways in which different words along with embedded emojis interact to give rise to an overall interpretation. In this regard, our ratings are similar to widely used word relatedness resources that seek to quantify context-independent lexical associations (Finkelstein et al., 2001) or word–emotion associations (Mohammad and Turney, 2013; Mohammad, 2018).

The degree of association was specified numerically as a score ranging from 0 (no association with the emotion) to 4 (representing the highest degree of association with the emotion). While we are cognizant of the challenges of directly eliciting scalar ratings from the annotators, we opted to follow prominent previous work on collecting association ratings (Rubenstein and Goodenough, 1965; Finkelstein et al., 2001; Hill et al., 2015; Gerz et al., 2016) in order to make our data comparable to such efforts.

3.2 EmoTag1200 Data Collection

Interface. We developed a web interface to collect ratings. We randomly split the target set of 150

---

[2] `http://emojitracker.com/`

emojis into a total of 6 subsets, each consisting of 25 emojis. When a rater selects a set from the main page, the corresponding 25 emojis are presented to the user alongside their official names, each to be annotated with respect to our set of 8 different emotions.

Within each set, we randomize the order of displayed emojis upon each page load, such that different raters do not observe and annotate them in the same order. This ensures that different emojis within a set are given equal attention on average when aggregating scores from different human raters, mitigating potential fatigue-driven biases in the final ratings.

In total, an annotator makes 8 selections for a single emoji, corresponding to the set of 8 basic emotions. We ask users to provide all 8 emotions ratings for every single emoji. This is because a single emoji may be tied to different kinds of emotions. For example, the Kiss Mark 💋 emoji may express joy, trust, anticipation, among others. This is why our annotation task was designed to solicit scores ranging from 0 to 4 for eight different emotions for each individual emoji.

Participants. We recruited a total of 9 different human participants to each rate 150 emojis for 8 different emotions. All selected participants were from the age group between 25 and 35 years and native or near-native speakers of English who reported having extensive prior familiarity with emojis in their personal communication or from social media use. As mentioned, the emojis were grouped into 6 sets, each consisting of 25 emojis. The annotators were asked to annotate one such set per day so as to avoid overburdening them, which might affect the quality of the rating.

The original intensity scores range from 0 to 4, but are rescaled to $[0, 1]$. Ultimately, for each pairing of emoji and emotion, we consider the mean value across the 9 individual raters as a real-valued score in $[0, 1]$ reflecting the association for that pairing. We also compute for each pairing the standard deviation among its ratings.

3.3 Analysis

In total, we collect 10,800 ratings for 1,200 pairings of emoji and emotion, covering 150 emojis, each rated with regard to 8 emotions by 9 human raters.

Inter-Annotator-Agreement. To evaluate the agreement between the raters, we first check the overall agreement between pairs of human raters across the entire set of emoji–emotion ratings. This was in part also motivated by quality control concerns, i.e., a desire to assess whether there was any individual rater that disagreed substantially with all other raters. Fortunately, this was not the case and we decided not to eliminate data from any rater. Figure 1 reports the pairwise Pearson correlation scores between raters.

	R1	R2	R3	R4	R5	R6	R7	R8	R9
R1	1	0.4	0.4	0.34	0.47	0.48	0.39	0.36	0.37
R2	0.4	1	0.58	0.57	0.53	0.46	0.54	0.65	0.38
R3	0.4	0.58	1	0.53	0.56	0.44	0.47	0.6	0.36
R4	0.34	0.57	0.53	1	0.42	0.35	0.51	0.54	0.31
R5	0.47	0.53	0.56	0.42	1	0.62	0.5	0.53	0.43
R6	0.48	0.46	0.44	0.35	0.62	1	0.39	0.46	0.34
R7	0.39	0.54	0.47	0.51	0.5	0.39	1	0.48	0.31
R8	0.36	0.65	0.6	0.54	0.53	0.46	0.48	1	0.4
R9	0.37	0.38	0.36	0.31	0.43	0.34	0.31	0.4	1

Figure 1: Pairwise Pearson correlation for 9 raters based on all 8 emotion scores for the set of 150 most popular Twitter emojis

We focus on Pearson correlation in this analysis in order to later be able to compare these scores against Pearson correlation scores obtained when comparing automated prediction methods against the ground truth (Section 4). In Figure 2, we consider separately for different emotions the average agreement (Pearson correlation) of raters with the mean ratings. We find that a fairly high agreement is observed for *sadness*, *joy*, and *fear*. In contrast, we conjecture that for *surprise*, *trust*, and *anticipation*, it appears somewhat less obvious which emojis one would normally use to convey such emotions. Instead, we observe that individual annotators sometimes provided high rating scores based on idiosyncratic associations. One rater, for instance, associated a gemstone with a high degree of anticipation, while the others did not. It is important to be aware of these varying correlation scores and compute separate correlation scores per emotion when evaluating emotion prediction models on this data. In Figure 3, we visualize the emotion-specific agreement for different individual raters.

Emoji-Specific Agreement. We also invoke Krippendorff's α as a measure of agreement between raters for each individual emoji along with its emotions. This allows us to understand to what

Emoji	**Name**	**Emotion**	**All Ratings**	**Emotion Score**	**K. α**	**SD σ**
U+1F621 😡	Pouting Face	Anger	1.00 (9×)	1.00	0.61	0.00
U+1F60A 😊	Smiling Face with Smiling Eyes	Joy	0.75 (3×), 1.00 (6×)	0.92	0.68	0.12
U+1F62D 😭	Loudly Crying Face	Sadness	1.00 (9×)	1.00	0.48	0.00
U+1F633 😳	Flushed Face	Fear	0.00 (2×), 0.25 (2 ×), 0.50, 0.75 (2×), 1.00 (2×)	0.50	0.12	0.37
U+1F449 👉	Backhand Index Pointing Right	Anticipation	0.00 (6×), 0.5, 0.75, 1.00	0.25	0.11	0.37

Table 1: Examples emoji emotion ratings along with Krippendorff's (K) α and Standard Deviation (SD) σ.

Groups	Anger	Anticipation	Disgust	Fear	Joy	Sadness	Surprise	Trust
B4 ($\geq$ 0.75)	3	1	0	3	**23**	6	2	2
B3 ($\geq$ 0.50)	3	5	14	8	**24**	8	5	**24**
B2 ($\geq$ 0.25)	19	**86**	20	18	35	13	33	38
B1 ($\geq$ 0.00)	**125**	58	116	121	68	123	110	86

Table 2: The distribution of 150 target emojis across four buckets B1, B2, B3, and B4 with respect to their gold intensity score for all 8 emotions. The bold score represents which emotion gets the highest number of emojis in the respective bucket.

Emotions	**Top 150 Emojis** (EmoTag1200)	**Other Predicted Emojis** (excluding Top 150)
Anger	😠 Angry Face	👺 Japanese Goblin
	😡 Pouting Face	👹 Japanese Ogre
	😤 Face with Steam from Nose	🔪 Hocho
Anticipation	👀 Eyes	🎆 Fireworks
	💭 Thought Balloon	🌠 Shooting Star
	💰 Money Bag	👰 Person with Veil
Disgust	😖 Confounded Face	🐜 Ant
	😣 Persevering Face	👹 Japanese Ogre
	👎 Thumbs Down	😲 Astonished Face
Fear	😨 Fearful Face	🔪 Hocho
	😱 Face Screaming in Fear	👹 Japanese Ogre
	😰 Anxious Face with Fear	👺 Japanese Goblin
Joy	☺️ Smiling Face	🎂 Birthday Cake
	😆 Grinning Squinting Face	🎊 Confetti Ball
	😂 Face with Tears of Joy	💝 Heart with Ribbon
Sadness	😢 Crying Face	🔪 Hocho
	😭 Loudly Crying Face	👼 Baby Angel
	💔 Broken Heart	😿 Crying Cat Face
Surprise	‼️ Double Exclamation Mark	😮 Face with Open Mouth
	❗ Exclamation Mark	😵 Dizzy Face
	😱 Face Screaming in Fear	🙀 Weary Cat
Trust	😙 Kissing Face with Smiling Eyes	⛪ Church
	💕 Two Hearts	👪 Family
	🌹 Rose	⚓ Anchor

Table 3: Three top-ranked emotion-intensive emojis for eight emotions, considering ground truth annotations from the top 150 emojis in our ground-truth EmoTag1200 dataset on the left, and using unsupervised emotion intensity predictions for the remaining emojis (i.e., those not included in the set of 150) on the right.

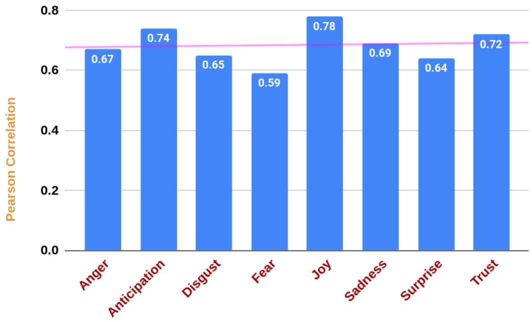

Figure 2: Average Pearson correlation coefficient between rater score and the gold score grouped by emotions. The pink line represents the overall trend.

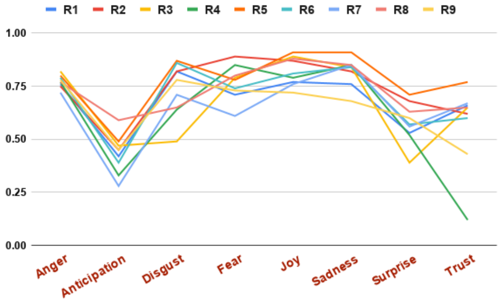

Figure 3: Variation of Pearson correlation coefficient for individual raters with the mean score across emotions

extent the raters agree or disagree on the rating of a *particular emoji–emotion* pairing. The scores range from 0 to 1, where $\alpha = 0$ denotes no agreement and $\alpha = 1$ represents the highest level of agreement among all users. Table 1 shows a few examples of emojis with specific emotions and their associated ratings, including the Krippendorff α value and standard deviation. We include examples with high as well as low agreement.

Distribution and Examples. In Table 2, we report the distribution of scores for different emotions. As one might reasonably expect, the lowest-intensity bucket is the largest for each considered emotion. Overall, fairly few emojis are strongly associated with *anger*, *disgust*, *fear*, *sadness*, or *surprise*. For *disgust*, no emoji falls into the highest-intensity bucket, although some show a moderate intensity level. There are numerous emojis associated with *anticipation*. The most atypical distribution is observed for *joy*, as there appear to be a wide range of objects and concepts that spark joy, in addition to the emojis that directly express joy.

Finally, in Table 3, we list the top-ranked 3 emotion-bearing emojis for each of the 8 considered emotions based on our dataset ("Top 150 Emojis" column) as well as based on an automated prediction for other emojis not in our annotated dataset (described later in Section 4.3). Indeed, for many emotions, we encounter some of the most prototypically expected emojis, especially facial expression ones. Note that in some cases, common use diverges from the original Unicode definitions of the emojis, as for instance for the "Persevering Face" 😣 emoji, which is also associated with *disgust* rather than just with perseverance.

4 Emotion Scoring Experiments

Given our manually collected data for 150 emojis, we next consider to what extent simple *unsupervised* methods and resources correlate with these associations such that they could be used to reproduce such associations automatically in a data-driven manner. The EmoTag1200 data compiled in Section 3, specifically the mean ratings for emoji–emotion pairs, serve as the ground truth.

4.1 Corpus Data

To enable an unsupervised prediction, we explore methods relying on several different kinds of resources, including existing pre-trained word embedding models and word emotion lexicons, which will be described later on in Section 4.2 when introducing the specific methods.

Additionally, we make use of distributional similarity to support several of the methods. For this, we draw on an emoji-centric corpus. In order to infer the correlation of emojis with emotion-bearing words and vice versa, we created a web crawl of tweets collected specifically to provide emoji statistics by seeking out tweets containing at least one emoji. We consider a set of 620 most frequently used emojis from Novak et al. (2015) and from Emoji Tracker. For each emoji, we then retrieved an equal number of tweets labeled as being in English. In total, we obtained a set of 20.8 million tweets over a span of one year (Shoeb et al., 2019).

Subsequently, we train simple 300-dimensional word2vec skip-gram (Mikolov et al., 2013) models on this corpus. As this corpus contains numerous occurrences of emojis, the resulting word vector representations include vectors for emojis, and we are able to compute the cosine similarity between emojis and words.

In the following, we explain how this data comes into play while predicting emotion ratings for any emojis available in our corpus.

4.2 Prediction Methods

We consider several methods to predict emoji–emotion association scores. These include methods that directly consult distributed word vectors, as well as methods that draw on different kinds of word emotion lexicons.

Distributed Word Vectors based on Emotion Words. The first method we consider is to directly rely on standard distributed word embeddings E (with vocabulary $\mathcal{V}_E$), as these have been shown to carry emotional associations (Raji and de Melo, 2020). Given an emoji e and an emotion (affect) a, we consult E attempting to obtain a vector $\mathbf{v}_e$ for the emoji as well as a vector $\mathbf{v}_{l_a}$ for the word l_a that serves as a label for the affect a (e.g., the words *joy*, *anger*, etc.). We then compute the association in terms of the cosine similarity and treat it as the rating:

$$\sigma(e,a) = \begin{cases} \mathrm{sim}(\mathbf{v}_e, \mathbf{v}_{l_a}) & e, l_a \in \mathcal{V}_E \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

Here, $\mathrm{sim}(\mathbf{v}_1, \mathbf{v}_2)$ denotes the cosine similarity between two vectors.

We first consider the widely used 300-dimensional GloVe (Pennington et al., 2014) models pretrained on CommonCrawl 840B and Twitter, as these contain emojis. However, given that their emoji coverage is limited, we additionally consider word2vec (Mikolov et al., 2013) skip-gram models that we trained on our crawled Twitter data from Section 4.1, using window sizes of 5 and 25.

Binary Word Emotion Lexicons based on Emoji Corpus Similarities. We next consider a series of approaches that rely on word emotion lexicons in conjunction with our emoji corpus to connect these lexicons to emojis. EmoLex by Mohammad and Turney (2013), also known as the NRC Emotion Lexicon, is among the most prominent English language word emotion lexicons. It assigns words binary labels for the same eight emotions that we consider in our study. Thus, a word may either be tagged as being associated with *trust* or as not being associated with it. Specifically, we consult EmoLex to find the subset of words $\mathcal{V}_a$ from the vocabulary $\mathcal{V}$ that are associated with affect a.

To find a connection between emojis and words in the lexicon, we again draw on our emoji corpus from Section 4.1. We rank the top $k = 5$ words from the lexicon's $\mathcal{V}_a$ based on the word–emoji cosine similarities induced from our corpus, and finally compute an emoji e's emotion score $\sigma(e,a)$ for affect a as the average of similarity scores for the top k words:

$$\sigma(e,a) = \frac{1}{k} \sum_{w \in \mathrm{T}(e,\mathcal{V}_a)} \mathrm{sim}(\mathbf{v}_e, \mathbf{v}_w) \quad (2)$$

Here, $\mathbf{v}_e$ denotes our emoji corpus vector embedding for an emoji e, while $\mathbf{v}_w$ denotes our emoji corpus vector embedding for a word w. Such words are taken from $\mathrm{T}(e,\mathcal{V}_a)$, defined as the set of top-k words w in $\mathcal{V}_a$, i.e., among those words tagged as having the affect a in the lexicon, ranked in terms of $\mathrm{sim}(\mathbf{v}_w, \mathbf{v}_e)$ scores, where $\mathrm{sim}(\mathbf{v}_1, \mathbf{v}_2)$ again denotes the cosine similarity between two vectors. Note that a top-k word can be considered only if it is available in the binary word emotion lexicon (EmoLex). Indeed, some potentially valuable out-of-vocabulary (OOV) word forms are disregarded, as they do not have any available emotion labels. Examples of such top-ranked OOV word forms are *helooooo*, *funnnn*, etc.

Word Emotion Intensity Lexicons using Emoji Corpus Similarities. Next, we consider emotion lexicons that, unlike EmoLex, provide real-valued emotion scores for English words. In this case, the emotion intensity scores of words directly figure into the predicted scores. We first consult the lexicon to find all words $\mathcal{V}_a$ for which the lexicon provides any emotion intensity score at all for affect a. We then identify the top k words in terms of the word–emoji cosine similarity scores based on our emoji corpus, as earlier. Finally, however, our predicted score $\sigma(e,a)$ is the arithmetic mean of emotion intensity scores of the top k words. Specifically,

$$\sigma(e,a) = \frac{1}{k} \sum_{w \in \mathrm{T}(e,\mathcal{V}_a)} \tau(w,a), \quad (3)$$

where $\tau(w,e)$ denotes the emotion intensity score provided by the lexicon and the remaining variables are defined as earlier.

In our experiments with this approach, we consider two separate word emotion lexicons: the NRC Emotion Intensity lexicon (NRC-EIL) by Mohammad (2018) and DepecheMood++ by Araque et al.

Source	Variant	Anger	Anticip.	Disgust	Fear	Joy	Sadness	Surprise	Trust	Average

Table 4: Pearson Correlation scores for all considered prediction methods. Bolded scores represent the highest correlation observed for the emotion in the respective column except for the human agreement score.

(2018). The latter has a different emotion inventory than the Plutchik (1980) emotion labels that we rely upon, so we apply the following mapping: *angry* ↦ *anger*, *afraid* ↦ *fear*, *happy* ↦ *joy*, *sad* ↦ *sadness*, and *amused* ↦ *surprise*. DepecheMood++ is an automatically constructed lexicon that provides frequencies of each word along with their emotion score. We apply a minimal frequency threshold of 50, as this was found to eliminate less reliable entries.

Word Emotion Intensity Lexicons using Emoji Corpus co-occurrences. Finally, we further consider a variant of the above formula, where $\mathrm{T}(e, \mathcal{V}_a)$ does not rank words in terms of word2vec cosine similarities, but instead based on their co-occurrence frequency with the emoji e in our Twitter corpus.

4.3 Results

Table 4 compares the mean human-annotated emotion ratings from EmoTag1200 against predicted scores induced using the aforementioned methods, evaluated in terms of Pearson correlation coefficients.

The pretrained GloVe embeddings exhibit very low correlations, as both models have a limited coverage of just 26 out of the 150 emojis in the ground truth data. Our emoji-centric corpus yields stronger results. Among the two variants, word vectors trained with a larger context window size of 25 perform better, because emojis are often placed at the end of tweets. This result also accords with previous studies that show that larger context windows tend to capture generic relatedness, while shorter ones emphasize functional similarity of words (Levy and Goldberg, 2014).

Using EmoLex with our binary emotion label scores, we observe varied results, including strong correlation for *disgust*, but low or even negative for several others. This is because the EmoLex lexicon merely signals whether or not it considers a word as being associated with an emotion. Such binary emotion labels do not appear to convey sufficient information for a more accurate prediction.

With the NRC Emotion Intensity lexicon (Mohammad, 2018), we are able to obtain substantially higher correlations for a range of different settings of top-k words, both with our emoji corpus vector similarity as well as with co-occurrence frequency rankings. Thus, high-quality emotion lexicons providing crowdsourced emotion intensity ratings provide valuable information beyond what distributed word vectors deliver directly.

DepecheMood++, owing to its automatic data-driven induction process, does not yield as good results as the high-quality crowdsourced scores compiled in the NRC Emotion Intensity lexicon. Moreover, DepecheMood++ does not cover all emotions in the ground truth dataset.

Overall, we find that we are able to obtain a high correlation with the human ratings in EmoTag1200. Thus, we apply our models to predict scores for a larger set of 620 emojis from our emoji corpus. In

Table 3, we list the top 3 emojis for each emotion in terms of the predictions using the similarity-based approach with NRC-EIL (k=300), but excluding any emojis already in our EmoTag1200 ground truth data. The results (column labeled "Other Predicted Emojis") show that we are automatically able to find additional emojis tied to emotions.

5 Conclusion

The desire to express an emotion is one of the factors that has driven the tremendous proliferation of emojis in interpersonal communication. However, this connection has not been studied in sufficient detail, at the level of individual emojis. In this work, we shed light on this connection by compiling the EmoTag1200 dataset, which quantifies people's reported association between emojis and emotion. From each of 9 human raters, we solicit 1,200 ratings covering a set of 150 emojis with regard to 8 core emotions from Plutchik (1980)'s Wheel of Emotions. This constitutes the first resource of this kind, which we thoroughly analyze and make freely available to enable further research.

An important avenue of future work will be to assess to what extent there may be cultural differences in these associations (see Discussion in Section 3.1). Similarly, variation with respect to age and other variables merits further study as well. Temporal aspects could be considered in diachronic studies, to account for the fact that emoji use has been evolving.

Finally, we rely on our annotated data to study how well we can automatically estimate emotional association ratings for a given emoji, considering a series of different baseline methods and resources. Our findings suggest that data-driven methods can fare quite well at this if combined with high-quality affective intensity information at the lexical level. Hence, we are able to predict high-quality emotion scores for a larger set of emojis.

This opens up further research avenues on possible downstream applications exploiting this knowledge. The most obvious use cases are sentiment analysis (Dong and de Melo, 2018), emotion analysis (Raji and de Melo, 2020), consumer behaviour analytics (Dong et al., 2020), context-sensitive emoji recommendation (Felbo et al., 2017), computational social science and public opinion mining (Wang et al., 2018; Du et al., 2020), and user modeling (Guo et al., 2018), but it may also be useful in dialogue systems (Delobelle and Berendt, 2019), e.g. to detect sarcasm. As emoji use is now ubiquitous on mobile devices and social media, we believe that ultimately any NLP task involving social media text may benefit from such emoji resources.

Acknowledgments

We sincerely thank all our annotators who volunteered to contribute to our study and helped us to establish this new resource for the community. Clearly, this research would not have been possible without their time and effort.

Abstract

Current approaches to empathetic response generation view the set of emotions expressed in the input text as a flat structure, where all the emotions are treated uniformly. We argue that empathetic responses often mimic the emotion of the user to a varying degree, depending on its positivity or negativity and content. We show that the consideration of these polarity-based emotion clusters and emotional mimicry results in improved empathy and contextual relevance of the response as compared to the state-of-the-art. Also, we introduce stochasticity into the emotion mixture that yields emotionally more varied empathetic responses than the previous work. We demonstrate the importance of these factors to empathetic response generation using both automatic- and human-based evaluations. The implementation of MIME is publicly available at `https://github.com/declare-lab/MIME`.

1 Introduction

Empathy is a fundamental human trait that reflects our ability to understand and reflect the thoughts and feelings of the people we interact with. In the social sciences, research on empathy has evolved into an entire field of study, addressing the social underpinning of empathy (Singer and Lamm, 2009), the cognitive and emotion aspects of empathy (Smith, 2006), and its connection to personal and demographic traits (Dymond, 1950; Eisenberg et al., 2014; Krebs, 1975). The study of empathy has found a wide range of applications in healthcare, including psychotherapy (Bohart and Greenberg, 1997) or more broadly as a mechanism to improve the quality of care (Mercer and Reynolds, 2002).

I am so excited because I am finally going to visit my parents next month! I did not see them for 3 years.

3 years is a long time. How come?

Figure 1: An instance where a positive context is responded with ambivalence.

Computational models of empathy have been proposed only in recent years, partly because of the complexity of this behavior which makes it difficult to emulate with computational approaches. In natural language processing, the methods proposed to date address the tasks of understanding expressions of empathy in newswire (Buechel et al., 2018), counseling conversations (Pérez-Rosas et al., 2017), or generating empathy in dialogue (Shen et al., 2020; Lin et al., 2019). Work has also been done on the construction of empathy lexicons (Sedoc et al., 2020) or large empathy dialogue datasets (Rashkin et al., 2019).

In this paper, we address the task of generating empathetic responses that mimic the emotion of the speaker while accounting for their affective charge (positive or negative). We adopt the idea of emotion mixture, as the state-of-the-art MoEL (Lin et al., 2019), to achieve the appropriate balance of emotions in positive and negative emotion groups. However, inspired by Serban et al. (2017), we introduce stochasticity into the mixture at emotion-group level for varied responses. This becomes particularly important in cases where the input utterance can be responded with ambivalent, yet befitting utterances. Fig. 1 shows one such example where the response to a positive utterance is ambivalent.

The paper makes two important contributions. First, it introduces a new approach for empathetic generation that encodes context and emotions, and uses emotion stochastic sampling and emotion

---

[*] signifies equal contribution

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8968–8979,
November 16–20, 2020.

mimicry to generate responses that are appropriate and empathetic for positive or negative statements. We show that this approach leads to performance exceeding the state-of-the-art when trained and evaluated on a large empathy dialogue dataset. Second, through extensive feature ablation experiments, we shed light on the role played by emotion mimicry and emotion grouping for the task of empathetic response generation.

2 Related Work

Open domain conversational models have made good progress in recent years (Serban et al., 2016; Vinyals and Le, 2015; Wolf et al., 2019). Many of them can generate persona-consistent (Zhang et al., 2018) and diverse (Cai et al., 2018) responses, but those are not necessarily empathetic.

Producing empathetic responses requires apt handling of emotions and sentiments (Fung et al., 2016; Winata et al., 2017; Bertero et al., 2016). Zhou et al. (2018) model psychological concepts as memory states in LSTM (Hochreiter and Schmidhuber, 1997) and employ emotion-category embeddings in the decoding process. Wang and Wan (2018) presents a GAN (Goodfellow et al., 2014) based framework with emotion-specific generators. On a larger scale, (Zhou and Wang, 2018) use the emojis in Twitter posts as emotion labels and introduce an attention-based (Luong et al., 2015) Seq-to-Seq (Sutskever et al., 2014) model with Conditional Variational Autoencoder (Sohn et al., 2015) for emotional response generation. However, they only produce affective responses with user-provided emotion, which may not necessarily be empathetic to the speakers. Wu and Wu (2019) introduce a dual-decoder network to generate responses with given sentiment (positive or negative). Shin et al. (2020) formulate a reinforcement learning problem to maximize user's sentimental feeling towards the generated response. Lin et al. (2019) present an encoder-decoder model with each emotion having a dedicated decoder.

Variational Bayes (Kingma and Welling, 2013; Rezende et al., 2014) has been widely adopted into natural language generation tasks (Bowman et al., 2015) and successfully extended to dialog generation tasks (Serban et al., 2017).The prominent approach by Hierarchical Encoder-Decoder (VHRED) (Serban et al., 2017) integrates VAE with the sequence-to-sequence decoder based on Markov assumptions.

3 Methodology

Our model MIME is based on the assumption that empathetic responses often mimic the emotion of the speaker (Carr et al., 2003) — in our case, the human subject or user. For example, positively-charged utterances are usually responded with positive emotions, although they can also be ambivalent as illustrated in Fig. 1. On the other hand, responding to negatively-charged utterances often requires composite emotions that agree with the user's emotion, but also tries to comfort them with some positivity, such as hopefulness or silver lining. As such, we strive to balance the mimicry of context/user emotion during empathetic response generation.

To this end, we first obtain context representation using a transformer encoder architecture (Vaswani et al., 2017). Similar to the state-of-the-art (SOTA) model MoEL (Lin et al., 2019), we enforce emotion understanding in the context representation by classifying user emotion during training. For the response emotion, we first group the 32 emotions into two groups containing *positive* and *negative* emotions (Section 3.3). Next, a probability distribution of emotions is sampled for each of these groups that corresponds to the emotion of the response. Positive and negative response emotion representations are formed from these distributions and emotion embeddings. These two representations are appropriately combined to balance the two kinds of emotions to form the emotional representation that drives the emotional state during response generation using transformer decoder (Vaswani et al., 2017). Fig. 2 shows the architecture of our model.

3.1 Task Definition

Given the context utterances $[u_0, u_1, \ldots, u_{n-1}]$, where utterance $u_i = [w_0^i, w_1^i, \ldots, w_{m-1}^i]$ consists of maximum m words, the task is to generate an empathetic response to the last utterance u_{n-1}, which is always from the target speaker or user. All the even-numbered $(u_0, u_2, \ldots)$ and odd-numbered $(u_1, u_3, \ldots)$ utterances belong to the user and the empathetic agent, respectively. Optionally, the context/user emotion e can be predicted for emotion understanding. The emotions are listed in Table 1.

3.2 Context Encoding

Following the MoEL system (Lin et al., 2019), firstly, the contextual utterances are sequentially concatenated into a string of k $(\leq mn)$

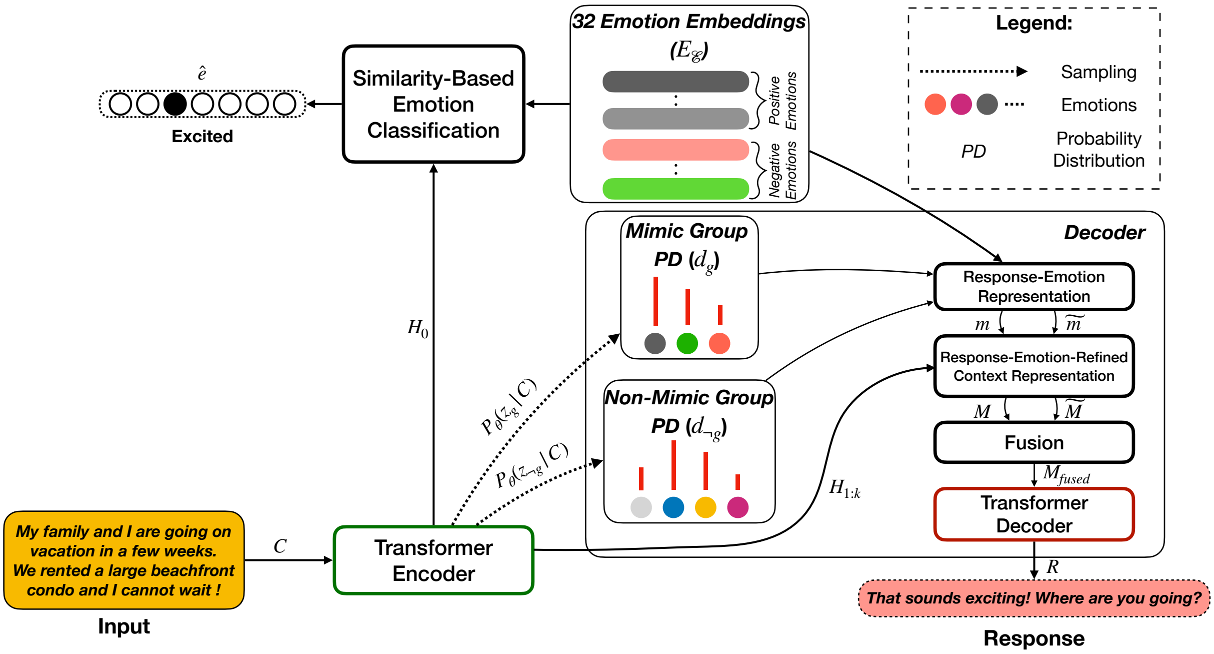

Figure 2: Architecture of our model (MIME).

words $C = [u_0 \oplus u_1 \oplus \cdots \oplus u_{n-1}] = [w_0^0, w_1^0, \ldots, w_0^1, w_1^1, \ldots, w_{m-1}^{n-1}]$, where $\oplus$ is the concatenation operator.

As in MoEL, each word w_j^i is represented as a sum of three embeddings (E_C): semantic word embedding (E_W), positional embedding (E_P), and speaker embedding (E_S), where $E_W(w_j^i), E_P(w_j^i), E_S(w_j^i) \in \mathbb{R}^{D_{emb}}$. Therefore, the context C is represented as

$$E_C(C) = E_W(C) + E_P(C) + E_S(C), \qquad (1)$$

where $E_C(C) \in \mathbb{R}^{k \times D_{emb}}$.

Also as in MoEL, a transformer encoder (Vaswani et al., 2017) is used for context propagation within the utterances and words in C. Moreover, inspired by BERT (Devlin et al., 2019), one additional token CTX is prepended to the context sequence C to encode the entirety of the context:

$$H = \text{TR}_{\text{Enc}}^{ctx}(E_C([CTX] \oplus C)), \qquad (2)$$

where $\text{TR}_{\text{Enc}}^{ctx}$ is the transformer encoder of output size D_h and $H \in \mathbb{R}^{(k+1) \times D_h}$ contains the context-enriched representations of the contextual words. A context-enriched representation of the CTX token, c, is taken as the overall context representation:

$$c = H_0. \qquad (3)$$

Emotion Embedding and Classification. As in MoEL and also as in Rashkin et al. (2018), to explicitly infuse emotion into the context representation c, we train a emotion classifier on c. We train emotion embeddings $E_{\mathcal{E}} \in \mathbb{R}^{n_{emo} \times D_h}$ ($n_{emo} = 32$ is the number of emotion classes) to represent each emotion. We maximize the similarity between c and the user-emotion representation $E_{\mathcal{E}}(e)$, e being the user-emotion label, using cross-entropy loss L_{cls}:

$$s = E_{\mathcal{E}} W_{\mathcal{E}} c^T, \qquad (4)$$

$$\mathcal{P} = \text{softmax}(s), \qquad (5)$$

$$L_{cls} = -\log \mathcal{P}[e], \qquad (6)$$

where $W_{\mathcal{E}} \in \mathbb{R}^{D_h \times D_h}$ and $s, \mathcal{P} \in \mathbb{R}^{n_{emo}}$.

3.3 Response Generation (Decoder)

Our primary assumption behind this model is that the empathetic agent mimics the user's emotion to some degree during response. Specifically, positive emotion is often responded with closely positive response. Negative emotion, however, is likely responded with negativity mixed with some positivity to uphold the moral.

Emotion Grouping. We split the 32 emotion types into two groups containing 13 *positive* and 19 *negative* emotions, as listed in Table 1. This split is guided by our intuition.

Positive	Negative
confident, joyful, grateful, impressed, proud, excited, trusting, hopeful, faithful, prepared, content, surprised, caring	afraid, angry, annoyed, anticipating, anxious, apprehensive, ashamed, devastated, disappointed, disgusted, embarrassed, furious, guilty, jealous, lonely, nostalgic, sad, sentimental, terrified

Table 1: 32 emotions are split into two groups by emotional positivity and negativity.

Response-Emotion Sampling. There is more than one correct way to respond empathetically. However, we observed that the SOTA model, MoEL, often resorts to generic and repetitive, although empathetic, responses. Therefore, inspired by Serban et al. (2017), we introduce stochasticity in the response-emotion determination that results in emotionally more varied responses. In Table 7, we present responses generated by MIME with and without stochasticity. To this end, we sample response-emotion distributions d_{pos} and d_{neg}, from the context C — specifically, c in $Eq.$ (3) —, for both positive and negative emotion groups, respectively. Hence, we sample an unnormalized distribution z_g ($g \in \{pos, neg\}$) from distribution $P_\theta(z_g|C)$. This z_g is passed to a fully-connected layer (FC_{d_g}) with softmax activation to obtain the normalized distribution $d_g \in \mathbb{R}^{n_g}$ ($n_{pos} = 13$ and $n_{neg} = 19$):

$$P_\theta(z_g|C) = \mathcal{N}(\mu_g^{\text{prior}}(C), \sigma_g^{\text{prior}}(C)), \tag{7}$$

$$z_g \sim P_\theta(z_g|C), \tag{8}$$

$$d_g = \text{softmax}(\text{FC}_{d_g}(z_g)). \tag{9}$$

The emotion representation for each emotion group, $e_g \in \mathbb{R}^{D_h}$, is obtained by pooling the corresponding emotion embeddings using the respective distribution d_g:

$$e_g = d_g E_{\mathcal{E}_g}, \tag{10}$$

where $E_{\mathcal{E}_g} \in \mathbb{R}^{n_g \times D_h}$ are emotion embeddings in the emotion group g — as defined in Table 1.

Sampling from distribution $P_\theta(z_g|C)$ is reparameterized as follows:

$$c' = \text{ReLU}(\text{FC}_{sample}(c)), \tag{11}$$

$$\mu_g^{\text{prior}}(C) = \text{FC}_{\mu_g}(c'), \tag{12}$$

$$\sigma_g^{\text{prior}}(C) = \exp(0.5\,\text{FC}_{\sigma_g}(c')), \tag{13}$$

$$r \sim \mathcal{N}(0, I), \tag{14}$$

$$z_g = \mu_g^{\text{prior}}(C) + r \odot \sigma_g^{\text{prior}}(C), \tag{15}$$

where $g \in \{pos, neg\}$, FC_* are fully-connected layers with output sizes D_h. Following Serban et al. (2017), $P_\theta(z_g|C)$ is obtained by maximizing the evidence lower-bound ($-L_g^{ELBO}$):

$$\begin{aligned} L_g^{ELBO} &= \text{KL}[Q_\psi(z_g|e_g, C)||P_\theta(z_g|C)] \\ &\quad - \mathbb{E}_{Q_\psi(z_g|e_g,C)}[\log P_\theta(e_g|z_g, C)], \end{aligned} \tag{16}$$

where $Q_\psi(z_g|e_g, C)$ is the approximate posterior distribution, defined as:

$$\begin{aligned} &Q_\psi(z_g|e_g, C) \\ &\quad = \mathcal{N}(\mu_g^{\text{posterior}}(e_g, C), \sigma_g^{\text{posterior}}(e_g, C)), \end{aligned} \tag{17}$$

which is similarly reparameterized, for sampling during the training only, as $P_\theta(z_g|C)$, except e_g is concatenated to c.

Emotion Mimicry. Following Carr et al. (2003), it is reasonable to assume that the empathetic response to an emotional utterance would likely mimic the emotion of the user to some degree. Responding empathetically to positive utterances usually requires positivity, occasionally including ambivalence (Fig. 1). On the other hand, the responses to negative utterances should contain some empathetic negativity, but mixed with some positivity to soothe the user's negativity. Thus, we generate two distinct response-emotion-refined context representations — mimicking and non-mimicking — that are appropriately merged to obtain response-decoder input.

Naturally, mimicking and non-mimicking emotion representations — m and $\widetilde{m}$ — are defined as follows:

$$m = e_{pos} \text{ if } e \text{ is positive, otherwise } e_{neg}, \tag{18}$$

$$\widetilde{m} = e_{neg} \text{ if } e \text{ is positive, otherwise } e_{pos}. \tag{19}$$

Firstly, response-emotion representations — m and $\widetilde{m}$ — are concatenated to the context-enriched word representations in $H_{1:k}$ (Eq. (2)) to provide the context (C) the cues on the response emotion:

$$H_{resp} = [H_i \oplus m]_{i=1}^{k}, \tag{20}$$

$$\widetilde{H}_{resp} = [H_i \oplus \widetilde{m}]_{i=1}^{k}, \tag{21}$$

where $H_{resp}, \widetilde{H}_{resp} \in \mathbb{R}^{k \times 2D_h}$ are fed to a transformer encoder ($\text{TR}_{\text{Enc}}^{resp}$) to obtain mimicking and non-mimicking response-emotion-refined context representations M and $\widetilde{M}$, respectively:

$$M = \text{TR}_{\text{Enc}}^{resp}(H_{resp}), \tag{22}$$

$$\widetilde{M} = \text{TR}_{\text{Enc}}^{resp}(\widetilde{H}_{resp}), \tag{23}$$

where $M, \widetilde{M} \in \mathbb{R}^{k \times D_h}$.

Response-Emotion-Refined Context Fusion. Enabling a mixture of positive and negative emotions could lead to diverse response generation as compared to considering exclusively positive or negative emotions. To achieve this mixture, we concatenate M and $\widetilde{M}$ at word level, as opposed to sequence level, to obtain $M' \in \mathbb{R}^{k \times 2D_h}$. Then, M' is fed to a gate consisting of a fully-connected layer ($\text{FC}_{contrib}$) with sigmoid activation, resulting $M_{contrib}$ that determines the contribution of postive and negative response-emotion-refined contexts to the response to be generated. Subsequently, M' is multiplied with the gate output, yielding the refined context M_{adjust} that is fed to another fully-connected layer FC_{fused} to obtain the fused response-emotion-refined context $M_{fused} \in \mathbb{R}^{k \times D_h}$:

$$M' = [M_i \oplus \widetilde{M_i}]_{i=0}^{k-1}, \tag{24}$$

$$M_{contrib} = \sigma(\text{FC}_{contrib}(M')), \tag{25}$$

$$M_{adjust} = M_{contrib} \odot M', \tag{26}$$

$$M_{fused} = \text{FC}_{fused}(M_{adjust}). \tag{27}$$

Response Decoding. For the final response generation from the response-emotion-refined context M_{fused}, following MoEL, a transformer decoder ($\text{TR}_{\text{Dec}}^{resp}$), with M_{fused} as key and value, is employed:

$$O = \text{TR}_{\text{Dec}}^{resp}(E_W(R_{0:t-1}), M_{fused}, M_{fused}), \tag{28}$$

$$\mathcal{P}_{resp} = \text{softmax}(\text{FC}_{decode}(O)), \tag{29}$$

$$p(R_i | C, R_{0:i-1}) = \mathcal{P}_{resp}[i], \tag{30}$$

where $O \in \mathbb{R}^{t \times D_h}$, t is the number tokens in response R (R_0 is `<start>` token), FC_{decode} is a fully-connected layer of output size $|V|$ — also the vocabulary size —, $\mathcal{P}_{resp} \in \mathbb{R}^{t \times |V|}$, and $p(R_i | C, R_{0:i-1})$ is the probability distribution on each response token.

Finally, categorical cross-entropy quantifies the generation loss with respect to the gold response R_{gold}:

$$L_{resp} = -\log p(R_{gold} | C). \tag{31}$$

3.4 Training

Naturally, we combine all the losses for model training:

$$\mathcal{L} = \alpha L_{cls} + \beta(L_{pos}^{ELBO} + L_{neg}^{ELBO}) + \gamma L_{resp}. \tag{32}$$

Total loss $\mathcal{L}$ is optimized using Adam (Kingma and Ba, 2015) optimizer with learning-rate, patience, and batch-size set to 0.0001, 2, and 16, respectively. Loss weights, α, β, and γ are set to 1. For the sake of comparability with the SOTA, the semantic word embeddings (E_W) are initialized with GloVe (Pennington et al., 2014) embeddings. All the hyper-parameters are optimized using grid search on the validation set, resulting D_h and beam-size being 300 and 5, respectively.

4 Experimental Settings

During inference, we use the emotion classifier (Eq. (5)) with emotion grouping (Table 1) to determine the positivity or negativity of the context that is necessary for the mimicking and non-mimicking emotion representations.

4.1 Dataset

We evaluate our method on EMPATHETICDIALOGUES[1] (Rashkin et al., 2018), a dataset that contains 24,850 open-domain dyadic conversations between two users, where one responds emphatically to the other. For our experiments, we use the 8:1:1 train/validation/test split, defined by the authors of this dataset. Each sample consists of a context — defined by an excerpt of a full conversation and the emotion of the user — and the empathetic response to the last utterance in the context. There are a total of 32 different emotion categories roughly uniformly distributed across the dataset.

4.2 Baselines and State of the Art

We do not compare MIME with affective response generation models (Zhou et al., 2018) as they require the response emotion to be explicitly provided, and the response may not necessarily be empathetic. As such, MIME is compared against the following models:

Multitask-Transformer Network (Multi-TR). Following Rashkin et al. (2018), a transformer encoder-decoder (Vaswani et al., 2017) generates a response as the user emotion is classified from the encoder output — equivalent to c in Eq. (3).

Mixture of Empathetic Listeners (MoEL). This state-of-the-art method (Lin et al., 2019) performs user-emotion classification as Multi-TR. However, in contrast to our method, it employs

---

[1] `https://github.com/facebookresearch/EmpatheticDialogues`

emotion-specific decoders whose outputs are aggregated and fed to a final decoder to generate the empathetic response.

4.3 Evaluation

Although BLEU (Papineni et al., 2002) has long been used to compare system-generated response against the human-gold response, Liu et al. (2016) argues against its efficacy in open-domain where the gold response is not necessarily the only correct response. Therefore, as MoEL, we keep BLEU mostly as reference. Following MoEL and Rashkin et al. (2018), we rely on human-evaluated metrics:

Human Ratings. Firstly, we randomly sample four instances of each of the 32 emotion labels from the test set, resulting in a total of 128 instances, compared to the 100 instances used for the evaluation of MoEL. Next, we ask three human annotators to rate each sub-sampled model response on a scale from 1 to 5 (best score) on three distinct attributes: **empathy** (How much *emotional understanding* does the response show?), **relevance** (How much *topical relevance* does the response have to the context?), and **fluency** (How much *linguistic clarity* does the response have?). Scores across 128 samples and three annotators are averaged to obtain the final rating.

Human A/B Test. Given two models A and B — in our case MoEL and MIME (our model), respectively — we ask three human annotators to pick the model with the best response for each of the 128 sub-sampled test instances. The annotators can select a *Tie* if the responses from both models are deemed equal. The final verdict on each instance is determined by majority voting. In case no two annotators agree on a selection – that is all three annotators reached three distinct conclusions: MoEL, MIME, and Tie – we bring in a fourth annotator. From this, we calculate the percentage of samples where A or B generates the better response and where A and B are equal.

5 Results and Discussions

5.1 Response-Generation Performance

Following Table 2, responses from MIME show improved *empathy* over MoEL and Multi-TR. We surmise this was achieved by modeling our primary intuition of appropriately mimicking user's emotion in the context through stochasticity and positive/negative grouping. Moreover, the usage of trained emotion embeddings ($E_{\mathcal{E}}$), shared between the emotion classifier and response decoder, seems to encode refined context-invariant emotional and emotion-specific linguistics cues that may lead to empathetically-improved response generation. The SOTA model, MoEL, does train a similar emotion embedding, but it is setup as the key of a key-value memory (Miller et al., 2016) which leads to a weaker connection with the decoder, resulting in less emotional-context flow. We believe this embedding sharing further leads to improved *relevance* rating for MIME, since contextual information flow is now shared between emotion embeddings and encoder output (Eq. (2)). This sharing intuitively leads to refinement in context flow.

Methods	#params.	BLEU	Human Ratings		
			Emp.	Rel.	Flu.
Multi-TR	16.95M	2.92	3.67	3.47	4.30
MoEL (SOTA)	23.10M	2.90	3.71	3.32	**4.31**
MIME	17.80M	2.98	**3.87**	**3.60**	4.28

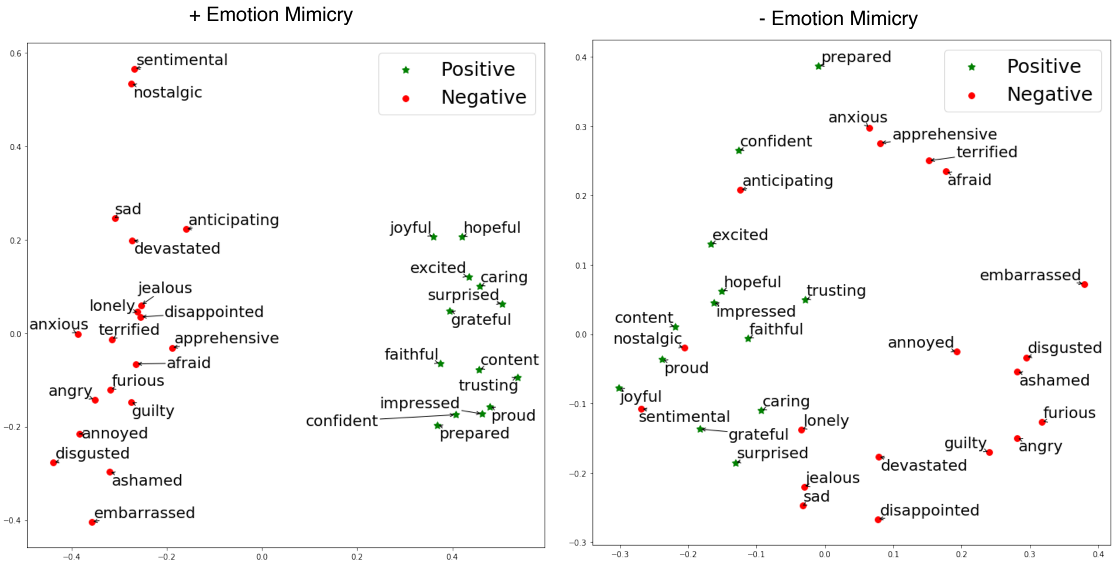
Table 2: Comparison among MIME (our model), baselines, and the state-of-the-art MoEL; Emp., Rel., and Flu. stand for Empathy, Relevance, and Fluency, respectively; the best score for each metric is highlighted by bold font.

MIME vs.	MIME Wins	MIME Loses	Tie
Multi-TR	42.25%	24.60%	33.15%
MoEL	38.82%	28.32%	32.86%
MIME w/o STC	39.84%	23.43%	36.73%

Table 3: Human A/B test results for MIME vs. MIME without stochasticity (STC), MoEL, and Multi-TR.

However, we also observe that the responses from our model have worse *fluency* than the other models, including MoEL. This might be attributed to the very structure of the decoder, that seems to refine emotional context well. This may have coerced the final transformer decoder to focus more on emotionally-apt tokens of the response than appropriate stop-words that have no intrinsic emotional content, but lead to grammatical clarity.

Human A/B Test. Based on the results in Table 3, we note that the responses from MIME are more often preferable to humans than the responses from MoEL and Multi-TR. This correlates with the results in Table 2 that indicate better empathy and contextual relevance for MIME. Further, the annotators prefer the responses from MIME with stochasticity (STC) than otherwise. Table 7 shows the impact of stochasticity on the responses.



(a) (b)

Figure 3: (a) and (b) plot the emotion embeddings, with and without emotion mimicry, respectively, mapped to two dimensions using top-two principal components.

Ratings	Multi-TR		MoEL		MIME	
	Pos	Neg	Pos	Neg	Pos	Neg
Empathy	3.77	3.61	3.73	3.76	**4.00**	**3.80**
Relevance	3.51	3.45	3.21	3.40	**3.77**	**3.49**
Fluency	4.33	4.28	**4.35**	**4.30**	4.33	4.26

Table 4: Models performance on positive and negative context; Pos and Neg stand for positive and negative emotions, respectively; the best score for each metric-polarity combination is highlighted by bold font.

Emotion Mimicry	Emotion Grouping	BLEU	Human Ratings		
			Emp.	Rel.	Flu.
✗	✗	2.45 ± 0.01	3.14	3.58	4.23
✗	✓	2.96 ± 0.02	3.67	**3.63**	4.09
✓	✓	2.98 ± 0.01	**3.87**	3.60	**4.28**

Table 5: Results of ablation; Emp., Rel., and Flu. stand for Empathy, Relevance, and Fluency, respectively.

Performance on Positive and Negative User Emotions. We observe (Table 4) that the responses generated by MIME for both positive and negative user emotions are generally better in terms of empathy and fluency. Interestingly, MoEL seems to perform better on responding to negative emotions than to positive emotions in terms of empathy and fluency. We posit this stems from the abundance of negative samples in the dataset as compared to positive samples — 13 positive and 19 negative emotions roughly uniformly distributed. This may suggest that MoEL is more sensitive to positive/negative context imbalance in the dataset than MIME and Multi-TR.

5.2 Ablation Study

Effect of Emotion Mimicry. To assess the contribution of user-emotion mimicry, we disabled it by passing e_g (Eq. (10)) directly to Eqs. (20) and (21). This results in a substantial drop in *empathy*, by 0.2 as per Table 5. We delve deeper by plotting the emotion embeddings produced with and without emotion mimicry in Fig. 3a and Fig. 3b, respectively. It is evident that the separation of positive and negative emotions clusters is much clearer with emotion mimicry than otherwise, suggesting better emotion understanding in the prior case through emotion disentanglement. On the other hand, we observe slight increase of *relevance*, by 0.03. We surmise this is caused by the absence of the confounding effect of swapping the value of m and $\widetilde{m}$, in Eqs. (18) and (19), depending on the user emotion type. This may coerce the same set of parameters to learn processing both positive and negative emotions.

Effect of Emotion Grouping. Looking at Table 5, we observe a performance drop in both *empathy* and *relevance*, by 0.73 and 0.02, respectively, in the absence of emotion grouping. This indicates the importance of having positive and negative emotions treated separately, rather than huddling them into a single distribution. We posit that the latter case causes all the emotions to compete for importance which may lead to emotion uniformity in some cases or one emotion-type overwhelming

Label	lonely
Context	**Speaker**: i there , dont know what to do , jst broke up with my girlfirned , we were 8 years together
MIME	oh no ! what happened ?
MoEL	oh wow , that must have been very exciting !
Gold	sorry to hear ! do you have any idea about the break up ? did you think about it ?
Label	excited
Context	**Speaker**: i have a huge chance to win a ps4 !
MIME	that is great ! are you excited ?
MoEL	that sounds like a lot of fun
Gold	wow , please make it real .
Label	faithful
Context	**Speaker**: there was this one time i was fairly drunk at a bar and this attractive girl was trying to make moves on me , but i did my best to ignore it all.. having a girlfriend and all .
MIME	wow , that must have been so **embarrassing** .
MoEL	that is terrible, did you confront her ?
Gold	that is good ! you should be proud of yourself
Label	disappointed
Context	**Speaker**: i lost my favorite hoodie somewhere . i am so upset . like how could i lose a hoodie ? it is so big , did i just leave it somewhere ?
MIME	well that is not good , i hope you have to be careful next time
MoEL	i am sorry to hear that . i am sorry to hear that . i am sorry to hear that .
Gold	did you retrace your steps

Table 6: Comparison between MIME (*with STC*) and MoEL.

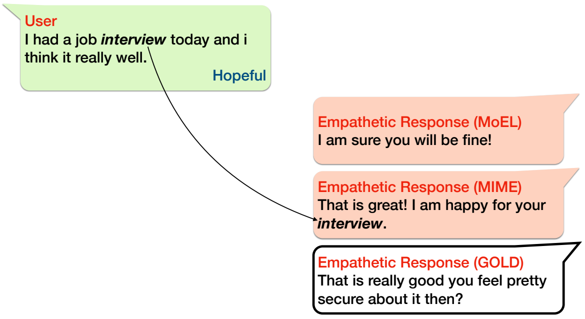


Figure 4: A test sample where MIME responds with key information from the context.

the other in other cases. This in turn may lead to emotionally mundane and generic responses.

5.3 Case Study

Context Capturing. Based on the comparative results for *relevance* shown in Table 2, MIME appears to generate responses that are a closer fit to the context than MoEL does. Fig. 4 shows a test instance where MIME pulls key information from the context — the word 'interview' — to generate an empathetic and relevant response. The response from MoEL is also empathetic, but somehow more generic. We surmise that this can be attributed to the two-way context flow through the emotion embedding sharing and encoder output, as discussed in Section 5.1.

Similarly, Fig. 5 shows a conversation with an *apprehensive* user who shares a frightening story with a positive outcome. Here, MoEL fixates on the initial negative emotion of the user and replies with an unwarranted negatively empathetic response. MIME, however, responds with appropriate positivity hinted at the last utterance. Moreover, it is able to correctly interpret the events described as a 'beautiful memory', which is truly empathetic and relevant. Again, strong mixture of context and emotion, facilitated by the emotion embedding sharing, is likely to be responsible for this. We show more examples generated by both MoEL and MIME in Table 6.

Figure 5: A test sample where MIME responds with subtle information from the context.

5.4 Error Analysis

Low Fluency. As evidenced by Table 2, MIME falters in *fluency* as compared to MoEL. Fig. 6 shows an instance where MoEL generates an empathetic, yet somewhat generic, and fluent response.

Label	anticipating
Context	**Speaker**: i am looking forward to going on vacation in a few weeks ! we have a condo reserved on the beach , with fantastic ocean views . i am ready !
with *STC*	that is **awesome** ! i have been there . i hope you have a great time !
no *STC*	that is great ! i have never been there .
Gold	ah , that sounds fantastic ! which ocean will you be enjoying ?
Label	jealous
Context	**Speaker**: my friend is a surgeon and we were discussing salary . he easily makes 200,000 a year and he is only 32. it is crazy and i was jealous of him .
with *STC*	i would be so **jealous** !
no *STC*	that is a good idea .
Gold	you should n't , because that is a very stressful job
Label	proud
Context	**Speaker**: my son graduated .
with *STC*	**congrats** ! that is a **great accomplishment** !
no *STC*	that is great ! how old is he ?
Gold	from where ?

Table 7: Comparison between some responses from MIME with and without stochasticity (*STC*).

I just moved to this neighborhood and some dumb criminals shot one of my neighbors and ran into the woods!

Thats not good. Do you own a gun?

i do ! i want to be able to protect my son

I am sorry to hear that. I hope it is not too bad for you !

I would have been to the police. ***I would be a little better.***

That is always number one goal.

Figure 6: A test sample where MIME responds with a malformed utterance.

In contrast, the first response utterance from MIME — "*I would have been to the police*" — does make contextual sense. However, the second utterance "*I would be a little better*" reads incoherent and semantically unclear. Perhaps the model meant something like 'I would have felt a little safer'. We repeatedly observed such errors, leading to poor fluency. Given the empathy- and relevance-focused structure of our model, we think MIME focused on learning empathy and relevance, at the cost of fluency. We believe this issue could be mitigated with additional training samples.

Response to Surprised User Context. In our experiments, we assumed the emotion *surprised* to be positive (Table 1), and thus MIME responds with positivity to most test instances incurring *surprise* as a user emotion. However, this is not accurate, as one can be both positively and negative surprised — "*I recently found out that a person I [...] admired did not feel the same way. I was pretty surprised*" vs "*This mother's day was amazing!*". We posit that re-annotating the instances with a negatively-surprised user with a new negative emotion, namely *shocked*, should help alleviate this issue significantly.

Emotion Classification. The $\{$top-1, top-2, top-5$\}$ emotion-classification accuracies for MoEL are $\{38\%, 63\%, 74\%\}$, as compared to $\{34\%, 58\%, 77\%\}$ for MIME. Since the emotion embeddings are shared between encoder and decoder in MIME, it supposedly also encodes some generation-specific information in addition to pure emotion as discussed in Section 5.1, thereby hindering the overall emotion-classification performance. Notably, MIME also performs well on top-5 classification. This is likely due to MIME's ability to discern positive and negative emotion types — as indicated by Fig. 3a — that comes into prominence as you add more likely-labels into the consideration of top-k classification by raising k.

6 Conclusion

This paper introduced a novel empathetic generation strategy that relies on two key ideas: emotion grouping and emotion mimicry. Also, stochasticity was applied to the emotion mixture for varied response generation. We have shown through several human evaluations and ablation studies that our model is better equipped for empathetic response generation than existing models. However, there remains much room for improvement, particularly in terms of *fluency* where our model falters. Moreover, emotions like 'surprise' and 'anticipation' might be explicitly dealt with due to their ambiguous polarity.

Abstract

In this work, we aim at equipping pre-trained language models with structured knowledge. We present two self-supervised tasks learning over raw text with the guidance from knowledge graphs. Building upon entity-level masked language models, our first contribution is an entity masking scheme that exploits relational knowledge underlying the text. This is fulfilled by using a linked knowledge graph to select informative entities and then masking their mentions. In addition, we use knowledge graphs to obtain distractors for the masked entities, and propose a novel distractor-suppressed ranking objective that is optimized jointly with masked language model. In contrast to existing paradigms, our approach uses knowledge graphs implicitly, only during pre-training, to inject language models with structured knowledge via learning from raw text. It is more efficient than retrieval-based methods that perform entity linking and integration during finetuning and inference, and generalizes more effectively than the methods that directly learn from concatenated graph triples. Experiments show that our proposed model achieves improved performance on five benchmarks, including question answering and knowledge base completion.

1 Introduction

Self-supervised pre-trained language models (LMs) like ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) learn powerful contextualized representations. With task-specific modules and finetuning, they have achieved state-of-the-art results on a wide range of natural language processing tasks. Nevertheless, open questions remain about what these models have learned and improvements can be made along several directions. One such direction is, when downstream task performance depends on relational knowledge – the kind modeled by knowledge graphs [1] (KGs) – directly finetuning a pre-trained LM often yields sub-optimal results, even though some works (Petroni et al., 2019; Davison et al., 2019) show pre-trained LMs have been partially equipped with such knowledge.

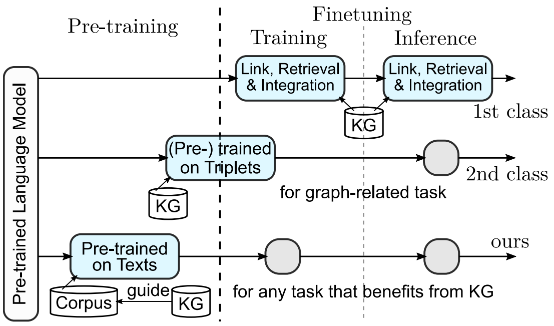

Figure 1: Taxonomy of different approaches to integrating pre-trained LMs with knowledge graphs.

To address this shortcoming, several recent works attempt to integrate KGs into pre-trained LMs. These approaches can be coarsely categorized into two classes, as shown in Figure 1. The first line of methods retrieves a KG subgraph (Liu et al., 2019a; Lin et al., 2019; Lv et al., 2019) and/or pre-trained graph embeddings (Zhang et al., 2019b; Peters et al., 2019) via entity linking during both training and inference on downstream tasks. While these methods inject domain-specific knowledge directly into language representations, they rely heavily on the performance of the linking algorithm and/or the quality of graph embeddings. Graph embeddings, to be tractable over large-scale KGs, are often learned using shallow models (e.g., TransE (Bordes et al., 2013), TuckER (Balazevic et al., 2019) and ConvE (Dettmers et al., 2018)) with limited expressive power. Besides, the linking and retrieval invoked during both finetuning and

[1] "Knowledge graph" and "knowledge base" are interchangeable in this paper, denoting triple-formatted graph.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8980–8994,
November 16–20, 2020.

inference are costly, hence limiting these methods' practicality.

The second class of methods (Bosselut et al., 2019; Malaviya et al., 2019; Yao et al., 2019) uses contextualized representations from pre-trained LMs to enrich graph embeddings and thus alleviates graph sparsity issues. This is especially helpful in the case of commonsense KGs (e.g., ConceptNet (Speer et al., 2017)) that consist of non-canonicalized text and hence suffer from severe sparsity (Malaviya et al., 2019). Specifically, these methods usually feed concatenated triples (e.g., [HEAD, *Relation*, TAIL]) into LMs for training or finetuning. The drawback is that focusing on knowledge base completion tends to over-adapt the models to this specific task, which comes at the cost of generalization to text-based tasks, e.g., QA.

In this work, we equip masked language models (MLMs), e.g., BERT (Devlin et al., 2019), with structured knowledge via self-supervised pre-training on raw text. Compared to the first class, we expose LMs to structured information only during pre-training, thus circumventing costly knowledge retrieval and integration in both finetuning and inference. Also the dependency on the performance of linking algorithm is greatly reduced. Compared to the second class, we learn from free-form text through MLMs rather than triples, which fosters generalization on other downstream tasks.

Specifically, given a corpus of raw text and a KG, two KG-guided self-supervision tasks are formulated to inject structured knowledge into MLMs. First, taking inspiration from Baidu-ERNIE (Sun et al., 2019a), we reformulate the masked language modeling objective to an *entity*-level masking strategy, where entities are identified by linking their text mentions to either *concepts* in a commonsense KG or *named entities* in an ontological KG (Bollacker et al., 2008). The role of KG here is to provide a "vocabulary" of entities to be masked. To further exploit implicit relational information underlying raw text, we design a KG-guided masking scheme that selects informative entities by considering both document frequency and mutual reachability of the entities detected in the text. In addition to the new entity-level MLM task above, a novel distractor-suppressed ranking task is proposed. Negative entity samples are derived from the KG and used as distractors for the masked entities to make the learning more effective.

Note that our approach never observes the KG directly, through triples or other forms. Rather, the KG plays a guiding role in the proposed self-supervised tasks. Its guidance helps the model exploit the corpus more effectively as verified in the experiments. If a downstream task can benefit from explicit exposure to KG, a method by Davison et al. (2019) can be used to transform KG triples into natural grammatical texts for our model.

We evaluate our method on five benchmarks (including question answering and knowledge base completion) and one zero-shot testing. Results show our method achieves state-of-the-art or competitive performance on all benchmarks.

2 Vanilla Masked Language Model

To ground our approach, this section summarizes MLMs for pre-training bidirectional Transformers (Devlin et al., 2019). Compared to causal LMs (Peters et al., 2018) trained unidirectionally, MLMs randomly mask some tokens and predict the masked tokens by considering their context on both sides. Formally, given a piece of text U, a tokenizer, e.g., BPE (Sennrich et al., 2016), is used to produce a sequence of tokens $[w_1, \ldots, w_n]$. A certain percentage of the original tokens are then masked and replaced: of those, 80% with the special token `[MASK]`, 10% with a token sampled from the vocabulary $\mathbb{V}$, and the remaining kept unchanged. The masked sequence, denoted as $[w_1^{(m)}, \ldots, w_n^{(m)}]$, is passed into a Transformer encoder to produce contextualized representations for the sequence:

$$\boldsymbol{H} = \text{TransformerEnc}\left(\left[w_1^{(m)}, \ldots, w_n^{(m)}\right]\right), \quad (1)$$

where $\boldsymbol{H} \in \mathbb{R}^{d_h \times n}$ and d_h denotes the hidden size. The training loss $\mathcal{L}_M$ for MLM task is defined as

$$\mathcal{L}_M = -\frac{1}{|\mathcal{M}|} \sum_{i \in \mathcal{M}} \log P(w_i | \boldsymbol{H}_{:,i}), \quad (2)$$

where $\mathcal{M}$ denotes the set of masked token indices, and $P(w_i|\boldsymbol{H}_{:,i})$ is the probability of predicting the original token w_i given the representations computed from the masked token sequence.

3 Proposed Method

This section begins with a description of entity-level masked language modeling. Section 3.2 proposes a KG-guided entity masking scheme for the entity-level MLM task. A novel distractor-suppressed ranking task is presented in Section 3.3,

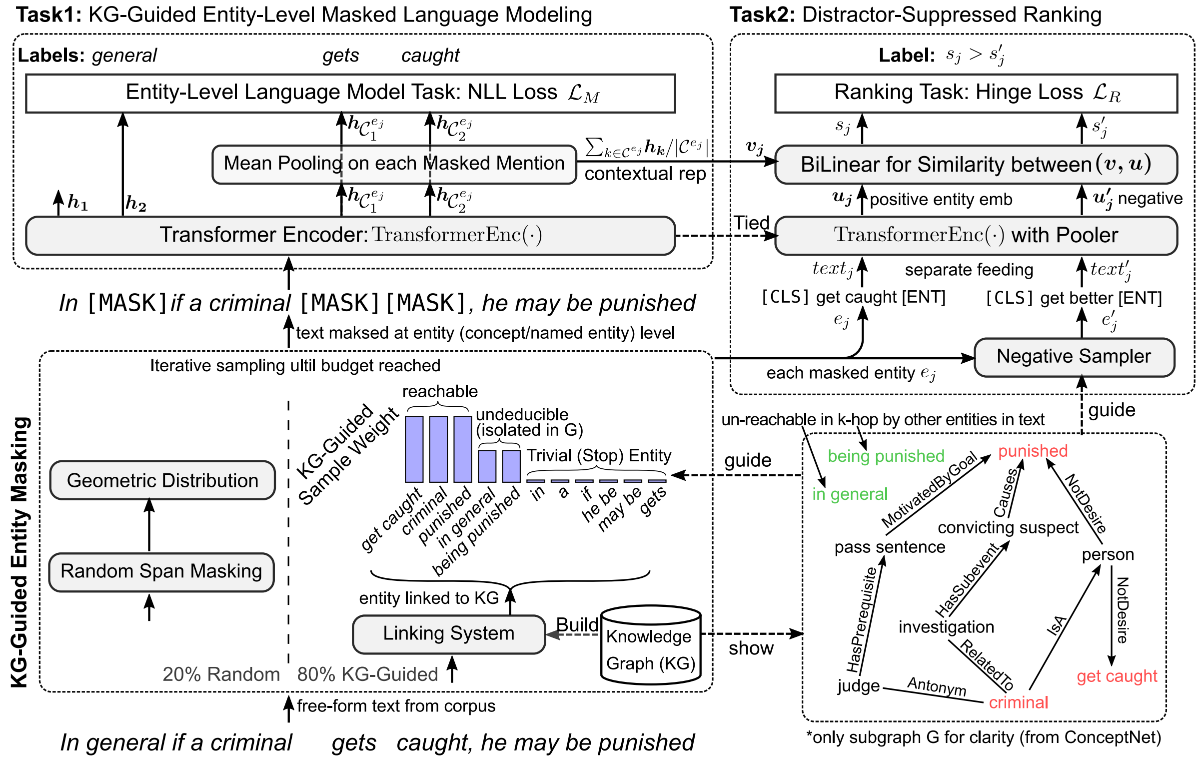

Figure 2: **G**raph-guided Masked **L**anguage **M**odel (GLM) with two self-supervised tasks for MLM training.

which operates on the masked entities and their negative entity samples from the KG. We use a multi-task learning objective combining the two tasks above to jointly train our proposed **G**raph-guided Masked **L**anguage **M**odel (GLM). An illustration of the GLM is shown in Figure 2.

3.1 Entity-Level Masked Language Model

As aforementioned, directly training an MLM with graph triples learns structured knowledge at the cost of the model's generalization to tasks involving natural text such as question answering. Inspired by distantly supervised relation extraction (Mintz et al., 2009) assuming that any sentence containing two entities can express the relation between these two entities in a KG, we argue that it is possible for an MLM to learn structured knowledge from raw text if appropriately guided by a KG.

Roughly speaking, we take detected entity mentions as masking candidates, where the entity can be a concept/phrase in a commonsense KG or a named entity in an ontological KG. The intuition is that the mentions in text often represent knowledge-grounded, semantically meaningful text spans. Formally, we first use a KG to provide a vocabulary of entities for building an entity linking system. We then detect all entity mentions appearing in a piece of text U from a corpus. This leads to a set of linked entities $\mathcal{E} = \{e_1, e_2, \dots\} \triangleq \{e|e \in \text{KG} \wedge e \in U\}$ with $\mathcal{C}^{e_j}$ being the corresponding token indices in U for each entity mention e_j.

The idea of entity-level masking is not new. For example, Sun et al. (2019a) and Joshi et al. (2019) randomly mask entity candidates under uniform distribution for training MLMs. We take this idea further by building our masking scheme with the guidance of a KG, as explained below.

3.2 KG-Guided Entity Masking Scheme

In this section, we develop a new entity masking scheme to facilitate structured knowledge learning for MLMs. It explores implicit relational information underlying raw text by the guidance of a KG, and is shown to mask more informative entities compared to the previous random approaches.

In particular, the scheme is designed to avoid or reduce masking two types of entities: trivial and undeducible. Trivial entities, such as *have been* and *what do* in ConceptNet, are ubiquitous in corpora, since they are used to compose sentences. However, they express bare semantics and function similarly to stop words. On the other hand, an undeducible entity is defined as an entity that is hardly reached from any other entities detected in the same text, within certain hops over the linked KG. Examples include general modifiers and ambiguous entity linking results, as shown with green in Figure 2.

Given a masking budget (e.g., 20% of total tokens in our setting), we sample token span iteratively as follows until the budget is reached: 1) 20% of the time we sample a random token span under a geometric distribution with $p = 0.2$; and 2) 80% of the time we sample an entity mention from the candidates detected in §3.1, where the probability to mask an entity mention $\mathcal{C}^{e_j}$ is defined as

$$P(\mathcal{C}^{e_j}) \propto \mathbb{I}_{\{\mathrm{DF}(e_j)<\mathrm{R}_{\text{thresh}}\}} \times \Big[\big|\,\mathrm{Nb}(e_j)\big|\Big]_{\mathrm{R}_{\text{min}}}^{\mathrm{R}_{\text{max}}}, \quad (3)$$

where $\mathrm{Nb}(e) \triangleq \{e' |\ \mathrm{PLen}(e' \leftrightarrow e) < \mathrm{R}_{\text{hop}} \wedge e' \in \mathcal{E}\}$. The term $\mathrm{DF}(\cdot)$ denotes document frequency, $\mathrm{PLen}(e \leftrightarrow e')$ is the length of the shortest undirected path between the two entities, $|\cdot|$ denotes the set size, and $[x]_a^b \triangleq \max(a, \min(x, b))$.

Note, the first part in Eq.(3) is designed to eliminate trivial entities that frequently appear. The second part measures whether an entity can be reached from other entities detected in the same text within R_{hop}-hops, and assigns a higher sampling weight to an entity (e.g., *criminal* in Figure 2) that could more easily be inferred by others. By guiding the model to favor masking deducible but non-trivial entities, this scheme facilitates the MLM ingesting relational knowledge into representation learning. $\mathrm{R}_{\text{hop/thresh/min/max}}$ are hyperparameters that trade off between trivial and undeducible entities.

Finally, it is worth noting, frequently appearing entities that are excluded via $\mathbb{I}_{\{\cdot\}}$ in Eq.(3) can still be masked via 20% random span masking budget, but now with much smaller probabilities.

3.3 Distractor-Suppressed Ranking Task

Empowered by the informative entity-level masks, it is natural to extend the MLM with "negative" entities sampled from the KG, by treating the masked entities as "positive". It has been verified that negative sampling is especially useful for structured knowledge learning in graph embedding approaches (Sun et al., 2019c; Cai and Wang, 2018), but how to effectively integrate negative samples from KGs into MLMs remains open.

Recently, Ye et al. (2019) propose to mask one entity mention in a sentence, and then formulate a multiple-choice QA task (Talmor et al., 2019) for representation learning, by treating the masked sentence as the question, and the masked entity plus its negative samples as answer candidates. However, this model does not quite match the MLM since the model is pre-trained by multiple-choice QA and only one entity can be masked in a sentence.

Here we propose a distractor-suppressed ranking objective that operates on each pair of a masked entity from §3.2 and its negative sample from the KG. The negative one is viewed as a distractor. We use a Transformer encoder to separately produce the embeddings of positive and negative entities using their associated node contents in the KG. We then contrast the positive and negative *entity embeddings*, $\boldsymbol{u}$ and $\boldsymbol{u}'$, against the *masked entity mention's contextualized representation*, $\boldsymbol{v}$, using vector similarity as plausible scores of both entities.

Specifically, given a set of masked entities from §3.2, $\mathcal{E}^p = \{e_1, \dots, e_m\} \subseteq \mathcal{E}$, with the corresponding entity mentions $\mathcal{C}^{e_j}$, we gather the contextualized representation for each masked entity mention, by mean-pooling over representations of its composite tokens, where the representations are generated by the Transformer encoder of the MLM:

$$\boldsymbol{v_j} = \frac{1}{|\mathcal{C}^{e_j}|} \sum_{k \in \mathcal{C}^{e_j}} \boldsymbol{H}_{:,k},\ j = 1, \dots \quad (4)$$

$\boldsymbol{v_j}$ is the resulting contextualized representation for e_j. Since each entity's original mention is invisible to the encoder, $\boldsymbol{v_j}$ is rich in contextual features.

We then sample negative entity(s) from the KG for each $e_j \in \mathcal{E}^p$ and derive a set of positive-negative entity pairs $\{(e_j, e'_j)\}_{j=1}^m$. In particular, given a positive entity e_j, the sampling method randomly selects an entity e'_j from the KG as a negative sample. The sampling favors its sibling entities with the same relation, whose sample weights are twice than the others. This is similar to Ye et al. (2019) and aims to provide strong distractors. Then, another Transformer encoder separately encodes positive and negative entities, which is parameter-tied with the MLM in 3.2 but uses distinct position embeddings. To distinguish entity text coming from KG's node or natural text, we append a special token to the entity text, i.e., $text_j$ = `[CLS]` + e_j + `[ENT]`. We pass $text_j$ into the encoder to obtain the entity embedding for e_j, i.e.,

$$\boldsymbol{u_j} = \mathrm{Pool}(\mathrm{TransformerEnc}(text_j)). \quad (5)$$

Here, $\mathrm{Pool}(\cdot)$ denotes collecting the contextualized embedding from the `[CLS]` as Devlin et al. (2019). The resulting $\boldsymbol{u_j} \in \mathbb{R}^{d_h}$ is an LM-augmented entity embedding for e_j. We apply the same process to e'_j to obtain negative entity embedding $\boldsymbol{u'_j}$.

The procedure above yields a set of tuples, $\{(\boldsymbol{v_j}, \boldsymbol{u_j}, \boldsymbol{u'_j})\}_{j=1}^{m}$. Finally, a BiLinear layer is used as a parameterized metric for a similarity score between $\boldsymbol{v_j}$ and $\boldsymbol{u_j}$ (or $\boldsymbol{u'_j}$). The score is

$$s_j = \text{BiLnr}(\boldsymbol{v_j}, \boldsymbol{u_j}), \;\; s'_j = \text{BiLnr}(\boldsymbol{v_j}, \boldsymbol{u'_j}), \quad (6)$$
$$\text{where BiLnr}(\boldsymbol{x}, \boldsymbol{y}) \triangleq \boldsymbol{x}^T \boldsymbol{W} \boldsymbol{y} + b.$$

s_j and s'_j are the plausible scores for positive and negative entities, respectively. The two BiLinear layers used in Eq.(6) are parameter-tied. We then use a margin-based hinge loss to train the MLM with the formulated pairwise ranking task, i.e.,

$$\mathcal{L}_R = \frac{1}{m} \sum_{j=1}^{m} \max(\lambda - s_j + s'_j, 0), \qquad (7)$$

where the margin λ is a hyperparameter.

The proposed distractor-suppressed ranking task has several nice properties. First, only a lightweight BiLinear layer is used to measure the score. Second, training to distinguish positive from negative samples may make the model more effective. Intuitively, two sibling entities in a KG are often assigned with similar distributed representations, but express differently in subtle context; this task helps discriminate them. Lastly, in contrast to the work of Ye et al. (2019), ours is fully compatible with the entity-level MLM training task.

The final loss function to optimize is defined as a combination of the entity-level MLM loss $\mathcal{L}_M$, and the distractor-suppressed ranking loss $\mathcal{L}_R$, with the latter weighted by a hyperparameter γ:

$$\mathcal{L} = \mathcal{L}_M + \gamma \mathcal{L}_R. \qquad (8)$$

3.4 Comparison to Prior Entity-Level MLMs

Our work differs from prior entity-level MLMs, including SpanBERT (Joshi et al., 2019) and Baidu-ERNIE (Sun et al., 2019a,b) in several ways. While the motivation of previous work is moving beyond token to another text unit, our method looks for ways to introduce structured knowledge from KGs into language models. As such, named entities in prior works are recognized via NLP toolkits and the entities are simply masked in random, so relational knowledge unlikely exists among them. In contrast, entities in GLM are linked to a supporting KG, and masking has taken into consideration how an entity interacts with its neighbors in the KG. Similarly for modeling objective, previously proposed objectives, such as span boundary objective (Joshi et al., 2019), aim at learning text semantics as in traditional MLM objectives. By exploiting relational knowledge among the recognized entities, we end up with a ranking task that is specially designed for the proposed entity-level MLM to directly acquire structured information by contrastive learning.

4 Experiments

In this section we demonstrate the effectiveness of GLM on multiple benchmarks. Additional insights are gained with ablation study and other analyses.

Setups. We focus on non-canonicalized commonsense KGs in this work, specifically ConceptNet, and the proposed approach is also applicable to ontological KGs such as Freebase. For training efficiency we use two relatively small free-form corpora. One is the Open Mind Common Sense (OMCS) raw corpus[2] consisting of 800K short sentences. The other is the ARC corpus (Clark et al., 2018) containing 14M unordered, science-related sentences. Both corpora are parsed to have their entities linked to ConceptNet by using an inverted index built with fuzzy matching. In addition, we initialize GLM with either BERT or RoBERTa rather than training from scratch. We choose to match the corresponding baseline model (whether it uses BERT or RoBERTa) in each downstream task. In practice, we can initialize GLM with any state-of-the-art pre-trained bidirectional LM. Experiment code is available at `https://github.com/taoshen58/glm-codes`, and detailed settings about training and testing are provided in Appendix A.

Entity Linking for Commonsense KG. To build a fast and effective graph linking system for commonsense knowledge graph, we first apply tokenization and lemmatization to all the concepts in the graph. The data structure of the resulting phrase vocabulary is optimized as a tree-formatted inverted index to achieve good matching efficiency. During the linking phase, we apply the same tokenization and lemmatization to an input, and execute token-level match starting from every token in the input. Besides inflection-irrelevant property from lemmatization, we also consider flexible token interval to allow extra modifier or article. In case multiple candidate mentions are found, the one with the minimum Levenshtein distance to the un-lemmatized concept is taken as the result.

Dataset	# Entity	# Rel	# Train	# Dev	# Test
CommonsenseQA	N/A	N/A	9,741	1,221	1,140
SocialIQA	N/A	N/A	33,410	1,954	2,224
WN18RR	40,943	11	86,835	3,034	3,134
WN11	38,696	11	112,581	2,609	10,544
CKBC	78,334	34	100,000	1,200/1,200	2,400

Table 1: Summary statistics of five benchmarks. The first two are multiple-choice question answering tasks. The rest includes one link prediction and two triple classification tasks.

Downstream Tasks. CommonsenseQA (Talmor et al., 2019) and SocialIQA (Sap et al., 2019b) are used to evaluate GLM's performance on natural question answering (QA) task. We also experiment with three knowledge base completion (KBC) tasks: WN18RR (Dettmers et al., 2018), WN11 (Bordes et al., 2013) and commonsense knowledge base completion (Li et al., 2016), to assess whether the proposed approach can benefit graph-related tasks. Their statistics are listed in Table 1. It is worth mentioning, although WordNet (Miller, 1998) is included in ConceptNet, the triples in ConceptNet are never used during GLM training but only raw texts from OMCS (which is a standalone source of ConceptNet and independent of WordNet), so the relation labels in WordNet are never seen by GLM.

Evaluation Metrics. For multiple-choice question answering tasks and triple classification tasks, we use accuracy as the metric. For link prediction task, there are two kinds of metrics: the first includes mean rank (MR) and mean reciprocal rank (MRR), and the second is H@N (namely Hits@N) which means the proportion of correct entities in top N after being sorted w.r.t. predicted confidence. We only report results under the *filtered* setting (Bordes et al., 2013) which removes all corrupted triples appearing in training, dev and test set.

4.1 Question Answering Task Evaluation

CommonsenseQA. Table 2 reports test results of single models from the leaderboard[3] and finetuning GLM. A brief introduction to each approach without reference can be found on the leaderboard. Compared to the previous best model RoBERTa+KE which is trained with an extra in-domain corpus (i.e., OMCS) and uses retrieval during finetuning, our approach achieves 0.8% absolute improvement to deliver a new state-of-the-art result. In addition, GLM based on RoBERTa-large outperforms its corresponding baseline RoBERTa-large by 2.0%.

Method	Dev	Test
Models from pre-trained language model finetuning		
BERT-large (Devlin et al., 2019)	-	56.7
XLNet-large (Yang et al., 2019)	-	62.9
RoBERTa-large (Liu et al., 2019b)	78.5	72.1
Models w/ IR* or extra supervisions during finetuning		
CoS-E (Rajani et al., 2019)	-	58.2
AristoBERTv7 (BERT-large)	-	64.6
DREAM (XLNet-large)	-	66.9
RoBERTa + IR	78.9	72.1
RoBERTa + KE	78.7	73.3
Models w/ further self-supervision tasks + finetuning		
BERT+AMS (Ye et al., 2019)	-	62.2
BERT+OMCS	-	62.5
RoBERTa+CSPT	76.2	69.6
FreeLB-RoBERTa (Zhu et al., 2019)	78.8	72.2
GLM (RoBERTa)†	**79.8**	**74.1**

Table 2: Results on CommonsenseQA for single models."-" denotes unavailable result, and underlined score is the previous best. *IR stands for information retrieval. †GLM is initialized with RoBERTa-large and falls into the last group.

Note, methods using IR (e.g., RoBERTa+KE) must retrieve from Wikipedia during finetuning and inference, which increases the computational overhead significantly. In contrast, methods based on additional self-supervised pre-training are more efficient, but often achieve sub-optimal performance since they lack explicitly retrieved contexts. The proposed GLM falls into the latter high-efficiency group while still outperforms IR-based approaches.

Some works (e.g., RoBERTa+CSPT) find pre-training on triples from a KG can hurt the performance. This evidence supports our hypothesis that pre-training on triples can over-adapt a model to graph-related tasks and limit their generalization.

Our approach is not comparable to Lv et al. (2019) and Lin et al. (2019), the first of which achieves 75.3% accuracy. This is because during finetuning and inference, those methods explicitly find a path from question to answer concept in ConceptNet. This helps filter human-generated distractor answers since they unlikely appear in ConceptNet. In contrast, our method never uses ConceptNet during finetuning and only observes a small subgraph of ConceptNet (about 30%$\sim$40% linked concepts without relations) during pre-training.

SocialIQA. The dataset is built upon the ATOMIC knowledge graph (Sap et al., 2019a) and

focuses on reasoning about people's actions and their social implications. It thus serves as an out-of-domain evaluation task for GLM trained using ConceptNet. Here, "out-of-domain" refers to out-of-domain KG: the model is trained with ConceptNet while SocialIQA is built upon ATOMIC. Moreover, the corpora used in continual pre-training are also out-of-domain for SocialIQA. Similar to CommonsenseQA, this task is formulated as a multiple-choice QA problem. The evaluation results listed in Table 3 demonstrate that our approach also achieves state-of-the-art performance on this out-of-domain dataset.

4.2 Graph-Related Task Evaluation

For this set of tasks we follow KG-BERT (Yao et al., 2019) that finetunes MLMs over a concatenation of a triple's head, relation, and tail, followed by an MLP to compute a score denoting if the triple is plausible. Since BERT-base model is used in KG-BERT, for fair comparison we train a GLM from BERT-base, denoted as "GLM (BERT-base)" and finetune it on KBC task following KG-BERT.

WordNet Knowledge Base Completion. Table 4 lists test results for the WN18RR link prediction task. GLM significantly outperforms KG-BERT and sets state-of-the-art or competitive results, which verifies the model's ability to retain relational knowledge. Further when type constraint is applied, "GLM+TypeCons" achieves overwhelming performance, especially in MR and Hits@10.

Method	**Dev**	**Test**
TransE (Bordes et al., 2013)	-	75.9
DistMult-HRS (Yang et al., 2015)	-	88.9
DOLORES (Wang et al., 2018)	-	87.5
ConvKB (Nguyen et al., 2018)	-	87.6
AATE (An et al., 2018)	-	88.0
KG-BERT$_{\text{BERT-base}}$ (Yao et al., 2019)	-	93.5
KG-BERT$_{\text{GLM(BERT-base)}}$	**94.8**	**94.0**

Table 5: Test accuracy on WN11 triple classification task.

Method	**Dev2**	**Test**
Bilinear AVG (Li et al., 2016)	90.3	91.7
Bilinear AVG + Data (Li et al., 2016)	91.8	92.5
KG-BERT$_{\text{BERT-base}}$	92.9	93.2
KG-BERT$_{\text{BERT-base}}$ + Data	92.3	92.4
KG-BERT$_{\text{GLM(BERT-base)}}$	93.0	93.5
KG-BERT$_{\text{GLM(RoBERTa-large)}}$	**94.7**	**94.6**

Table 6: Test accuracy on CKBC triple classification task..

Test results for the WN11 triple classification task are listed in Table 5. Consistent with the results on WN18RR, finetuning our model outperforms translation-based graph embedding models and convolution-based methods, and improves state-of-the-art accuracy by 0.5%.

Commonsense Knowledge Base Completion. Lastly, we evaluate our approach on the CKBC task, which should directly benefit from commonsense knowledge. Since CKBC is derived from the OMCS corpus, for fair comparison, we provide a baseline model with equivalent training data ("+ Data" in Table 6). In addition, we remove raw sentences belonging to CKBC's test set from our GLM pre-training corpora to avoid data leakage.

Results in Table 6 show our approach outperforms KG-BERT baseline even when the latter is equipped with equivalent data (increasing training triples from 100K to 600K). There are two possible reasons why performance actually drops with more data: 1) the training triples are sorted w.r.t annotated confidence, so additional triples have a lower quality and may introduce noise; 2) more negative sampling must be done with more training triples, which introduces more false negative examples (from 1.25% to 2.42% by our observation).

Method	**F1 Score**
BERT-large (Davison et al., 2019)	78.8
BERT-large (our implementation)	77.1
GLM (BERT-large)	**83.4**

Table 7: Zero-shot evaluation following Davison et al. (2019).

Method	**Dev Accu**
BERT-large (w/o GLM continual pre-training)	65.5
GLM (BERT-large)	69.0
◇ w/o KG-guided Masking	68.6
◇ w/o Ranking	68.1
◇ w/o Ranking & Entity Mask (= BERT-large)	67.7
◇ Ranking→SBO	66.8
◇ Ranking→SBO, Entity Mask→Span	68.2

Table 8: Ablation study on CommonsenseQA dev set. Note, "SBO" denotes span boundary objective (Joshi et al., 2019) and "→" stands for module replacement.

4.3 Zero-Shot Evaluation

To explore whether GLM can indeed learn the structured information from raw text, we conduct a zero-shot evaluation on CKBC by following Davison et al. (2019). We re-train the GLM (BERT-large) on new corpora in which all raw texts containing the CKBC testing pairs are discarded. We re-implement coherency ranking and estimate PMI (Davison et al., 2019), and the results are shown in Table 7. The GLM significantly outperforms its baseline, which demonstrates the capability of retaining structured information in a language model.

4.4 Ablation Study

To evaluate the effectiveness of each component in GLM, we conduct an ablation study in Table 8 via pre-training language models with different setups and then finetuning on CommonsenseQA.

When KG-guided entity masking introduced in §3.2 is replaced with random entity masking during GLM pretraining, 0.4% accuracy drop is observed when the model is subsequently evaluated on CommonsenseQA dev set. If we set γ in Eq.(8) to zero when pre-training GLM, this leads to 0.9% accuracy drop. When both entity-level masking and distractor-suppressed ranking are removed, the setting becomes equivalent to performing continual pre-training of BERT-large on our corpora. This helps us separate the contribution of extra corpora from the proposed approach. Compared with BERT-large baseline, we observe a 2.2% (65.5% to 67.7%) accuracy improvement contributed by the corpora. Thus GLM yields an extra 1.3% (67.7% to 69.0%) improvement by better data exploitation.

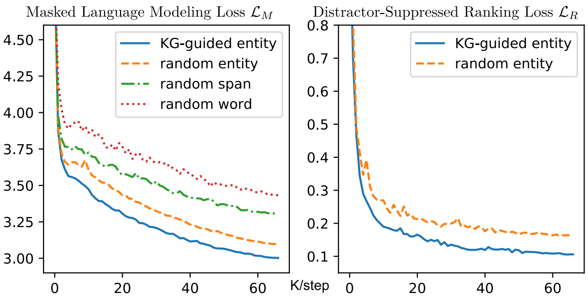

Figure 3: Dev loss in pre-training phase for different training or masking schemes. Note only entity-level masking has $\mathcal{L}_R$.

When we replace distractor-suppressed ranking with span boundary objective (Joshi et al., 2019), a significant performance decrease (-2.2%) is observed. Further replacing our entity-level masking with random span masking, however, only loses 0.8% in accuracy. It is worth noticing that the latter setup is equivalent to continual pre-training with SpanBERT (Joshi et al., 2019) on our corpora. In line with SpanBERT's conclusion that the performance of linguistic masking is not consistent, our KG-guided entity-level MLM (i.e., GLM w/o the ranking task) is worse than random span with SBO (68.1% vs. 68.2%). This suggests that objective to mask and objective to learn need to be paired, and linguistic masking can be useful if equipped with appropriate learning objective (e.g., our distractor-suppressed ranking task) during pre-training.

4.5 Analysis of Training & Masking Schemes

Given the same dev set of texts with the same masked tokens, Figure 3 compares different learning/masking schemes by plotting $\mathcal{L}_M$ (left) and $\mathcal{L}_R$ (right) defined in Eq.(8) w.r.t pre-training steps. It is observed our KG-guided entity masking is more efficient than three other masking schemes, including random entity masking (Sun et al., 2019a), random span masking (Joshi et al., 2019), and random whole-word masking (Devlin et al., 2019).

Table 9 lists a few example sentences with masked tokens highlighted according to the corresponding masking scheme. Both KG-guided and random entity masking can mask informative chunks and long-term dependency needs to be modeled in order to infer the masked tokens. In contrast, random span or word masking is likely to mask tokens that can be easily inferred from local context – a much simpler task. Furthermore, our KG-guided entity masking tends to select more informative phrases compared to random entity masking.

No.	Masked Text with different masking schemes
1	something you need to *do before* ***you*** get up **early** is **set** an alarm ← (leave the office)
2	you would talk **with** someone far ***away*** *because you* want keep in touch ← (meet strangers)
3	if you want **to** drill *a* ***hole then*** you **should** carefully plan **where** you will drill it ← (cut of beef)

Table 9: Case study for different masking schemes. Note that 1) underline: KG-guided entity masking; 2) underline wave: random entity masking; 3) *italic*: random span masking; and 4) **bold**: random whole-word masking. Text in parenthesis is a negative entity sampled for KG-guided entity masking.

4.6 Error Analysis

Compared with previous pre-trained LMs (e.g., BERT and RoBERTa), some limitations are found in our current models pre-trained on OMCS and ARC corpora, which mainly fall into three aspects:

- **Over masking:** Compared to random masking, our KG-guided masking scheme is prone to masking all key parts of a sentence, which leaves little room for MLM task.
- **Short context:** Since our employed pre-training corpora (i.e., OMCS and ARC) consist of just single, unordered sentences, information that spans across multiple sentences is not encoded effectively. When downstream tasks rely heavily on adjacent sentences, finetuning our model yields inferior performance. This can be empirically verified by the performance drop on the datasets (e.g., HellaSWAG in Appendix B) that involves long contexts.
- **Pipeline model:** Same as any other method aiming to integrate LMs with KG, a linking system is first applied to detect entities in text, which inevitably suffers from graph sparsity and leads to error propagation. However, our method is less sensitive to such errors compared with the methods that link entities during both finetuning and inference.

5 Related Work

Our work is related to Baidu-ERNIE (Sun et al., 2019a) and SpanBERT (Joshi et al., 2019), which both extend token level masking to the span level. For example, Baidu-ERNIE does so to improve the model's knowledge learning, using uniformly random masking for phrases and entities. As summarized in §1, existing methods for integrating knowledge into pre-trained LMs can be coarsely categorized into two classes. For example, Peters et al. (2019) retrieve entities' embeddings according to the similarity between Transformer's hidden states and pre-trained graph embeddings, then treat the retrieved embeddings as extra inputs to the next layer. In contrast, Bosselut et al. (2019) directly finetune a pre-trained LM on partially-masked triples from a KG, aiming at commonsense KBC tasks. This however limits the applications in KG-based tasks rather than natural language processing tasks like question answering (Shen et al., 2019a), sentiment analysis (Li et al., 2019), sentence classification (Shen et al., 2019b), etc. And our work is also related to using negative samples for effective learning (Cai and Wang, 2018). Moreover, our work is distinct from the works combining knowledge graph with text information via joint embedding (Wang et al., 2014; Toutanova et al., 2015; Yamada et al., 2016). They usually use the texts containing co-occurrence of entities to enrich the graph embeddings, which are specially designed for graph-related tasks. (Full in Appendix C.)

6 Conclusion

In this work, we aim at equipping pre-trained LMs with structured knowledge via self-supervised tasks. Building on entity-level MLMs, we propose an entity masking scheme under KG's guidance. It masks informative mentions and facilitates learning structured knowledge in free-form text. Moreover, we propose a distractor-suppressed ranking objective to utilize negative samples from KG as distractors for effective training. Experiments show finetuning our KG-guided pre-trained MLMs yields improved performance on related downstream tasks.

In the future, instead of pre-training on sentences, we will leverage raw text at passage or document level to alleviate the performance degeneration brought by short context. Moreover, we will use a combination of commonsense and ontological KGs, and large-scale corpora (e.g., Common Crawl) to pre-train an MLM from scratch, which we expect to benefit a wide range of tasks.

Acknowledgement

The authors would like to thank Siqi Sun for valuable suggestions about the model, Alon Talmor and Jonathan Herzig for evaluating CommonsenseQA test accuracy, and anonymous reviewers for their insightful and constructive feedback.

A Implementation Details

Pre-trained language models implemented by Huggingface[4] are adapted for our models.

Pre-Training Hyperparameters. For continual pre-training, we do not tune hyperparameters due to the computational cost. Only a limited set of hyperparameters is tried according to empirical intuitions. Currently $R_{hop/min/max}$ in Eq.(3) of main paper are set to 3/1.0/2.0 respectively, and R_{thresh} aims to filter out entities with top 5% document frequency, thus varies with corpora. We set λ in Eq.(7) of main paper to be 1.0 and γ in Eq.(8) of main paper to be 0.2. The continual pre-training runs for 5 epochs, with a batch size of 128, a learning rate of 3e-5/1e-5 (BERT/RoBERTa), learning warmup proportion of 10%/5% (BERT/RoBERTa) and weight decay of 0.01. For both BERT and RoBERTa, max sequence length is set to be 80 and 20 for sentence-level encoding and entity embedding respectively. The masking proportion is lifted from 15% to 20% without tuning compared with BERT and RoBERTa. An intuition is that our model is initialized with well-trained language models (e.g., BERT), a slightly larger masking proportion could hold the entity with longer text span, and make the learning more efficient.

Finetuning Hyperparameters. During finetuning on downstream tasks, we conduct grid search for hyperparameters, including batch size, number of epochs/steps, learning rate, which are summarized in Table 10. As for the number of learnable parameters, the models heavily depends on the Transformer encoder since only light-weight BiLinear layer or neural classifier is introduced during finetuning. In particular, BERT-base, RoBERTa-base, BERT-large and RoBERTa-large have $\sim$ 110M, 130M, 340M and 360M parameters respectively.

Details about KG-Guided Entity Masking. In addition to finding informative and non-trivial masks, the KG-guided entity masking method can be used to filter the corpus, since if a piece of text (e.g., sentence or passage) contains only trivial and undeducible entities, the text may hardly contribute to model learning. With this strategy, most ($\sim$ 90%) sentences in ARC corpus were filtered out, which leads to a very efficient training for our models. Training our model based on BERT-large or RoBERTa-large only costs about 1 day on single V100 GPU with mixed float precision, in total about 70K steps.

Fair Comparison on WordNet KBC. There are two aspects to prevent data leakage from ConceptNet to WN18RR. First, ConceptNet is derived from OMCS, WordNet, Wiktionary, etc., and each source is independent of others. Our method only uses OMCS raw text as the training corpus and has no access to WordNet. On the other hand, even though entire ConceptNet is used to guide entity masking/sampling, unlike traditional methods taking KG's triples as training examples, our method doesn't use the relation labels but only the entities/concepts. Since WordNet's entities/concepts are also provided in the training set of WN18RR/WN11, there is no risk of leakage when testing.

Model Implementation for KBC. For CKBC dataset, we find the performance is poor when we directly finetune either BERT-base or our approach on the concatenated triples, i.e., "`[CLS]` HEAD `[SEP]` *Rel* `[SEP]` TAIL `[SEP]`". Hence, we follow Davison et al. (2019) to transform the triples to natural language sentences, and then use these sentences as input to finetune the pre-trained LMs. For WN18RR, we directly use the data processed by Yao et al. (2019), in which a description sen-

Table 10: Candidate values for hyperparameter search during finetuning. Note "# steps" is shown for CQA and "# epochs" for the others. The hyperparameters with underline can lead to best-performing models. Each hyperparameter grid search is conducted four times with different random seed. The time data is collected on single NVIDIA V100.

tence is attached to each entity/phrase. For WN11, we follow KG-BERT to directly concatenate triples and then use them to finetune the pre-trained LMs.

Knowledge Graph and Entity Linking. We aim at enhancing the pre-trained language models with commonsense structured knowledge, so we employ ConceptNet (Speer et al., 2017) as the backend knowledge graph. Since ConceptNet is a multi-lingual knowledge graph, we first filter out all the triples which include non-English items. In addition, we treated the KG as an undirected graph when identifying entity's mutual reachability. As for entity linking, there are many mature entity linking systems for ontological or factoid KGs, such as S-MART (Yang and Chang, 2015), DBpeida Lookup, and DeepType (Raiman and Raiman, 2018). However, for a commonsense KG whose content consists of non-canonicalized or free-form texts, there is no such a system to complete its entity linking. Therefore, we build an efficient inverted index out of lemma-based fuzzy matching as our entity linking system.

B More Experiments

PhysicalIQA. In addition to CommonsenseQA and SocialIQA shown in the main paper, a dataset named PhysicalIQA[5] is also used to evaluate our method. It is also regarded as an out-of-domain dataset compared with our training corpora. However, our implemented code base cannot reproduce the state-of-the-art results that are achieved by RoBERTa-large finetuning, possibly due to different pre-processing and feeding strategies for pre-trained LMs, e.g., special token, concatenation scheme, representation gathering method (Mitra et al., 2019). Hence, we only report re-implemented results with the same network structure, same data-preprocessing method, same random seed and same hyperparameter grid search, for fair comparison. The accuracy on dev set is 78.7% and 80.2% for RoBERTa-large baseline and GLM (RoBERTa) respectively, which further demonstrates the effectiveness of our approach on out-of-domain datasets.

HellaSWAG. We also try to apply our approach to HellaSWAG[6] (Zellers et al., 2019). It is a plausible inference task and requires reasoning over linguistic context and external knowledge. The task is to choose one plausible ending from four candidates. Same as PhysicalIQA, we only fairly report the accuracy on dev set for a fast comparison. With our implementation, finetuning RoBERTa-large on this dataset achieves 84.1% dev accuracy which is much higher than the best dev accuracy (83.5%) on leaderboard. However, finetuning our approach achieves 83.9% accuracy, which is slightly worse than the baseline. We notice that examples in HellaSWAG frequently have multiple consecutive sentences for inference, thus our model trained on single, unordered sentences may only achieve sub-optimal performance. On the other hand, this is another out-of-domain dataset which may not benefit from our training knowledge graph and corpora.

C Related Work (extended)

This work is in line with Baidu-ERNIE (Sun et al., 2019a) and SpanBERT (Joshi et al., 2019) which replace word-level mask (Devlin et al., 2019) with span-level one for knowledge information and long-term dependency. In particular, Baidu-ERNIE uses

---

[5] `https://leaderboard.allenai.org/physicaliqa/submissions/public`

[6] `https://leaderboard.allenai.org/hellaswag`

uniformly random masking for phrases and entities, whereas SpanBERT directly masks out token spans sampled under geometric distribution.

The work of Petroni et al. (2019) finds that, without finetuning, pre-trained LMs (e.g., BERT) contains relational knowledge competitive with traditional NLP methods with oracle knowledge. Nevertheless, how to integrate the oracle knowledge into the pre-trained LMs for further performance improvement remains an open question.

As briefly summarized in the introduction of the main paper, existing methods can be coarsely categorized into two classes. For the first class, those methods retrieve a KG subgraph or/and pre-trained graph embeddings via entity linking during finetuning and inference. K-BERT (Liu et al., 2019a) retrieves a path from KG as description for each detected entity in text, and inserts such description into input sequence to Transformer encoder with carefully designed attention mask and position embedding. KnowBert (Peters et al., 2019) and THU-ERNIE (Zhang et al., 2019b) first retrieve the detected entities' embeddings from pre-trained graph embeddings (Bordes et al., 2013), and then treat these retrieved embeddings as extra inputs for each layer of Transformer encoder. Lin et al. (2019) and Lv et al. (2019) aim to solve commonsense multiple-choice QA problem. They retrieve a graph path from entities detected in question to each answer entry, and then encode (e.g., via LSTM) these paths as heterogeneous representations for higher-level modules.

The second class of methods uses contextualized representations from pre-trained LMs to enrich graph embeddings and thus alleviates graph sparsity issues. COMET (Bosselut et al., 2019) finetunes pre-trained LM on partially-masked KG triples, which aims at commonsense knowledge graph completion tasks. Malaviya et al. (2019) perform transfer learning from pre-trained language models to knowledge graphs for enhanced contextualized representation of the knowledge. KG-BERT (Yao et al., 2019) directly concatenates the head, relation and tail of a triple, and finetunes pre-trained LMs on such data with binary classification objective, i.e., whether a triple is correct or not.

More recently, K-Adapter (Wang et al., 2020) keeps the pre-trained LMs unchanged and proposes two neural adapters that are trained with relation classification and dependency parsing respectively, based on the LM's hidden states. During finetuning, these two adapters can benefit relevant downstream tasks, e.g., entity typing and QA.

How to generate and utilize negative samples is important for learning graph embeddings and structured knowledge (Sun et al., 2019c; Ye et al., 2019). For example, KBGAN (Cai and Wang, 2018) uses a knowledge graph embedding model as negative sample generator to assist the training of the desired model, which acts as the discriminator in GANs. Rather than a standalone generator, self-adversarial sampling (Sun et al., 2019c) generates negative samples according to the current entity or relation embeddings. BERT-AMS (Ye et al., 2019) and our proposed ranking task share a similar motivation that the model is able to effectively learn the structured knowledge from negative samples, but they differ in the task designs. BERT-AMS builds a multiple-choice question answering task for utilizing negative samples, which imitates the developing procedure of CommonsenseQA (Talmor et al., 2019) and aims to improve performance on that particular dataset. In contrast, our approach is more general and formulates a ranking task along with the entity-level masked language modeling objective for pre-training knowledge-aware LMs.

This work differs from the works combining knowledge graph with text information via joint embedding (Yamada et al., 2016). They usually use the texts containing co-occurrence of entities to enrich the graph embeddings, which are specially designed for graph-related tasks. For example, Wang et al. (2014) embed entities from KG and the entities' text contents in the same latent space, however, regardless of textual co-occurrences and their textual relations in natural language corpus. Further taking into account the sharing of substructure in the textual relations of a large-scale corpus, Toutanova et al. (2015) apply a CNN to the lexicalized dependency paths of the textual relation, for an augmented relation representation. The representation can be fed into any previous graph embedding approach for enhanced performance on KBC. We share similar inspirations when utilizing the texts containing entity co-occurrences and embedding entities' text contents into latent space. But beyond the shallow joint embeddings, our work takes advantage of pre-trained MLMs and equips them with structured knowledge via two self-supervised objectives built upon raw text. Hence it can produce generic text representations to benefit various downstream tasks.

Named Entity Recognition Only from Word Embeddings

Abstract

Deep neural network models have helped named entity recognition achieve amazing performance without handcrafting features. However, existing systems require large amounts of human annotated training data. Efforts have been made to replace human annotations with external knowledge (e.g., NE dictionary, part-of-speech tags), while it is another challenge to obtain such effective resources. In this work, we propose a fully unsupervised NE recognition model which only needs to take informative clues from pre-trained word embeddings. We first apply Gaussian Hidden Markov Model and Deep Autoencoding Gaussian Mixture Model on word embeddings for entity span detection and type prediction, and then further design an instance selector based on reinforcement learning to distinguish positive sentences from noisy sentences and then refine these coarse-grained annotations through neural networks. Extensive experiments on two CoNLL benchmark NER datasets (CoNLL-2003 English dataset and CoNLL-2002 Spanish dataset) demonstrate that our proposed light NE recognition model achieves remarkable performance without using any annotated lexicon or corpus.

1 Introduction

Named Entity (NE) recognition is a major natural language processing task that intends to identify words or phrases that contain the names of PER (Person), ORG (Organization), LOC (Location), etc. Recent advances in deep neural models allow us to build reliable NE recognition systems (Lample et al., 2016; Ma and Hovy, 2016; Liu et al., 2018; Yang and Zhang, 2018; Luo et al., 2020; Luo and Zhao, 2020). However, these existing methods require large amounts of manually annotated data for training supervised models. There have been efforts to deal with the lack of annotation data in NE recognition, (Talukdar and Pereira, 2010) train a weak supervision model and use label propagation methods to identify more entities of each type; (Shen et al., 2017) employ Deep Active Learning to efficiently select the set of samples for labeling, thus greatly reduce the annotation budget; (Ren et al., 2015; Shang et al., 2018; Fries et al., 2017; Yang et al., 2018b; Jie et al., 2019) use partially annotated data or external resources such as NE dictionary, knowledge base, POS tags as a replacement of hand-labeled data to train distant supervision systems. However, these methods still have certain requirements for annotation resources. Unsupervised models have achieved excellent results in the fields of part-of-speech induction (Lin et al., 2015; Stratos et al., 2016), dependency parsing (He et al., 2018; Pate and Johnson, 2016), etc. Whereas the development of unsupervised NE recognition is still kept unsatisfactory. (Liu et al., 2019) design a Knowledge-Augmented Language Model for unsupervised NE recognition, they perform NE recognition by controlling whether a particular word is modeled as a general word or as a reference to an entity in the training of language models. However, their model still requires type-specific entity vocabularies for computing the type probabilities and the probability of the word under given type.

Early unsupervised NE systems relied on labeled seeds and discrete features (Collins and Singer, 1999), open web text (Etzioni et al., 2005; Nadeau et al., 2006), shallow syntactic knowledge (Zhang and Elhadad, 2013), etc. Word embeddings learned from unlabeled text provide representation with rich syntax and semantics and have shown to be valuable as features in unsupervised learning prob-

lems (Lin et al., 2015; He et al., 2018). In this work, we propose an NE recognition model with word embeddings as the unique feature source. We separate the entity span detection and entity type prediction into two steps. We first use Gaussian Hidden Markov Model (Gaussian-HMM) to learn the latent Markov process among NE labels with the IOB tagging scheme and then feed the candidate entity mentions to a Deep Autoencoding Gaussian Mixture Model (DAGMM) (Zong et al., 2018) for their entity types. We further apply BiLSTM and an instance selector based on reinforcement learning (Yang et al., 2018b; Feng et al., 2018) to refine annotated data. Different from existing distant supervision systems (Ren et al., 2015; Fries et al., 2017; Shang et al., 2018; Feng et al., 2018), which generate labeled data from NE lexicons or knowledge base which are still from human annotation, our model may be further enhanced by automatically labeling data with Gaussian-HMM and DAGMM.

The contribution of this paper is that we propose a fully unsupervised NE recognition model that depends on no external resources or annotation data other than word embeddings. The empirical results show that our model achieves remarkable results on CoNLL-2003 English and CoNLL-2002 Spanish benchmark datasets.

The rest of this paper is organized as follows. The next section introduces our proposed basic model in detail. Section 3 further gives a refinement model. Experimental results are reported in Section 4, followed by related work in Section 5. The last section concludes this paper.

2 Model

As shown in Figure 1, the first layer of the model is a two-class clustering layer, which initializes all the words in the sentences with 0 and 1 tags, where 0 and 1 represent non-NE and NE, respectively. The second layer is a Gaussian-HMM used to generate the boundaries of an entity mention with IOB tagging (Inside, Outside and Beginning). The representation of each candidate entity span is further fed into a Deep Autoencoding Gaussian Mixture Model (DAGMM) to identify the entity types.

2.1 Clustering

The objective of training word embeddings is to let words with similar context occupy close spatial positions. (Seok et al., 2016) conduct experiments on the nearest neighbors of NEs and discover that similar NEs are more likely to be their neighbors, since NEs are more similar in position in the corpus and syntactically and semantically related. Based on the discoveries above, we perform K-Means clustering algorithm on the word embeddings of the whole vocabulary. According to the clusters, we assign words in the cluster with fewer words 1 tags, and the other cluster 0 tags (according to the statics of (Jie et al., 2019), the proportion of NEs is very small on CoNLL datasets), and generate a coarse NE dictionary using the words with 1 tag.

2.2 Gaussian HMM

Hidden Markov model is a classic model for NE recognition (Zhou and Su, 2002; Zhao, 2004), since hidden transition matrix exists in the IOB format of the NE labels (Sarkar, 2015). We follow the Gaussian hidden Markov model introduced by (Lin et al., 2015; He et al., 2018). Given a sentence of length l, we denote the latent NE labels as $z = \{z_i\}_{i=1}^{l}$, the cluster embeddings as $v = \{v_i\}_{i=1}^{l}$, observed (pre-trained) word embeddings as $x = \{x_i\}_{i=1}^{l}$, transition parameters as θ. The joint distribution of observations and latent labels is given as following:

$$p(z, x, v; \theta) = \prod_{i=1}^{l} p(z_i|z_{i-1}; \theta) p(x_i|z_i) p(v_i|z_i) \tag{1}$$

where $p(z_i|z_{i-1}; \theta)$ is the multinomial transition probability, $p(x_i|z_i)$ is the multivariate emission probability, which represents the probability of a particular label generating the embedding at position i.

Cluster features (0, 1 tags) carry much word-level categorization information and can indicate the distribution representation, which we map to 3-dimension cluster embeddings $v \in \mathbb{R}^{2\times3}$. We initialize $v^{2\times3}$ as $[[1, 0, 0], [0, 0.5, 0.5]]$ (corresponding to *O*, *I*, *B* tag, respectively), which means that if the cluster tag of a word is 0, we initialize the word with all the probability of being *O* tag, otherwise it will be half of the probability of being *B* or *I* tag. $p(v_i|z_i)$ is obtained through this lookup table, and we fine-tune the cluster embeddings during the training.

.

Gaussian emissions Given a label $z \in \{B, I, O\}$, we adopt multivariate Gaussian distribution with mean μ_z and covariance matrix Σ_z as the emission probability. The conditional probability density is

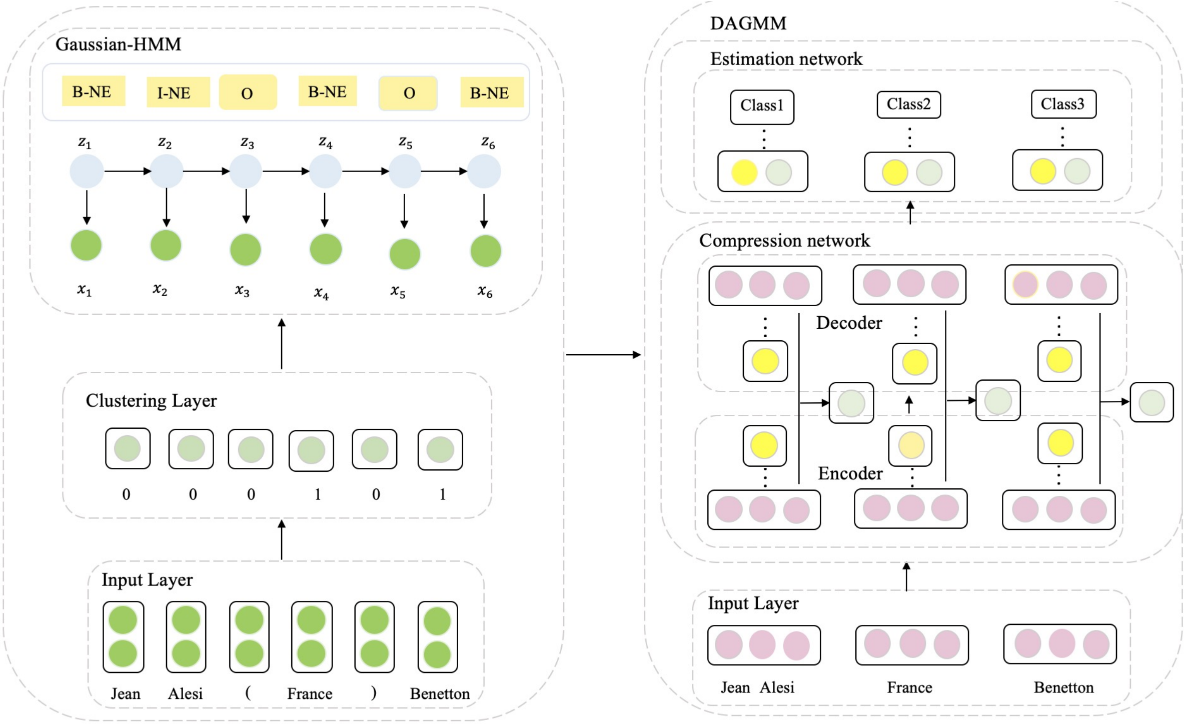

Figure 1: Architecture of the unsupervised NE recognition model. The left part is designed for entity span detection and the right part is used for entity type prediction.

in a form as:

$$p(x; \mu_z, \Sigma_z) = \frac{exp(-\frac{1}{2}(x-\mu_z)^T\Sigma_z^{-1}(x-\mu_z))}{\sqrt{(2\pi)^d|\Sigma_z|}} \tag{2}$$

where d is the dimension of the embeddings, $|\cdot|$ denotes the determinant of a matrix. The equation assumes that embeddings of words labeled as z are concentrated around the point μ_z, and the concentration is attenuated according to the covariance matrix Σ_z.

The joint distribution over a sequence of observations x, cluster sequence v and the latent label sequence z is:

$$p(z, x, v; \theta, \mu_t, \Sigma_t) = \prod_{i=1}^{l} p(z_i|z_{i-1}; \theta)p(x; \mu_z, \Sigma_z)p(v_i|z_i) \tag{3}$$

We use forward algorithm to calculate the probability of x which we maximize during training.

We present two techniques to refine the output of Gaussian-HMM.

Single-word NEs We check the experimental results of Gaussian-HMM and discover that they perform well on the recognition of multi-word NEs, but inferiorly on single-word NEs, which incorrectly gives many false-positive labels, so we need to do further word-level discrimination. For a single-word NE identified by the above model, if it is less than half of the probability of being marked as an NE in the corpus and does not appear in the coarse NE dictionary generated in the clustering step, then we modify it to a non-NE type. Through this modification, the precision is greatly improved without significantly reducing the recall.

High-Quality phrases Another issue of the above models is the false-negative labels, a long NE may be divided into several short NEs, in which case we need to merge them with phrase matching. We adopt a filter to determine high quality phrases according to word co-occurrence information in the corpus:

$$\frac{p(word_{last}, word_{current})}{p(word_{last}) * p(word_{current})} * n > T \tag{4}$$

where $p(\cdot)$ represents the frequency of one word appearing in the corpus, n is the total number of words and T is the threshold, which is set as the default value in word2vec[1] for training phrase embeddings. The intuition behind this is that if the ratio of the co-occurrence frequency of two adjacent words to their respective frequencies is greater than the threshold, then we consider that these two

---

[1] https://code.google.com/archive/p/word2vec

words are likely to form a phrase. Being aware of these high-quality phrases, we expect to enhance the recall of our model.

After obtaining the candidate entity span mentions, we represent them by separating words in them into two parts, the boundary and the internal (Sohrab and Miwa, 2018). The boundary part is important to capture the contexts surrounding the region, we directly take the word embedding as its representation. For the internal part, we simply average the embedding of each word to treat them equally. In summary, given the word embeddings x, we obtain the representation u of $NE(i, j)$ as follows:

$$u = NE(i, j) = [x_i; \frac{1}{j - i + 1} \sum_{k=i}^{j} x_k; x_j] \quad (5)$$

2.3 DAGMM

After obtaining the candidate entity mentions, we need to further identify their entity types. Gaussian Mixture Model (GMM) is adopted to learn the distribution of each entity type. Experimental result of (Zong et al., 2018) suggested to us that it is more efficient to perform density estimation in the low-dimensional space, in which case the distribution of words are denser and more suitable for GMM. Therefore, we adopt Deep Autoencoding Gaussian Mixture Model (DAGMM) (Zong et al., 2018) to identify NE types. DAGMM consists of two major components: compression network utilizes a deep autoencoder to perform dimension reduction and concatenate the reduced low-dimensional representation and the reconstruction error features as the representations for the estimation network; The estimation network takes the low-dimension representation as input, and uses GMM to perform density estimation.

Compression network contains an encoder function for dimension reduction and a decode function for reconstruction, both of which are multi-layer perceptron (MLP), and we use tanh function as the activation function. Given NE representation u, the compression generates its low-dimensional representation t as follows.

$$\begin{aligned} t_e &= MLP(u; \theta_e) \quad & u' &= MLP(t_e; \theta_d) \\ t_r &= f(u, u') \quad & t &= [t_e, t_r] \end{aligned} \quad (6)$$

where θ_e and θ_d are respectively the parameters of the encoder and decoder, u' is the reconstruction counterpart of u, $f(\cdot)$ denotes the reconstruction error, we take the concatenation of relative Euclidean distance and cosine similarity as t_r in our experiment. t is then fed into the input layer of estimation network. Intuitively, we need to make the reconstruction error low to ensure that the low-dimensional representations preserve the key information of the NE representations. Thus the reconstruction error is taken as part of the loss function and is designed as the L_2-norm.

$$L(u_i, u_i') = \|u_i - u_i'\|_2^2 \quad (7)$$

Estimation network contains an MLP to predict the mixture membership for each instance and a GMM with unknown mixture-component distribution ϕ, mixture means μ and covariance matrix Σ for density prediction. During the training phase, the estimation network estimates the parameters of GMM and evaluates the likelihood for the instances. Given the low-dimensional representation t and the number of entity types K as the number of mixture components, MLP maps the representation to the K-dimension space:

$$\begin{aligned} m &= MLP(t; \theta_m) \\ \hat{\gamma} &= softmax(m) \end{aligned} \quad (8)$$

where θ_m is the parameter of MLP, $\hat{\gamma}$ is a K-dimension vector for the soft mixture-component membership prediction. The estimation network estimates the parameters of GMM as follows ($\forall 1 \leq k \leq K$),

$$\begin{aligned} \hat{\phi}_k &= \sum_{i=1}^{N} \frac{\hat{\gamma}_{ik}}{N}, \hat{\mu}_k = \frac{\sum_{i=1}^{N} \hat{\gamma}_{ik} t_i}{\sum_{i=1}^{N} \hat{\gamma}_{ik}} \\ \hat{\Sigma}_k &= \frac{\sum_{i=1}^{N} \hat{\gamma}_{ik} (t_i - \hat{\mu}_k)(t_i - \hat{\mu}_k)^T}{\sum_{i=1}^{N} \hat{\gamma}_{ik}} \end{aligned} \quad (9)$$

where $\hat{\gamma_i}$ is the membership prediction for t_i, and $\hat{\phi}_k, \hat{\mu_k}, \hat{\sigma_k}$ are mixture probability, mean, covariance for component k in GMM, respectively.

The likelihood for the instance is inferred by

$$E(t) = -log(\sum_{k=1}^{K} \hat{\phi}_k \frac{exp(-\frac{1}{2}(t - \hat{\mu}_k)^T \hat{\Sigma}_k^{-1} (t - \hat{\mu}_k)}{\sqrt{(2\pi)^d |\hat{\Sigma}_k|}}) \quad (10)$$

To avoid the diagonal entries in covariance matrices degenerating to 0, we penalize small values on the diagonal entries by

$$p(\hat{\Sigma}) = \sum_{k=1}^{K} \sum_{j=1}^{d} \frac{1}{\hat{\Sigma}_{kjj}} \quad (11)$$

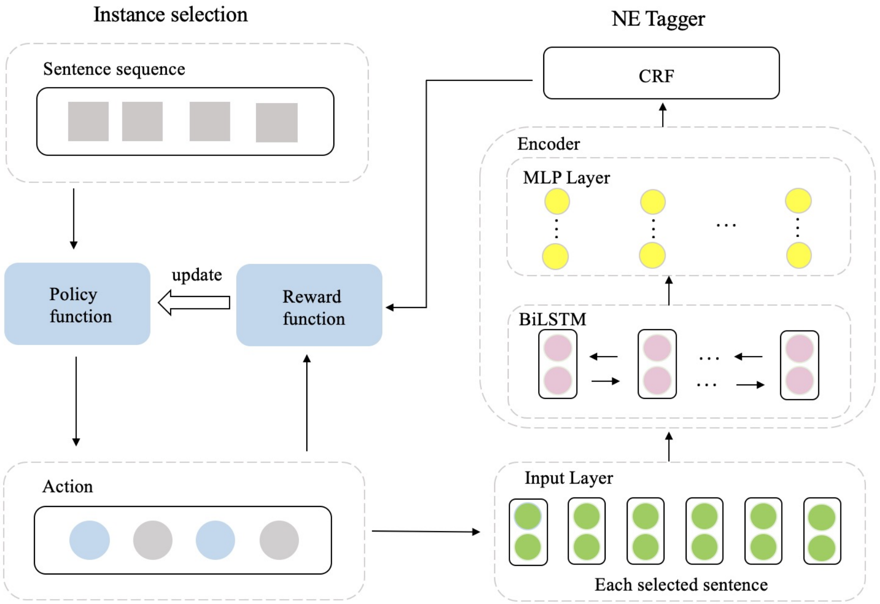

Figure 2: The framework of the reinforcement learning model, which consists of two parts. The left instance selector filters sentences according to a policy function, and then the selected sentences are used to train a better NE tagger. The instance selector updates its parameters based on the reward computed from NE tagger.

where d is the dimension of the t.

During training, we minimize the joint objective function:

$$J(\theta_e, \theta_d, \theta_m) = \frac{1}{N}\sum_{i=1}^{N} L(u_i, u_i') + \frac{\lambda_1}{N}\sum_{i=1}^{N} E(t_i) + \lambda_2 P(\hat{\Sigma}) \tag{12}$$

where λ_1 and λ_2 are two user-tunable parameters.

The final output is the result of K (the number of entity types) classification. We can only identify whether a word is an NE and whether several NEs are of the same category, since the entity type names as any other user-defined class/cluster/type names are just a group of pre-defined symbols by subjective naming. Therefore, following most work of unsupervised part-of-speech induction such as (Lin et al., 2015), we use matching to determine the corresponding entity category of each class, just for evaluation.

3 Refinement

The annotations obtained from the above procedure are noisy, we apply Reinforcement Learning (RL) (Feng et al., 2018; Yang et al., 2018b) to distinguish positive sentences from noisy sentences and refine these coarse-grained annotations. The RL model has two modules: an NE tagger and an instance selector.

3.1 NE tagger

Given the annotations generated by the above model, we take it as the noisy annotated label to train the NE tagger. Following (Lample et al., 2016; Yang et al., 2018a; Yang and Zhang, 2018), we employ bi-directional Long Short-Term Memory network (BiLSTM) for sequence labeling. In the input layer, we concatenate the word-level and character-level embedding as the joint word representation. We employ BiLSTM as the encoder, the concatenation of the forward and backward network output features $[\overrightarrow{h_k}, \overleftarrow{h_k}]$ is fed into an MLP, and then feed the output of MLP to a CRF layer.

CRF (Lafferty et al., 2001) has been included in most sota models, which captures label dependencies by adding transition scores between adjacent labels. During the decoding process, the Viterbi algorithm is used to search the label sequence with the highest probability. Given a sentence of length l, we denote the input sequence $x = \{x_1, ..., x_l\}$, where x_i stands for the i^{th} word in sequence x. For $y = \{y_1, ..., y_l\}$ being a predicted sequence of labels for x. We define its score as

$$score(x, y) = \sum_{i=0}^{l-1} T_{y_i, y_{i+1}} + \sum_{i=1}^{l} P_{i, y_i} \tag{13}$$

where $T_{y_i,y_{i+1}}$ represents the transmission score from the y_i to y_{i+1}, P_{i,y_i} is the score of the i^{th} tag of the i^{th} word from the BiLSTM.

A softmax over all possible tag sequences in the sentences generates a probability for the sequence y:

$$p(y|x) = \frac{e^{score(x,y)}}{\sum_{\tilde{y}\in Y} e^{score(x,\tilde{y})}} \tag{14}$$

where Y is the set of all possible tag sequences. During the training, we consider the maximum log-likelihood of the correct NE tag sequence. While decoding, we predict the optimal sequence which achieves the maximum score:

$$y^* = \arg\max_{\tilde{y}\in Y} score(x, \tilde{y}) \tag{15}$$

3.2 Instance Selector

The instance selection is a reinforcement learning process, where the instance selector acts as the agent and interacts with the environment (sentences) and the NE tagger, as shown in Figure 2. Given all the sentences, the agent takes an action to decide which sentence to select according to a policy network at each state, and receives a reward from the NE tagger when a batch of N sentences have been selected.

State representation. We follow the work of (Yang et al., 2018b) and represent the state s_j as the concatenation of the serialized vector representations from BiLSTM and the label scores from the MLP layer.

Policy network. The agent makes an action a_j from set of $\{0, 1\}$ to indicate whether the instance selector will select the j^{th} sentence. We adopt a logistic function as the policy function:

$$\begin{aligned} A(s_j, a_j) &= a_i\sigma(W * s_j + b) \\ &+ (1 - a_j)(1 - \sigma(W * s_j + b)) \end{aligned} \tag{16}$$

where W and b are the model parameters, and $\sigma(\cdot)$ stands for the logistic function.

Reward. The reward function indicates the ability of the NE tagger to predict labels of the selected sentences and only generates a reward when all the actions of the selected N sentences have been completed,

$$r = \frac{1}{N}\Big(\sum_{x,y\in\tilde{H}} \log p(y|x)\Big) \tag{17}$$

where $\tilde{H}$ represents the set of selected N sentences.

Training During the training phase, we optimize the policy network to maximize the reward of the selected sentences. The parameters are updated as follows,

$$\Theta = \Theta + \alpha \sum_{j=1}^{N} r\nabla_{\Theta} \log A(s_j, a_j) \tag{18}$$

where α is the learning rate and Θ is the parameter of the instance selector.

We train the NE tagger and instance selector iteratively. In each round, the instance selector first selects sentences from the training data, and then the positive sentences are used to train the NE tagger, the tagger updates the reward to the selector to optimize the policy function. Different from the work of (Yang et al., 2018b), we relabel the negative sentences by the NE tagger after each round, and merge them with the positive sentences for the next selection.

4 Experiments

We conduct experiments [2] on two standard NER datasets: CoNLL 2003 English dataset (Tjong Kim Sang and De Meulder, 2003) and CoNLL 2002 Spanish dataset (Tjong Kim Sang, 2002) that consist of news articles. These datasets contain four entity types: LOC (location), MISC (miscellaneous), ORG (organization), and PER (person). We adopt the standard data splitting and use the micro-averaged F_1 score as the evaluation metric.

4.1 Setup

Pre-trained Word Embeddings. For the CoNLL 2003 dataset, we use the pre-trained $50D$ SENNA embeddings released by (Collobert et al., 2011) and $100D$ GloVe (Pennington et al., 2014) embeddings for clustering and training, respectively. For CoNLL 2002 Spanish dataset, we train $64D$ GloVe embeddings with the minimum frequency of occurrence as 5, and the window size of 5.

Parameters and Model Training. For DAGMM, the hidden dimensions for compression network and estimation network are $[75, 15]$ and 10, respectively. For NE Tagger, we follow the work of (Yang and Zhang, 2018) and use the default experimental settings. We conduct optimization with the stochastic gradient descent, the learning rate is initially set to 0.015 and will shrunk by 5% after each epoch. The number of selected sentences at each time is set

as 10. Dropout (Srivastava et al., 2014) of a ratio 0.5 is applied for embeddings and hidden states.

4.2 Compared Methods

Supervised benchmarks on each dataset are represented to show the gap between supervised and our unsupervised model without any annotation data or external resources. LSTM-CRF (Lample et al., 2016) is the state-of-the-art supervised NE recognition model.

(Jie et al., 2019) propose an approach to tackle the incomplete annotation problem. This work introduces q distribution to model missing labels instead of traditionally uniform distribution for all possible complete label sequences, and uses k-fold cross-validation for estimating q. They report the result of keeping 50% of all the training data and removing the annotations of the rest entities together with the O labels for non-NEs.

(Liu et al., 2019) proposes a Knowledge-Augmented Language Model (KALM), which recognizes NEs during training language models. Given type-specific entity vocabularies and the general vocabulary, KALM computes the entity probability of the next word according to its context. This work extracts 11,123 vocabularies from WikiText-2 as the knowledge base. WikiText-2 is a standard language modeling dataset and covers 92.80% of entities in CoNLL 2003 dataset.

Category	SENNA	Handcraft

Total	171,142	305,117

Table 2: Number of entries for each category in lexicons for (Shang et al., 2018) for comparisons with our model, which need no lexicon.

(Shang et al., 2018) propose a distant supervision NE recognition model AutoNER using domain-specific dictionaries. This work designs a *Tie or Break* tagging scheme that focuses on the ties between adjacent tokens. Accordingly, AutoNER is designed to distinguish Break from Tie while skipping unknown positions. The authors report their evaluation results on datasets from a specific domain and their method needs necessary support from an NE lexicon. For better comparisons, we use the lexicon from the training data, the SENNA lexicon presented by (Collobert et al., 2011) and our handcraft lexicon [3] as the domain-specific dictionary to re-implement their work on CoNLL-2003 English dataset, the size of each category

in each lexicon is shown in Table 2. Due to the resource constraints, we only extract the lexicon in training data without labeling a larger dictionary for wider comparisons for CoNLL-2002.

4.3 Results and Comparisons

We present F_1, precision, and recall scores on both datasets in Table 1. All the models compared in Table 1 besides ours need extra resources to some extent, like partially annotated training data, NE dictionary, etc. While our model achieves comparable results without using any resources mentioned above. We compare the prediction results for each entity type with (Liu et al., 2019) in Table 3, and it is shown that our model performs well in LOC, ORG and PER types. These NEs have specific meanings, and more similar in position and length in the corpus, thus their word embeddings can better capture semantic and syntactic regularities, and thus better represent the words, while MISC includes various entity types which may bring significant confusion on learning type patterns. While (Liu et al., 2019) better regularize the type information from NE dictionaries and re-trained type information.

Though (Shang et al., 2018) achieves better results when using golden NE dictionary for English, they perform poorly on SENNA and our manually annotated dictionary. Specially, when using the gold NE dictionary for training Spanish dataset, the result is especially unsatisfactory. According to our statistics, over half of the MISC NEs in CoNLL 2002 Spanish training data are labeled as other types in the same dataset, while the ratio is 28% in CoNLL 2003 English dataset, thus the results differs a lot in the two datasets. Our models achieve much better performance than those of (Shang et al., 2018) by more than doubling their F_1 scores in the general NE dictionary (SENNA and human-labeled Wikipedia dictionary). Besides, our unsupervised NE recognition method is shown more general and gives a more stable performance than the distant supervision model in (Shang et al., 2018), which highly relies on the quality of the support dictionary and the domain relevance of the dictionary to the corpus.

We acknowledge that there still exists a gap between our unsupervised NE recognition model with the sota supervised model (Lample et al., 2016; Jie et al., 2019), but the applicability of unsupervised models and the robustness of resource dependence are unreachable by supervised models.

Table 4 lists the results of entity span detection. Our Gaussian-HMM absorbs informative clue from clustering, and greatly improves the results of entity span detection. For the English dataset, we apply SENNA embedding, which is trained on English Wikipedia and Reuters RCV1 corpus, thus the result of clustering becomes better, leading to a better result of Gaussian-HMM. While for the Spanish dataset, the embedding is trained on Wikipedia corpus only, which has little connection with the CoNLL-2002 datasets, thus the result is slightly lower. Overall, unsupervised modeling based on word embeddings may be more general and robust than dictionary-based and corpus-based modeling.

4.4 Discussion

Our model is good at dealing with common NEs, because their word embeddings well represent meanings, thus leading to a better prediction. However, our model is not very satisfactory in dealing with nested NEs. For example, *South Africa* and *Africa* can be taken as NEs respectively, and *south* is recognized as *O* labels in most of the other cases, thus in this case, our model makes a bias prediction, and only recognizes *Africa*. Table 5 shows an example of a positive instance and a negative instance before RL and after RL. During the training process, the instance selector takes action to select the first instance for training a silver NE Tagger. Then the second instance is relabeled after one epoch, and merged with the first instance for the next turn. We can discover that the NE Tagger learns the effective features of the ORG type, and can modify

the wrong labels in the second instance.

Using Pre-trained Languages Models. We have also tried language models such as ELMo and BERT as encoders for Gaussian-HMM, but their sparse characteristics in high-dimensional space are not conducive to Gaussian modeling. Unsupervised models have fewer parameters and simpler training phase, thus there is no guarantee that the language model will retain its key properties when it is reduced to low dimensions. We further add the pre-trained language model BERT as the additional embeddings for the NE Tagger to refine the output of Gaussian-HMM and DAGMM, which slightly improves our result to 69.99 for CoNLL-2003 English NER and 56.66 for CoNLL-2002 Spanish NER.

5 Related work

Deep neural network models have helped peoples released from handcrafted features in a wide range of NLP tasks (Zhang et al., 2019; Li et al., 2018a,b, 2019; Zhou and Zhao, 2019; Xiao et al., 2019; Zhang et al., 2020a,b,c). LSTM-CRF (Lample et al., 2016; Ma and Hovy, 2016) is the most state-of-the-art model for NE recognition. In order to reduce the requirements of training corpus, distant supervised models (Shang et al., 2018; Yang et al., 2018b; Ren et al., 2015; He, 2017; Fries et al., 2017) have been applied to NE recognition. Recently, (Liu et al., 2019) proposed a Knowledge-Augmented Language Model, which trains language models and at the same time compute the probability of the next word being different entity types according to the context given type-specific entity/general vocabularies. Unlike these existing approaches, our study focuses on unsupervised NE recognition learning without any extra resources.

Noisy data is another important factor affecting the neural network models, reinforcement learning has been applied to many tasks, (Feng et al., 2018) use reinforcement learning for Relation Classification from Noisy Data. (Yang et al., 2018b) show how to apply reinforcement learning in NE recognition systems by using instance selectors, which can tell high-quality training sentences from noisy data. Their work inspires us to use reinforcement leaning after obtaining coarse annotated data from Gaussian-HMM.

6 Conclusion

This paper presents an NE recognition model with only pre-trained word embeddings and achieves remarkable results on CoNLL 2003 English and CoNLL 2002 Spanish benchmark datasets. The proposed approach yields, to the best of our knowledge, first fully unsupervised NE recognition work on these two benchmark datasets without any annotation data or extra knowledge base.

Abstract

Current text classification methods typically require a good number of human-labeled documents as training data, which can be costly and difficult to obtain in real applications. Humans can perform classification without seeing any labeled examples but only based on a small set of words describing the categories to be classified. In this paper, we explore the potential of only using the label name of each class to train classification models on unlabeled data, without using any labeled documents. We use pre-trained neural language models both as general linguistic knowledge sources for category understanding and as representation learning models for document classification. Our method (1) associates semantically related words with the label names, (2) finds category-indicative words and trains the model to predict their implied categories, and (3) generalizes the model via self-training. We show that our model achieves around 90% accuracy on four benchmark datasets including topic and sentiment classification without using any labeled documents but learning from unlabeled data supervised by at most 3 words (1 in most cases) per class as the label name[1].

1 Introduction

Text classification is a classic and fundamental task in Natural Language Processing (NLP) with a wide spectrum of applications such as question answering (Rajpurkar et al., 2016), spam detection (Jindal and Liu, 2007) and sentiment analysis (Pang et al., 2002). Building an automatic text classification model has been viewed as a task of training machine learning models from human-labeled documents. Indeed, many deep learning-based classifiers including CNNs (Kim, 2014; Zhang et al., 2015) and RNNs (Tang et al., 2015a; Yang et al., 2016) have been developed and achieved great success when trained on large-scale labeled documents (usually over tens of thousands), thanks to their strong representation learning power that effectively captures the high-order, long-range semantic dependency in text sequences for accurate classification.

Recently, increasing attention has been paid to semi-supervised text classification which requires a much smaller amount of labeled data. The success of semi-supervised methods stems from the usage of abundant unlabeled data: Unlabeled documents provide natural regularization for constraining the model predictions to be invariant to small changes in input (Chen et al., 2020; Miyato et al., 2017; Xie et al., 2019), thus improving the generalization ability of the model. Despite mitigating the annotation burden, semi-supervised methods still require manual efforts from domain experts, which might be difficult or expensive to obtain especially when the number of classes is large.

Contrary to existing supervised and semi-supervised models which learn from labeled documents, a human expert will just need to understand the label name (*i.e.*, a single or a few representative words) of each class to classify documents. For example, we can easily classify news articles when given the label names such as “sports”, “business”, and “politics” because we are able to understand these topics based on prior knowledge.

In this paper, we study the problem of weakly-supervised text classification where only the label name of each class is provided to train a classifier on purely unlabeled data. We propose a language model self-training approach wherein a pre-trained neural language model (LM) (Devlin et al., 2019; Peters et al., 2018; Radford et al., 2018; Yang et al., 2019) is used as both the general knowledge source for category understanding and feature representation learning model for classification. The LM

November 16–20, 2020.

creates contextualized word-level category supervision from unlabeled data to train itself, and then generalizes to document-level classification via a self-training objective.

Specifically, we propose the **LOTClass** model for **L**abel-Name-**O**nly **T**ext **Class**ification built in three steps: (1) We construct a category vocabulary for each class that contains semantically correlated words with the label name using a pre-trained LM. (2) The LM collects high-quality category-indicative words in the unlabeled corpus to train itself to capture category distinctive information with a contextualized word-level category prediction task. (3) We generalize the LM via document-level self-training on abundant unlabeled data.

LOTClass achieves around 90% accuracy on four benchmark text classification datasets, *AG News*, *DBPedia*, *IMDB* and *Amazon* corpora, *without* learning from any labeled data but only using at most 3 words (1 word in most cases) per class as the label name, outperforming existing weakly-supervised methods significantly and yielding even comparable performance to strong semi-supervised and supervised models.

The contributions of this paper are as follows:

- We propose a weakly-supervised text classification model **LOTClass** based on a pre-trained neural LM without any further dependencies[2]. **LOTClass** does not need any labeled documents but only the label name of each class.

- We propose a method for finding category-indicative words and a contextualized word-level category prediction task that trains LM to predict the implied category of a word using its contexts. The LM so trained generalizes well to document-level classification upon self-training on unlabeled corpus.

- On four benchmark datasets, **LOTClass** outperforms significantly weakly-supervised models and has comparable performance to strong semi-supervised and supervised models.

2 Related Work

2.1 Neural Language Models

Pre-training deep neural models for language modeling, including autoregressive LMs such as ELMo (Peters et al., 2018), GPT (Radford et al., 2018) and XLNet (Yang et al., 2019) and autoencoding LMs such as BERT (Devlin et al., 2019) and its variants (Lan et al., 2020; Lewis et al., 2020; Liu et al., 2019b), has brought astonishing performance improvement to a wide range of NLP tasks, mainly for two reasons: (1) LMs are pre-trained on large-scale text corpora, which allow the models to learn generic linguistic features (Tenney et al., 2019) and serve as knowledge bases (Petroni et al., 2019); and (2) LMs enjoy strong feature representation learning power of capturing high-order, long-range dependency in texts thanks to the Transformer architecture (Vaswani et al., 2017).

2.2 Semi-Supervised and Zero-Shot Text Classification

For semi-supervised text classification, two lines of framework are developed to leverage unlabeled data. Augmentation-based methods generate new instances and regularize the model's predictions to be invariant to small changes in input. The augmented instances can be either created as real text sequences (Xie et al., 2019) via back translation (Sennrich et al., 2016) or in the hidden states of the model via perturbations (Miyato et al., 2017) or interpolations (Chen et al., 2020). Graph-based methods (Tang et al., 2015b; Zhang et al., 2020) build text networks with words, documents and labels and propagate labeling information along the graph via embedding learning (Tang et al., 2015c) or graph neural networks (Kipf and Welling, 2017).

Zero-shot text classification generalizes the classifier trained on a known label set to an unknown one without using any new labeled documents. Transferring knowledge from seen classes to unseen ones typically relies on semantic attributes and descriptions of all classes (Liu et al., 2019a; Pushp and Srivastava, 2017; Xia et al., 2018), correlations among classes (Rios and Kavuluru, 2018; Zhang et al., 2019) or joint embeddings of classes and documents (Nam et al., 2016). However, zero-shot learning still requires labeled data for the seen label set and cannot be applied to cases where no labeled documents for any class is available.

2.3 Weakly-Supervised Text Classification

Weakly-supervised text classification aims to categorize text documents based only on word-level descriptions of each category, eschewing the need of any labeled documents. Early attempts rely on distant supervision such as Wikipedia to interpret

---

[2] Other semi-supervised/weakly-supervised methods usually take advantage of distant supervision like Wikipedia dump (Chang et al., 2008), or augmentation systems like trained back translation models (Xie et al., 2019).

the label name semantics and derive document-concept relevance via explicit semantic analysis (Gabrilovich and Markovitch, 2007). Since the classifier is learned purely from general knowledge without even requiring any unlabeled domain-specific data, these methods are called dataless classification (Chang et al., 2008; Song and Roth, 2014; Yin et al., 2019). Later, topic models (Chen et al., 2015; Li et al., 2016) are exploited for seed-guided classification to learn seed word-aware topics by biasing the Dirichlet priors and to infer posterior document-topic assignment. Recently, neural approaches (Mekala and Shang, 2020; Meng et al., 2018, 2019) have been developed for weakly-supervised text classification. They assign documents pseudo labels to train a neural classifier by either generating pseudo documents or using LMs to detect category-indicative words. While achieving inspiring performance, these neural approaches train classifiers from scratch on the local corpus and fail to take advantage of the general knowledge source used by dataless classification. In this paper, we build our method upon pre-trained LMs, which are used both as general linguistic knowledge sources for understanding the semantics of label names, and as strong feature representation learning models for classification.

3 Method

In this section, we introduce **LOTClass** with BERT (Devlin et al., 2019) as our backbone model, but our method can be easily adapted to other pre-trained neural LMs.

3.1 Category Understanding via Label Name Replacement

When provided label names, humans are able to understand the semantics of each label based on general knowledge by associating with it other correlated keywords that indicate the same category. In this section, we introduce how to learn a category vocabulary from the label name of each class with a pre-trained LM, similar to the idea of topic mining in recent studies (Meng et al., 2020a,b).

Intuitively, words that are interchangeable most of the time are likely to have similar meanings. We use the pre-trained BERT masked language model (MLM) to predict what words can replace the label names under most contexts. Specifically, for each occurrence of a label name in the corpus, we feed its contextualized embedding vector $\boldsymbol{h} \in \mathbb{R}^h$ produced by the BERT encoder to the MLM head, which will output a probability distribution over the entire vocabulary V, indicating the likelihood of each word w appearing at this position:

$$p(w \mid \boldsymbol{h}) = \text{Softmax}\left(W_2\, \sigma\left(W_1 \boldsymbol{h} + \boldsymbol{b}\right)\right), \quad (1)$$

where $\sigma(\cdot)$ is the activation function; $W_1 \in \mathbb{R}^{h \times h}$, $\boldsymbol{b} \in \mathbb{R}^h$, and $W_2 \in \mathbb{R}^{|V| \times h}$ are learnable parameters that have been pre-trained with the MLM objective of BERT.

Table 1 shows the pre-trained MLM prediction for the top words (sorted by $p(w \mid \boldsymbol{h})$) to replace the original label name "sports" under two different contexts. We observe that for each masked word, the top-50 predicted words usually have similar meanings with the original word, and thus we use the threshold of 50 words given by the MLM to define valid replacement for each occurrence of the label names in the corpus. Finally, we form the category vocabulary of each class using the top-100 words ranked by how many times they can replace the label name in the corpus, discarding stopwords with NLTK (Bird et al., 2009) and words that appear in multiple categories. Tables 2, 3, 4 and 9 (Table 9 is in Appendix A) show the label name used for each category and the obtained category vocabulary of *AG News*, *IMDB*, *Amazon* and *DBPedia* corpora, respectively.

3.2 Masked Category Prediction

Like how humans perform classification, we want the classification model to focus on category-indicative words in a sequence. A straightforward way is to directly highlight every occurrence of the category vocabulary entry in the corpus. However, this approach is error-prone because: (1) Word meanings are contextualized; not every occurrence of the category keywords indicates the category. For example, as shown in Table 1, the word "sports" in the second sentence does not imply the topic "sports". (2) The coverage of the category vocabulary is limited; some terms under specific contexts have similar meanings with the category keywords but are not included in the category vocabulary.

To address the aforementioned challenge, we introduce a new task, Masked Category Prediction (MCP), as illustrated in Fig. 1, wherein a pre-trained LM creates *contextualized* word-level category supervision for training itself to predict the implied category of a word with the word masked.

To create contextualized word-level category supervision, we reuse the pre-trained MLM method in

Sentence	Language Model Prediction
The oldest annual US team **sports** competition that includes professionals is not in baseball, or football or basketball or hockey. It's in soccer.	sports, baseball, handball, soccer, basketball, football, tennis, sport, championship, hockey, . . .

Table 2: The label name used for each class of *AG News* dataset and the learned category vocabulary.

Section 3.1 to understand the contextualized meaning of each word by examining what are valid replacement words. As shown in Table 1, the MLM predicted words are good indicators of the original word's meaning. As before, we regard the top-50 words given by the MLM as valid replacement of the original word, and we consider a word w as "category-indicative" for class c_w if more than 20 out of 50 w's replacing words appear in the category vocabulary of class c_w. By examining every word in the corpus as above, we will obtain a set of category-indicative words and their category labels $\mathcal{S}_{\text{ind}}$ as word-level supervision.

For each category-indicative word w, we mask it out with the `[MASK]` token and train the model to predict w's indicating category c_w via cross-entropy loss with a classifier (a linear layer) on top of w's contextualized embedding $\boldsymbol{h}$:

$$\mathcal{L}_{MCP} = -\sum_{(w,c_w)\in\mathcal{S}_{\text{ind}}} \log p(c_w \mid \boldsymbol{h}_w), \qquad (2)$$

$$p(c \mid \boldsymbol{h}) = \text{Softmax}\left(W_c \boldsymbol{h} + \boldsymbol{b}_c\right), \qquad (3)$$

where $W_c \in \mathbb{R}^{K\times h}$ and $\boldsymbol{b}_c \in \mathbb{R}^K$ are learnable parameters of the linear layer (K is the number of classes).

We note that it is crucial to mask out the category-indicative word for category prediction, because this forces the model to infer categories based on the word's *contexts* instead of simply memorizing context-free category keywords. In this way, the BERT encoder will learn to encode category-discriminative information within the sequence into the contextualized embedding $\boldsymbol{h}$ that is helpful for predicting the category at its position.

3.3 Self-Training

After training the LM with the MCP task, we propose to self-train the model on the entire unlabeled corpus for two reasons: (1) There are still many unlabeled documents not seen by the model in the MCP task (due to no category keywords detected) that can be used to refine the model for better generalization. (2) The classifier has been trained on top of words to predict their categories with them masked, but have not been applied on the `[CLS]` token where the model is allowed to see the entire

Label Name	Category Vocabulary

Table 4: The label name used for each class of *Amazon* dataset and the learned category vocabulary.

sequence to predict its category.

The idea of self-training (ST) is to iteratively use the model's current prediction P to compute a target distribution Q which guides the model for refinement. The general form of ST objective can be expressed with the KL divergence loss:

$$\mathcal{L}_{ST} = \mathrm{KL}(Q \| P) = \sum_{i=1}^{N} \sum_{j=1}^{K} q_{ij} \log \frac{q_{ij}}{p_{ij}}, \quad (4)$$

where N is the number of instances.

There are two major choices of the target distribution Q: Hard labeling and soft labeling. Hard labeling (Lee, 2013) converts high-confidence predictions over a threshold τ to one-hot labels, *i.e.*, $q_{ij} = \mathbb{1}(p_{ij} > \tau)$, where $\mathbb{1}(\cdot)$ is the indicator function. Soft labeling (Xie et al., 2016) derives Q by enhancing high-confidence predictions while demoting low-confidence ones via squaring and normalizing the current predictions:

$$q_{ij} = \frac{p_{ij}^2 / f_j}{\sum_{j'} \left(p_{ij'}^2 / f_{j'} \right)}, \; f_j = \sum_i p_{ij}, \quad (5)$$

where the model prediction is made by applying the classifier trained via MCP (Eq. (3)) to the `[CLS]` token of each document, *i.e.*,

$$p_{ij} = p(c_j \mid \boldsymbol{h}_{d_i:\texttt{[CLS]}}). \quad (6)$$

In practice, we find that the soft labeling strategy consistently gives better and more stable results than hard labeling, probably because hard labeling treats high-confident predictions directly as ground-truth labels and is more prone to error propagation. Another advantage of soft labeling is that the target distribution is computed for every instance and no confidence thresholds need to be preset.

We update the target distribution Q via Eq. (5) every 50 batches and train the model via Eq. (4). The overall algorithm is shown in Algorithm 1.

Algorithm 1: LOTClass Training.

Return $M$;
```

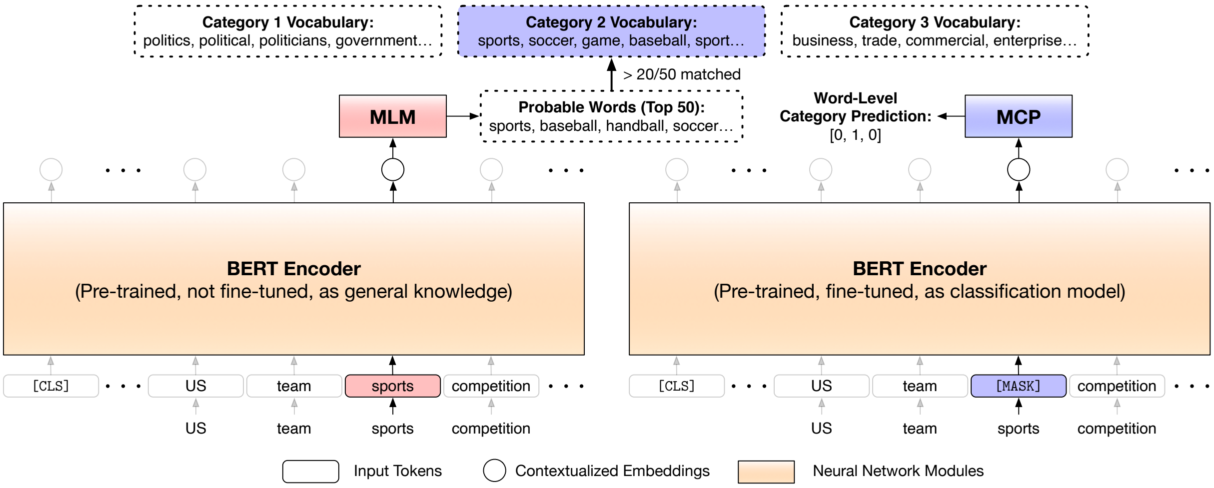

Figure 1: Overview of Masked Category Prediction (MCP). The Masked Language Model (MLM) head first predicts what are probable words to appear at each token's position. A token is considered as "category-indicative" if its probable replacement words highly overlap with the category vocabulary of a certain class. The MCP head is trained to predict the implied categories of the category-indicative words with them masked.

Dataset	Classification Type	# Classes	# Train	# Test
AG News	News Topic	4	120,000	7,600
DBPedia	Wikipedia Topic	14	560,000	70,000
IMDB	Movie Review Sentiment	2	25,000	25,000
Amazon	Product Review Sentiment	2	3,600,000	400,000

Table 5: Dataset statistics. Supervised models are trained on the entire training set. Semi-supervised models use 10 labeled documents per class from the training set and the rest as unlabeled data. Weakly-supervised models are trained by using the entire training set as unlabeled data. All models are evaluated on the test set.

4 Experiments

4.1 Datasets

We use four benchmark datasets for text classification: *AG News* (Zhang et al., 2015), *DBPedia* (Lehmann et al., 2015), *IMDB* (Maas et al., 2011) and *Amazon* (McAuley and Leskovec, 2013). The dataset statistics are shown in Table 5. All datasets are in English language.

4.2 Compared Methods

We compare **LOTClass** with a wide range of weakly-supervised methods and also state-of-the-art semi-supervised and supervised methods. The label names used as supervision on each dataset for the weakly-supervised methods are shown in Tables 2, 3, 4 and 9. (Table 9 can be found in Appendix A.) Fully supervised methods use the entire training set for model training. Semi-supervised method **UDA** uses 10 labeled documents per class from the training set and the rest as unlabeled data. Weakly-supervised methods use the training set as unlabeled data. All methods are evaluated on the test set.

Weakly-supervised methods:

- **Dataless** (Chang et al., 2008): Dataless classification maps label names and each document into the same semantic space of Wikipedia concepts. Classification is performed based on vector similarity between documents and classes using explicit semantic analysis (Gabrilovich and Markovitch, 2007).
- **WeSTClass** (Meng et al., 2018): WeSTClass generates pseudo documents to pre-train a CNN classifier and then bootstraps the model on unlabeled data with self-training.
- **BERT w. simple match**: We treat each document containing the label name as if it is a labeled document of the corresponding class to train the BERT model.
- **LOTClass w/o. self train**: This is an ablation version of our method. We train **LOTClass**

only with the MCP task, without performing self-training on the entire unlabeled data.

Semi-supervised method:

- **UDA** (Xie et al., 2019): Unsupervised data augmentation is the state-of-the-art semi-supervised text classification method. Apart from using a small amount of labeled documents for supervised training, it uses back translation (Sennrich et al., 2016) and TF-IDF word replacing for augmentation and enforces the model to make consistent predictions over the augmentations.

Supervised methods:

- **char-CNN** (Zhang et al., 2015): Character-level CNN was one of the state-of-the-art supervised text classification models before the appearance of neural LMs. It encodes the text sequences into characters and applies 6-layer CNNs for feature learning and classification.
- **BERT** (Devlin et al., 2019): We use the pre-trained BERT-base-uncased model and fine-tune it with the training data for classification.

4.3 Experiment Settings

We use the pre-trained BERT-base-uncased model as the base neural LM. For the four datasets *AG News*, *DBPedia*, *IMDB* and *Amazon*, the maximum sequence lengths are set to be 200, 200, 512 and 200 tokens. The training batch size is 128. We use Adam (Kingma and Ba, 2015) as the optimizer. The peak learning rate is $2e-5$ and $1e-6$ for MCP and self-training, respectively. The model is run on 4 NVIDIA GeForce GTX 1080 Ti GPUs.

4.4 Results

The classification accuracy of all methods on the test set is shown in Table 6. **LOTClass** consistently outperforms all weakly-supervised methods by a large margin. Even without self-training, **LOTClass**'s ablation version performs decently across all datasets, demonstrating the effectiveness of our proposed category understanding method and the MCP task. With the help of self-training, **LOTClass**'s performance becomes comparable to state-of-the-art semi-supervised and supervised models.

How many labeled documents are label names worth? We vary the number of labeled documents per class on *AG News* dataset for training **Supervised BERT** and show its corresponding performance in Fig. 2(a). The performance of **LOTClass** is equivalent to that of **Supervised BERT** with 48 labeled documents per class.

4.5 Study of Category Understanding

We study the characteristics of the method introduced in Section 3.1 from the following two aspects. (1) Sensitivity to different words as label names. We use "commerce" and "economy" to replace "business" as the label name on *AG News* dataset. Table 7 shows the resulting learned category vocabulary. We observe that despite the change in label name, around half of terms in the resulting category vocabulary overlap with the original one (Table 2 "business" category); the other half also indicate very similar meanings. This guarantees the robustness of our method since it is the category vocabulary rather than the original label name that is used in subsequent steps. (2) Advantages over alternative solutions. We take the pre-trained 300-d GloVe (Pennington et al., 2014) embeddings and use the top words ranked by cosine similarity with the label names for category vocabulary construction. On *Amazon* dataset, we use "good" and "bad" as the label names, and the category vocabulary built by **LOTClass** (Table 4) accurately reflects the sentiment polarity, while the results given by GloVe (Table 8) are poor—some words that are close to "good"/"bad" in the GloVe embedding space do not indicate sentiment, or even the reversed sentiment (the closest word to "bad" is "good"). This is because context-free embeddings only learn from local context windows, while neural LMs capture long-range dependency that leads to accurate interpretation of the target word.

4.6 Effect of Self-Training

We study the effect of self-training with two sets of experiments: (1) In Fig. 2(b) we show the test accuracy and self-training loss (Eq. (4)) when training **LOTClass** on the first $1,000$ steps (batches) of unlabeled documents. It can be observed that the loss decreases within a period of 50 steps, which is the update interval for the target distribution Q—when the self training loss approximates zero, the model has fit the previous Q and a new target distribution is computed based on the most recent predictions. With the model refining itself on unlabeled data iteratively, the performance gradually improves. (2) In Fig. 2(c) we show the performance of **LOTClass** vs. **BERT w. simple match** with the same self-

Supervision Type	Methods	AG News	DBPedia	IMDB	Amazon

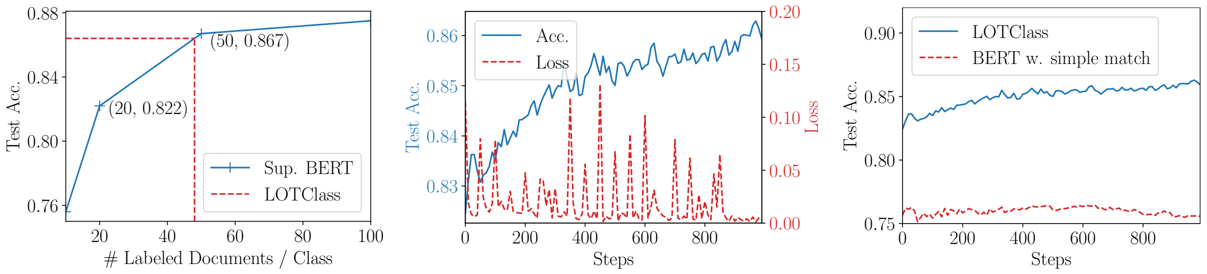
Table 8: GloVe 300-d pre-trained embedding for category understanding on *Amazon* dataset.

training strategy. **BERT w. simple match** does not seem to benefit from self-training as our method does. This is probably because documents containing label names may not be actually about the category (*e.g.*, the second sentence in Table 1); the noise from simply matching the label names causes the model to make high-confidence wrong predictions, from which the model struggles to extract correct classification signals for self-improvement. This demonstrates the necessity of creating word-level supervision by understanding the contextualized word meaning and training the model via MCP to predict the category of words instead of directly assigning the word's implied category to its document.

5 Discussions

The potential of weakly-supervised classification has not been fully explored. For the simplicity and clarity of our method, (1) we only use the BERT-base-uncased model rather than more advanced and recent LMs; (2) we use at most 3 words per class as label names; (3) we refrain from using other dependencies like back translation systems for augmentation. We believe that the performance will become better with the upgrade of the model, the enrichment in inputs and the usage of data augmentation techniques.

Applicability of weak supervision in other NLP tasks. Many other NLP problems can be formulated as classification tasks such as named en-



(a) **Supervised BERT**: Test acc. vs. number of labeled documents.

(b) **LOTClass**: Test accuracy and self-training loss.

(c) **LOTClass** vs. **BERT w. simple match** during self-training.

Figure 2: (On *AG News* dataset.) (a) The performance of **LOTClass** is close to that of **Supervised BERT** with 48 labeled documents per class. (b) The self-training loss of **LOTClass** decreases in a period of 50 steps; the performance of **LOTClass** gradually improves. (c) **BERT w. simple match** does not benefit from self-training.

tity recognition and aspect-based sentiment analysis (Huang et al., 2020). Sometimes a label name could be too generic to interpret (*e.g.*, "person", "time", etc). To apply similar methods as introduced in this paper to these scenarios, one may consider instantiating the label names with more concrete example terms like specific person names.

Limitation of weakly-supervised classification. There are difficult cases where label names are not sufficient to teach the model for correct classification. For example, some review texts implicitly express sentiment polarity that goes beyond word-level understanding: *"I find it sad that just because Edward Norton did not want to be in the film or have anything to do with it, people automatically think the movie sucks without even watching it or giving it a chance."* Therefore, it will be interesting to improve weakly-supervised classification with active learning where the model is allowed to consult the user about difficult cases.

Collaboration with semi-supervised classification. One can easily integrate weakly-supervised methods with semi-supervised methods in different scenarios: (1) When no training documents are available, the high-confidence predictions of weakly-supervised methods can be used as ground-truth labels for initializing semi-supervised methods. (2) When both training documents and label names are available, a joint objective can be designed to train the model with both word-level tasks (*e.g.*, MCP) and document-level tasks (*e.g.*, augmentation, self-training).

6 Conclusions

In this paper, we propose the **LOTClass** model built upon pre-trained neural LMs for text classification with label names as the only supervision in three steps: Category understanding via label name replacement, word-level classification via masked category prediction, and self-training on unlabeled corpus for generalization. The effectiveness of **LOTClass** is validated on four benchmark datasets. We show that label names is an effective supervision type for text classification but has been largely overlooked by the mainstreams of literature. We also point out several directions for future work by generalizing our methods to other tasks or combining with other techniques.

A Label Names Used and Category Vocabulary Obtained for DBPedia

We show the label names used for *DBPedia* corpora and the obtained category vocabulary in Table 9. In most cases, only one word as the label name will be sufficient; however, sometimes the semantics of the label name might be too general so we instead use 2 or 3 keywords of the class to represent the label name. For example, we use “school” and “university” to represent the class “educational institution”; we use “river”, “lake” and “mountain” to represent the class “natural place”; we use “book”, “novel” and “publication” to represent the class “paper work”.

Label Name	Category Vocabulary
company	companies, co, firm, concern, subsidiary, brand, enterprise, division, partnership, manufacturer, works, inc, cooperative, provider, corp, factory, chain, limited, holding, consortium, industry, manufacturing, entity, operator, product, giant …
school university	academy, college, schools, ecole, institution, campus, university, secondary, form, students, schooling, standard, class, educate, elementary, hs, level, student, tech, academic, universities, branch, degree, universite, universidad, …
artist	artists, painter, artistic, musician, singer, arts, poet, designer, sculptor, composer, star, vocalist, illustrator, architect, songwriter, entertainer, cm, painting, cartoonist, creator, talent, style, identity, creative, duo, editor, personality, …
athlete	athletes, athletics, indoor, olympian, archer, events, sprinter, medalist, olympic, runner, jumper, swimmer, competitor, holder, mile, ultra, able, mark, hurdles, relay, amateur, medallist, footballer, anchor, metres, cyclist, shooter, athletic, …
politics	politics, political, government, politicians, politician, elections, policy, party, affairs, legislature, politically, democracy, democratic, governing, history, leadership, cabinet, issues, strategy, election, religion, assembly, law, …
transportation	transportation, transport, transit, rail, travel, traffic, mobility, bus, energy, railroad, communication, route, transfer, passenger, transported, traction, recreation, metro, shipping, railway, security, transports, infrastructure, …
building	buildings, structure, tower, built, wing, hotel, build, structures, room, courthouse, skyscraper, library, venue, warehouse, block, auditorium, location, plaza, addition, museum, pavilion, landmark, offices, foundation, headquarters, …
river lake mountain	river, lake, bay, dam, rivers, water, creek, channel, sea, pool, mountain, stream, lakes, flow, reservoir, hill, flowing, mountains, basin, great, glacier, flowed, pond, de, valley, peak, drainage, mount, summit, brook, mare, head, …
village	village, villages, settlement, town, east, population, rural, municipality, parish, na, temple, commune, pa, ha, north, pre, hamlet, chamber, settlements, camp, administrative, lies, township, neighbourhood, se, os, iran, villagers, nest, …
animal	animal, animals, ape, horse, dog, cat, livestock, wildlife, nature, lion, human, owl, cattle, cow, wild, indian, environment, pig, elephant, fauna, mammal, beast, creature, australian, ox, land, alligator, eagle, endangered, mammals, …
plant tree	shrub, plants, native, rose, grass, herb, species, jasmine, race, vine, hybrid, bamboo, hair, planted, fire, growing, flame, lotus, sage, iris, perennial, variety, palm, cactus, trees, robert, weed, nonsense, given, another, stand, holly, poppy, …
album	lp, albums, cd, ep, effort, recording, disc, compilation, debut, appearance, soundtrack, output, genus, installation, recorded, anthology, earth, issue, imprint, ex, era, opera, estate, single, outing, arc, instrumental, audio, el, song, offering, …
film	films, comedy, drama, directed, documentary, video, language, pictures, miniseries, negative, movies, musical, screen, trailer, acting, starring, filmmaker, flick, horror, silent, screenplay, box, lead, filmmaking, second, bond, script, …
book novel publication	novel, books, novels, mystery, memoir, fantasy, fiction, novelist, reader, read, cycle, romance, writing, written, published, novella, play, narrative, trilogy, manga, autobiography, publication, literature, isbn, write, tale, poem, year, text, reading, …

Table 9: The label name used for each class of *DBPedia* dataset and the learned category vocabulary.

Neural Topic Modeling with Cycle-Consistent Adversarial Training

Abstract

Advances on deep generative models have attracted significant research interest in neural topic modeling. The recently proposed Adversarial-neural Topic Model models topics with an adversarially trained generator network and employs Dirichlet prior to capture the semantic patterns in latent topics. It is effective in discovering coherent topics but unable to infer topic distributions for given documents or utilize available document labels. To overcome such limitations, we propose Topic Modeling with Cycle-consistent Adversarial Training (ToMCAT) and its supervised version sToMCAT. ToMCAT employs a generator network to interpret topics and an encoder network to infer document topics. Adversarial training and cycle-consistent constraints are used to encourage the generator and the encoder to produce realistic samples that coordinate with each other. sToMCAT extends ToMCAT by incorporating document labels into the topic modeling process to help discover more coherent topics. The effectiveness of the proposed models is evaluated on unsupervised/supervised topic modeling and text classification. The experimental results show that our models can produce both coherent and informative topics, outperforming a number of competitive baselines.

1 Introduction

Topic models, such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), aim to discover underlying topics and semantic structures from text collections. Due to its interpretability and effectiveness, LDA has been extended to many Natural Language Processing (NLP) tasks (Lin and He, 2009; McAuley and Leskovec, 2013; Zhou et al., 2017). Most of these models employ mean-field variational inference or collapsed Gibbs sampling (Griffiths and Steyvers, 2004) for model inference as a result of their intractable posteriors. However, such inference algorithms are model specific and require dedicated derivations.

To address such limitation, neural topic models with black-box inference have been explored, with more flexible training schemes. Inspired by variational autoencoder (VAE) (Kingma and Welling, 2013), Miao et al. (2016) proposed Neural Variational Document Model which interprets the latent code in VAE as topics. Following this way, Srivastava and Sutton (2017) adopted the logistic normal prior rather than Gaussian to mimic the simplex properties of topic distribution. Logistic normal is a Laplace approximation to the Dirichlet distribution (MacKay, 1998). However, logistic normal can not exhibit multiple peaks at the vertices of the simplex as the Dirichlet distribution. Therefore, it is less capable of capturing the multi-modality which is crucial for topic modeling (Wallach et al., 2009).

To overcome such limitation, Wang et al. (2019a) proposed Adversarial-neural Topic Model (ATM), a topic model based on Generative Adversarial Networks (GANs) (Goodfellow et al., 2014) and sampling topics directly from the Dirichlet distribution to impose a Dirichlet prior. ATM employs a generator transforming randomly sampled topic distributions to word distributions, and an adversarially trained discriminator estimating the probability that a word distribution came from the training data rather than the generator. Although ATM was shown to be effective in discovering coherent topics, it can not be used to induce the topic distribution given a document due to the absence of a topic inference module. Such limitation hinders its application to downstream tasks, such as text classification. Moreover, ATM fails to deal with document labels which can help extract more co-

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9018–9030,
November 16–20, 2020.

herent topics. For example, a document labeled as *'sports'* more likely belongs to topics such as *'basketball'* or *'football'* rather than *'economics'* or *'politics'*.

To address such limitations of ATM, we propose a novel neural topic modeling approach, named Topic Modeling with Cycle-consistent Adversarial Training (ToMCAT). In ToMCAT, topic modeling is cast into the transformation between topic distributions and word distributions. Specifically, the transformation from topic distributions to word distributions is used to interpret topics, and the reverse transformation is used to infer underlying topics for a given document. Under such formulation, ToMCAT employs a generator to transform topic distributions randomly sampled from the Dirichlet prior into the corresponding word distributions, and an encoder to reversely transform documents represented as word distributions into their topic distributions. To encourage the generator/encoder to produce more realistic target samples, discriminators for word/topic distributions are introduced to enable adversarial training. Additional cycle-consistency constraints are utilized to align the learning of the encoder and the generator to prevent them from contradicting each other. Furthermore, for documents with labels, we propose sToMCAT that introduces an extra classifier to regularize the topic modeling process.

The main contributions of the paper are:

- ToMCAT, a novel topic model with cycle-consistent adversarial training is proposed. To the best of our knowledge, it is the first adversarial topic modeling approach with both topic discovery and topic inference.
- sToMCAT, a supervised extension to ToMCAT, is proposed to help discover more coherent topics with available document labels.
- Experimental results on unsupervised/supervised topic modeling and text classification demonstrate the effectiveness of the proposed approaches.

2 Related Work

Our work is related to neural topic modeling and unsupervised style transfer.

2.1 Neural Topic Modeling

Recent advances on deep generative models, such as VAEs (Kingma and Welling, 2013) and GANs (Goodfellow et al., 2014), attract much research interest in the NLP community.

Based on VAE, Neural Variational Document Model (NVDM) (Miao et al., 2016) encodes documents with variational posteriors in the latent topic space. NVDM employs Gaussian as the prior distribution of latent topics. Instead, Srivastava and Sutton (2017) proposed that Dirichlet distribution is a more appropriate prior for multinomial topic distributions, and constructed a Laplace approximation of Dirichlet to enable reparameterisation (Kingma and Welling, 2013). Furthermore, the word-level mixture is replaced with a weighted product of experts (Srivastava and Sutton, 2017). Later, a non-parametric neural topic model utilizing stick-breaking construction was presented in (Miao et al., 2017). There are some attempts in incorporating supervised information into neural topic modeling. For example, Card et al. (2018) extended the Sparse Additive Generative Model (Eisenstein et al., 2011) in the neural framework and incorporated document metadata such as document labels into the modeling process.

Apart from VAE-based approaches, Adversarial-neural Topic Model (ATM) (Wang et al., 2019a)) was proposed to model topics with GANs. The generator of ATM projects randomly sampled topic distributions to word distributions, and is adversarially trained with a discriminator that tries to distinguish real and generated word distributions. Moreover, Wang et al. (2019b) extended ATM for open-domain event extraction by representing an event as a combination of an entity distribution, a location distribution, a keyword distribution and a date distribution. Such joint distributions are adversarially learned in a similar manner as ATM. The proposed ToMCAT is partly inspired by ATM but differs in its capability of inferring document-specific topic distributions and incorporating supervision information. BAT (Wang et al., 2020) is an extension to ATM that employs bidirectional adversarial training (Donahue et al., 2016) for document-specific topic distribution inference. Although BAT similarly utilizes an adversarial training objective to guide the learning of topic distribution, there are some major differences. Apart from different adversarial losses, ToMCAT also incorporates two cycle-consistency constraints which encourage the model to generate informative representations and are shown to be crucial for generating coherent topics as in our experiments.

2.2 Unsupervised Style Transfer

Style transfer, aiming at transforming representations from one style to another, has been found many interesting applications, such as image and text style transfer. However, training data paired between different styles are not available for many tasks. To solve this problem, Zhu et al. (2017) imposed cycle-consistency constraints to align mappings between two styles and proposed CycleGAN for unsupervised image style translation. Similarly, DiscoGAN (Kim et al., 2017) was proposed to discover the relations between different image styles and transformed images from one style to another without paired data. In the NLP field, Lee et al. (2018) developed a CycleGAN-based approach to transfer the sentiment style (positive, negative) of the text.

Inspired by CycleGAN, Our work views topic modeling as unsupervised distribution transfer and follows the framework of CycleGAN.

3 Methodology

Given a corpus $\mathcal{D}$ consisting of N documents $\{\boldsymbol{x}_i\}_{i=1}^N$, two main purposes of topic modeling are:

1. Topic discovery. Given a one-hot topic indicating vector $\boldsymbol{I}_k \in \mathbb{R}^K$ where K is the number of topics and $I_{kk} = 1$, discover the corresponding word distribution $\boldsymbol{t}_k \in \mathbb{R}^V$ from $\mathcal{D}$ where V is the vocabulary size. More generally, we can consider topic discovery as finding a mapping from topic distribution to word distribution.

2. Topic inference. Infer the topic distribution $\boldsymbol{z}_j \in \mathbb{R}^K$ of the document $\boldsymbol{x}_j \in \mathbb{R}^V$. Similarly, the topic inference can be considered as finding a mapping from word distribution to topic distribution.

We now formalize the above observations. Let X be the word distribution set and Z the topic distribution set. Given training samples $\{\boldsymbol{x}_i\}_{i=1}^N$ where $\boldsymbol{x}_i \in X$ and document-specific topic distributions $\{\boldsymbol{z}_j\}_{j=1}^M$ where $\boldsymbol{z}_j \in Z$, the goal of topic modeling is to learn a mapping function G, called *generator*, to transform samples in Z into X and a reverse function E, called *encoder*, to transform samples in X into Z. However, it should be noted that training samples in X and Z are unpaired since the topic distribution of a document is unknown before topic modeling. Thus, the problem is how to learn G and E to model topics in the absence of paired samples between X and Z.

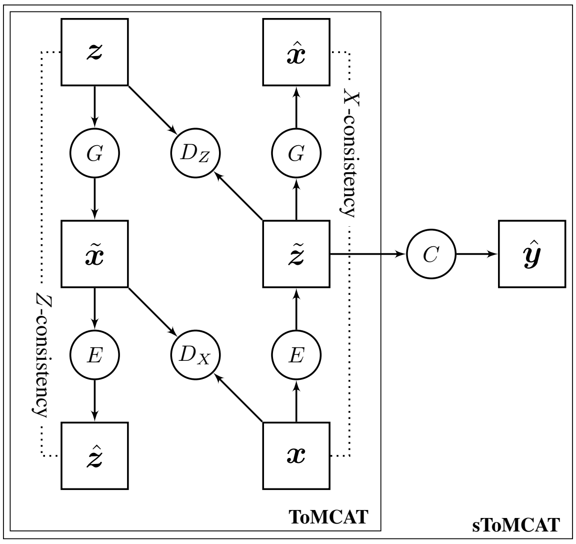

Figure 1: The framework of ToMCAT and sToMCAT. Circles are neural networks, squares are data representations, and arrows indicate the forward pass directions.

3.1 ToMCAT

We now introduce the proposed ToMCAT, which is shown in the inner panel of Figure 1.

ToMCAT consists of a generator G: $Z \to X$, an encoder E: $X \to Z$, and adversarial discriminators D_X and D_Z of G and E respectively. Following CycleGAN (Zhu et al., 2017), ToMCAT employs two types of losses, namely adversarial losses and cycle-consistency losses, to guide the training of the encoder E and the generator G. The details of these modules are described below.

3.1.1 Encoder Network E

Encoder E transforms a word distribution $\boldsymbol{x}_i \in \mathbb{R}^V$ into its corresponding topic distribution $\boldsymbol{z}_i \in \mathbb{R}^K$. Following (Wang et al., 2019a), we represent $\boldsymbol{x}_i \in X$ with the normalized TF-IDF (Term Frequency–Inverse Document Frequency) representation of i-th document:

$$\hat{d}_{ij} = \frac{d_{ij}}{\sum_j d_{ij}} \cdot \log \frac{N}{1 + \sum_{n=1}^{N} \mathbb{1}(d_{nj} \neq 0)}, \quad (1)$$

$$x_{ij} = \frac{\hat{d}_{ij}}{\sum_v \hat{d}_{iv}}, \quad (2)$$

where d_{ij} is the count of j-th word in i-th document, $\mathbb{1}(\cdot)$ denotes the indicator function. Equation 1 calculates the smoothed TF-IDF of $\boldsymbol{d}_i$, which is then normalized to sum to one in Equation 2. We use TF-IDF as the document representation because TF-IDF generally preserves the relative importance of words in a document and reduce the noise of stop words. As the target distribution of the generator G, such property of TF-IDF will help generate more informative topics.

The implementation of the encoder is a multilayer perception (MLP) with LeakyReLU activation (Maas et al., 2013) and batch normalization (BN) (Ioffe and Szegedy, 2015). The detailed transformations are: $[\,\text{Linear}(V,H) \rightarrow \text{LeakyReLU}(0.1) \rightarrow \text{BN} \rightarrow \text{Linear}(H,K) \rightarrow \text{Softmax}\,]$, where $\text{Linear}(I,J)$ denotes a linear transformation from I-dim to J-dim, H is the number of hidden units, and the final Softmax makes sure that the final output is one-normalized to match the input of the generator G. Inputs of E are either sampled from the corpus $\mathcal{D}$ or generated by G.

3.1.2 Generator Network G

The generator G performs the reverse operation of the encoder by transforming a topic distribution $\boldsymbol{z}_j \in \mathbb{R}^K$ into a word distribution $\boldsymbol{x}_j \in \mathbb{R}^V$, where the input $\boldsymbol{z}_j$ is generated by the encoder or sampled from the prior distribution. To draw the topic distribution $\boldsymbol{z}_j$, a common practice for topic modeling is to use the Dirichlet distribution, the conjugate prior of the multinomial distribution. We also stick with this choice in our model. Specifically, we draw topic distributions from a symmetric Dirichlet distribution with parameters $\boldsymbol{A} \in \mathbb{R}^K$ where $\boldsymbol{A}_k = \alpha$ for $1 \leq k \leq K$.

After sampling a topic distribution $\boldsymbol{z}_j$ from the Dirichlet prior, the generator then maps $\boldsymbol{z}_j$ from Z to X, and the transformations is similar to the encoder: $[\,\text{Linear}(K,H) \rightarrow \text{LeakyReLU}(0.1) \rightarrow \text{BN} \rightarrow \text{Linear}(H,V) \rightarrow \text{Softmax}\,]$, where the final output is also normalized by the Softmax to match the input of the encoder.

3.1.3 Training Objective

Following CycleGAN (Zhu et al., 2017), we employ adversarial losses and cycle-consistency losses to guide the training of G and E. The adversarial losses encourage G and E to generate samples matching the data distribution in the target space (X for G and Z for E) while the cycle-consistency losses align G and E in these two distribution spaces to prevent them from contradicting each other.

Adversarial Loss Generator G is adversarially trained with a discriminator D_X, which takes as input either real samples from training data, i.e., $\boldsymbol{x} \sim p_{\text{data}}(\boldsymbol{x})$, or fake samples generated by G, i.e., $G(\boldsymbol{z})$. The goal of D_X is to distinguish real samples from fake ones, while G instead aims to fool D_X by generating samples similar to $\boldsymbol{x}$. Therefore, the adversarial training encourages G to mimic the pattern of X and produce realistic word distributions. We employ a Wasserstein GAN (WGAN) (Arjovsky et al., 2017) based adversarial loss to G and D_X:

$$\begin{aligned}\mathcal{L}_{\text{adv}}(G, D_X) = \mathbb{E}_{\boldsymbol{x}\sim p_{\text{data}}(\boldsymbol{x})}[D_X(\boldsymbol{x})] - \\ \mathbb{E}_{\boldsymbol{z}\sim p_{\text{data}}(\boldsymbol{z})}[D_X(G(\boldsymbol{z}))],\end{aligned} \tag{3}$$

where D tries to maximize $\mathcal{L}_{\text{adv}}(G, D_X)$ while G tries to minimize it. Similarly, the adversarial loss applied to E and D_Z is:

$$\begin{aligned}\mathcal{L}_{\text{adv}}(E, D_Z) = \mathbb{E}_{\boldsymbol{z}\sim p_{\text{data}}(\boldsymbol{z})}[D_Z(\boldsymbol{z})] - \\ \mathbb{E}_{\boldsymbol{x}\sim p_{\text{data}}(\boldsymbol{x})}[D_Z(E(\boldsymbol{x}))].\end{aligned} \tag{4}$$

Discriminators D_X and D_Z are implemented with MLPs, and we use the same architecture for them: $[\,\text{Linear}(S,H) \rightarrow \text{LeakyReLU}(0.1) \rightarrow \text{BN} \rightarrow \text{Linear}(H,1)\,]$, where S equals to V for D_X and K for D_Z. Since we are using WGAN rather than the original GAN loss as in CycleGAN, we do not apply a sigmoid transformation to discriminator outputs.

Cycle-Consistency Loss Adversarial training might lead to generating samples identically distributed as corresponding target samples (Goodfellow et al., 2014). However, the relationship between the source distributions and the transformed distributions is unconstrained. Zhu et al. (2017) argued that adversarial losses alone is not able to fulfill this task and that the learned mappings should be cycle-consistent to reduce the search space of possible mapping functions, i.e., $\boldsymbol{x} \rightarrow E(\boldsymbol{x}) \rightarrow G(E(\boldsymbol{x})) \approx \boldsymbol{x}$ and $\boldsymbol{z} \rightarrow G(\boldsymbol{z}) \rightarrow E(G(\boldsymbol{z})) \approx \boldsymbol{z}$. To this end, two cycle-consistency losses $\overrightarrow{\mathcal{L}_{\text{cyc}}}(G, E)$ and $\overleftarrow{\mathcal{L}_{\text{cyc}}}(G, E)$ are added to the training objective, as shown in the inner panel (dotted lines) of Figure 1. Specifically,

$$\begin{aligned}\overrightarrow{\mathcal{L}_{\text{cyc}}}(G, E) = \mathbb{E}_{\boldsymbol{x}\sim p_{\text{data}}(\boldsymbol{x})}[\|G(E(\boldsymbol{x})) - \boldsymbol{x}\|_1], \\ \overleftarrow{\mathcal{L}_{\text{cyc}}}(G, E) = \mathbb{E}_{\boldsymbol{z}\sim p_{\text{data}}(\boldsymbol{z})}[\|E(G(\boldsymbol{z})) - \boldsymbol{z}\|_1],\end{aligned} \tag{5}$$

where $\|\cdot\|_1$ denotes L1 norm.

Overall Objective Summing up adversarial losses in Equation 3, 4 and cycle-consistency losses in Equation 5, the overall objective of ToMCAT is:

$$\begin{aligned}\mathcal{L}(G,E,D_X,D_Z) = \\ &\mathcal{L}_{\text{adv}}(G,D_X)+\mathcal{L}_{\text{adv}}(E,D_Z)+ \\ &\lambda_1\overrightarrow{\mathcal{L}_{\text{cyc}}}(G,E)+\lambda_2\overleftarrow{\mathcal{L}_{\text{cyc}}}(G,E), \quad (6)\end{aligned}$$

where λ_1 and λ_2 respectively control the relative importance of $\overrightarrow{\mathcal{L}_{\text{cyc}}}(G,E)$ and $\overleftarrow{\mathcal{L}_{\text{cyc}}}(G,E)$ w.r.t. adversarial losses.

3.2 sToMCAT

The encoder E transforms the word distribution $\boldsymbol{x}$ to corresponding topic distribution $\boldsymbol{z}$, which effectively captures the key semantic information of $\boldsymbol{x}$ and can be directly used to downstream tasks, e.g., text classification. Therefore, for labeled documents we extend ToMCAT with a classifier C to allow the incorporation of label information, as shown in Figure 1. We name the supervised version as sToMCAT.

For a word distribution $\boldsymbol{x}$ and its one-hot label $\boldsymbol{y}$, $\boldsymbol{x}$ is first encoded by the encoder E into the topic distribution $\boldsymbol{z}$, and then $\boldsymbol{z}$ is fed to the classifier C to predict the probability of $\boldsymbol{y}$. The predictive objective is defined as:

$$\mathcal{L}_{\text{cls}}(E,C)=-\mathbb{E}_{(\boldsymbol{x},\boldsymbol{y})\sim p_{\text{data}}(\boldsymbol{x},\boldsymbol{y})}[\boldsymbol{y}\log C(E(\boldsymbol{x}))], \quad (7)$$

where L is the dimension of $\boldsymbol{y}$. We employ an MLP classifier: [Linear(K,H) → LeakyReLU(0.1) → BN → Linear(H,L) → Softmax].

For sToMCAT, the topic model and the classifier are trained jointly, and its overall objective is defined as:

$$\begin{aligned}\mathcal{L}\text{sup}(G,E,D_X,D_Z,C) = \\ &\mathcal{L}(G,E,D_X,D_Z)+\lambda_3\mathcal{L}_{\text{cls}}(E,C). \quad (8)\end{aligned}$$

3.3 Training Details

The proposed ToMCAT and sToMCAT are trained with the Adam optimizer (Kingma and Ba, 2014), whose learning rate and momentum term β_1 are set to 0.0001 and 0.5 respectively for (G, E, D_X) and D_Z, while 0.001 and 0.9 for the classifier C. The hidden unit numbers are set to 100 for all modules. Besides, to enforce the Lipschitz constraints required by WGAN, a weight clipping of 0.01 is adopted (Arjovsky et al., 2017). [1]

During training, the parameters of discriminators D_X, D_Z and mappings G, E are alternately updated. Specifically, at each training iteration, firstly we optimize D_X and D_Z for 5 steps with adversarial losses, and then another training step is taken to optimize G and E with adversarial losses and cycle-consistency losses (Equation 6). When the model is trained in a supervised way, the predictive objective is additionally applied to E and C at the last training step (Equation 8).

We found that relatively good choices of λ_1 and λ_2 fall into different regions for different datasets and topic number settings, which implies a further tuning of these hyperparameters is needed. To ease this kind of burden, we apply a gradient-based mechanism to adversarial losses and cycle-consistency losses. It balances these two types of losses with the L2 norms of their gradients w.r.t. the output of their preceding mapping functions. E.g., for $\mathcal{L}_{\text{adv}}(G,D_X)$ and $\overrightarrow{\mathcal{L}_{\text{cyc}}}(G,E)$, we replace λ_1 in Equation 6 with:

$$\lambda_1=\hat{\lambda}_1\frac{\|\partial\mathcal{L}_{\text{adv}}(G,D_X)/\partial G(\boldsymbol{z})\|_2}{\|\partial\overrightarrow{\mathcal{L}_{\text{cyc}}}(G,E)/\partial G(\boldsymbol{z})\|_2}, \quad (9)$$

where $\hat{\lambda}_1$ is the new balancing factor and $\|\cdot\|_2$ denotes L2 norm. Similarly, $\mathcal{L}_{\text{adv}}(E,D_Z)$ and $\overleftarrow{\mathcal{L}_{\text{cyc}}}(G,E)$, $\mathcal{L}_{\text{adv}}(E,D_Z)$ and $\mathcal{L}_{\text{cls}}(E,C)$ are also balanced in this way with $\hat{\lambda}_2$ and $\hat{\lambda}_3$. The resulting $\hat{\lambda}_1$, $\hat{\lambda}_2$ and $\hat{\lambda}_3$ are set to 2, 0.2 and 1 respectively for all datasets and topic number settings in our experiments, thus avoiding the time-consuming hyperparameter tuning process.

4 Experiments

In this section, we first describe datasets and compared baselines. Then we present topic modeling results under both unsupervised and supervised settings. Finally, we report the text classification results.

Dataset	#Train	#Test	Vocab Size	#Class
NYT	99,992	-	12,604	-
GRL	29,762	-	15,276	-
DBP	99,991	69,993	9,005	14
20NG	11,258	7,492	2,000	20

Table 1: Dataset statistics.

---

[1] We also experiment with the gradient-penalty WGAN (Gulrajani et al., 2017), but the weight clipping version performs better in general.

4.1 Experimental Setup

We evaluate the performance of proposed models on four datasets: NYTimes[2] (**NYT**), Grolier[3] (**GRL**), DBpedia ontology classification dataset (**DBP**) (Zhang et al., 2015) and 20 Newsgroups[4] (**20NG**). For NYTimes and Grolier datasets, we use the processed version of (Wang et al., 2019a). For the DBpedia dataset, we first sample $100,000$ documents from the whole training set, and then perform preprocessing including tokenization, lemmatization, removal of stopwords, and low-frequency words. The same preprocessing is also applied to the 20 Newsgroups dataset. The statistics of the processed datasets are shown in Table 1.

We choose the following approaches as our baselines:

- LDA (Blei et al., 2003). We use GibbsLDA++, an implementation using Gibbs sampling for parameter estimation and inference[5].
- sLDA[6] (Mcauliffe and Blei, 2008), a supervised extension to LDA.
- NVDM[7] (Miao et al., 2016), a VAE-based model that employs Gaussian prior for the latent topics.
- ProdLDA[8] (Srivastava and Sutton, 2017), a VAE-based model that replaces the mixture model with a product of experts.
- Scholar[9] (Card et al., 2018), a ProdLDA-based model that enables optional incorporation of metadata.
- ATM (Wang et al., 2019a), a neural topic model utilizing adversarial training.
- BAT (Wang et al., 2020), a neural topic model utilizing bidirectional adversarial training.

4.2 Topic Modeling

We evaluate the performance of the proposed models and baselines using topic coherence measures. Topic coherence measures are metrics for quantifying the understandability of the extracted topics, which are shown highly correlated with human subjects (Newman et al., 2010; Aletras and Stevenson, 2013). Since a topic is typically represented as a word distribution over the vocabulary or n top-weighted words (i.e., topic words) in this distribution, we calculate the coherence of a topic by measuring the relatedness between its topic words. The word relatedness scores are estimated based on some kind of word co-occurrence statistics on Wikipedia, for example, by applying a sliding window over the Wikipedia corpus and collecting word co-occurrences to calculate NPMI (Normalized Pointwise Mutual Information) (Bouma, 2009) for word pairs. We refer readers to (Röder et al., 2015) for detailed calculation and comparison of different topic coherence measures. In our experiments, we use top-10 topic words of each topic to calculate topic coherence and report the results of 3 topic

coherence measures: C_A (Aletras and Stevenson, 2013), C_P (Röder et al., 2015), and NPMI (Aletras and Stevenson, 2013). The topic coherence scores are calculated using Palmetto [10].

4.2.1 Unsupervised Topic Modeling

To make a more comprehensive comparison of our model with baselines for topic modeling, we experiment on each dataset with five topic number settings: 20, 30, 50, 75, 100. The average topic coherence scores of 5 settings are presented in Table 2. We can see from the left part of Table 2 that, among all unsupervised topic models, our model achieves the highest scores on all datasets and topic coherence measures.

With an improper Gaussian prior, NVDM shows the worst performance among all neural topic models with no exception. The logistic-normal based ProdLDA and Scholar achieve higher topic coherence scores compared to NVDM, but are still largely underperformed compared to our model. BAT achieves the second-best place most of the time in unsupervised topic modeling experiments. Compared to ToMCAT, BAT has a similar adversarial objective but lacks the cycle-consistency constraints, Therefore, the generator and encoder of BAT only aim to fool the discriminator by mimicking the pattern of the joint distribution of real documents and topics. With the incorporation of two cycle-consistency losses, ToMCAT is explicitly encouraged to generate not only realistic but also informative representations in order to reduce the cycle-consistency losses.

To give an insight into the generated topics, 8 out of 50 topics discovered by ToMCAT on NYTimes are presented in Table 3, where a topic is represented by the ten words with the highest probability in the topic. We can observe that the extracted topics are highly coherent and interpretable. The corresponding full list of topics can be found in the appendix.

Vehicle	**Election**	**Court**	**Fashion**

Table 3: 8 topics discovered by our model on NYT.

4.2.2 Supervised Topic Modeling

Supervised topic modeling aims to leverage available document labels to benefit topic modeling. Therefore we only conduct experiments on labeled datasets, i.e., DBpedia and 20 Newsgroups. The experimental results are shown on the right part of Table 2. We expect the topic extraction results would be improved with the incorporation of topic labels. However, this is not always the case as shown in Table 2. The supervised Scholar outperforms its unsupervised version on 20 Newsgroups but the unsupervised one achieves higher coherence scores on DBpedia. While sLDA fails to surpass its unsupervised counterpart LDA on both DBpedia and 20 Newsgroups. On the contrary, improvements of sToMCAT over the unsupervised ToMCAT can be observed under all settings. The results show that the incorporation of the supervised information seems to be more effective in our proposed model, probably contributing to the gradient-based loss balancing mechanism. Overall, our model consistently outperforms sLDA and Scholar on all datasets and all topic coherence measures.

4.2.3 Impact of Topic Numbers

To investigate how topic coherence scores vary with respect to different topic number settings, we show in Figure 2 the topic coherence measures on four datasets for all models. Although there are exceptions that some baselines achieve higher scores on specific experimental settings, the general conclusion is that our models perform the best in both unsupervised and supervised topic modeling tasks. On DBpedia and 20 Newsgroups datasets, sToMCAT consistently outperforms ToMCAT, indicating the additional supervision helps generate more co-

---

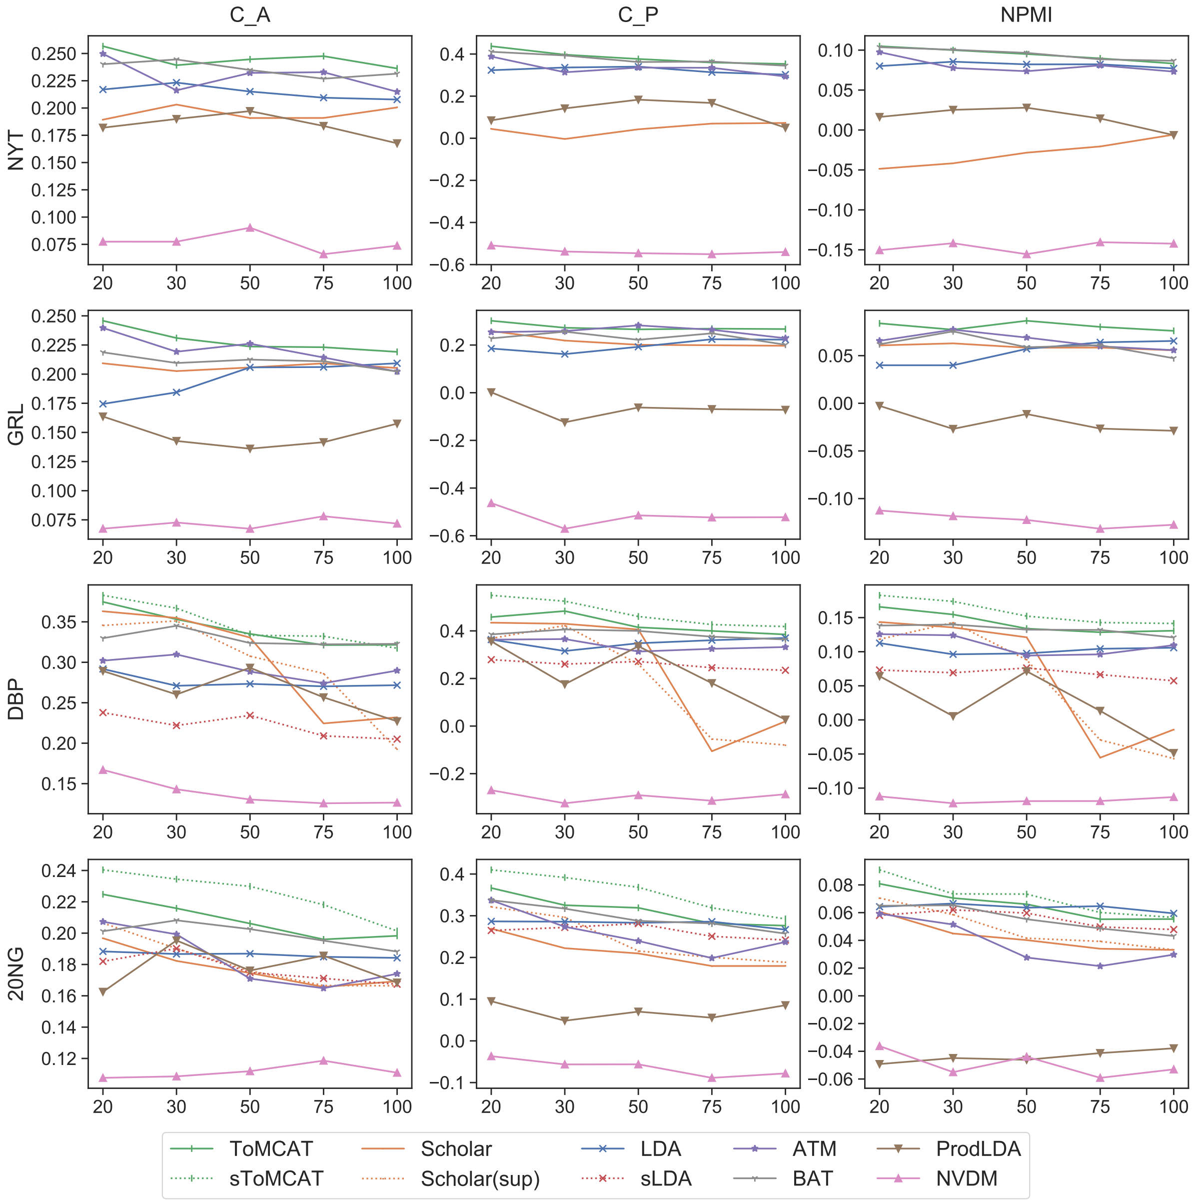

Figure 2: Topic coherence (C_A, C_P, NPMI) w.r.t. topic numbers on 4 datasets. Dotted lines denote supervised topic models.

herent topics. We also notice that although the topic coherence measures of our models remain relatively stable across topic numbers, there are slight drops on the DBpedia and 20 Newsgroups datasets when the topic number becomes bigger. This phenomenon may result from the fact that DBpedia and 20 Newsgroups datasets are less diverse than others. There are only 14 and 20 categories in DBpedia and 20 Newsgroups datasets, respectively. When the topic number is much larger than the ground-truth category number, discriminating different topics would be more challenging. Nevertheless, the overall superiorities of our models are significant as in Figure 2.

4.3 Text Classification

We now report text classification results of supervised topic models : sLDA, Scholar, and sToMCAT. To show that our model can learn both coherent and informative topics concurrently, we use the same models as in the topic modeling experiments to classify test set documents, and do not perform any further fine-tuning. In our experiments, we found that the text classification performance is influenced by topic numbers. Therefore we conduct experiments with five topic number settings: 20, 30, 50, 75, and 100.

Classification results are presented in Table 4. We can see that our model not only achieves the

Dataset	Model	20 (↑)	30 (↑)	50 (↑)	75 (↑)	100 (↑)	Min (↑)	Avg (↑)	Max (↑)	Δ (↓)
DBP	sLDA	0.871	0.906	0.909	0.918	0.922	0.871	0.905	0.922	0.051
	Scholar	0.949	**0.951**	0.948	0.920	0.900	0.900	0.934	0.951	0.051
	sToMCAT	**0.951**	**0.951**	**0.953**	**0.936**	**0.928**	**0.928**	**0.944**	**0.953**	**0.025**
20NG	sLDA	0.529	0.572	0.563	0.608	0.613	0.529	0.577	0.613	0.084
	Scholar	0.523	0.576	0.598	**0.617**	0.610	0.523	0.585	0.617	0.094
	sToMCAT	**0.642**	**0.628**	**0.616**	**0.617**	**0.616**	**0.616**	**0.624**	**0.642**	**0.026**

Table 4: Classification accuracy of supervised topic models with different topic numbers (20, 30, 50, 75, 100). 'Min/Avg/Max' shows the minimum/average/maximum accuracy among different topic numbers. 'Δ' shows the variance of the classification accuracy across different topic numbers.

best overall performance (the Max and Avg column), but also has the highest accuracies on all dataset and topic number settings. Compared to Scholar, our model achieves a slightly higher accuracy on DBpedia and an accuracy improvement of 2.5% on 20 Newsgroups. The performance gain of our model over sLDA is more significant. In addition to better classification results, our model is also more robust to the change of topic numbers (the Δ column). With the topic number increasing from 20 to 100, the variance of the classification accuracy of our model is only 0.025 and 0.026 on DBpedia and 20 Newsgroups respectively, which is much lower than that of sLDA and Scholar.

5 Conclusion

We have presented ToMCAT, a neural topic model with adversarial and cycle-consistent objectives, and its supervised extension, sToMCAT. ToMCAT employs a generator to capture semantic patterns in topics and an encoder to encode documents into their corresponding topics. sToMCAT further incorporates document labels into topic modeling. The effectiveness of ToMCAT and sToMCAT is verified by experiments on topic modeling and text classification. In the future, we plan to extend our model to cope with external word or document semantics. It would also be interesting to explore alternative architectures other than CycleGAN under our formulation of topic modeling.

Abstract

Data augmentation is proven to be effective in many NLU tasks, especially for those suffering from data scarcity. In this paper, we present a powerful and easy to deploy text augmentation framework, **Data Boost**, which augments data through reinforcement learning guided conditional generation. We evaluate Data Boost on three diverse text classification tasks under five different classifier architectures. The result shows that Data Boost can boost the performance of classifiers especially in low-resource data scenarios. For instance, Data Boost improves F1 for the three tasks by 8.7% on average when given only 10% of the whole data for training. We also compare Data Boost with six prior text augmentation methods. Through human evaluations (N=178), we confirm that Data Boost augmentation has comparable quality as the original data with respect to readability and class consistency.

1 Introduction

Data augmentation is a widely-used technique in classification tasks. In the field of computer vision (CV), data is augmented by flipping, cropping, tilting, and altering RGB channels of the original images (Krizhevsky et al., 2012; Chatfield et al., 2014; Szegedy et al., 2015); however, similar intuitive and simple strategies do not obtain equal success in NLP tasks. Existing methods tend to produce augmentation with low readability or unsatisfying semantic consistency (Yang et al., 2020).

Original	So Cute! The baby is very lovely!
Naive Aug. *Delete + Swap*	So Cute! is The baby very!
Word2Vec Aug. *Insert + Replace*	So Cute *adorable*! The baby is very *fabulous*!
Back Translate Aug. *Eng. → Fr. → Eng.*	*Cute*! The baby is very *cute*!
Data Boost	***Look at this adorable baby!*** ***He is so cute!***

Table 1: A simple demo of existing text data augmentation methods on *positive* sentiment label.

Table 1 shows some output samples of popular text augmentation methods. Naive methods imitate pixel manipulation in CV, augmenting sentences by adding spelling errors (Xie et al., 2017), or randomly deleting and swapping tokens (Wei and Zou, 2019). The output of such augmentation methods are often illegible since the word order is disrupted (e.g., *"is The baby very!"*); even worse, crucial feature words (e.g., the word *lovely* which is a signal-carrying word for sentiment detection) could be mistakenly removed through random deletion. A more advanced method is synonym insertion or replacement (Zhang et al., 2015; Wang and Yang, 2015), which uses Word2Vec (Mikolov et al., 2013) to replace words with their synonyms. Such a method respects the original sentence structure but fails to consider the context. It sometimes replaces words with synonyms that are awkward in the full context of the sentence. For example, replacing *lovely* with *fabulous* to get the sentence *"The baby is fabulous!"*. Recent work leans towards translation-based methods for augmentation (Fadaee et al., 2017; Silfverberg et al., 2017). In particular, Yu et al. (2018) proposed a back-translation method that first translates the text to French and then translates back to English, using the noisy output as the augmentation data. Although back-translation is intuitive and valid, its generation skews towards high frequency words (e.g., *cute, lovely* are both back-translated to *cute*), which not only causes repetition but also leads to lexical shrinkage in the augmented data. In a nutshell, existing techniques are still far from perfect, partially due to the strong interdependency of syntactic and semantic features in text data.

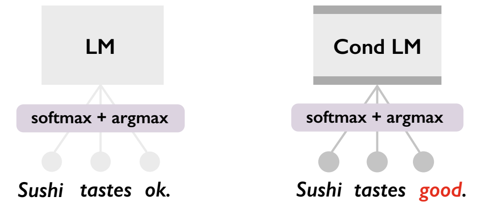
Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9031–9041,
November 16–20, 2020. ©2020 Association for Computational Linguistics

In recent years, we have witnessed extensive progress in language models (LM). Large-scale LMs such as BERT (Devlin et al., 2019), XL-Net (Yang et al., 2019), and GPT-2 (Radford et al., 2019), are commonly trained on large amounts of text data (e.g., GPT-2 was trained on 8 million web pages that emphasized content diversity). One of the most interesting usages of these models is utilizing them as text generators (Raffel et al., 2019; Lewis et al., 2019; Dong et al., 2019). In this paper, we explore whether we can leverage the generation ability of the state-of-the-art LMs, to *generate* augmented samples for a given target class.

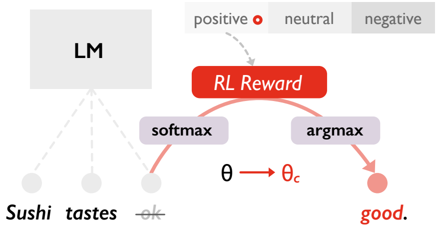
Augmentation samples should exhibit features of the target class. Off-the-shelf LMs cannot be directly used to augment data; since they are not trained for specific contexts, their generation is undirected and random. Conditional LMs can generate text directed by certain condition (e.g., target class), but they require training a LM from scratch with data covering all the conditions. Keskar et al. (2019), for instance, trained a 1.6 billion-parameter LM conditioned to a variety of control codes. The training is rather costly; however, collecting sufficient data for the training is also tedious, especially in low-resource tasks (Waseem, 2016).

We thus present **Data Boost**: a reinforcement learning guided text data augmentation framework built on off-the-shelf LM (GPT-2). Data Boost requires neither collecting extra data nor training a task-specific LM from scratch. We convert GPT-2 into a conditional generator, and for a given task, we guide the generator towards specific class labels during its decoding stage through reinforcement learning. The generated samples can then serve as augmentation data which are similar to the original data in terms of semantics and readability.

The advantages of Data Boost are three-fold: *First*, Data Boost is powerful. We achieve significant advances in three tasks on five different classifiers compared with six related works. *Second*, Data Boost generates sentence-level augmentation. Unlike prior methods that do word-level or phrase-level replacement (Kobayashi, 2018; Wei and Zou, 2019), our augmented data is of much greater variety in terms of vocabulary and sentence structure. Human evaluations also verify the high readability and label consistency of our augmentation. *Third*, Data Boost is easy to deploy. It does not require external datasets or training separate systems (like machine translation model in the back-translation method). Instead, we take the off-the-shelf GPT-2 language model and modify its decoding stage without changing its architecture.



(a) Unconditional Generation (b) Conditional Generation



(c) **Ours** : RL-guided Conditional Generation

Figure 1: General illustration of previous generation models and Data Boost. We add an additional RL stage between the softmax and argmax function, to update the LM hidden-states parameter θ towards target label (e.g. *positive*).

2 Data Boost

2.1 Conditional Generator

Given tokens $x_{<t} = \{x_0, x_1, ..., x_{t-1}\}$ and accumulated hidden states $h^{\theta}_{<t}$ [1] before time step t, a vanilla auto-regressive language model (LM) is trained to maximize probability of the next step token $\hat{x}_t$. Normally the model will pick the token that has the highest probability x_t as the t step decoding output:

$$x_t \sim \underset{\hat{x}_t}{\arg\max}\, p(\hat{x}_t|x_{<t}) = \mathrm{LM}(x_{<t}, h^{\theta}_{<t}) \quad (1)$$

The generation of such step-by-step decoding is unconditional, since the model is trained on unannotated data (Figure 1 (a)). Conditional generation, however, normally needs to train a conditional LM. By modifying the LM architecture to allow for extra input (target label), the conditional LM can model the language and its corresponding label at the same time (Figure 1 (b)). Its generation is thus conditional on the label but the training of LM is always costly.

---

[1] Hidden states are basically key-values pairs in the attention blocks. We denote their values as parameter set θ.

Different from the above conditional generation method, we keep the architecture of the existing LM unchanged but postpone the argmax function to a later stage. In this way, the output of softmax is still differentiable (as it is a probability over the whole vocab rather than decoded tokens), which allows for gradient-based optimization. As shown in Figure 1 (c), we add a reinforcement learning (RL) stage within the gap between the softmax and argmax function. The RL reward (defined in Section 2.2.1) is where we inject the controlling signal of target label to guide the generation towards the target label. Specifically, in each decoding step, we update the hidden states parameter θ to the conditional θ_c in terms of the back-propagated reward after several iterations of RL optimization. The final decoded output shall be conditional on the target label (which is *positive* in Figure 1 (c)).

2.2 Reinforcement Learning Optimization

2.2.1 Reward

In the reinforcement learning framework, we define the state at step t as all the generated sequence before t (i.e., $s_t = x_{<t}$), and the action at step t as the t-th output token (i.e., $a_t = x_t$). The policy π_θ is interpreted as the probability we choose token x_t (action a_t) given the state $s_t = x_{<t}$, which is the softmax output of the hidden states (i.e., $\pi_\theta(a_t|s_t) = \text{softmax}(h^\theta_{<t})$, and similar for the conditional case).

We define the single-step reward of the conditional generated token x^c_t at step t as:

$$R(x^c_t) = \mathbb{E}_t\left[\frac{\pi_{\theta_c}(a_t|s_t)}{\pi_\theta(a_t|s_t)} G(x^c_t)\right] - \beta \text{KL}(\theta||\theta_c) \tag{2}$$

where $G(x^c_t)$ is the salience gain that measures how closely the generated token resembles the salient lexicon of the target label, and serves as a guide signal for the conditional generation. We also consider the Kullback–Leibler (KL) divergence between the conditional θ_c and unconditional distribution of θ as an auxiliary constraint (with weight β). Such a reward composition follows the classic PPO (Proximal Policy Optimization) (Schulman et al., 2017) form. Note that we are using an off-policy strategy to collect unconditional (s_t, a_t) pairs as trajectory to estimate the conditional reward $R(x^c_i)$. In this way, we are able to perform several iterations of updates on θ to maximize the reward without changing the sampling policy frequently, which avoids potential instability (Munos et al., 2016). As a result, we use the probability ratio between the conditional policy π_{θ_c} and the unconditional policy π_θ to re-calibrate the reward in the first term of Equation 2.

Salience Gain. For a given task that has K classes, we define the salience score of word x belonging to a certain class c as:

$$\mathcal{S}_{x,c} = \text{GM}\left(\frac{|x \in c|}{\sum_{k=1}^{K} |x \in c_k|}, \frac{|x \in c|}{\sum_{x_i \in |V|} |x_i \in c|}\right) \tag{3}$$

where $|x \in c|$ refers to the count of word x in samples with class label c, $|V|$ is the total vocabulary, and GM is geometric mean of the two terms. The two fractions try to guarantee that both $\mathbb{P}(c|x)$ and $\mathbb{P}(x|c)$ probabilities are high for a word marked as salient. We calculate the salience score for each word and pick the top-N highest words [2] as the salient lexicon for class label c (denoted as w_c). Compared with other methods such as training a discriminator (Dathathri et al., 2020) or deriving control codes (Keskar et al., 2019), we find our frequency-based method is relatively simple but efficient especially in data hungry cases, where the performance of a discriminator could be limited given very few training data.

For the t-th step token x^c_t conditional on the target class c, we calculate the salience gain as the logarithm summation of cosine similarity with each word in the salient lexicon w_c:

$$G(x^c_t) = \sum_{w_i \in w_c} \log(\text{softmax}(h^{\theta_c}_{<t}) \cdot \text{emb}(w_i)) \tag{4}$$

We use the embedded vector of w_i and the softmax output of t-th step hidden states $h^{\theta_c}_t$ to compute a dot product in the latent space. The salience gain measures how much the current step token resembles the salient lexicon of the target class.

KL Penalty. It is possible that the conditional policy π_{θ_c} drifts away too much from the unconditional policy π_θ resulting in an unreadable generation. Therefore, we incorporate a KL divergence penalty term measuring the distance between the

---

[2] N is a hyperparameter that is related to the size of the dataset. In our case, we set N=500 for sentiment analysis and irony classification tasks, and N=1000 for offense detection task.

two policies, in order to have better insurance that we are optimizing within a trust region. The KL divergence on the policies is computed as:

$$\mathrm{KL}(\theta||\theta_c) = \sum_{i\in[1,t]} \pi_\theta(a_i|s_i) \cdot \log \frac{\pi_\theta(a_i|s_i)}{\pi_{\theta_c}(a_i|s_i)} \quad (5)$$

We deduct KL divergence with weight β as a penalty term in the reward function (Equation 2). One can either choose a constant β or vary it dynamically.

2.2.2 Policy Gradient

Given the reward and the definitions described above, we update our policy at t-th step as:

$$\theta_c \leftarrow \theta + \eta \sum_{i=1}^{k} \frac{\nabla R(x_t^c/T)}{||\nabla R(x_t^c/T)||} \quad (6)$$

where η is the learning rate and θ_c is the parameter for the conditional hidden states. In general, we follow the classical SGD update rule, but make two main changes: (1) We use temperature parameter T to control the stochastic sampling during token decoding (Keskar et al., 2019). $T \to 0$ approximates a greedy decoding strategy that amplifies the peak in the vocab distribution while $T \to \infty$ makes the distribution more uniform. (2) We sum the normalized gradient of the reward for k steps. k can be treated as the strength of control over the conditional generation. Combining all above definitions, the policy gradient of Data Boost is summarized in Algorithm 1.

Algorithm 1: Data Boost Policy Gradient

```
Input: Target class label $c$, hidden-states
       param $\theta$, target KL-divergence $\sigma$.
for $t = 0, 1, 2, \ldots$ do
    Generate $(a_t|s_t)$ by unconditional policy
      $\pi_\theta$ as trajectories;
    Estimate reward $R(x_t^c)$ using Eq. 2;
    Compute policy update using Eq. 6 by
      taking $k$ steps of SGD (via Adam);
    if $KL(\theta||\theta_c) \geq 2\sigma$ then
        $\beta_{t+1} = 2\beta_t$;
    else if $KL(\theta||\theta_c) \leq \sigma/2$ then
        $\beta_{t+1} = \beta_t / 2$;
    end
    Return the conditional policy $\pi_{\theta_c}$;
end
```

We use a dynamic β to control the KL penalty within the reward function. The target divergence σ depends on the users' need: smaller σ means more resemblance to the unconditional generation while larger σ provides more space for RL guidance. After several iterations of RL optimization, the updated parameter set θ_c should be conditional on the target class label, whose feature lexicon contribute to the calculation of the reward R. We then use the conditional policy π_{θ_c} (which is based on the hidden states with θ_c) to decode this step token. The token should conform to the specified target class label c, since its corresponding hidden states have shifted towards c due to RL optimization.

3 Tasks & Datasets

We evaluated and compared Data Boost with several state-of-the-art text augmentation methods on the following three tasks:

Offense Detection[3] ICWSM 20' Data Challenge dataset ($N = 99,603$) for offensive language detection on tweets. The dataset consists of four classes: {*normal*, *spam*, *abusive* and *hateful*} with ratio {53.9%, 27.1%, 14.1%, 4.9%} respectively.

Sentiment Analysis[4] SemEval 2017 Task 4A dataset ($N = 20,631$) for sentiment analysis in tweets. There are three classes in the dataset: {*positive*, *neutral* and *negative*} with ratio {34.7%, 49.8%, 15.5%}.

Irony Classification[5] SemEval 2018 Task 3A dataset ($N = 3,817$) for irony detection in tweets. It has binary classes: {*ironic*, *non-ironic*}, with ratio {50.2%, 49.8%}.

Offense Detection and Irony Classification are popular NLU tasks that are low-resource. Sentiment Analysis, though seemingly well-resolved according to some literature (Baziotis et al., 2017; Cliche, 2017), is reported to have severe overfitting problems when given extremely limited training data (Elming et al., 2014; Severyn and Moschitti, 2015). We choose challenging datasets varying in total data size ($N \approx$ 80k, 17k, 3k) and the number of class (# of class $= 4, 3, 2$) for a realistic evaluation of our framework.

We removed all punctuation, stop words, hashtags and url links in the samples for all datasets. Samples whose length was above 30 tokens were filtered out (around 2% of the data on average) as

[5] https://competitions.codalab.org/competitions/17468

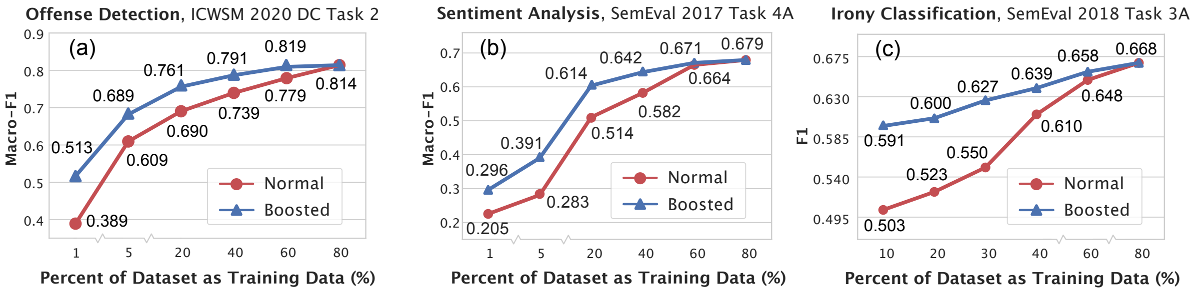

Figure 2: Performance with and without Data Boost on three classification tasks: (a) Offensive Language Detection on Tweets, (b) Sentiment Analysis in Twitter, (c) Irony Detection in English Tweets. The performance is reported by the Macro-F1 (F1 for binary task) of a BERT classifier averaged on five times repeated experiments.

30 was also used as the max sequence length for Data Boost generation. We further split the data into training and test set by the ratio $\{80\%, 20\%\}$, and maintained the original class distributions. We made sure the distributions remained the same in all of our experiments.

4 Experiments[6]

We conducted extensive experiments to answer the following three overarching questions about Data Boost:

4.1 Does Data Boost Improve Performance?

Several sets of data starvation tests are prepared, each using restricted fractions of the total data as training data. We keep test data the same (20% of the whole dataset) but gradually decrease the size of training data from 80% (as the fully-loaded case) to 1% (as the extremely low-resource case). We run both normal training and boosted training over the following training set fractions (%): $\{1\%, 5\%, 20\%, 40\%, 60\%, 80\%\}$ of the total data for both Offense Detection and Sentiment Analysis. Since the dataset for Irony Classification is small ($N = 3,810$), we use the following fractions: $\{10\%, 20\%, 30\%, 40\%, 60\%, 80\%\}$. Note that for boosted training we add augmentation samples to training data until the training data size reaches 80% of the total size (same as fully-loaded size), to make sure that the size of the training set does not influence the results.

Figure 2 shows the performance of the BERT (Devlin et al., 2019) (bert-base-cased) classifier fine-tuned on the three tasks with and without Data Boost over all training set fractions. Data Boost has greater improvements on extremely low-resource cases: we achieve absolute F1 increases of 12.4% (Offense), 9.1% (Sentiment) and 8.8% (Irony) when using only 1% (10% for the Irony task) of the original data as training data. The results show that Data Boost can benefit a wide range of tasks with different characteristics. Also, since we used BERT as our classifier, which is already pre-trained on a large corpus, our results confirm that Data Boost can even improve the performance of large-scale LM based classifiers.

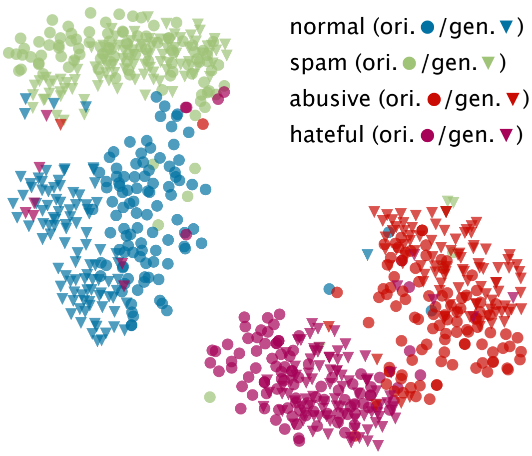

Figure 3: t-SNE visualization of the vectorized original and Data Boost augmented sentences in the offense detection task. The augmented sentences (triangles) mostly overlap with the original sentences (circles), suggesting that augmented sentences maintain the original class distribution.

4.2 Does Boosted Data Resemble the Original?

A common concern in text data augmentation is whether the augmented sentences preserve the qual-

---

[6] We run our generation and classification training on 2 RTX 2080 GPUs for all the experiments. The average time for Data Boost to generate a 30 token long sequence is under 1 second.

Classifier	**Offense Detection**			**Sentiment Analysis**			**Irony Classification**

PPL	33.47	36.85	40.71	45.53

Table 3: Evaluation of the generation quality in terms of F1 deterioration and perplexity (PPL) increase. We keep the training data size the same, but control the ratio of original/boosting. The first results column corresponds to no boosting.

ity of the original data. This is especially true for generation-based methods since we create new sentences rather than simply replace tokens to produce augmented data. We will illustrate the quality of our data generation with two approaches: (1) Visualizing the class distribution of the original and the augmented data (2) By using the boosting ratio experiments described in Section 4.1 to see whether data augmentation causes performance deterioration and perplexity increase.

For visualization, we randomly pick 400 (100 for each class) original and generated sentences in the Offense Detection task (since it has the largest number of classes) and vectorize with Sentence-BERT (Reimers and Gurevych, 2019). We apply t-SNE (Maaten and Hinton, 2008) to these vectors and plot their 2-D representations in Figure 3. From the figure, we can see that our RL-based algorithm manages to guide the generation towards the target labels, and for the most part, the distribution of generated sentences matches that of the original data.

Ratio-controlled experiments test the quality of boosted data by comparing training performance. If training on augmented dataset has comparable performance (F1) as training on purely original data, one may infer that the quality of the augmentation data resembles that of the original data. We also use perplexity (PPL) as an auxiliary metric to evaluate the augmentation quality. We trained three language models using kenLM (Heafield, 2011) on the original data of the three tasks. We use these models to calculate the perplexity of the ratio-controlled sets.

In Table 3 we show the F1 deterioration and perplexity increase (higher perplexity means poorer fit to the LM) for different augmentation ratios. Even when we use 25% original data fused with 75% generated samples, the F1 score only undergoes a slight decrease (0.06, absolute) compared to when using 100% original data. We found that the perplexity also did not substantially increase even with higher boosting ratios.

4.3 Is Data Boost Classifier-Agnostic?

We have shown Data Boost to be effective when used in conjunction with a BERT classifier, but can the performance be replicated with other clas-

Methods	Offense Detection			Sentiment Analysis			Irony Classification		
	10%	40%	PPL	10%	40%	PPL	10%	40%	PPL

Table 4: Performance comparison with other text augmentation methods. 10%: 10% original data + 30% augmented data; 40%: 40% original data + 40% augmented data. We report the F1 score of the BERT classifier over five times repeat experiments. We also report the perplexity score (PPL) of the augmented data (10,000 randomly sampled) from different methods scored by kenLM language models trained on the training data of each task.

sifiers? In other words, is Data Boost a classifier-agnostic augmentation method? To answer this question, we ran experiments on four other mainstream classifiers, including the plain CNN classifier (Kim, 2014), the Bi-LSTM with attention mechanism (Zhou et al., 2016), the self-attention based Transformer network (Vaswani et al., 2017), and another LM-based classifier XLNet (Yang et al., 2019) for comparison. We trained all classifiers on three different training data settings: {20%, 40%, 80%} of the total data used as training data, the first two datasets are doubled in size using Data Boost augmentation. As shown in Table 2, Data Boost generally improves the performance of all the classifiers (from 1% to 13%, absolute), regardless of the classifier architecture. Moreover, we find Data Boost is not only effective for relatively simple classifiers (e.g., CNN), but also beneficial to complex LM-based classifiers (e.g., BERT and XLNet), which are already trained on a large corpus and generally used as very strong baselines for text classification tasks.

Table 5 shows sample generations by Data Boost.

5 Comparison with Related Work

Table 4 compares the performance of Data Boost with six prior text augmentation methods on all three tasks and using a BERT classifier. Naive methods (Coulombe, 2018; Xie et al., 2017) and translation-based methods (Fadaee et al., 2017; Sennrich et al., 2016) treated data noise either from artificial typos or translation errors as augmentation. Wei and Zou (2019) proposed EDA which is a combination of token-level augmentation (randomly delete, swap, etc.); they reported modest improvement (0.8% on average) on several benchmark datasets. Zhang et al. (2015) performed character-level augmentation. These methods were usually compromised by low readability and flawed syntactic structure. Other methods utilized external resources to improve augmentation quality. For example, Wang and Yang (2015) leveraged Word2Vec to extract synonyms. Kobayashi (2018) trained a Bi-RNN LM to propose replacements that are context-aware. Our tests find that these methods have higher perplexity than others. The reason could be that Word2Vec does not take context into account, while LM replacement highly depends on the quality of self-trained LM. Data Boost, however, is built on a state-of-the-art LM (GPT-2) and generates augmentations from scratch using RL rather than by replacement. Data Boost outperforms the other methods in the majority of the experiments (Table 4).

A few words about conditional generation: CTRL (Keskar et al., 2019) and BART (Lewis et al., 2019) are large-scale conditional LMs trained

Class	Generation Samples
ironic	freezing cold winter air can be a real treat but if your room temperature stays below freezing for a long time then the best way to cool down is death.
non-ironic	FoxNewscom reporter Michelle Fields is being sued by a Republican donor for disrespecting him and his family the Republican National Committee announced Wednesday.
positive	Congratulations to our friends at Bored Panda Pizza for the wonderful promotion that they have done We are very happy and proud to be able to share.
neutral	Results of the study revealed that the amount of protein ingested was similar in each group but not significantly different in total fat total carbohydrate or total protein.
negative	disappointed by the news media reports In the United States media have been covering reports on the killing of a woman by two men on a train.

Table 5: Sample generation of Data Boost for all classes from three tasks. Salient words are underlined.

on self-collected data. PPLM (Dathathri et al., 2020) does conditional generation through perturbing the vocabulary distribution during token decoding. These methods have not been explored for text augmentation applications. More importantly, they do not use reinforcement learning to have fine-grained control over generation, which we found especially helpful when dealing with multiple labels within the same task.

6 Human Evaluation

6.1 Experimental Design

We conducted human evaluation on Amazon Mechanical Turk (MTurk) in May 2020. Participants (N = 178) were randomly assigned to evaluate one of the three tasks, respectively Irony Classification (n = 60), Sentiment Analysis (n = 58), and Offense Detection (n = 60). Participants were all from the United States and above 18 years old. The average age of participants was 36.92 years-old. More than half (57.3%) of participants were male, and 42.1% were female, one participant self-report gender as other. Each participant was paid 75 cents for their participation in this study.

6.2 Procedures

For each class, participants were asked to read three samples from each version (the original, unconditionally generated (vanilla GPT-2), and RL-conditional generated(Data Boost)). They were not informed of actual labels and versions of samples. After reading, participants were shown the actual label and version of those samples they just read. They were then asked to answer a series of questions about label agreement (e.g., *"How much do you agree with the assigned class label?"* on a 7-point scale (1-strongly disagree to 7-strongly agree)). Additionally, they were asked to rate the readability of samples on a 7-point scale (lower scores correspond to lower readability and vice versa). The readability measure included five items adapted from previous studies (Graefe et al., 2018), namely well-written, concise, comprehensive, coherent, and clear.

6.3 Results

6.3.1 Label Agreement

We conducted paired sample t-tests to examine how much participants agreed with the assigned labels. To conduct an ablation study, we included samples generated using vanilla GPT-2 and Data Boost. Compared to the vanilla GPT-2, Data Boost samples received higher label agreement scores in eight out of nine classes. Five of which were statistically significantly ($p < .05$) higher. No statistically significant differences were seen between the original

Task	Class	Mean (SD) Original	 Data Boost	 Vanilla	F	df	p-value
Irony Classification	*ironic*	4.65 (1.27)	5.04 (1.16)	5.04 (1.10)	2.21	177	0.11
	non-ironic	4.76 (1.31)	4.96 (1.17)	4.74 (1.36)	0.53	177	0.59
Sentiment Analysis	*positive*	4.92 (1.10)	4.90 (1.17)	4.51 (1.38)	2.03	171	0.13
	neutral	4.26 (1.39)	4.83 (1.23)	4.88 (1.16)	4.40	171	0.01**
	negative	4.41 (1.46)	4.72 (1.19)	4.94 (1.06)	2.61	171	0.08
Offense Detection	*hateful*	4.35 (1.51)	4.53 (1.43)	5.00 (1.27)	3.42	177	0.04*
	abusive	4.42 (1.38)	4.61 (1.21)	5.05 (1.19)	3.82	177	0.02*
	spam	4.43 (1.60)	4.86 (1.17)	4.63 (1.40)	1.39	177	0.25
	normal	4.83 (1.25)	5.15 (1.04)	4.92 (1.27)	1.11	177	0.33

Table 6: Human evaluation results on readability. p-value describes the significance of difference. (* corresponds to $p < 0.05$, ** to $p < 0.01$ and *** to $p < 0.001$.)

and boosted data, except for the *spam* and *normal* class in Offense Detection ($p = .02$ and $p = .03$). This result further confirms that Data Boost samples look very similar to the original samples and that Data Boost generates higher quality samples than the vanilla GPT-2.

6.3.2 Readability

We conducted several one-way analyses of variance (ANOVA) to test whether there were any statistically significant differences in the readability of the three models (Table 6). There were no significant differences for six of the classes. Curiously, for the *neutral* (Sentiment), *abusive* (Offense) and *hateful* (Offense) labels, both Data Boost and vanilla GPT-2 generated samples were rated as more readable than the original samples ($p < .05$). This could be explained by the fact that original samples are generally noisy tweets. These results indicate that the Data Boost generation has similar readability as the vanilla GPT-2 or original samples.

7 Limitations

In this section we discuss the limitations of Data Boost. The performance gain achieved by using Data Boost could be marginal on certain tasks, especially those whose classes cannot be modeled well by lexical features. For example, we experimented with Data Boost for metaphor detection using the LCC dataset (Mohler et al., 2016), sarcasm classification using the GHOSH dataset (Ghosh and Veale, 2017), and formality detection using the GYAFC formality style transfer dataset (Rao and Tetreault, 2018). We saw marginal improvements in the tasks, with an absolute increase in F1 scores of 1.3%, 0.9%, and 0.7% for the three tasks respectively (in the extreme data scarcity case, where we expect Data Boost to help the most; i.e., when boosting 1% of the original data to 80%). We found that it was difficult for our model to extract explicit lexical features for the *metaphor*, *sarcastic*, and *formal* classes. This could be because syntactic features play a role in these classes. It is challenging for Data Boost to compose meaningful augmentation in such cases, given that our guidance on the generation is token-by-token.

8 Conclusion

We have proposed a powerful and easy to deploy approach to augment text data through conditional generation. By leveraging an off-the-shelf language model (GPT-2), we successfully guide the generation towards a specified direction (i.e, target class), with the help of reinforcement learning. We find that Data Boost improves the performance of classification tasks, is classifier-agnostic, and that it surpasses several prior augmentation methods in three diverse classification tasks.

In the future, we plan to implement a more sophisticated guidance for the augmentation by adding syntactic and position features to the reward function, to enable augmentation of more diverse types of text data. The code will be made available upon request.

A State-independent and Time-evolving Network for Early Rumor Detection in Social Media

Rui Xia[*], **Kaizhou Xuan**[*] **and Jianfei Yu**[†]

Abstract

In this paper, we study automatic rumor detection for in social media at the event level where an event consists of a sequence of posts organized according to the posting time. It is common that the state of an event is dynamically evolving. However, most of the existing methods to this task ignored this problem, and established a global representation based on all the posts in the event's life cycle. Such coarse-grained methods failed to capture the event's unique features in different states. To address this limitation, we propose a state-independent and time-evolving Network (STN) for rumor detection based on fine-grained event state detection and segmentation. Given an event composed of a sequence of posts, STN first predicts the corresponding sequence of states and segments the event into several state-independent sub-events. For each sub-event, STN independently trains an encoder to learn the feature representation for that sub-event and incrementally fuses the representation of the current sub-event with previous ones for rumor prediction. This framework can more accurately learn the representation of an event in the initial stage and enable early rumor detection. Experiments on two benchmark datasets show that STN can significantly improve the rumor detection accuracy in comparison with some strong baseline systems. We also design a new evaluation metric to measure the performance of early rumor detection, under which STN shows a higher advantage in comparison.

1 Introduction

Rumor is defined as an unverified statement, which may be unintentionally created or deliberately fabricated (DiFonzo and Bordia, 2007). False rumors are damaging as they may cause public panic and social unrest. Social media platforms have been ideal places for spreading rumors. It is important to automatically detect the rumors and debunk them before they are widely spread.

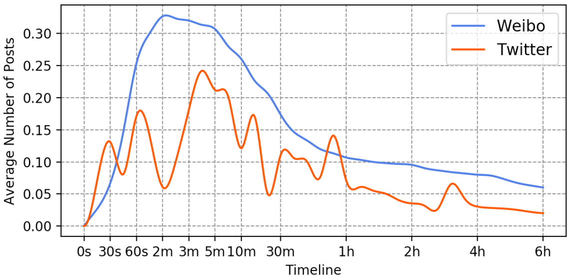

Figure 1: An illustration of the spread of rumors, which displays the average number of posts on Twitter and Weibo datasets (Ma et al., 2016) over the propagation timeline.

In recent years, the rumor detection task has attracted continuous attention from many researchers in the NLP community. We denote a statement in social media as an event consisting of a source post and its following posts such as comments or reposts (collectively called posts). Given an event, the rumor detection task is typically defined as a text classification problem (Zubiaga et al., 2018). The former aims to detect whether an event is a rumor or not.

In the literature, the typical method was to first obtain a global representation of the event based on all posts in the event's life cycle, and then employ a machine learning algorithm, such as Random Forest (RF, Kwon et al. 2013), Support Vector Machine (SVM, Ma et al. 2015), Convolution Neural Network (CNN, Yu et al. 2017) and Recurrent Neural Network (RNN, Ma et al. 2016) to learn the connection between the representation and the class labels.

On the one hand, events in social media evolve dynamically. According to communication stud-

ies, the dissemination of an event can be roughly divided into an evolution period, a high-tide period and an extinction period (Li et al., 2014; Han et al., 2014). As shown in Figure 1, similar curves can be observed in two real-world social media rumor datasets (i.e., Twitter and Weibo). Each state of the event has different posting density and data distribution. However, most of the aforementioned coarse-grained methods ignored the dynamics in the text data stream, and failed to capture the unique features in different states. Although part of these methods have considered temporal features or modeled the sequential dynamics with RNN, they still failed to establish fine-grained representations for different states.

On the other hand, the early detection of rumors is of great importance. According to our observation on the two rumor datasets, most events reach the high-tide period in less than five minutes. Although some of the previous work segmented the timeline by equal time span or equal number of posts for early rumor detection (Ma et al., 2016; Guo et al., 2018; Chen et al., 2018), they potentially ignored the vital features of early states and failed to train targeted models for early detection.

To address the limitations mentioned above, we propose a new State-independent and Time-evolving Network (STN) for rumor detection based on propagation state detection and segmentation, and apply it to early rumor detection in this paper. Specifically, since an event in social media is actually a sequence of posts sorted according to the posting time, it can be viewed as a time-series text data stream. To learn the propagation states in the text data stream, we first employ the Kleinberg algorithm (Kleinberg, 2003) to segment an event into several sub-events based on the state transition, each of which represents a continuous and identical state. Subsequently, we train an encoder to fit each sub-event separately. We furthermore propose a time-evolving fusion (He et al., 2018) mechanism to merge the current sub-event representation with previous ones, and combine them together for incremental prediction. STN no longer outputs one predictive label for one event, but outputs a sequence of labels for each state-independent sub-event, which enables early detection of rumors. Moreover, we further present a new evaluation metric, called Time-series Smoothing Accuracy (TS-Acc), for measuring the performance of early rumor detection.

Experimental results on two real-world rumor detection datasets released by Ma et al. (2016) demonstrate the effectiveness of our STN model. It not only achieves significant improvements for rumor detection in comparison with several strong baseline systems, but also greatly improves the early rumor detection performance.

2 Related Work

In recent years, rumor classification system has developed rapidly. Based on the definition in (Zubiaga et al., 2018), a complete rumor classification system consists of four components: i. rumor detection; ii. rumor tracking; iii. stance classification; iv. rumor verification. Among the four sub-tasks, rumor verification resembles rumor detection closely. For rumor detection, the goal is to detect whether a statement is a rumor or not (i.e, the class labels are rumor and non-rumor); for rumor verification, the goal is to determine whether a rumor is true, false or unconfirmed. Some following work have also combined the class labels together and consider it as a four-class classification problem (non rumor, true rumor, false rumor, unverified rumor) (Ma et al., 2017)[1].

During the prophase study of rumor detection, researchers focused on extracting various obvious features of microblog events on social media platforms, and combined the features with traditional machine learning classifiers to detect rumors or identify information credibility (Castillo et al., 2011; Yang et al., 2012; Kwon et al., 2013; Liu et al., 2015; Ma et al., 2015; Wu et al., 2015; Zhao et al., 2015; Wang and Terano, 2015; Vosoughi, 2015). These manually-designed features can be roughly categorized into three groups, including text content, user portraits and propagation states. However, it is hard for these traditional approaches to capture the dynamic characteristics during the spread of an event and the relationship between the posts.

To address this issue, Kwon et al. (2013) constructed a massage propagation model to find the diversity of the amount of related posts between rumor and nor-rumor. Ma et al. (2015) first proposed to divide the event timeline into equal-span periods and utilized the dynamic changes of fea-

---

[1] It should be noted our proposed framework is compatible with both rumor detection and rumor verification, although they have different space of class labels. Therefore, we make no distinction between the two and use the terminology of "rumor detection" instead of both, for simplicity.

tures in adjacent periods. Based on this, Ma et al. (2016) further introduced RNN models to encode the time periods, which verified the effectiveness of RNN models on encoding sequential posts. Zubiaga et al. (2017) utilized a sequential approach based on Linear-chain Conditional Random Fields (CRF) to learn the dynamic relations between posts, which relies on the content of a source microblog and its related posts. Kwon et al. (2017) employed different sets of features to keep the properties of the propagation structure and temporal relations among posts. Moreover, Guo et al. (2018) incorporated the attention mechanism into stacked RNNs to model the temporal propagation of an event.

In addition, there is another line of researches focusing on modeling the post sequences with tree structures, which aims to useful relations among the responsive posts (Nadamoto et al., 2013; Wu et al., 2015; Ma et al., 2017, 2018; Kumar and Carley, 2019). Among them, the representative studies are Ma et al. (2018) and Kumar and Carley (2019), which respectively proposed a recursive neural network and a Tree-LSTM architecture to explicitly model the tree structure. Different from all the studies mentioned above, a recent study by Ma et al. (2019) proposed to leverage Generative Adversarial Networks (GAN) to improve the robustness of rumor detection, where a generative model is trained to confuse the rumor detection discriminator by generating pseudo real examples.

Although much work has been done for rumor detection, only a few previous studies focused on the early detection of rumors (EDR). Zhao et al. (2015) argued that rumors are more likely to arouse users' suspicion, and proposed to aggregate related posts with specific phrases, followed by performing EDR with cluster-based classifiers. However, this work inevitably involved much human effort. To alleviate the reliance of feature engineering, Nguyen et al. (2017) utilized deep neural networks to automatically capture features at the post level. Although it achieves better early detection performance, it is difficult to be applied to large events. Liu and Wu (2018) believed that early posts are easy to be manipulated by the source microblog, while user characteristics are relatively stable. They integrated RNN and CNN models to capture user characteristics in the propagation process of an event. However, only using user features makes their model unable to achieve continuous performance improvement as time goes by. More recently, Song et al. (2019) introduced the concept of credible detection points, and proposed to gather every ten posts along the timeline as one time-step of RNN and made prediction at each step. But tens of thousands of posts make the number of time steps large, which may reduce the reliability of long-distance dependence.

3 Approach

3.1 Task Definition

Suppose $\mathcal{D} = \{(\mathbb{E}^{(1)}, y^{(1)}), \ldots, (\mathbb{E}^{(|\mathcal{D}|)}, y^{(|\mathcal{D}|)})\}$ is a rumor detection dataset, where $\mathbb{E}$ denotes one event, and y denotes its class label. Each event $\mathbb{E}$ consists of a large amount of posts:

$$\mathbb{E} = \{\mathbf{c}_0, \mathbf{c}_1, \ldots, \mathbf{c}_{|\mathbb{E}|}\}, \tag{1}$$

where $|\mathbb{E}|$ is the number of posts in it. The first post $\mathbf{c_0}$ in $\mathbb{E}$ is regarded as the source post published at time t_0. Each of the following posts $\mathbf{c}_i$ has an arrival time t_i and $\mathbf{c}_i$ denotes the feature representation of each post. After sorting all the posts in event $\mathbb{E}$ according to the arrival time, $\mathbb{E}$ can be considered as a time-series text data steam $\mathbb{E} = [(\mathbf{c}_0, t_0), (\mathbf{c}_1, t_1), \ldots, (\mathbf{c}_{|\mathbb{E}|}, t_{|\mathbb{E}|})]$.

We train a rumor detection model based on $\mathcal{D}$, and use it to predict the class labels y on an unseen event $\mathbb{E}$.

3.2 Event State Detection and Segmentation

The Kleinberg algorithm (Kleinberg, 2003) was originally used to detect burst incidents on news or e-mails. In this paper, we employ it to detect the state for each post in an event. Based on the hidden Markov model, the Kleinberg algorithm can identify the hidden state sequence corresponding to a post sequence.

For an event consisting of multiple posts $\mathbb{E} = [(\mathbf{c}_0, t_0), (\mathbf{c}_1, t_1), \ldots, (\mathbf{c}_{|\mathbb{E}|}, t_{|\mathbb{E}|})]$, we first build a sequence of arrival time intervals

$$X = [x_1, x_2, \ldots, x_{|\mathbb{E}|}], \tag{2}$$

where

$$x_i = t_i - t_{i-1}, i = 1, 2, \ldots, |\mathbb{E}|. \tag{3}$$

Our goal is to obtain the corresponding state sequence Q for the interval sequence X:

$$Q = [q_1, q_2, \ldots, q_{|\mathbb{E}|}], \tag{4}$$

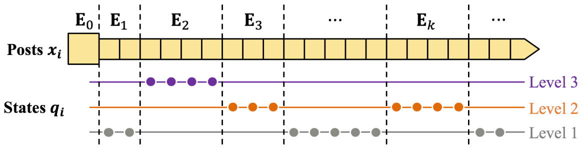

Figure 2: An example of the state sequence given the post sequence where the number of state levels $N = 3$. Each post is assigned with a hidden state $q_i \in \{1, 2, 3\}$. For example, $q_1 = 1$, $q_2 = 1$ and $q_3 = 3$.

where $q_i \in \{1, 2, \ldots, N\}$ denotes the state of x_i, and N number of state levels in Q. Figure 2 illustrates a case of the state changes of part of the posts in an event when $N = 3$.

The Kleinberg algorithm assumes the arrival time interval has a memoryless exponential distribution:

$$p(x_i|q_i = j) = \alpha_j e^{-\alpha_j x_i}, \tag{5}$$

where α_j can be regarded as the arrival rate of posts. It can be derived that the expected value of x_i is α_j^{-1}.

For the basic state $q = 1$, we set its arrival rate as the reciprocal of the average intervals of all posts in $\mathbb{E}$:

$$\alpha_1 = \frac{|\mathbb{E}|}{t_{|\mathbb{E}|} - t_0}. \tag{6}$$

The values of α_j corresponding to higher states $q_i = j$ are then set as:

$$\alpha_j = s^{(j-1)} \cdot \alpha_1, \tag{7}$$

where $s > 1$ is a preset scaling parameter.

For adjacent arrival time intervals x_i and x_{i+1} with the corresponding states $q_i = a$ and $q_{i+1} = b$, the loss of transition from state a to b is defined as:

$$\tau(a, b) = \begin{cases} (b - a)\gamma \ln n, b > a \\ \hfill 0, b \le a \end{cases}, \tag{8}$$

where γ is a preset parameter to control the magnitude of transition loss.

The objective of the algorithm is to solve a state sequence Q, which minimizes the cost function $L(Q|X)$:

$$L(Q|X) = \sum_{i=1}^{|\mathbb{E}|-1} \tau(q_i, q_{i+1}) - \sum_{i=1}^{|\mathbb{E}|} \ln p(x_i|q_i). \tag{9}$$

where the first item is the loss of state transition, based on which we expect the frequency of transition to be as small as possible. The second term is the log-likelihood, based on which we want to maximize the density functions $p(X|Q)$ given the sequence of x_i and q_i pairs.

After obtaining the optimal state sequence Q, we then merge the continuous posts with the same state into a single sub-event, and finally represents an event $\mathbb{E}$ by a sequence of K state-independent sub-events:

$$\mathbb{E} = [\mathbf{E}_0, \mathbf{E}_1, \ldots, \mathbf{E}_{K-1}]. \tag{10}$$

Each sub-event $\mathbf{E}_k$ includes a series of continuous posts:

$$\mathbf{E}_k = [c_{k,1}, c_{k,2}, \ldots, c_{k,|\mathbf{E}_k|}]. \tag{11}$$

where $c_{k,l}$ denotes the l-th post in the k-th sub-event.

3.3 State-independent Sub-event Encoder

For each sub-event $\mathbf{E}_k$, we train a state-independent sub-event encoder e_k to get the sub-event representation.

Firstly, the mean pooling of the embedding of all words in a post is used as the post representation:

$$\mathbf{c}_i = \text{mean}(\mathbf{w}_1^{(c_i)}, \mathbf{w}_2^{(c_i)}, \ldots, \mathbf{w}_{|c_i|}^{(c_i)}), \tag{12}$$

where $\mathbf{w}_l^{(\mathbf{c}_i)}$ is the word embedding vector retrieved from a pre-trained word embedding matrix, and $\mathbf{c}_i$ denotes the representation of the i-th post. Based on $\mathbf{c}_i$, we can then get the input representation of the sub-event $\mathbf{E}_k$, denoted by $\mathbf{X}_k = [\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_{|\mathbf{E}_k|}]$.

Secondly, we employ a basic encoder (e.g., CNN, LSTM) to get the sub-event representation $\mathbf{h}_k$ based on the input post representation $\mathbf{X}_k$. The encoding of the sub-event $\mathbf{E}_k$ can finally be expressed as follows:

$$\mathbf{h}_k = \text{Encoder}(\mathbf{X}_k). \tag{13}$$

Note that here the state-independent sub-event encoder is a general framework compatible with the widely used encoders of texts, e.g., CNN, LSTM, GRU, etc. In the experiments, in addition to CNN, we also report the results based on LSTM and GRU.

3.4 Time-evolving Representation and Classification

The social media event evolve dynamically, and the representations of pre-ordered sub-events may be helpful for current sub-event prediction. Therefore,

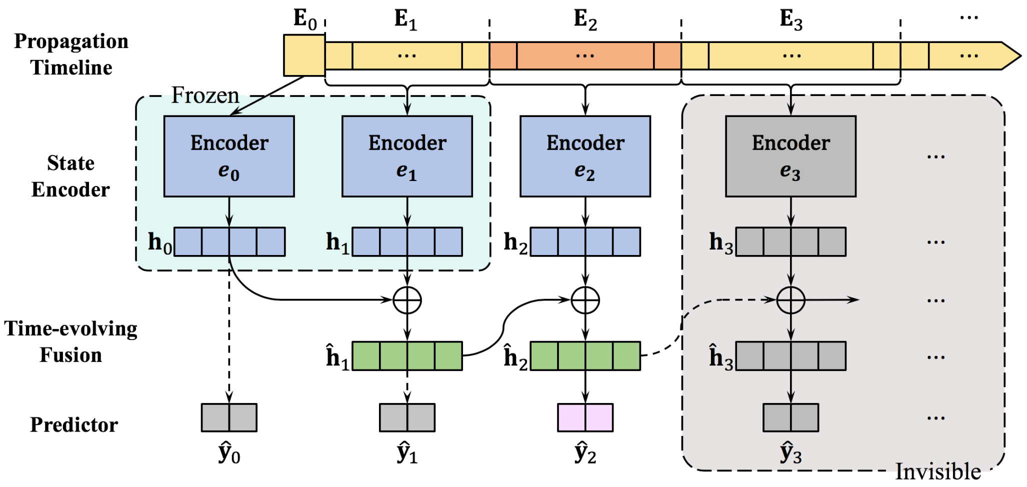

Figure 3: A schematic diagram of our model when learning for sub-event $\mathbf{E}_2$. The model outputs the prediction result $\hat{\mathbf{h}}_2$ and updates all the visible and unfrozen modules accordingly.

we add a time-evolving fusion module after each sub-event encoder to fuse the representation of the current sub-event with previous ones:

$$\begin{aligned}\hat{\mathbf{h}}_k &= \delta(\mathbf{W}_k(\mathbf{h}_k \oplus \hat{\mathbf{h}}_{k-1}))\\ &= \delta\big(\mathbf{W}_k\big(\mathbf{h}_k \oplus \delta(\mathbf{W}_{k-1}(\mathbf{h}_{k-1} \oplus \hat{\mathbf{h}}_{k-2}))\big)\big)\\ &= \ldots,\end{aligned} \tag{14}$$

where δ is a Sigmoid activation function and $\mathbf{W}_k$ is a weight matrix. Similarly, $\hat{\mathbf{h}}_k$ will be used to guide the encoding $\hat{\mathbf{h}}_{k+1}$ of next sub-event, forming a recursive encoding mode.

We independently predict the authenticity of sub-event $\mathbf{E}_k$ under each state. The encoding $\hat{\mathbf{h}}_k$ of $\mathbf{E}_k$ will be fed into a separate softmax classifier to get the prediction result $\hat{\mathbf{y}}_k$:

$$\hat{\mathbf{y}}_k = \mathrm{softmax}(\mathbf{V}_k \hat{\mathbf{h}}_k + \mathbf{b}_k), \tag{15}$$

where $\mathbf{V}_k$ and $\mathbf{b}_k$ are parameters representing weights and bias.

Given the sequence of sub-events $\mathbb{E} = [\mathbf{E}_0, \mathbf{E}_1, \ldots, \mathbf{E}_{K-1}]$, our model incrementally outputs a corresponding sequence of predictive probabilities:

$$Y = [\hat{y}_0, \hat{y}_1, \ldots, \hat{y}_{K-1}]. \tag{16}$$

The training objective of each sub-event is to minimize the cross-entropy loss between the predictive probability $\hat{\mathbf{y}}_k$ and the true class label $\mathbf{y}$:

$$L_{\mathbf{E}_k} = \mathbf{y} \cdot \log \hat{\mathbf{y}}_{\mathbf{k}}, \tag{17}$$

where $L_{\mathbf{E}_k}$ denotes the loss for sub-event $\mathbf{E}_k$.

It should be noted that our model is learned in an incremental training mechanism. In training for the current sub-event $\mathbf{E}_k$, the parameters of all previous encoders are frozen. That is, we only update the parameters in current encoder. But the fusion parameters (i.e., $\mathbf{W}_{k-1}, \mathbf{W}_{k-2}, \ldots$) should be fine-tuned synchronously. The incremental training process is illustrated in Figure 3.

3.5 Early Detection of Rumors

In this subsection, we further propose a new evaluation metric, named **Time-series Smoothing Accuracy (TS-Acc)**, to measure the performance of early rumor detection.

Since the earlier prediction results are more important for rumor detection, we first employ a smoothed exponential function to assign a weight to the accuracy for the predictions in each sub-event:

$$v(t) = e^{-\log_\lambda (t+\lambda)}, \tag{18}$$

where t is the arrival time of sub-events and and λ is a smoothing parameter defined as 60 in our experiments.

TS-Acc is then defined as a weighed sum of accuracies of already-appeared sub-events:

$$\text{TS-Acc} = \sum_k Acc^{(k)} \cdot \mathrm{Norm}(v(t^{(k)})). \tag{19}$$

where $\mathrm{Norm}(v(t^{(k)}))$ denotes the normalized weight among k already-appeared sub-events.

It is also worth noting that in case of discrete time-points, the area under accuracy-time curve

Table 1: Statistics of Twitter and Weibo datasets.

	Twitter	Weibo
Events	992	4,664
Non-rumor events	498	2,313
Rumor events	494	2,351
Posts	949,224	3,805,656
Avg. post number/event	957	816
Avg. time length/event	360.8Hours	1,808.7Hours

is equivalent to the sum of accuracies at all timepoints. Since TS-Acc is a weighted sum of accuracies, it can also be regarded as a weighted version of area under accuracy-time curve.

4 Experiment

4.1 Datasets and Experimental Settings

Twitter and Weibo datasets were published by Ma et al. (2016), both of which provided a large number of relevant posts for each microblog event. Due to the protection policy of Twitter, we re-crawl all the posts in the Twitter dataset according to their ID numbers. However, since some of the tweets are no longer available, we discard those unresponsive source microblogs and finally obtain 90% of the original dataset for our experiments. For Weibo dataset, the events of misinformation are marked as rumor. According to the definition in (Zubiaga et al., 2018), it is more related to true rumor. But to be be consistent with (Ma et al., 2016), we still regard the event category as rumor and non-rumor.

The detailed statistics of both datasets are shown in Table 1. Following the same settings in the previous papers, we hold out 10% of the events in both datasets for model tuning, and the rest of the events are split with a ratio of 3:1 for training and test. To guarantee obtaining global states for different events, we have not performed the Kleinberg algorithm for each post. Instead, we combine all events in the dataset together and align the posts in them according to the posting time. The Kleinberg algorithm is then performed on the combined entire dataset. We use the Chinese word embeddings from Tencent AI Lab (Song et al., 2018) and the English word embeddings from Google News. When training the model, we use the Adam optimizer (Kingma and Ba, 2014).

4.2 Rumor Detection Performance

In this subsection, we compare our proposed STN model with the following rumor detection methods on the standard rumor detection task, i.e., evaluating the detection accuracy after the end of the event propagation:

- **DTR**: A ranking model based on a decision tree to identify trending rumors through searching for disputed claims (Zhao et al., 2015);
- **SVM**: A linear SVM model to identify rumors with the handcrafted features and feature change gradient (Ma et al., 2015);
- **GRU**: A GRU model with the text data extracted from the variable-length time series as the input (Ma et al., 2016);
- **PPC**: A time series classifier based on RNN and CNN, which captures the user characteristics along the propagation path (Liu and Wu, 2018);
- **AIM**: An attention-based classification model which can extract valid content and temporal features (Liu et al., 2018);
- **CED**: A continuous detection model which first obtains credible detection points for each repost sequence, followed by making reliable prediction based on the information before the credible detection point (Song et al., 2019).

Based on the results reported in Table 2, we can make a couple of observations. First, compared with the traditional model DTR and SVM, GRU achieves obvious improvements on both datasets, and AIM shows even better performance by using attention mechanism. Second, based on the credible detection point, CED further boosts the detection accuracy on Weibo to 94.6%. Finally, our model STN consistently achieves the best performance on both Twitter and Weibo datasets, which outperforms the state-of-the-art models by around two percentage points on both detection accuracy and $\mathbf{F_1}$ score.

4.3 Early Detection Performance

In this subsection, we compare the performance of all the models in early detection of rumors (EDR), i.e., predicting the credibility of microblog events based on the posts released before a detection time point.

(1) The curve of detection accuracy

In Figure 4, we show the detection accuracy of all the models as the time goes by. In particular, we illustrate more detection results within the first 6 hours.

First, we can see from Figure 4 that the accuracy of DTR and that of SVM grow slowly on both

Table 2: Results of conventional rumor detection on Twitter and Weibo datasets. Results are evaluated by accuracy, macro-precision, recall, and F_1-score. Part of the data are excerpted from published papers. (#CED only uses half of the Twitter dataset.)

Method	Twitter				Weibo			
	Accuracy	Precision	Recall	F_1	Accuracy	Precision	Recall	F_1
DTR	0.681	0.679	0.680	0.679	0.732	0.732	0.732	0.732
SVM	0.745	0.758	0.741	0.749	0.857	0.859	0.858	0.858
GRU	0.757	0.760	0.757	0.758	0.910	0.914	0.910	0.912
PPC	-	-	-	-	0.921	0.923	0.926	0.924
AIM	0.796	0.799	0.800	0.799	0.936	0.936	0.937	0.936
CED	0.744#	0.708#	0.791#	0.747#	0.946	0.946	0.944	0.945
Ours	**0.821**	**0.824**	**0.823**	**0.824**	**0.963**	**0.963**	**0.963**	**0.963**

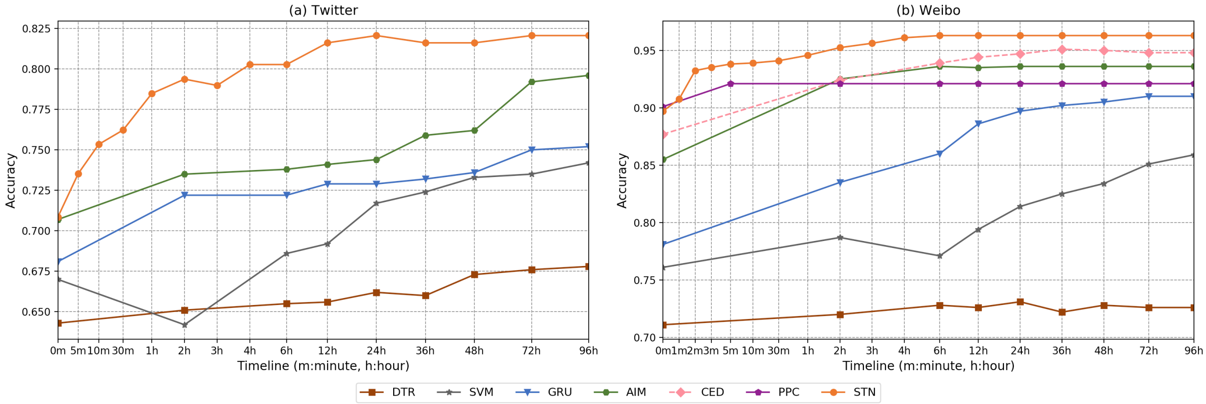

Figure 4: Early detection results on (a) Twitter and (b) Weibo. More time points within 6 hours are shown. (We reproduced the curve of CED, but it may be slightly different from the original.)

Twitter and Weibo datasets. In contrast, the GRU model has a faster and more stable rising curve on both datasets. Second, compared with the previous methods, we can find that AIM consistently improves the detection accuracy at each detection time point. Moreover, PPC can quickly improve the detection accuracy to over 92% in the first 5 minutes, but it cannot continue to perform better, whereas CED can continuously improve its detection accuracy to over 94% within the first 6 hours on the Weibo dataset. Finally, in comparison with all the methods mentioned above, STN shows a significant improvement within the first 6 hours. Specifically, it is easy to see that STN has achieved over 75% and 94% accuracy respectively at the 10th minute. In addition, as the time goes by, we can clearly see that STN can gradually improve its detection accuracy, and outperform all the state-of-the-art models at each detection time point.

(2) Time-series Smoothing Accuracy

As introduced in Section 3.5, we propose the Time-series Smoothing Accuracy (TS-Acc) to evaluate the efficiency of EDR. In Table 3, we report the results of using this evaluation metric to compare all the models. To be consistent with Figure 4, we respectively select 3 and 9 time points within the first 6 and 96 hours to re-evaluate the TS-Acc performance of all the models.

First, we can see that for each approach, the overall trend of the TS-Acc performance is similar to that of the accuracy performance in Figure 4. Second, it is worth noting that for the Weibo dataset, the TS-Acc of PPC in 96 hours is slightly lower than AIM and CED, whereas its TS-Acc in 6 hours is significantly higher than AIM and CED. This indicates that our evaluation metric TS-Acc primarily reflects the speed of improvement in the early stage. Finally, we can clearly observe that the TS-Acc of STN is significantly higher than that of all the state-of-the-art models on both datasets, which is consistent with the performance trend shown in Figure 4.

4.4 Discussion on State Detection and Event Segmentation

(1) Discussion on the Dynamics of Data Distribution

To show the state detection and event segmentation advantages of Kleinberg algorithm, we com-

Table 3: Evaluation results of early detection efficiency with our TS-Acc metric.

Model	6-hours' TS-Acc		96-hours' TS-Acc	
	Twitter	Weibo	Twitter	Weibo
DTR	0.6487	0.7183	0.6576	0.7225
SVM	0.6652	0.7719	0.6936	0.7994
GRU	0.7048	0.8189	0.7210	0.8603
PPC	-	0.9126	-	0.9169
AIM	0.7240	0.8985	0.7435	0.9175
CED	-	0.9082	-	0.9283
STN	**0.7603**	**0.9366**	**0.7897**	**0.9477**

Table 4: Mean values of intra-class distance on Weibo datasets when using different event segmentation methods.

Method	Sub-events/event	Intra-class distance
VTS	30	1.0570
VTS	50	1.2641
CPT	2000	0.9302
Kleinberg	33	**0.8177**

Table 5: Effects of different encoders of STN. (The number of detection points for TS-Acc are 12 and 33 respectively.)

s	1.5	1.2	1.1	1.1
γ	1	1	1	0.8
Max state level	5	10	19	19
State change times	247	89	84	104
Number of final sub-events	39	33	32	33

Table 6: Effects of different encoders of STN. Results are evaluated by regular accuracy and Time-series Smoothing Accuracy. (The number of detection points for TS-Acc are 3 and 9 respectively.)

Encoder	in 6-hours		in 96-hours	
	Accuracy	TS-Acc	Accuracy	TS-Acc
LR	0.9295	0.9149	0.9323	0.9197
LSTM	0.9476	0.9317	0.9486	0.9365
GRU	0.9505	0.9346	0.9514	0.9395
GRU-ATT	0.9524	0.9331	0.9533	0.9390
CNN	**0.9629**	**0.9366**	**0.9629**	**0.9477**

pare it with some representative state segmentation methods, such as Variable-length Time Series (VTS, Ma et al. 2016) and Constructing Post Series (CPS, Chen et al. 2018), which divide the event with equal time span and equal number of posts respectively.

Specifically, we calculate the intra-class distance of each divided sub-event, and obtain the mean value of all the distances of sub-events for each model. Note that the smaller the intra-distance is, the closer the post features in the sub-event are. In Table 4, it is easy to observe that Kleinberg algorithm can obtain the lowest intra-class distance, which demonstrates its better state segmentation ability, and it may reduce the dynamics of data distribution of sub-events and further enhance the feature extraction ability of our encoders.

(2) Effects of Parameters of Kleinberg

Kleinberg algorithm has two important preset parameters s and γ which are used to set the expected arrival rate of posts and the transfer loss between different state levels. As shown in Table 5, we explore the impact of several pairs of s and γ on the sub-event partition.

In order to ensure effective training of STN, we adjust the state division of the Kleinberg algorithm. If the number of events that have posts under a single state is less than 30% of the total number of events, we merge the current state with the sequential state, and if the duration of a single state exceeds two hours, we truncate it at the 2nd hour. Finally, we find that the reasonable changes of s and γ have little effect on the number and the segmented position of sub-events. Thus, we draw the conclusion that the performance of STN is not subject to the parameter adjustment of Kleinberg.

4.5 Discussion on the Compatibility of State-independent Encoders

As mentioned above, the state encoder of STN is a general framework compatible with traditional feature extraction and classification algorithms or deep neural networks. We do experiments with the following encoders on Weibo dataset: **LR** (Logistic Regression), **LSTM**, **GRU**, **GRU-ATT** (GRU with self-attention) and **CNN**.

Table 6 shows the detection accuracy and early detection efficiency TS-Acc of STN in the first 6 and 96 hours with different encoders. First, we can see that the traditional machine learning model LR can already achieve good performance. Second, among all the deep learning encoder, CNN obtains the best performance in both settings. Moreover, by comparing the results in Table 3 and Table 6, we can see that all the deep learning encoders can obtain better performance than all the state-of-the-art models, which indicates the effectiveness and the generalization ability of our STN model.

4.6 Discussion on the Incremental Training

Finally, to verify the effect of the time-evolving fusion module, we replace the module of STN with a standard GRU, and make STN degenerate into an integrated training model (GRU with Kleinberg, GK).

Table 7: Comparison between GK and other models. Results are evaluated by accuracy, macro-precision, recall, and $\mathbf{F_1}$-score.

Model	Accuracy	Precision	Recall	$\mathbf{F_1}$
GRU	0.910	0.914	0.910	0.912
GK	0.949	0.948	0.949	0.948
STN	**0.963**	**0.963**	**0.963**	**0.963**

As shown in Table 7, we can easily find that our incremental training method (i.e., STN) can consistently perform better than GRU and GK, which demonstrates the usefulness of our time-evolving fusion module. Moreover, in our experiments, we also find that since the prediction of the current state is dependent on the previous state in our time-evolving fusion module, events that are predicted correctly in the earlier states rarely change in the follow-up state, but most of the events that are wrongly predicted in the earlier states can be largely corrected in the follow-up state. This further proves the effectiveness of our STN model.

5 Conclusion and Future Work

In this paper, we first introduce the Kleinberg algorithm to identify the propagation states for an event composed of a sequence of posts and segment the sequence into several state-independent sub-events. On this basis, we propose a state-independent and time-evolving network (STN) for rumor detection as well as early rumor detection. We also present a new metric called time-series smoothing accuracy (TS-Acc) for measuring the efficiency of early rumor detection. The experimental results on two real-world microblog rumor datasets demonstrates the advantages of our STN approach in terms of both rumor detection accuracy and our proposed TS-Acc metric, in comparison with some strong rumor detection systems.

One disadvantage of this work is that the Kleinberg algorithm is performed on the combination of all events in the dataset to maintain global states. This way may fail to capture the individual state transition in single events. Secondly, it is a retrospective algorithm which depends on the condition all posts along the timeline should be provided in advance. Therefore, one direction for future work is to explore an online state detection algorithm and perform it for each event, but at the same time ensure that the state of each event is globally defined. It would be even better if the state detection and segmentation step can be integrated with subsequent state-independent feature extraction and rumor detection in an end-to-end framework.

Abstract

Simultaneously modeling source code and natural language has many exciting applications in automated software development and understanding. Pursuant to achieving such technology, we introduce PYMT5, the PYTHON method text-to-text transfer transformer, which is trained to translate between all pairs of PYTHON method feature combinations: a single model that can both predict whole methods from natural language documentation strings (docstrings) and summarize code into docstrings of any common style. We present an analysis and modeling effort of a large-scale parallel corpus of 26 million PYTHON methods and 7.7 million method-docstring pairs, demonstrating that for docstring and method generation, PYMT5 outperforms similarly-sized auto-regressive language models (GPT2) which were English pre-trained or randomly initialized. On the CODESEARCHNET test set, our best model predicts 92.1% syntactically correct method bodies, achieved a BLEU score of 8.59 for method generation and 16.3 for docstring generation (summarization), and achieved a ROUGE-L F-score of 24.8 for method generation and 36.7 for docstring generation.

1 Introduction

Software is a keystone of modern society, touching billions of people through services and devices daily. Writing and documenting the source code of this software are challenging and labor-intensive tasks; software developers need to repeatedly refer to online documentation resources in order to understand existing code bases to make progress. Developer productivity can be improved by the presence of source code documentation and a development environment featuring intelligent, machine-learning-based code completion and analysis tools.

Recent progress in natural language processing (NLP), especially encoder/decoder-based transformer models (Vaswani et al., 2017) and pre-training (Radford et al., 2018; Lewis et al., 2019), has led to state-of-the-art performance on language modeling, classification (Devlin et al., 2018), translation (Raffel et al., 2019), summarization (Liu and Lap-

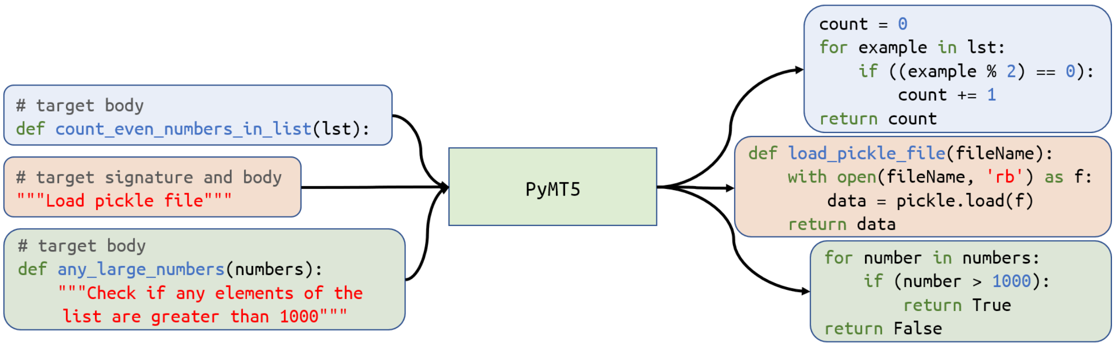
ata, 2019), grammar correction (Bryant et al., 2017), entity recognition, dialogue generation (Budzianowski and Vulić, 2019), and more. Along with these quantitative advances have come deeper understanding of the learned hidden representations which power transformers (Kovaleva et al., 2019; Voita et al., 2019; Clark et al., 2019; Ethayarajh, 2019). While they are arguably not 'natural,' programming languages are increasingly becoming modeling playgrounds for NLP modeling. Since these languages by definition have a grammar, syntax, and known relationships between entities, they offer enticing opportunities for an even deeper probing of NLP models and tasks. Beyond theoretical importance, many NLP tasks have practical utility in software development environments: language modeling or generation can be used for code completion (Raychev et al., 2014; Bruch et al., 2009; Svyatkovskiy et al., 2019, 2020), translation/summarization to generate documentation or natural language summaries (Moreno et al., 2013; Scalabrino et al., 2017; Wan et al., 2018; Alon et al., 2018) or even summarize a set of code changes (Moreno et al., 2014), translation and grammar error correction to patch and detect bugs (Zhai et al., 2019), and joint embedding of code and natural language for code search (Husain et al., 2019; Gu et al., 2018).

In this work we focus on jointly modeling both source code (PYTHON) and concomitant natural language documentation (docstrings) with transformers, through the study of dual tasks: generating method code bodies from signatures and docstrings, and generating docstrings from signatures and method code bodies. While previous work (Allamanis et al., 2015; Yin and Neubig, 2017) has leveraged the grammar of code to extract features like the Abstract Syntax Tree for modeling (treating code and natural language as separate modalities), we follow examples like Barone and Sennrich (2017) and treat PYTHON and its docstrings as fundamentally no different than other 'natural' languages, representing both source code and natural language docstrings as sequences of tokens sharing the same vocabulary. Here we present a multi-mode translation method resulting in PYMT5, the PYTHON method text-to-text transfer transformer (inspired by the text-to-text transfer transformer T5 (Raffel et al., 2019)). Our single model can both learn code/language generation and understand the relationships between them.

The paper is organized as follows: we begin in sec. 2 by presenting examples of the performance of our novel multi-mode PYMT5 —the PYTHON method text-to-text transfer transformer model—which we trained to translate between all pairs of combinations of method signatures, docstrings, and bodies which do not have the same feature in both the source and target. In sec. 2.1 we describe our training data and the pre-processing steps for source code and natural language we followed, and compared it to existing parallel docstring-method corpora like CODESEARCHNET (CSN)(Husain et al., 2019) and that presented by Barone et al (Barone and Sennrich, 2017). In sec.2.2 we explain our BART-like (Lewis et al., 2019) pre-training scheme, demonstrating a 25× speed-up in training time for docstring generation. Next, in sec. 2.3 we analyze and classify PYTHON docstrings, enabling style-conditioned docstring generation in PYMT5. In sections 3 and 4, we discuss PYMT5 results on method generation and docstring generation respectively and compare it to two GPT2 models randomly initialized and pre-trained on English.

2 Multi-mode training

Figure 1 shows examples of inputs and outputs of our model PYMT5 for 3 example tasks: (top, blue) predicting a body from a method



```
# target body
def count_even_numbers_in_list(lst):
```

```
# target signature and body
"""Load pickle file"""
```

```
# target body
def any_large_numbers(numbers):
    """Check if any elements of the
     list are greater than 1000"""
```

```
count = 0
for example in lst:
    if ((example % 2) == 0):
        count += 1
return count
```

```
def load_pickle_file(fileName):
    with open(fileName, 'rb') as f:
        data = pickle.load(f)
    return data
```

```
for number in numbers:
    if (number > 1000):
        return True
return False
```

Figure 1: Real examples of PyMT5 performing method generation using combinations of signatures and docstrings. A leading comment in the input sequence instructs the model to output a particular combination of features, e.g. ‘`# target signature and body`’ instructs PyMT5 to predict both a signature and body.

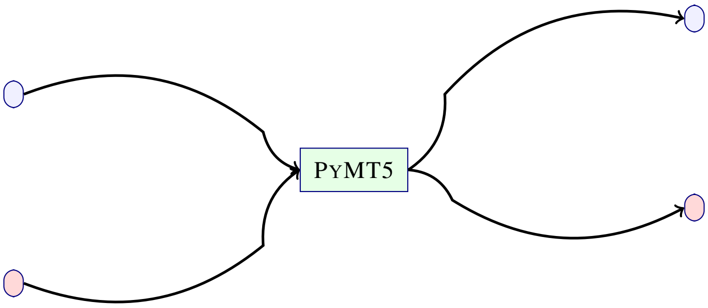


Figure 2: PyMT5 performing docstring generation on an example method, showing the output when the target prefix indicates one line (top, blue) and Numpydoc docstring (bottom, red) styles.

signature, (middle, red) predicting a whole method from a natural language docstring, and (bottom, green) predicting a body from a signature and docstring. Note that the comment ‘`# target <specification>`’ instructs the model to choose a particular form of output. Further note that PyMT5 correctly learns to interpret natural language: it interprets ‘`even`’ as being related to ‘`(example %2) == 0`’, and ‘`greater than 1000`’ as ‘`number > 1000`’. The model also produces syntactically correct code (as we will discuss later, we never show the model syntactically incorrect code), and correctly infers the types of ‘`lst`’ and ‘`numbers`’ to be iterables containing numbers.

PyMT5 can also be prompted with source code to produce a docstring summary in various styles. Figure 2 shows the model prompted with one of the methods generated by PyMT5 in Fig. 1 (top, blue), in both a ‘one line’ (top, blue) style and a ‘Numpydoc’ (bottom, red) style. It infers the intent from the signature name and code, and even infers that type of the argument is a `list` and return type `int`. It produces the same terse one sentence summary of the function in both cases.

In order to teach PyMT5 to maximally relate the separate method features (signatures, docstrings, bodies), we trained it to translate between all pairs of feature combinations in which the same feature does not appear in both the source and target. This scheme is also advantageous as our corpus is unbalanced, with only 1/5 methods featuring docstrings, and so the model can learn to leverage all the features whether they are present or not. Additionally, it has been shown that code is more 'predictable' than natural language (Hindle et al., 2012). If the method and argument names are a dominating signal due to their relatively rigid structure, the model may learn to ignore the content of docstrings. This multi-mode method overcomes that by training the model to generate method bodies from docstrings alone. See the appendix for a more detailed description of the multi-mode training scheme.

2.1 Dataset

Our data consists of 118k GITHUB repositories, which includes all public repositories labelled as containing primarily PYTHON source code, featuring at least 10 stars, and which have had a commit in the past 5 years. We successfully cloned 112k of these repositories, extracting 5.3 million PYTHON files from the default `HEAD` state of each repository. We then removed literal duplicate files, resulting in 2.3 million unique files, but did not remove finer-grained clones. After removing license from the files, the literal contents were used in the pre-training step, comprising about 27GB of raw text.

In order to extract method-level information for fine-tuning, we used the `python3.7` standard library `ast` to produce the file-level Abstract Syntax Tree (AST) for each PYTHON file, extracting every individual and class method. For each file which failed to parse, we used `2to3` and `autopep8` to overcome the issue of different styles and white space or tab conventions, successfully parsing 97.3% of the 2.3 million unique PYTHON files. We used the PYTHON module `astunparse` to take the AST for each method and unparse them back into source code, so that our fine-tuned model was never trained on syntactically incorrect code. The statistics of our method-docstring corpus are summarized in Table. 1. Our parallel method-docstring corpus is twice as large as the next largest irrespective of language and over 15× as large as the next largest PYTHON parallel corpus, both in CSN.

For each method, we ignored comments as they generally represent trivia and are not part of the normal language syntax. We cleaned the docstrings by removing non-ASCII characters, normalizing Unicode, and replacing commit hashes, file paths, and URLs with placeholder tokens. In all studies here, we randomly split the files at the repository level (to prevent data leakage) with 90% for training, 5% for validation, and 5% for a test set.

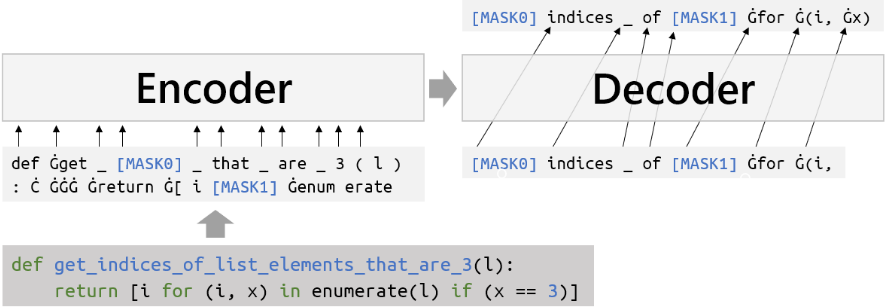
2.2 Pre-training

The majority of our PYTHON methods—over 20 million methods— do not possess docstrings. This imbalance is, in fact, an opportunity in light of the recent trend for NLP: unsupervised pre-training of language models on vast amounts of raw text (Devlin et al., 2018). Using these pre-trained models as starting points for downstream tasks—like classification, translation, summarization, and question answering—consistently yields state-of-the-art results (Lewis et al., 2019; Raffel et al., 2019).

Following this trend, we use a similar span-masking objective used by the recent text-to-text transfer transformer (T5) (Raffel et al., 2019). As shown in Figure 3, after tokenizing the inputs, we sample a random subset of the token spans up to length 3 to be replaced with, e.g. a `[MASK0]` token, and then teach the sequence-to-sequence model to replace the missing tokens. The training target is com-

Dataset	Methods	w/ docstring	Languages
PyMT5	2.6×10^7	7.7×10^6	Python
CSN (Husain et al., 2019)	6.4×10^6	2.3×10^6	Python, et al.
Ciurumelea et al. (2020)	1.6×10^5	1.6×10^5	Python
Barone and Sennrich (2017)	1.6×10^5	1.5×10^5	Python

Table 1: Summary statistics of our Python parallel corpus compared to others presented in the literature. CSN contains 500k Python methods with docstrings, among 6 other languages. Our parallel corpus is 3× as large as the next largest, and over 15× the size of the next largest Python parallel corpus.



```
def get_indices_of_list_elements_that_are_3(l):
    return [i for (i, x) in enumerate(l) if (x == 3)]
```

Figure 3: Denoising auto-encoder pre-training for sequence-to-sequence tasks, based on the span-masking objective used by the T5 (Raffel et al., 2019). Python files are first tokenized with spaces replaced by the character Ġ, which is 256 in ordinal above the space character (similarly for newlines, tabs, etc.). Note that indentation is a token of multiple Ġ's. We replace random sub-sequences of tokens with numbered masks, and train the model to return each mask followed by the tokens it replaced.

prised of numbered mask tokens followed by the tokens that mask represents.

The architecture of PyMT5 is an encode-decoder transformer with a vocabulary of 50181 (byte-pair BPE encoder trained on raw python files), 6 self-attention encoder/decoder layers in each encoder layers, and a hidden dimension of 1472, totaling 374 million parameters. All the experiments in this paper, including GPT2 were done using this same extended GPT tokenizer. We pre-trained PyMT5 on 27GB of raw source code in total, for 3 weeks on sixteen 32GB Tesla V100 GPUs, or 73 epochs total. When training on docstring generation alone, we observed 25× faster convergence to a lower loss when starting with this pre-trained model as compared to a random initialization. See the appendix for details. In all experiments PyMT5 is trained starting with this pre-trained model.

2.3 Docstring analysis

When examining docstring samples from our corpus, one of the most salient features is the different styles of documentation. The Python community has no prescribed or de facto style for docstrings, but Python enhancement protocol 257 (Goodger and van Rossum, 2001) does describe one-line and multi-line docstrings, and mandates indentation as well. Most modern large-scale projects utilize docstring styles which are parseable, allowing the automatic creation and synchronization of source code and documentation websites, see, e.g. `sphinx`. Therefore, a number of standard styles have evolved in the community.

The currently dominant parseable docstring styles (and the ones supported by `sphinx`) are ReStructuredText (reST) (Jones, 2013), the official Google style (Google, 2020), Numpy style (also technically satisfies reST) (Maintainers, 2020), and javadoc style (jav, 2011). The difference between each style is mainly in the syntax of denoting sections (if they exist) and the name/type/description annotation of the method arguments and returned/yielded quantities (if they exist). We defined, in addition to these styles, one-line (containing only one line), one-paragraph (containing no empty lines), and 'other' to label any docstring not described so far, which includes informal user docstring styles and a few project-specific styles like the SAGE mathematics toolkit library.

Table 2 shows the breakdown of the fraction of each of these styles in our corpus. The plurality of docstrings (44%) are one-line. The next most common style is one-paragraph at 14%. The next four most-common styles are the machine parseable styles discussed above, comprising 26.2% of the total number of docstrings. The appendix contains detailed distributions of method signature, docstring, and method body character and line lengths.

Style	Fraction of methods
One line	44%
One paragraph	14%
reST	13%
Google	7.3%
Numpy	4.8%
Javadoc	1.6%
Other	15%

Table 2: Docstring style statistics from 7.7 million Pythondocstrings.

To visualize the space of these styles, we used FastText vector embeddings of the docstrings, obtaining 100-dimension continuous vector representations of each. We then used PCA to reduce the dimensionality to 50 and applied the t-distributed stochastic neighbor embedding (t-SNE) to obtain a two-dimensional visualization. Figure 4 shows 1/10th of our corpus (700k docstrings) embedded, colored by docstring style as defined above. We can see clear clustering of styles, indicating that similar docstrings use the same style (for the parseable styles). There is also a natural dichotomy between parseable and non-parseable styles: the left side is dominated by 'one line,' 'one paragraph,' and 'other' styles, and the four parseable styles are largely on the right side. This observation can be used to generate documentation consistent with the style of a given project, or it could be used to translate methods into more informal descriptions useful for search indices.

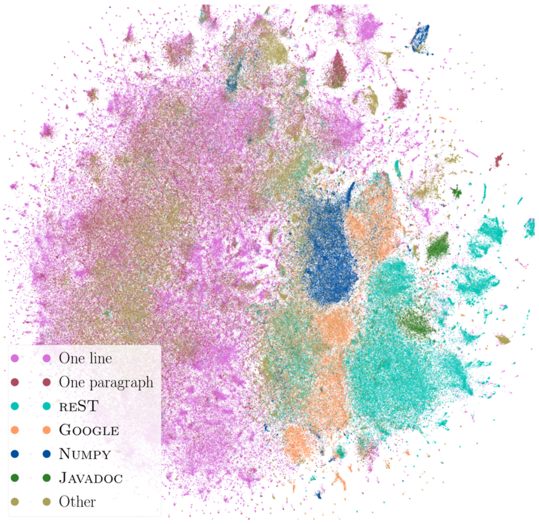


Figure 4: Visualization of continuous embeddings of 1/10th of our docstring corpus (770k docstrings), colored by docstring style. Embeddings were obtained using FastText, and the two-dimensional embedding was obtained via PCA (for dimensionality reduction and initialization) and t-SNE.

Table 3: Comparing 3 models–GPT2 with a random weight initialization, GPT2 pre-trained on English, and PyMT5–on the task of method generation from a signature and natural language docstring. The first three rows use our test set consisting of 1,285,794 methods. The fourth and fifth rows compare the performance of PyMT5 and GPT2-medium on the CodeSearchNet Python test set. The final rows compare the performance of PyMT5 on the parallel corpus test set of Barone and Sennrich (2017). Syntax is the fraction of predicted methods which had correct syntax using the Python 3.7 grammar.

3 Method generation

Now we turn our attention to method generation: predicting a whole method code body from either a method signature, a natural language docstring, or both. We first discuss a benchmark of this task using a GPT2-medium model (345 million parameters, see the appendix for details), training from scratch and starting with the publicly released OpenAI English pre-trained checkpoint with weights from HuggingFace(Wolf et al., 2019). In all experiments we used an extended GPT2 tokenizer—including white-space (one tab, two tabs, etc.) tokens—for a total vocabulary size of 50337, and we used beam decoding with a beam width of 5.

The third row of tab. 3 shows PyMT5 has more than double the BLEU score, overall better recall, and significantly better ROUGE-2 and ROUGE-L F-scores than our GPT2 baselines. Further, 93.6% of the methods generated by PyMT5 were syntactically correct Python 3.7, whereas only 86% of GPT2 methods were syntactically correct. PyMT5 was trained on 16 Tesla V100 16GB GPUs for 62 epochs, or 5 weeks training time (see the appendix for its hyper-parameters) and the GPT2 baselines were trained on the same hardware for 1 week training time (achieving the same or better validation loss/perplexity as PyMT5).

The English pre-trained initialization of GPT2 only slightly beats the random initialization of GPT2, which could indicate that the learned biases of English are not particularly beneficial for writing Python code; the metrics are almost all within our margin of error. Note that Barone and Sennrich (2017) also modeled methods from docstrings, obtaining a similar BLEU score of 10.9 on their own Python parallel corpus. On the Barone et al. test set, PyMT5 obtains nearly double these scores at 20.2; such a large discrepancy could be explained by data leaking from their test set

Table 4: Comparing 3 models–GPT2 with a random weight initialization, GPT2 pre-trained on English, and PyMT5–on the task of natural language docstring generation from a signature and method body. The first three rows are evaluated on our test set of 383695 methods. The fourth and fifth rows shows performance of PyMT5 and GPT2-medium on the CSN Python test set, and the last two rows compare our model to Barone et al. on their test set.

into our training set. Barone's test set is also 200× smaller than ours and may not be a representative sample of the whole Python code domain.

The third and fourth rows of tab. 3 show the performance of PyMT5 using the publicly available CSN Python test set, from which we find notably worse results than on our own test set. CSN curated their whole set by removing any methods with 'test' in the name and any methods with fewer than 3 lines of code. We calculated the performance of PyMT5 only on a subset of our test set curated the same way as CSN, observing F-scores for R1, R2, and R-L on our test set of 29.7, 17.2, and 26.1, which is lower than our nominal test set performance of 35.1, 21.5, and 32.2 and closer to the CSN performance of 28.4, 13.5, and 24.8. We believe this curating choice explains the difference between our test set and the CSN test set. We also conclude that tests and short methods are 'easier' to complete, which is plausible, and bodes well for automatic code completion applications.

4 Docstring Generation

We now examine results from the docstring generation task, which for evaluation purposes were conditioned on both signatures and method bodies. As in method generation, we set a GPT2 benchmark with random initialization and pre-trained English initialization as well as the same hyperparameters. Table 4 shows that the ROUGE scores of the GPT2 baselines are within the margin of error; a somewhat surprising result given the English domain of docstrings. The third row shows PyMT5 to be superior to GPT2-medium in terms of BLEU and all of the ROUGE metrics.

We again present the results from the publicly available CSN test set. Similar to the method generation task, PyMT5 performs worse on the CSN data than our own, likely for the same reasons we discussed in sec. 3. We also evaluated PyMT5 on the Barone et al. parallel test set, as shown in the second to last row of tab. 4, and find PyMT5 performs notably worse on Barone's test set than our own test set, contradicting the hypothesis that our doubling of the method generation BLEU score is due to data leakage. PyMT5 has a much higher BLEU score than that reported by Barone et al, perhaps indicating real progress in the code summarization field.

Docstring generation is similar to code summarization, though the domains are different as docstrings also contain structured annotations of arguments, return values, raised exceptions, and even in-line unit tests (`doctest`). TranS^3 by Wang et al. (Wang et al., 2020) reports a best ROUGE-L of 51.27 on the same test set for code summarization, but does not specify which statistic they are reporting, so we cannot make strong conclusions about the performance of PYMT5 compared to the state of the art.

5 Conclusion

In this work, we presented a novel multi-mode PYTHON method text-to-text transfer transformer model PYMT5as well as the largest parallel corpus of PYTHON source code and docstrings reported in the literature to date. We have trained PYMT5 to translate between all pairs of combinations of method signatures, docstrings, and method bodies which do not have the same feature in both the source and target. Further, we introduced control token prefixes for docstring generation to facilitate docstring generation of various styles. Focusing on two modeling tasks – predicting PYTHON methods from docstrings and summarizing PYTHON source code methods into docstrings of various commonly occurring styles – we have compared this new approach to the auto-regressive GPT2 baselines trained on individual docstring or method generation tasks. On the CODESEARCHNET test set PYMT5 achieves a BLEU score of 8.59 for method generation and 16.3 for docstring generation, and a ROUGE-L F-score of 24.8 for method generation and 36.7 for docstring generation. We have demonstrated the effectiveness of dynamic masked pre-training, reducing docstring generation training time by 25×. Looking forward, we plan to leverage PYMT5 for various downstream automated software engineering tasks—including code documentation and method generation from natural language statements—and develop more model evaluation criteria to leverage the unique properties of source codes.

A Appendix

A.1 Docstring statistics

Figure 5 shows the distributions of various features of docstrings in our corpus. The top row is the distribution of total character-level length of the method signatures (left), docstrings (center), and code bodies. The blue lines are for methods possessing a docstring, and we can see that the vast majority of these methods have docstrings with more than 10 characters. The bottom row shows the distribution of line lengths of the concomitant features from the top row. While the most common line length of docstrings is 1 (comprising 41%), the vast majority of docstrings have multiple lines.

A.2 Pre-training details

Figure 7 is the complete training script, using the Facebook AI Research Sequence (FAIRSEQ) modeling library, with which we pre-trained PYMT5. The data was pre-noised and processed using the `fairseq-preprocess` command, and placed in the directory indicated by `$DIR`. The architecture and training hyper-parameters are set in this script. PYMT5 was trained with the same hyperparameters, but with data described in sec.A.4.

Figure 7 shows learning curves of a single seq2seq model of the same architecture as PYMT5 trained only on docstrings, starting from random initializations, and starting from our pre-trained model. As the figure shows, the

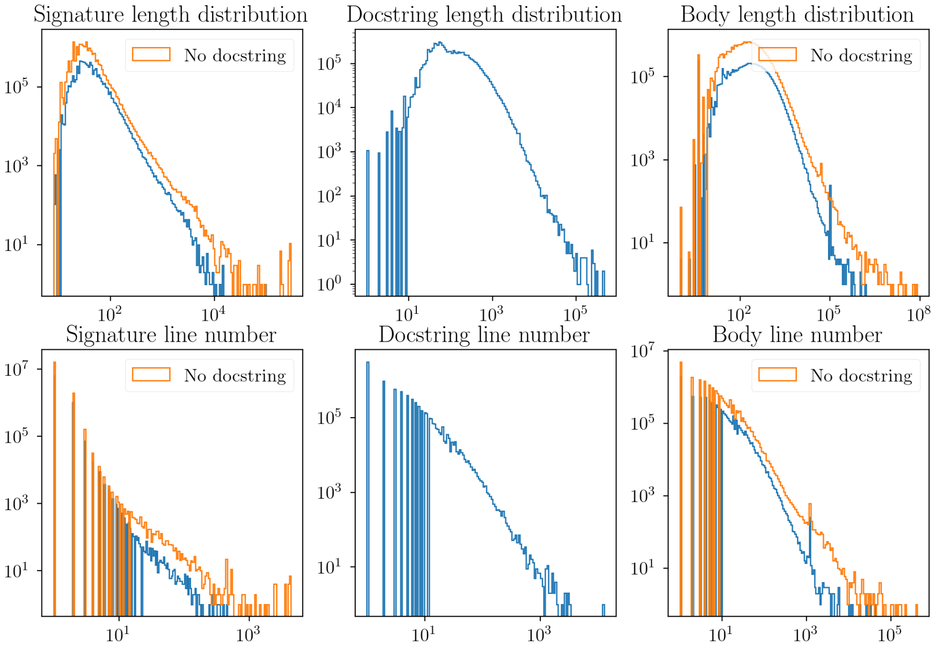

Figure 5: Histogram of the number of characters (top row) in the PYTHON signatures (left), docstrings (middle), and method body (right). The blue lines are for methods with docstrings, the yellow lines are for methods without docstrings. The vast majority of docstrings have more than 10 characters. The bottom row shows histograms of the number of lines for the same features described in the top row.

pre-trained initialization converged to a better validation loss 25× faster than the randomly initialized model.

A.3 GPT2 training details

Our GPT2 experiments also used the FAIRSEQ library, with the OpenAI English checkpoint supplied by the HuggingFace library. Figure 8 shows the complete training script, where for the English pre-trained initialization a pre-trained checkpoint was provided. Each models was trained on 4 Tesla V100 GPUs with 16GB of memory each, for 7 days.

A.4 Multi-mode training details

In order to better teach PYMT5 to understand the relationships between all the different features of code (signatures, docstrings, and bodies) we taught it to translate between

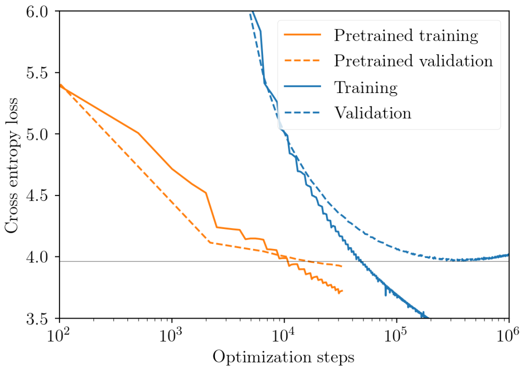

Figure 6: Learning curves for training a sequence-to-sequence transformer, translating from python method definitions to their docstrings. Blue curves represent the training and validation loss, and show that convergence (validation loss stops decreasing) occurs after 3.97×10^5 steps or 183 epochs. The optimization of the pre-trained model with identical hyperparameters reaches and beats the best validation loss at 1.5×10^4 steps or 7 epochs.

Figure 7: The `fairseq-train` script used to pre-train PyMT5, setting all the relevant hyper-parameters.

Figure 8: The `fairseq-train` script we used to train our GPT model baselines

all pairs of combinations of these features which do not contain the same feature in both the source and target. In this way, the model can learn to produce method bodies using both signatures and docstrings, or one or the other. Table 5 spells out exactly which combinations were provided to the model as a source and target. For each source example the comment string '`# target <feature> (<style>)`' was added, instructing the model which feature combination (e.g. signature and body). Only if a docstring was in the target, a style imperative was added, where the styles are defined and discussed in the main text.

Figure 9 shows the training curves for PyMT5, where the solid black line is the training loss, and all the other curves are the validation loss for each of the tasks indicated in tab. 5. The dashed lines indicate tasks where docstrings are present in the target, showing that these are generally less predictable than code-only targets (as the validation loss is larger). PyMT5was trained on 16 Tesla V100 16GB GPUs for 62 epochs, or 5 weeks training time.

		Sources					
		Signature	Docstring	Body	Sig + doc	Sig + body	Doc + body
Targets	Signature		✓	✓			✓
	Docstring	✓		✓		✓	
	Body	✓	✓		✓		
	Sig + doc			✓			
	Sig + body		✓				
	Doc + body	✓					

Table 5: A table of all possible translation possibilities between the 3 features of a function: the signature (sig), docstring (doc), and body. We train our model to translate between sources and targets indicated with a ✓, which were chosen as all pairs of feature combinations which do not contain the same feature in both the source and target. The system is then instructed to target code bodies when performing function completion.

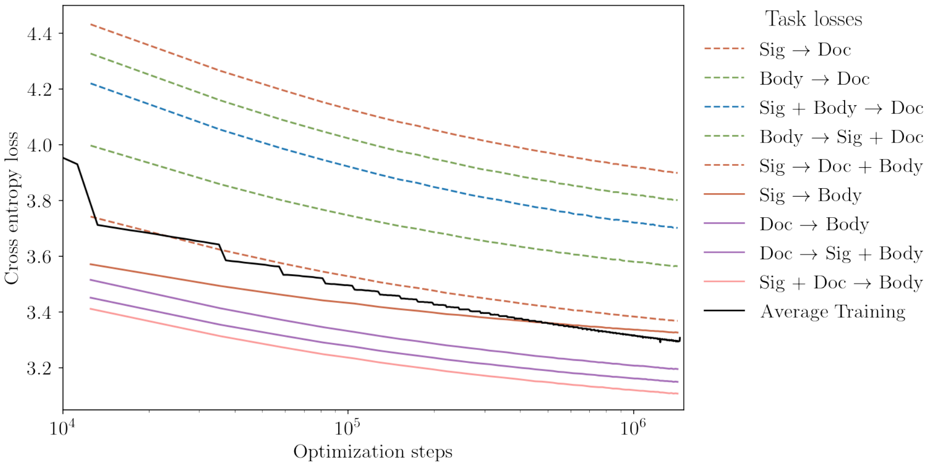

Figure 9: Learning curve for the multi-mode training, where the black line is the training loss, and the other lines are the validation loss for each mode of translation. Dashed lines indicate the docstrings are in the target, solid lines have only code in the target.

PathQG: Neural Question Generation from Facts

Abstract

Existing research for question generation encodes the input text as a sequence of tokens without explicitly modeling fact information. These models tend to generate irrelevant and uninformative questions. In this paper, we explore to incorporate facts in the text for question generation in a comprehensive way. We present a novel task of question generation given a query path in the knowledge graph constructed from the input text. We divide the task into two steps, namely, query representation learning and query-based question generation. We formulate query representation learning as a sequence labeling problem for identifying the involved facts to form a query and employ an RNN-based generator for question generation. We first train the two modules jointly in an end-to-end fashion, and further enforce the interaction between these two modules in a variational framework. We construct the experimental datasets on top of SQuAD and results show that our model outperforms other state-of-the-art approaches, and the performance margin is larger when target questions are complex. Human evaluation also proves that our model is able to generate relevant and informative questions.[1]

1 Introduction

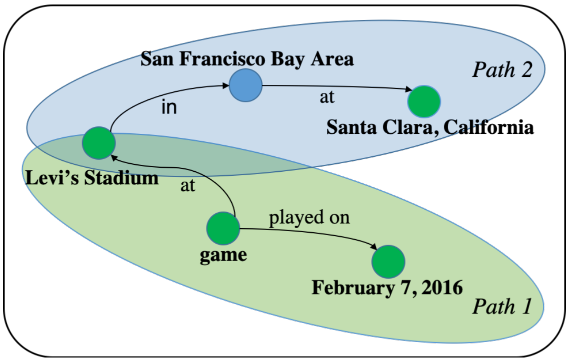
Question Generation (QG) from text aims to automatically construct questions from textual input (Heilman and Smith, 2010). It receives increasing attentions from research communities recently, due to its broad applications in scenarios of dialogue system and educational reading comprehension (Piwek et al., 2007; Duan et al., 2017). It can also help to augment the question set to enhance the performance of question answering systems.

Sentence:
The game was played on February 7, 2016, at Levi's Stadium in the San Francisco Bay Area at Santa Clara, California.

Generated questions:
- Q1: On what date was the game played ?
- Q2: Where was the Everton Fc Stadium located?

Ground truth questions:
- GTQ1: When was the game at Levi's Stadium played?
- GTQ2: Which state is the Levi's Stadium in?

(a) Machine generated questions (Qs) for an input text together with human generated ones (GTQs). Phrases underlined are the answers to ground-truth questions.



(b) Knowledge graph constructed based on the input text shown in top sub-figure. Two colored ellipsoid are two query paths related to two ground truth questions in sub-figure (a) respectively. Nodes in green are covered by ground-truth questions.

Figure 1: A sample paragraph from SQuAD with machine generated questions (Zhou et al., 2017) (a), ground truth questions (a) and corresponding knowledge graph (b).

Current QG systems mainly follow the sequence-to-sequence structure with an encoder for modeling the textual input and a decoder for text generation (Du et al., 2017). These neural-based models have shown promising performance, however, they suffer from generating irrelevant and uninformative questions. Figure 1a presents two sample questions generated by a nueral QG model. *Q2* contains irrelevant information "Everton Fc". Although *Q1* is correct, it is a safe play without mentioning any

specific information in the input text. One possible reason causing the problem is that current sequence-to-sequence models learn a latent representation for the input text without explicitly modeling semantic information included. We therefore argue that modeling facts in the input text can help to alleviate the problem of existing neural QG models.

Some researchers explore to incorporate the answer entity (Zhou et al., 2017) or a so called *question worthy phrase* (Wang et al., 2019) as the fact to guide the generation of target question and make some progresses. However, a complex question usually involves multiple facts. Therefore, a single word piece or phrase is not able to provide enough information for the generation. In this paper, we propose to represent facts in the input text as a knowledge graph (KG) and present a novel task of generating a question given a *query path* from the KG. More specifically, a KG contains a set of fact triples, and a *query path* is an ordered sequence of triples in the KG. A fact triple consists of two entities and their relationship.

Figure 1b shows the KG of the input text in Figure 1a and it includes two query paths. We can see that not all facts in a query path are mentioned in a specific target question (see Path 2 and GTQ2). Therefore, the model needs to extract the involved facts to form a query before it generates a question. Intuitively, we divide the task of question generation from a query path into two steps, namely, query representation learning and query-based question generation. We formulate the former step as a sequence labeling problem for identifying the involved facts to form a query. For query-based question generation, an RNN-based generator is used to generate the question word by word. We first train the two modules jointly in an end-to-end fashion (*PathQG* in Section 3). In order to further enforce the interaction between theses two modules, we employ a variational framework to train the two modules (Chen et al., 2018; Zhang et al., 2018) that treats query representation learning as an inference process from the query path taking the generated question as the target (*PathQG-V* in Section 4).

For model evaluation, we build the experimental environment on top of the benchmark dataset SQuAD (Rajpurkar et al., 2016). In specific, we automatically construct the KG for each piece of input text, and pair ground-truth questions with corresponding query paths from the KG. Experimental results show that our generation model outperforms other state-of-the-art QG models, especially when the questions are more complicated. Human evaluation also proves the effectiveness of our model in terms of both relevance and informativeness.

2 Task Definition

We first introduce some notations in our task:

- $x = (x_1, ..., x_n)$: an input text with n tokens, where x_i is the ith token;
- $\mathcal{G}$: a knowledge graph constructed from x, which is a set of fact triples $\{(e_1, r, e_2), ...\}$, where e_i is an entity and r_i is the relation between e_i and e_{i+1};
- $s = (e_1, r_1, e_2, ..., e_m)$: a query path in the knowledge graph, which is an ordered sequence of triples, and it's a subset of the $\mathcal{G}$;
- $y = (y_1, ..., y_{|y|})$: the generated question based on the x and s, where y_i is a token.

The task is described as following: given an input text x and its corresponding knowledge graph $\mathcal{G}$, our model aims to generate a question y_i based on a query path s_i from $\mathcal{G}$.

3 Path-based Question Generation

We divide the task of question generation from a given query path into two steps, namely, query representation learning and query-based question generation. A *Query Representation Learner* and a *Query-based Question Generator* are designed for the two steps separately. We directly combine these two modules into a unified framework *PathQG* and the overall architecture is illustrated in Figure 2.

3.1 Query Representation Learner

Query (representation) learner takes a query path s as input and learn the query representation L. Considering entities and relations in a query path have different contributions to generate the target question, we calculate their contribution weights for query representation learning.

3.1.1 Contribution Weight Calculation

We treat the task of contribution weight calculation as a sequence labeling task on the query path $s = (e_1, r_1, e_2, r_2, ..., e_m)$ taking entities and relations as tokens.

Context Encoding Considering the input text x can be useful to identify the weights of components in the path, we first encode the input text via a

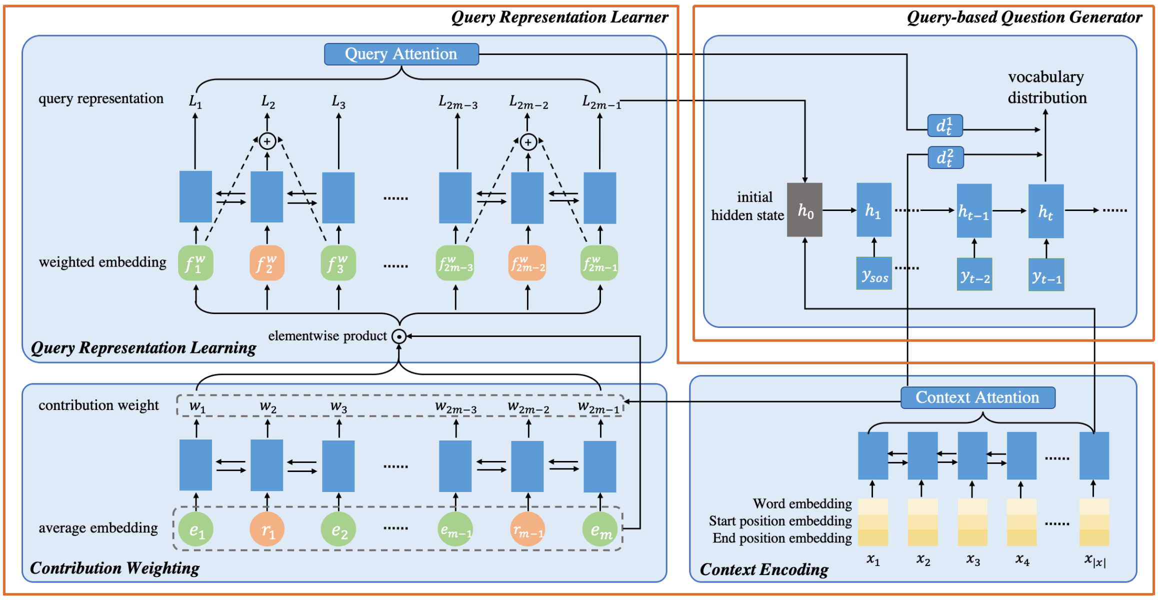

Figure 2: The overall architecture of *PathQG*.

context encoder. Following (Zhou et al., 2017), we use additional entity information (e.g., start, end entity of the query path) to improve the encoding of x. We use two BIO tags $b^a = (b_1^a, ..., b_n^a)$ and $b^e = (b_1^e, ..., b_n^e)$ to mark the positions of start and end entities in x. Then we concatenate the embeddings of x and two BIO tags as the input of the context encoder and use a bi-directional LSTM (Huang et al., 2015) to get the context states h_i^c as Eq. 1, where E_w and E_b are word embedding and tag embedding matrix respectively.

$$h_i^c = \text{BiLSTM}([E_w x_i;\ E_b b_i^a;\ E_b b_i^e], h_{i-1}^c) \quad (1)$$

Contribution Weighting Since each entity or relation in the path is also a sequence of tokens, we take the average pooling of their word embeddings as input $f_i = \text{average}(E_w s_i)$ where

$$s_i = \begin{cases} e_{(i+1)/2} & i \bmod 2 = 1 \\ r_{i/2} & i \bmod 2 = 0 \end{cases} \quad (2)$$

The encoding process of the path sequence labeling is as $h_i^s = \text{BiLSTM}(f_i, h_{i-1}^s)$. And the encoding state h_i^s at each step i will attend to h^c and the attention output is computed as c_i. Then c_i will be concatenated with hidden state h_i^s to calculate the sigmoid probability of i_{th} component s_i in path as its contribution weight w_i where

$$w_i = P_{\theta_1}(s_i|x, s) = \sigma(\text{FFN}_2([h_i^s; c_i])) \quad (3)$$

where $\sigma(\cdot)$ is the sigmoid activation function and FFN_l is a l-layers feed-forward network.

3.1.2 Query Representation Learning

With the contribution weights of entities and their relations as $w = (w_1, w_2, ..., w_{2m-1})$, we encode the query path s in a weighted manner to learn the query representation. First we also utilize the average embeddings of entities and relations to compose the whole weighted query path as Eq. 4.

$$f^w = (w_1 \cdot f_1,\ w_2 \cdot f_2,\ ..., w_{2m-1} \cdot f_{2m-1}) \quad (4)$$

Considering a path has two different types of elements: entity and relation appearing in an alternating order, and the basic structural units constituting a path are triples, an RNN encoder is not able to capture these special structural information. Thus we adopt the recurrent skipping network (RSN) (Guo et al., 2019) instead of BiLSTM to encode the weighted path sequence and form a query representation as Eq. 5, 6,

$$\begin{aligned} \overrightarrow{h_i^L} &= \overrightarrow{\text{LSTM}}(f_i^w, \overrightarrow{h_{i-1}^L}) \\ \overleftarrow{h_i^L} &= \overleftarrow{\text{LSTM}}(f_i^w, \overleftarrow{h_{i+1}^L}),\ f_i^w \in f^w \end{aligned} \quad (5)$$

$$L_i = \begin{cases} [\overrightarrow{h_i^L}; \overleftarrow{h_i^L}] & i \bmod 2 = 1 \\ \text{FFN}_1([\overrightarrow{h_i^L}; f_{i-1}^w; \overleftarrow{h_i^L}; f_{i+1}^w]) & i \bmod 2 = 0 \end{cases} \quad (6)$$

where $L = (L_1, ..., L_{2m-1})$ is the learned query representation.

3.2 Query-based Question Generator

Taking the query representation L as input, we generate the corresponding question. Following the sequence-to-sequence paradigm of NQG model (Du et al., 2017), we take the concatenation of final query representation L_{2m-1} and final hidden state h^c_n of the input text from Eq. 1 as the initial state of the decoder and generate the question word by word. For the decoder, a LSTM is applied with attention mechanism and both sentence context and learned query L are utilized in the attention module.

The decoder attends to the learned query $L = (L_1, ..., L_{2m-1})$ and gets an attention-based query representation d^1_t. Besides, it also attends to the textual context states $h^c = (h^c_1, ..., h^c_n)$ and computes an attended context d^2_t. The h_t, d^1_t and d^2_t are concatenated to calculate the softmax probability distribution over the whole vocabulary,

$$P(y_t|y_{<t}, L, x) = \text{softmax}(\text{FFN}_2([h_t; d^1_t; d^2_t])) \tag{7}$$

where the y_t is the prediction at time t, and the generated question is $y = (y_1, ..., y_{|y|})$.

4 Variational Path-based Question Generation

The query representation learning can be treated as an inference process from the query path with the input text as the condition. Motivated by the variational models for KG reasoning, we propose a variational inference model *PathQG-V* to train the query learner and question generator to further enforce the interaction between them. Additionally, it introduces a posterior query learner to infer a posterior query distribution assuming the target question provided.

Compared with the original objective of *PathQG* as Eq. 8, the variational model aims to minimize its negative evidence lower bound (ELBO) as Eq. 9,

$$\log P(y|x, s) = \log \sum_L P_{\theta_1}(L|x, s) P_{\theta_2}(y|L, x) \tag{8}$$

$$\begin{aligned} -ELBO = KL(&P_{\theta_3}(L|y, x, s)||P_{\theta_1}(L|x, s)) \\ &- E_{P_{\theta_3}(L|y,x,s)}[\log P_{\theta_2}(y|L, x)] \end{aligned} \tag{9}$$

where $P_{\theta_1}(L|x, s)$, $P_{\theta_3}(L|y, x, s)$ and $P_{\theta_2}(y|L, x)$ are prior and posterior query distribution, and the likelihood of question y respectively. The structure of the variational model *PathQG-V* is shown in Figure 3. Note that the *prior query learner* and the *query-based question generator* are the same with query learner and question generator in Section 3.

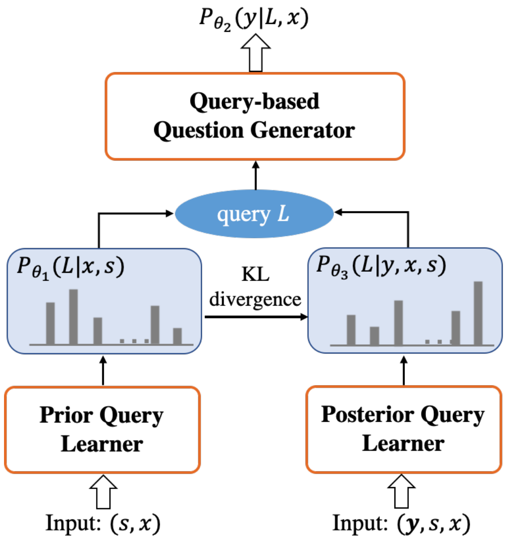

Figure 3: Overview of the *PathQG-V* model. x, s and y are the input text, query path and the question respectively.

4.1 Posterior Query Learner

The posterior query learner is designed in a similar manner as the query learner in Section 3.1, except that the target question is given. We incorporate the target question y in the same way as the input text x, where we employ a BiLSTM to encode the question y and get their hidden states $h^q = (h^q_1, ..., h^q_t)$. In the decoder of contribution weighting process, those question states are attended as same as context states h^c and get the attention output q_i at each step i. Then q_i together with c_i are concatenated with the encoding hidden state h^s_i to compute the posterior contribution weight of i_{th} component s_i in path as

$$w'_i = P_{\theta_3}(s_i|y, x, s) = \sigma(\text{FFN}_2([h^s_i; c_i; q_i])) \tag{10}$$

Then following Eq. 4, 5, 6, the posterior query representation $L' = (L'_1, ..., L'_{2m-1})$ can be learned.

4.2 Optimization and Inference

During training period the posterior learned query representation L' is fed to the question generator, and the objective is to minimize the negative ELBO as Eq. 9. And the first term of negative ELBO can be viewed as Eq. 11:

$$\begin{aligned} \mathcal{L}_1 = KL(&P_{\theta_3}((s_1, ..s_{2m-1})|y, x, s)|| \\ &P_{\theta_1}((s_1, ..s_{2m-1})|x, s)) \end{aligned} \tag{11}$$

Then the $P_{\theta_2}(y|L,x)$ is the generation probability of question y and the log-likelihood can be rewritten as Eq. 12. We use the weighted path to form a query representation instead of sampling from the query distribution, therefore the second term of negative ELBO can be formulated as Eq. 13 where the expectation over posterior distribution $E_{P_{\theta_3}(L|y,x,s)}[\cdot]$ is omitted.

$$\log P_{\theta_2}(y|L,x) = \sum_{t=1}^{|y|} \log P_{\theta_2}(y_t|y_{<t},L,x) \tag{12}$$

$$\mathcal{L}_2 = -\log P_{\theta_2}(y|L,x,s) \tag{13}$$

To ensure the performance of query representation learner, we also add a contribution weighting loss defined as Eq. 14:

$$\mathcal{L}_3 = -\log P_{\theta_1}(L|x,s) \tag{14}$$

We combine all losses in a weighted manner as $\mathcal{L} = \lambda\mathcal{L}_1 + \mathcal{L}_2 + \beta\mathcal{L}_3$ to jointly train the framework, where λ and β are weighted hyper-parameters.

For the inference, only the prior query learner and the question generator are involved. The process is the same as PathQG.

5 Experiments

5.1 Experimental Dataset

Our experiments are conducted on SQuAD (Rajpurkar et al., 2016) consisting of 61,623 sentences. Each sentence is annotated with several questions together with their answers extracted from the input text. We build our experimental dataset on top of SQuAD. We construct knowledge graph for each sentence automatically and identify query paths for ground truth questions for evaluation. The resulted dataset consists of 89,976 tuples (input sentence x, query path s, ground truth question y).

KG construction We employ the scene graph parser (Schuster et al., 2015) for KG construction from a textual description. It identifies entities and their relationships from a text and build a scene graph. It turns out that the generated scene graph usually misses some key information in the text, thus we employ the part-of-speech tagger to extract verb phrases between entities to further enrich relationship labels. The extended scene graph is used as the knowledge graph for the input text. The average quantities of entities and facts in each KG are 6.53 and 4.68 respectively. The average information coverage rate of the input text by constructed KG is 68.52%. Note that our question generation models are compatible with KGs constructed by other methods.

Complex question set construction Our setting is motivated by the scenario where questions are related to multiple facts. We are then curious about the effectiveness of our model for complex question generation. Therefore we further construct a complex question set. A question is treated as complex if the corresponding query path contains more than 3 triples. The resulted complex question set contains 16,578 samples[2]. The detailed statistics of *complex* and *whole* datatset can be seen in Table 1. The datasets are split following Du et al. (2017).

dataset	train	valid	test	len. of ques.
complex	12,828	1,895	1,855	14.7
whole	68,704	10,313	10,959	13.3

Table 1: Statistics of complex and whole datasets. *len. of ques.* is the average number of tokens in questions.

Query path and question pairing We then identify corresponding query paths from the KG for ground truth questions. In practice, a path can be determined by a start node and an end node. We thus use answer entity of the question as the start node and use the entity identified in the question as the end node. If the question contains multiple entities, we take the one farthest to the start node in the KG as the end node. We ignore the edge directions to simplify the modeling of query path.

5.2 Implementation Details

We construct different vocabularies for input texts and questions respectively by keeping words which appear more than twice. Glove (Pennington et al., 2014) is used to initialize word embedding with dimension 300 and the embedding for BIO tag is randomly initialized of size 20. The size of hidden units in LSTM cell in all encoders is 300 while the size of the generation decoder is 1200. The hyper-parameters to balance weights of losses are chosen as $\lambda = 0.5$ and $\beta = 0.1$. We evaluate our model on validation set to choose parameters. During test

process, we use beam search of beam size 5. Refer to Appendices A for further information of training details and parameter numbers.

5.3 Models for Comparison

We compare our approach with some state-of-the-art models. For fair comparison, the start and the end nodes of the query path are provided for all models.

- **NQG$_+$** follows Zhou et al. (2017), which is an attention-based encoder-decoder model with the sentence as input and uses BIO tagging scheme to incorporate additional entity information (start and end nodes) to generate questions.
- **AFPA** (Sun et al., 2018) combines answer-focused model and position-aware model for question generation. For fair comparison, the model is re-trained with rich features including NE and POS removed and end entity provided.
- **ASs2s** (Kim et al., 2019) utilizes additional answer information via answer separation. For fair comparison, we do not implement the retrieval style word generator and the model is re-trained in our setting with the end entity supplied.
- **NQG$_+$(pl)** is an extension of **NQG$_+$**. Instead of learning a continuous latent query L, we sample entities and relations from the path via sequence labeling. Together with the start and end entities, those identified extra information are all encoded using BIO scheme for question generation.
- **PathQG** is our proposed generation framework consisting of a query representation learner and a query-based question generator. **PathQG-V** is the variational version of **PathQG** with an additional posterior query learner.
- **NQG$_{++}$** is an oracle model that is aware of all path information contained in the target question and encode them via BIO scheme. It can be treated as the upper bound of **NQG$_+$(pl)**. We present this result for reference.

5.4 Automatic Evaluation Results

For the automatic evaluation, we utlize some widely adopted metrics including BLEU 1-4 (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and ROUGE$_L$ (Lin and Hovy, 2003). Besides, we also compare results in the semantic content level by using a metric named SPICE (Anderson et al., 2016). It evaluates the similarity of scene graphs generated from candidate and reference questions. Evaluation results on both *whole* and *complex* datasets are shown in the Table 2 and 3. We have several findings:

- **PathQG-V** outperforms other models in terms of all metrics on both datasets by a considerable margin. This indicates the effectiveness of our variational inference framework for modeling the query path for better question generation.

- **PathQG** identifying involved entities and relations along the path performs better than **NQG$_+$**, **AFPA** and **ASs2s**, which demonstrates the effectiveness of introducing more related facts for question generation. And the improvement of **PathQG** compared to **NQG$_+$(pl)** shows the necessity of joint training.
- Our model generates larger improvement on the *complex* dataset compared to the *whole* dataset. This follows our intuition that questions related to longer query path are more complicated and our model has more advantage on these cases. Using length of query path to control the difficulty of questions is also a novel design (Gao et al., 2018).
- **NQG$_+$**, **AFPA** and **ASs2s** utilize answer for QG in different ways and our model **PathQG-V** follows the way of **NQG$_+$** for simplicity. From the improvement of **AFPA** and **ASs2s** compared to **NQG$_+$**, our model can further be adapted to follow them and performs better.
- Although good performance is achieved by **PathQG-V**, there is still a certain gap between it and the oracle model **NQG$_{++}$**. It shows the query learning from the path still has potential to be improved.

5.5 Human Evaluation Results

To better evaluate the quality of the generated questions, we conduct human evaluation through Amazon Mechanical Turk (AMT). We randomly choose 100 instances and 3 crowd annotators are invited to compare the questions generated by **PathQG-V** with **NQG$_+$**, **AFPA** and **ASs2s** in pair-wise . For each instance, the annotators are asked to read the text with the answer, and compare two candidate questions to determine which one is better in terms of three aspects respectively. (1) Fluency: the question is fluent. (2) Correctness: the question is consistent to the text and the answer. (3) Informativeness: the question contains specific information of the input text. The comparison results are shown in Figure 4. We can see that our model outperforms others in terms of all characteristics. This further proves that our model can generate more informative and consistent questions.

5.6 Further Analysis

In order to evaluate whether our model can utilize the facts in the input text to generate questions with less irrelevant information. We analyse the relevance of the generated question to the text. We also demonstrate case studies.

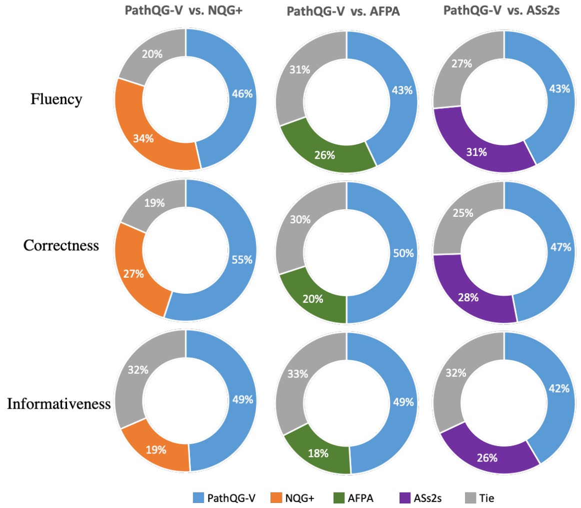

Figure 4: Pairwise comparison between the questions generated by **PathQG-V** and other methods in three characteristics. Each color is the percentage of annotators who consider the question generated by the corresponding method is better. "Tie" represents hard to tell.

Relevance of generated questions We evaluate the relevance of the generated questions to the input texts from different models by computing the overlapping rate. The results are presented in Figure 5. On both datasets, **PathQG-V** achieves the highest overlapping rate among all models, which shows our model can better utilize facts in the input text to generate more relevant questions. And the improvement of **PathQG** compared to other models reveals the effectiveness of learning involved entities and relations among path for question generation.

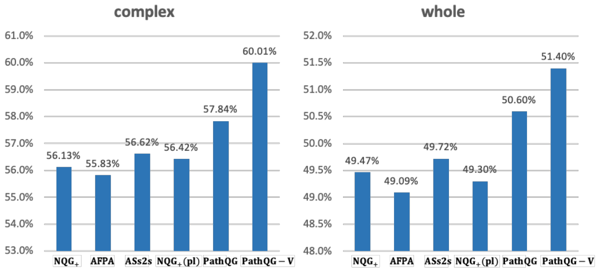

Figure 5: The overlapping rate between the input texts and the generated questions from different models.

Case study Two examples are presented in Figure 6. In sample 1, compared with the question generated by **NQG$_+$**, our generated question by

	Sample 1	Sample 2
Input	the three towns conurbation of plymouth , stonehouse and devonport enjoyed some prosperity during the late 18th and early 19th century and were enriched by a series of neo-classical urban developments designed by london architect john foulston .	because of its coastal location , the economy of plymouth has traditionally been maritime , in particular the defence sector with over 12,000 people employed and approximately 7,500 in the armed forces .
Path	(the three towns conurbation, of, plymouth, and, stonehouse, enjoyed, some prosperity, during, the late 18th, and, early 19th century, enriched by, a series, of, neo-classical urban developments, designed by, london architect john foulston). model **PathQG-V** is more informative and specific, which consists of information "plymouth" and "late 18th". In sample 2, our generated question is consistent to the input text while the one from **NQG$_+$** contains irrelevant phrase "swazi economy".

6 Related Work

Question Generation, aiming at generating questions from a range of inputs, such as raw text (Heilman and Smith, 2010), structured data (Serban et al., 2016) and images (Mostafazadeh et al., 2016; Fan et al., 2018a,b), has attracted increasing attention in recent years. Most previous studies on textual question generation are rule-based and transform a declarative sentence into an interrogative sentence according to hand-crafted patterns (Heilman and Smith, 2010; Heilman, 2011).

With the advance of neural network, Du et al. (2017) propose to apply a seq2seq structure with attention for automatic question generation. As follow-up, Zhou et al. (2017); Sun et al. (2018); Kim et al. (2019) propose to utilize the answers to decrease the generation uncertainty. Meanwhile, Song et al. (2018) and Li et al. (2019) explore to use answer-relevant context to guide question generation. Besides, some studies (Wang et al., 2017; Tang et al., 2017; Wang et al., 2019) take question generation as a subtask, and jointly learn it with other tasks, such as question answering and phrase extraction, which also help to alleviate the uncertainty and improve the generation performance.

Another stream of research for question generation is from KG to question. Reddy et al. (2017); Elsahar et al. (2018) explore to generate questions from a single KG triple using text as context information. It is close to our setting, but we are different in two aspects. First, we propose to form a query path consisting of multiple triples for question generation instead of a single triple. Second, the context we process is where the extracted triples from. This setting is more natural and different from using retrieved text as context as they did.

7 Conclusion and Future Work

In this paper, we propose to model facts in the input text as knowledge graph for question generation. We present a novel task of generating a question based on a query path from the constructed KG. We propose to learn query representation for question generation in a joint model and a variational inference model is also proposed. We extend the SQuAD dataset by automatic constructing KG for each input sentence and identifying corresponding query paths for ground truth questions. Experimental results proves the effectiveness of our proposed model qualitatively and quantitatively.

In the future, there can be two research directions. First, we would like to explore more explainable reasoning method for question generation, such as symbolic-based models. Second, novel evaluation metrics for question generation taking consistency and informativeness into consideration would be of interest.

A Appendices

A.1 Training Details

We train our proposed model and other comparison models on RTX 2080, using Adam optimizer with learning rate of 0.001, and decay at rate 0.96 per epoch, up to 20 epochs. Mini-batch of size 64 is taken for training. The dropout rate is 0.3 and we also clip the gradient once it exceeds 5. The average runtime for each method is listed in Table 4.

Model	runtime (minutes)
NQG_{+}	116
AFPA	160
ASs2s	97
NQG_{+}(pl)	127
PathQG	137
PathQG-V	170
NQG_{++}	113

Table 4: Average runtime of each method.

A.2 Model Parameters

We also compute the number of parameters in each model as shown in Table 5.

Model	number of parameters
NQG_{+}	23,769,132
AFPA	23,975,883
ASs2s	27,775,572
NQG_{+}(pl)	42,794,074
PathQG	33,775,934
PathQG-V	36,661,634
NQG_{++}	23,817,172

Table 5: Number of parameters in each model.

What time is it? Temporal Analysis of Novels

Allen Kim, Charuta Pethe, Steven Skiena
Department of Computer Science,
Stony Brook University, NY, USA
`{allekim,cpethe,skiena}@cs.stonybrook.edu`

Abstract

Recognizing the flow of time in a story is a crucial aspect of understanding it. Prior work related to time has primarily focused on identifying temporal expressions or relative sequencing of events, but here we propose computationally annotating each line of a book with wall clock times, even in the absence of explicit time-descriptive phrases. To do so, we construct a data set of hourly time phrases from 52,183 fictional books. We then construct a time-of-day classification model that achieves an average error of 2.27 hours. Furthermore, we show that by analyzing a book in whole using dynamic programming of breakpoints, we can roughly partition a book into segments that each correspond to a particular time-of-day. This approach improves upon baselines by over two hour. Finally, we apply our model to a corpus of literature categorized by different periods in history, to show interesting trends of hourly activity throughout the past. Among several observations we find that the fraction of events taking place past 10 P.M jumps past 1880 - coincident with the advent of the electric light bulb and city lights.

1 Introduction

The flow of time is an indispensable guide for our actions, and provides a framework in which to see a logical progression of events. Just as in real life, the clock provides the background against which literary works play out: when characters wake, eat, and act. In most works of fiction, the events of the story take place during recognizable time periods over the course of the day. Recognizing a story's flow through time is essential to understanding the text.

In this paper, we try to capture the flow of time through novels by attempting to recognize what time of day each event in the story takes place at.

As our motivating example, we use *"The Great Gatsby"* (Fitzgerald, 1925), a short novel with a familiar plot that can be analyzed with our techniques. Figure 1 presents the work of two human annotators, independently making their best guesses of the clock time at every paragraph of the book. The x-axis of Figure 1 represents the full text of the book as enumerated by paragraph numbers, while the y-axis represents the 24 hours of the day. The times identified by the annotators are shown in blue, while our model's time predictions are shown in red.

We first note that there is general but not perfect agreement between the annotators, with an average disagreement of 1.85 hours. There is also a strong general agreement between the model and the annotators, with an average absolute error of 2.62 hours, computed by taking the minimum time difference from either of the annotators.

Although human readers are generally able to track the flow of texts, this task is more difficult than may initially be supposed – because there are surprisingly few actual times reported in most books. Figure 2 shows how many explicit hourly time phrases appear in our dataset of 52,183 novels. About 6,000 of these books contain *zero* time references to any hour. Among the books that do contain clock times, most of them contain fewer than twenty references. Events are often described in a neutral manner that does not signal much about exactly when it is taking place.

This scarcity of time references presents a big challenge in developing good models and in interpreting the evidence associated with a particular text. Because of the lack of explicit references, some notion of likelihood must be part of the model. For this reason, we model time as a probability distribution of what hour it likely is at this juncture.

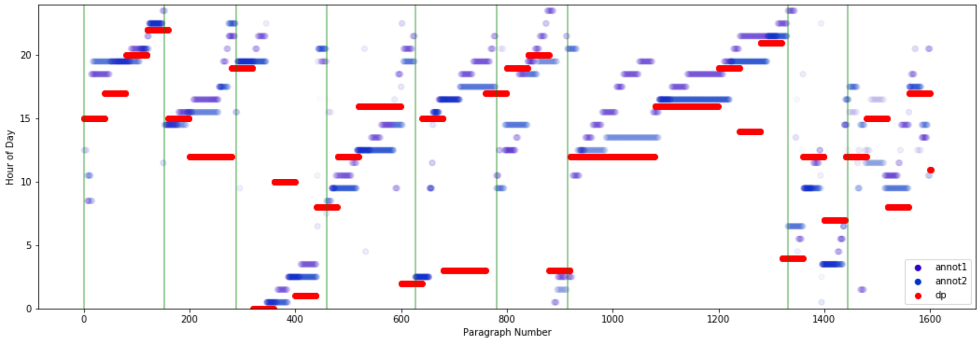

Figure 1: Comparing annotator times (in blue) versus algorithmically generated times for *The Great Gatsby*, shown in red. Blue colored dots represent the common agreed upon points of time. Green lines represent start of chapters. (A half-hour offset between the annotator and the model prediction to eliminate direct overlaps).

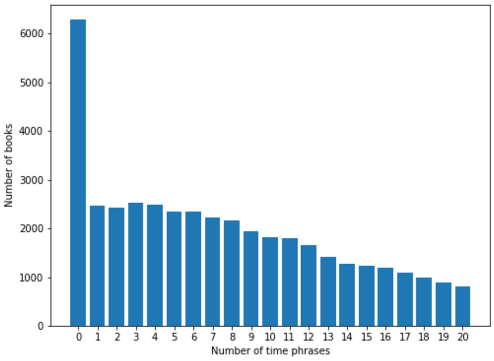

Figure 2: Number of books with explicit time references out of 52,183 books. 12.04% of these books contain no clock times within them.

Our contributions[1] in this paper include:

- **Literary Time Reference Dataset** – We build a clean data resource containing all explicit time references in a dataset of 52,183 novels whose full text is available via Project Gutenberg (Gutenberg, n.d.) and the HathiTrust Digital Library[2]. The times extracted via regular expressions generally do not include AM or PM designations, so we build models to predict the AM/PM label for a window of text with the best model achieving an accuracy of 86.3% at this task.

- **Models for Local Time Prediction** – We develop three language-based models to forecast the time (on the military hour scale from 0 to 23) from local text windows. This task is distinguished from typical regression problems in that time is periodic: thus the difference between 23:00 and 1:00 is the same as that between 10:30 and 12:30. We treat this task as a 24-class classification problem, with our strongest model (based on BERT) achieving an average error of 2.27 hours.

- **Global Time-Flow Analysis in Novels** – Predictions of time signals from local text features are doomed to be of bounded accuracy because, as previously detailed, books contain relatively rare explicit time references. Significant episodes typically require several pages to present, so we anticipate times to hold constant through large segments of text, and then proceed in a forward direction.

  We define an optimization criteria to partition texts into coherent time windows, and provide an efficient dynamic programming algorithm, which reduces the average absolute prediction error by over an hour against baselines.

- **Historical Trends in Hourly Activities** – By analyzing times extracted from our corpus of novels and the lifespan of its authors, we can identify how waking periods and peak times of activity have changed over the past two hundred years. In particular, we demonstrate that the fraction of events in novels taking place after 10 PM has grown steadily since 1880 – a tribute to the power of the electric light. Characters rose with the sun far more often in the agrarian society of old. Contemporary characters spend more time at lunch and less

[2] `www.hathitrust.org`

at dinner than their forebearers.

Our paper is organized as follows. We first discuss related works in temporal analysis and NLP for fiction (Section 2). We then describe our data collection process, specifically how we extracted temporal expressions along with some analysis of the phrases (Section 3). We then describe how the time-of-day models were constructed and their evaluations (Section 4). With these models, we show our book-length prediction algorithms and their corresponding metrics as well (Section 5). Finally, we present a trend of time activity over history based on our book-length prediction algorithm (Section 6).

2 Related Works

Work related to temporal analysis stems back to foundations in logic, which defined time in the context of sets and relations (Bruce, 1972; Allen, 1983). Less formally, we associate time with events (Setzer and Gaizauskas, 2000) and indeed most recent work has similarly approached understanding time in the context of events.

There has been much work done on temporal event analysis, primarily in the areas of identifying time phrases as well as extracting temporal relations between them (Pustejovsky et al., 2005; Bramsen et al., 2006; Chambers et al., 2007; Bethard and Martin, 2007; Lapata and Lascarides, 2006). Standards have been set up to properly categorize what kind of phrases are considered to be "time phrases" (Pustejovsky et al., 2003), and methods using regular expressions (Mani and Wilson, 2000; Strötgen and Gertz, 2010) as well as machine learning approaches (Mani et al., 2006; Min et al., 2007; UzZaman and Allen, 2010) have been used to parse these expressions. Looking more broadly, there has also been much work done in understanding a document's time dimension, which can involve determining when the document was created/published (De Jong et al., 2005; Garcia-Fernandez et al., 2011) or determining the time in which the contents of the story is focused on (Jatowt et al., 2013) or analyzing dates in German literature (Fischer and Strötgen, 2015).

Not only are we interested in just time, we are interested in time in the context of literature. There is a vast field of research in analyzing literature such as sentiment analysis of plot (Alm and Sproat, 2005; Mohammad, 2013; Elsner, 2012; Reagan et al., 2016; Jockers, 2015). Since time is inherently connected to events, we also refer to literature in parsing literary events within books as well (Ahn, 2006; Liao and Grishman, 2010; Li et al., 2013; Feng et al., 2018; Sims et al., 2019). Within literature, we are also interested in the activities of humans over history. For example, electric lighting began to become more popularized in the form of lightbulbs and city lights in the 1880s (DiLaura, 2008), and with electric lighting, people can more readily be active during the night. Prior to then, we are inclined to believe that people were not as active late at night.

3 Dataset Preparation

We initially started with a dataset of 10,489 Gutenberg books as well as 97,772 HathiTrust books, which were filtered to be English fiction (Underwood), but these contained numerous duplicates of the same book as well as duplicates between the Gutenberg dataset. These were deduplicated based on title and author similarity for a resulting count of 52,183 unique books over both sets. For the sake of completeness, we present results in this paper that use Gutenberg and HathiTrust books independently.

Regarding the format of the data, the Gutenberg books are provided as a raw text files and were cleaned to strip headers and front matter. The HathiTrust books were provided as a folder of text files representing pages. These were preprocessed to strip headers using the HathiTrust Research Center RunningHeaders tool [3] as well as to separate out the body of the book from its front and back matter (McConnaughey et al., 2017). We also performed further preprocessing to split them into paragraphs, sentences, and tokens. Among the preprocessing tasks, the most important task was to annotate which tokens belong to time phrases. This was done using SUTime library (Chang and Manning, 2012) to tag time terms, which uses a regular expression based approach. In particular, we focused on times that pinpointed hours within a day such as "two o'clock" or "noon". The library provides the terms as well as the time it can be translated to.

Table 1 shows the number of time tokens for every hour. The first two columns show the number of time references that can be determined down to

11	410	460	2,055	2,737

Table 1: Number of time examples by hour. The most frequent explicit time references are to noon and midnight.

an hour out of the 24 hour clock while the third column shows the number of time references that can only be determined down to the 12 hour clock. Time phrases can be disambiguated with words such as “AM” or “PM”, or if the time is connected to a prepositional phrase such as “three in the afternoon”. However, it is more often the case that time phrases are used without explicit labels. References to a certain time like “eight o’clock” usually do not come with an “AM” or “PM” tag as it is often inferred from context. Note that we especially have many samples for hour 0 - midnight and noon - simply because those are more commonly used phrases as opposed to prepositional phrases such as “five o’clock at night”. We also note that there are abnormally large amounts of examples for 1 A.M. in the Hathi dataset. We found that this was largely due to OCR errors that transcribed “I am” to “1 am”.

3.1 Associating Words with Hours of the Day

Given the references in each hour, we now want to examine words that are over-represented in different time periods. For each time reference, we take a window including three sentences before and after the reference, concatenate all of the windows referring to the same hour, and tokenize and count the words among them. This effectively creates 24 bag of words, one for each hour in the day. Since time periods with a difference of one hour are practically similar in the context in which they can appear, we also merge neighboring hour bag of words with each other.

word	top three hours
breakfast	7, 8, 6
bright	10, 11, 12
sun	12, 13, 11
lunch	12, 13, 11
park	15, 16, 11
dinner	18, 19, 13
dark	23, 0, 1
moon	23, 0, 1

Table 2: Top three hours for select feature words, consistent with common experience.

We now want to determine how closely related a word is to a particular hour. To do so, we define a scoring function that takes in a word and hour, and outputs a score between 0 and 1 representing how closely related the word is to that hour. As examples, we would expect the word “lunch” and the hour 12 to have a high score and the word “dinner” and the hour “8” to have a low score.

Scoring Description Intuitively, we want to measure how surprised we are when observing the frequency of word in the context of a hourly phrase versus the frequency of the word in any standard text. For a given word and hour, we look at the frequency of the word within the hour’s bag of words and compare it to the standard normalized frequency of the word in all of our dataset. We model the occurrence of the word as a geometric distribution with probability equal to the standard normalized frequency, and thus, we can score each word by using their frequencies within the bag of words and using a binomial cumulative distribution function to find a corresponding likelihood.

Formally, for a given word w and hour h, let k be the number of occurrences of w in the bag of words of h, $p[w]$ be the probability of w appearing in a text – computed by taking the normalized frequency of w in all of the text – and N_h be the total number of words in the bag of words of h. We then define the scoring function $s(w, h)$ as:

$$s(w, h) = \sum_{i=0}^{k} \binom{N_h}{i} p[w]^i (1 - p[w])^{N_h - i}$$

With this scoring function, for any given word, we can rank the top hours it is associated with. We show the top three hours for several common words in Table 2. We considered words with common associated times with them such as eating breakfast in the morning, lunch at noon, and dinner at night. We see that there is a general agreement between the top hours for the given words and the times an average person would associate them with.

4 Time Prediction from Text

For a given window of sentences, we seek to predict the hour it is most likely taking place in. To construct models for this task, we use the time phrases from Section 3, but recall much of the time phrases were unlabeled. Given the limited amount of labeled data, we first want to augment our dataset by labeling the unlabeled data as well. Thus, we have a two step approach:

1. Build a model to resolve ambiguous time terms (AM versus PM) and label the unlabeled data.
2. Train a model for time of day prediction by hour using the augmented dataset.

4.1 Resolving Ambiguity in Time Terms

As shown in Table 1, a majority of the time terms do not have AM or PM tags. In order to get rid of this ambiguity, we first label this data with AM/PM tags.

Our problem is as follows: Given a reference to a phrase representing some hour of the day as well as the words in the context around it, determine whether the time the phrase is referring to is "A.M" or "P.M". Intuitively, this problem requires 12 different models, one for each hour from 0 to 11. We require separate models for each hour since neighboring hours can have similar words but different labels. For example, "11 A.M" can have words quite similar to "12 P.M", but their labels are clearly different. Additionally, we use a window that spans three sentences before the time phrase and three sentences afterwards. We found that empirically, the predictive power of the model did not significantly improve past this window size.

We consider three main models along with a baseline and an ensemble of the three models.

- **Baseline:** We use the majority class for each hour as the default prediction.
- **Naive Bayes (NB):** We convert the window of sentences to a binary bag of word representation using StanfordNLP (Qi et al., 2019) for every hour and train Naive Bayes classifier for prediction.
- **LSTM:** We represent the window of sentences as vectors using GloVe (Pennington et al., 2014). We use the 6B tokens, 400K vocab, uncased, 100d pre-trained word vectors to convert windows to sequences of vectors that were then used to train an LSTM.
- **BERT:** We tokenize the windows using the BERT tokenizer and fine-tune the pre-trained 12-layer, 768-hidden, 12-heads, 110M parameters uncased BERT model (Devlin et al., 2018).

Experimental Details. For each of these model types, we construct twelve classifiers (one for each hour up to twelve). We also split the training and testing set in a 70-30% split and further split the training set in a 90-10% split for validation. Additionally, we take advantage of the fact that the windows of words around one hour are quite similar to the hours near it. We can imagine that replacing "1 P.M" with "2 P.M" in a window will have minimal impact. Thus, we take the neighboring hours training set as well when training for each hour.

All models were run on a compute server with 2.30 GHz CPU and TeslaV100 GPU. No hyperparameter tuning was done on any models; default values were run for all models. The average training time of all the neural models were within several hours. This is true for future experimentation as well.

One point to note is the necessity of masking the time phrase that the window was based on. Words such as "AM/PM" or "in the morning/night" provided the temporal cues to parse the time phrase in the first place, and any decent model with access to these words will perform with unrealistic accuracy. These features do not exist in the unlabeled training set, to ensure the models learn to identify the proper AM/PM label without cheating. Thus, we replace all the time phrases with the same special

Table 3: AM - PM Prediction Results for Gutenberg / HathiTrust

token. In some models such as BERT, we use this while tokenizing. In other models such as GloVe + LSTM, we create a new random vector to represent this token.

Results. The results are shown in Table 3 with the metrics of accuracy and F1 scores for each class. We include results when running these models purely on Gutenberg data as well as the results when running these models with the HathiTrust data. We see clear improvement across the board, especially for BERT with the extra data. The macro metrics are the averaged values over all 12 models while the micro metrics are the values over all the test examples over all the models. The results show that this is a challenging task given the limited amount of data we have. Analyzing the dataset shows that many windows that contain a time reference can be sensible with either A.M or P.M, so it is not easy to disambiguate mentions of time in generic dialogue. However, all our models substantially outperform the baseline. In the end, we use the winning BERT model to label our unlabeled data for training.

hour	agreement	hour	agreement
0	0.79	6	0.76
1	0.69	7	0.76
2	0.79	8	0.80
3	0.82	9	0.69
4	0.75	10	0.71
5	0.80	11	0.77
Mean Agreement = 0.761			

Table 4: Agreement between Annotators and Model for AM/PM prediction

Since we are imputing our data with computer-generated labels, we compare its output to human annotators to test how reliable it is. We manually annotated 1200 instances of AM/PM windows — 100 examples for each hour pair — and compared it to our model's output to see the agreement. In cases where the label can be ambiguous, the annotators made their best intuitive guess. Figure 4 shows the agreement between the annotators and our model, where the agreement is measured in number of matching predictions divided by the total number.

We see that the model performs respectably with an overall average of 76% accuracy. We comment that the human annotations contain some anomalies due to linguistic changes such as "dinner" being eaten as lunchtime and "supper" being the canonical name for a later meal, but these anomalies were relatively minor.

4.2 Time of Day Prediction

Given the words in the context of the time phrase, we now predict the most likely time of day. We treat this problem as a 24-class classification problem, where each class is defined to be an hour of the day. We again consider the same three models as in the AM-PM models: bag of words with Naive Bayes, GloVe with LSTM, and BERT fine-tuning, but with 24-class outputs as opposed to binary.

Results. The results are shown in Table 5 and 6. The models shown in these results were trained on exclusively HathiTrust books. We also show the results when purely trained on Gutenberg books as well. We note that error is measured in number of

hour	NB	LSTM	BERT
0	2.92	2.56	**1.69**
1	2.07	1.56	**1.05**
2	4.24	3.28	**2.57**
3	5.21	3.54	**2.71**
4	5.75	3.51	**2.57**
5	5.94	3.87	**2.66**
6	5.68	3.85	**2.88**
7	5.72	4.01	**2.85**
8	5.05	3.89	**2.55**
9	5.04	3.81	**2.58**
10	5.11	4.13	**2.87**
11	5.10	3.63	**2.27**
12	5.21	3.46	**1.73**
13	4.98	3.29	**1.88**
14	4.38	3.41	**2.18**
15	3.86	3.32	**2.12**
16	3.57	3.32	**2.00**
17	3.57	3.19	**2.23**
18	3.86	3.51	**2.31**

20	3.79	3.29	**2.10**
21	3.42	3.20	**2.01**
22	3.25	3.17	**2.19**
23	3.17	2.61	**2.17**

Table 5: Time-of-day prediction error by hour for HathiTrust books

hours. Thus, the worst possible error is 12 hours on a 24 hour clock. A baseline model with random guessing would have an expected error of 6 hours.

We see that the BERT model performs the best with an error of 2.28 hours while Naive Bayes performs the worst with an error of 4.38 hours. We clearly see that this problem is heavily influenced by the amount of data available. We see that by simply adding more data to the LSTM and BERT models, the average error improves significantly and unsurprisingly, the naive Bayes model only improves slightly.

hour	NB	LSTM	BERT
Gutenberg	4.69	4.72	**4.09**
HathiTrust	4.38	3.36	**2.28**

Table 6: Average time-of-day prediction error for Gutenberg and HathiTrust books

5 Book-length Time Prediction

Given a model that can predict the time of day for a single window of sentences, we now consider predicting the time of day over an entire book – constructing a time flow through the book. The simplest idea is to partition the book into windows that fit into the model and independently predict an hour for each window using the model. However, this will have very poor performance since many windows will consist of sentences that have no bearing to time and in these cases, the model will output an arbitrary time that will not fit with its surroundings. To resolve this, we consider the problem of optimally partitioning the windows into larger segments corresponding to particular hours.

More formally, given a sequence of sentence windows $s_1, s_2, \ldots, s_n$ and the number of segments, parameterized as k, our goal is to generate the most likely list of indices $i_1, i_2, \ldots, i_k$ that represent the start of each segment, and a list of hours $h_1, h_2, \ldots, h_k$ that represents the corresponding hour assigned to each segment.

5.1 Generating Probability Distributions

For every window, we now want to generate a probability distribution over the 24 hours. We present two different means of acquiring these probabilities and in the end, we combine these two probability distributions.

Model Probabilities. The first approach applies our BERT time of day model from Section 4. As discussed in the introductory paragraph of this section, we can simply run our model on each window of text and min-max normalize the scores to get probabilities. We additionally smooth the probability by averaging the probabilities with their neighboring hours since we expect neighboring hour classes to be similar to each other. With this, we now have a probability distribution over 24 hours for each window using our model. However, one limiting feature of just using our model is the fact that our model was trained with core time phrases removed from its training. Recall that phrases such as "eight o'clock at night" were masked entirely to prevent skewing the testing procedure.

Tag-based Probabilities. To make use of these crucial time phrases, we consider another probability distribution based on key time phrases that are also annotated by SUTime: "morning", "afternoon", "evening", and "night". For each tag, we define a probability over the standard hours in which they refer to (morning: 6-11, afternoon: 12-16, evening: 17-20, night: 21-5). For any window containing these tags, we define a uniform probability over the hours the tag refers to with zeros for other hours. This defines a probability distribution for windows containing these tags. For windows not containing any time tags, we simply let it equal the probability of the previous known tag.

Merging. We average our model probabilities with the tag-based probabilities to get our final probability distribution for every window.

5.2 Optimal Partitioning of Probabilities

Given the probability distribution for each window, we now want to find the optimal partitioning of the windows. Recall that in the formulation of this problem, one of the required parameters is the number of partitions we want to make among the windows of text. We consider this number as a parameter we can control. If we allow too many segments, then the model will probably overfit to noisy windows whereas if the number of segments is too small, then the times will not be accurate to the book. For our experiments, we approximate the ratio of the number of windows to number of partitions in a book to be approximately eight, which is about 55 sentences on average per partition. We saw that this worked well empirically with several sample texts such as *The Great Gatsby* and maintained a good balance between not overfitting and getting sensible results.

To determine the location of partition breaks, we present a baseline and two methods.

- **Baseline:** We assign every window to be the same constant hour - we choose noon in particular since that is the middle of the day.
- **Max Hour:** We first partition the windows into equal sizes. Each partition now contains a series of probability distributions. For each partition, we take the sum of the probabilities across each window and assigns to each partition the hour that corresponds to the maximal sum in the summed partition probabilities.

classifer	error
Noon Baseline	6.215
Max Hour	4.250
DP	4.232

Table 7: Book Time Prediction Results

- **Dynamic Programming (DP):** The dynamic programming takes in the number of text windows and number of partitions as parameters and optimizes the size of the segments to maximize the alignment of each section with its underlying probability. We define the DP recurrence relation to score the alignment $f(n,k)$, where n is the number of windows and k is the number of breaks, as:

$$\max_{i\in[1,n-k]}\left(f(n-i,k-1)+\max_{h\in[0,23]}\sum_{j=n-i}^{n}p_h[j]\right)$$

  where we define p as the array of array of 24 probabilities for every window, and thus, $p[j]$ can be described as an array of 24 probabilities for window j. By taking the max, the DP prioritizes the hour with maximal probability sum over the length of the partition.

5.3 Evaluation

To evaluate our methods, we construct ground truth for the books in our dataset. While the example with "The Great Gatsby" was manually annotated, we have no annotations of times for our book dataset. Thus, we approximate the ground truth by considering books that contain time references to specific hours of the day and annotate the text window containing that phrase to be that hour. Additionally, to raise the quality of the test set, we only consider books with multiple time references that include references beyond just noon and midnight. We note that our "ground truth" is not correct in many circumstances such as when a specific time is referred to in dialogue referencing some point in the past or future, but suffices to show general trends in our results.

Results. Our results for average error in hours are shown in Table 7. Even with the low quality of

	year	num	0/1	2/3	4/5	6/7	8/9	10/11	12/13	14/15	16/17	18/19	20/21	22/23
0	-1800	501	9.79	1.33	7.61	5.66	7.64	15.19	8.99	4.99	3.61	6.10	22.19	6.93
1	-1820	942	10.63	1.14	7.80	6.78	8.54	12.28	9.20	6.85	2.92	4.84	22.27	6.74
2	-1840	1553	9.35	1.18	8.47	8.26	7.03	11.68	9.20	8.02	3.07	5.12	21.53	7.08
3	-1860	1629	9.51	1.36	8.94	7.20	6.48	10.17	10.70	9.38	3.35	5.05	20.80	7.05
4	-1880	2641	10.04	1.41	9.30	7.43	5.35	9.59	11.37	9.83	3.25	4.74	20.09	7.60
5	-1900	479	11.01	1.38	8.71	7.10	5.64	9.12	11.93	9.50	3.34	4.75	20.67	6.85
6	1900-	518	8.35	0.66	9.54	8.73	1.71	7.37	9.32	13.81	1.69	3.64	28.47	6.71

Figure 3: Activity in Different Time Periods by Percentage - shaded by relative weight within each column

labels in the test set, we see that the local method of maximal hours over uniform segments as well as the dynamic programming method beat the noon baseline by about two hours. Overall, the dynamic programming method performs best, but the local maximization method performs admirably as well.

One might ask why the error is higher compared to the 24 hour model. This is due to the fact that while the model performs well on local windows that contain a time reference, the neighboring windows tend to give little signal about time and confuses which windows should be emphasized more than others. Quite often, the probabilities provided by the models do not fully represent confidence. For future work, it would be worth considering a different model that uses probabilistic labels as classes or a variant of a regression model.

6 Historical Trends

In the end, we use our book-length time prediction through all the Gutenberg books in our dataset and found the distribution of times throughout each book. While the dataset does not have the publication date of the book in the metadata, we were able to access the authors and the years the author was alive. Thus, we created groupings of our data by time period based on the year of the author's birth. We group the authors by year of birth, separated every 20 years.

Figure 3 shows the results for six groupings of years. We consider all books up to 1800 to be one group, then every 20 years afterwards up to 1900, and all books from 1900 and beyond to be the final group. We first note the number of books in each grouping. Given copyright laws, most of the books we have access to are in the late 1800s as shown by the number column.

We see some interesting trends. For example, noon and afternoons (12 to 5 P.M) are referenced more as the periods pass. Additionally, the times around dinner (6 to 9 P.M.) are referenced much more in earlier books, but become less relevant in later periods. The emphasis tends to shift towards later at night (11 P.M to 1 A.M). We also see a decrease in emphasis in the morning from 8 to 9 A.M. Overall, the emphasis seems to shift towards the afternoon and late nights and away from mornings and evenings as we progress through the books historically, which can potentially be attributed to the rise in the emphasis on lunch times as well as the advent of electric lighting, along with a decreased emphasis on family dinners.

7 Conclusions and Future Work

We have constructed a dataset of time phrases to build models that can predict the most relevant hour of the day for a given text window. Our models are a good start, but we release the dataset to encourage others to improve on this task. We note that this dataset can be further cleaned by resolving OCR errors in the source text as well as improving upon the time extraction algorithm. More annotations of complete novels would permit better models and evaluation.

Full time annotations of novels additionally include the challenging task of distinguishing between narrator and recall time in discussing past events. We also seek to annotate information about dates and seasons. Future work includes applying time inference models to question answering and other NLP systems.

COGS: A Compositional Generalization Challenge Based on Semantic Interpretation

Najoung Kim

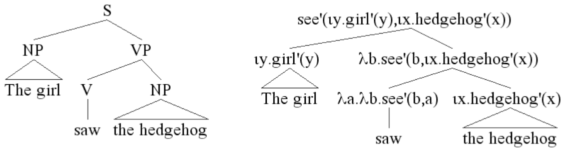
linzen@nyu.edu

Abstract

Natural language is characterized by compositionality: the meaning of a complex expression is constructed from the meanings of its constituent parts. To facilitate the evaluation of the compositional abilities of language processing architectures, we introduce COGS, a semantic parsing dataset based on a fragment of English. The evaluation portion of COGS contains multiple systematic gaps that can only be addressed by compositional generalization; these include new combinations of familiar syntactic structures, or new combinations of familiar words and familiar structures. In experiments with Transformers and LSTMs, we found that in-distribution accuracy on the COGS test set was near-perfect (96–99%), but generalization accuracy was substantially lower (16–35%) and showed high sensitivity to random seed (±6–8%). These findings indicate that contemporary standard NLP models are limited in their compositional generalization capacity, and position COGS as a good way to measure progress.



(a)

TRAINING
[[The girl]] = $\iota x.girl'(x)$, [[The cat]] = $\boldsymbol{\iota x.cat'(x)}$, [[The boy]] = $\iota x.boy'(x)$
[[The cat loves the girl]] = $love'(\boldsymbol{\iota x.cat(x)}, \iota x.girl'(x))$
[[The hedgehog sees the cat]] = $see'(\iota x.hedgehog'(x), \boldsymbol{\iota x.cat'(x)})$

GENERALIZATION
[[The boy loves the hedgehog]] = $love'(\iota x.boy'(x), \boldsymbol{\iota x.hedgehog(x)})$

(b)

Figure 1: (a) The meaning of a sentence (right) is compositionally built up from the meanings of its parts, in accordance with its structure (left). (b) Interpreting a familiar word in a structure it has not appeared in before. In colors: expressions providing the primitive meanings; in bold: expressions providing evidence that definite NPs may appear in both argument positions of a transitive verb. $[[x]]$ denotes the meaning of x.

1 Introduction

Humans can produce and understand linguistic expressions that they have not encountered before, by systematically combining atomic building blocks (Montague, 1974). For instance, a speaker that knows the meaning of *John loves Mary* is necessarily able to understand *Mary loves John*, even if the speaker has not heard or uttered this sentence before (Fodor and Pylyshyn, 1988). The discipline of formal semantics concerns itself with characterizing these building blocks, or "primitives", and the ways in which they combine to construct the meaning of a complex expression (e.g., Figure 1a).

To assess the abilities of computational models of language to generalize compositionally, we propose COGS, a **CO**mpositional **G**eneralization Challenge based on **S**emantic Interpretation, in which a model of language is expected to construct a semantic representation of a given English sentence (semantic parsing). The key component of this challenge is that the training and evaluation sets systematically differ in their properties, such that success on the evaluation set requires out-of-distribution generalization. Of the many possible ways that a model could systematically fill such gaps, we expect it to do so in a way that is consistent with the compositional principles that guide human linguistic generalization. Figure 1b illustrates how the meaning of the unseen expression *The boy loves the hedgehog* could be compositionally inferred from known parts. In this case, the noun phrase (NP) *the hedgehog*, which has only been observed as a subject, needs to be interpreted in the direct object position. The generalizations tested by COGS, described in detail in Section 3, in-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9087–9105,
November 16–20, 2020.

clude interpreting novel combinations of primitives and grammatical roles, interpreting novel combinations of modified phrases and grammatical roles, generalizing phrase nesting to unseen depths, verb argument structure alternation, and sensitivity to verb class.

Rule-based semantic parsing systems such as Boxer (Bos, 2008) are able to generalize compositionally by design. By contrast, this ability does not constitute a part of the design of the neural network models of language that are standard in NLP; it could only arise in such models through learning, inductive biases, or a combination of the two. To test whether standard NLP models are equipped with the ability to generalize compositionally, we used COGS to evaluate three architectures: Transformer, Bidirectional LSTM, and Unidirectional LSTM (Section 5). We found that the out-of-distribution generalization set was significantly more challenging (16–35% mean accuracy) than an in-distribution test set (96–99% mean accuracy). Furthermore, generalization accuracy varied greatly across runs of the same architecture that differed only in random seed (6–8% standard deviation). Further analysis revealed that structural generalization (to novel combinations of familiar syntactic structures) poses greater difficulties than lexical generalization (to novel combinations of a familiar primitive and a familiar structure). These results suggests that higher accuracy on COGS would require a stronger structural bias than that of Transformers and LSTMs.

2 Compositional Generalization

Fodor and Pylyshyn (1988) highlighted the intrinsic connection between the ability to produce and understand different sentences that are made up of the same building blocks, such as *John loves Mary* and *Mary loves John*. This connection, which they refer to as *systematicity*, derives from a combinatorial mechanism that constructs the meaning of a complex expression from its parts: understanding *John loves Mary* and *Mary loves John* involves combining the same primitives using the same rules. The question of whether neural networks can display human-like systematicity has a long history. In a review of early work, Hadley (1994) argued that none of the connectionist models he examined displayed the degree of systematicity that humans do. Recently Lake and Baroni (2018) revisited this question using contemporary neural architectures—sequence-to-sequence models with LSTM and GRU units—and came to the same conclusion as Hadley.

Lake and Baroni based their study on the SCAN task, a novel task in which word sequences in a synthetic language need to be mapped to navigation command sequences (e.g., *jump twice* → JUMP JUMP). Crucially, their training/evaluation split required compositional generalization. A number of models have been developed that have improved performance on SCAN (Li et al., 2019; Gordon et al., 2020). However, since the semantic representation used by SCAN only covers a small subset of English grammar, SCAN does not enable testing various systematic linguistic abstractions that humans are known to make (e.g., verb argument structure alternation). Thus, it is unclear whether progress on SCAN would generalize to natural language. To bring the evaluation of compositional generalization a step closer to natural language, COGS includes a wide range of syntactic constructions, and uses semantic representations based on lambda calculus, inspired by the formalisms employed in formal semantics (Parsons, 1990) and semantic parsing (Palmer et al., 2005; Reddy et al., 2017). Following Dong and Lapata (2016) and Daza and Frank (2018), we cast semantic parsing as a sequence-to-sequence problem.

3 Overview of COGS

In a semantic parsing task such as COGS, the goal is to map a sentence to a logical form. Following recent works such as Marvin and Linzen (2018) and Keysers et al. (2020), we generate the dataset using a rule-based approach; this allows us to maintain full control over the distribution of inputs that the learners are exposed to, and to ensure coverage of rare constructions that are not guaranteed to appear in natural corpora. COGS is not inherently grounded but could potentially be linked to a knowledge base or a visual world. The COGS dataset[1] is split into a training set and a generalization set. The training set includes systematic gaps that, in the generalization set, must be filled via compositional generalization. Success on the generalization set relies on several types of linguistic generalizations that humans are able to make. Instead of providing individual splits for each of the targeted generalizations, we expect the learner to make *all* of the target generalizations at once.

---

Case	Training	Generalization
S.3.1. Novel Combination of Familiar Primitives and Grammatical Roles		
Subject → Object (common noun)	A **hedgehog** ate the cake.	The baby liked the **hedgehog**.
Subject → Object (proper noun)	**Lina** gave the cake to Olivia.	A hero shortened **Lina**.
Object → Subject (common noun)	Henry liked a **cockroach**.	The **cockroach** ate the bat.
Object → Subject (proper noun)	The creature grew **Charlie**.	**Charlie** worshipped the cake.
Primitive noun → Subject (common noun)	**shark**	A **shark** examined the child.
Primitive noun → Subject (proper noun)	**Paula**	**Paula** sketched William.
Primitive noun → Object (common noun)	**shark**	A chief heard the **shark**.
Primitive noun → Object (proper noun)	**Paula**	The child helped **Paula**.
Primitive verb → Infinitival argument	**crawl**	A baby planned to **crawl**.
S.3.2. Novel Combination Modified Phrases and Grammatical Roles		
Object modification → Subject modification	Noah ate **the cake on the plate.**	**The cake on the table** burned.
S.3.3. Deeper Recursion		
Depth generalization: Sentential complements	Emma said **that** Noah knew **that** the cat danced.	Emma said **that** Noah knew **that** Lucas saw **that** the cat danced.
Depth generalization: PP modifiers	Ava saw the ball **in the bottle on the table**.	Ava saw the ball **in the bottle on the table on the floor**.
S.3.4. Verb Argument Structure Alternation		
Active → Passive	The crocodile **blessed** William.	A muffin **was blessed**.
Passive → Active	The book **was squeezed**.	The girl **squeezed** the strawberry.
Object-omitted transitive → Transitive	Emily **baked**.	The giraffe **baked a cake**.
Unaccusative → Transitive	The glass **shattered**.	Liam **shatterd** the jigsaw.
Double object dative → PP dative	The girl **teleported** Liam the cookie.	Benjamin **teleported** the cake **to** Isabella.
PP dative → Double Object Dative	Jane shipped the cake to John.	Jane shipped John the cake.
S.3.5. Verb Class		
Agent NP → Unaccusative subject	The **cobra** helped a dog.	The cobra **froze**.
Theme NP → Object-omitted transitive subject	The hippo **decomposed**.	The hippo **painted**.
Theme NP → Unergative subject	The hippo **decomposed**.	The hippo **giggled**.

Table 1: A full list of generalization cases. Each sentence in the table represents a (sentence, logical form) pair. For instance, the sentence *A hedgehog ate the cake* represents the following input-output mapping:

A hedgehog ate the cake → *cake(x_4) ; hedgehog(x_1) AND eat.agent(x_2,x_1) AND eat.theme(x_2,x_4)

"Subject" and "Object" include subjects and objects of both simple and embedded sentences. Due to space constraints, some sentences are simplified or rephrased versions of the sentences included in the dataset.

We describe below the five categories of generalizations targeted by COGS (see Table 1 for a full list). For a discussion of our design decisions from the perspective of formal semantics, see Appendix H.

3.1 Novel Combination of Familiar Primitives and Grammatical Roles

English speakers can easily interpret an open-class primitive (e.g., a noun) in a grammatical role that is different from the one in which it was first observed. For example, a noun that was only observed as a subject can easily be interpreted as an object. This generalization capacity has been attested in children as young as 20 months old (Tomasello and Olguin, 1993). We ensured that in the training set some lexical items only appear in subject position, and some only appear in object. In the generalization set, these lexical items appear in the opposite grammatical role. We test for generalization to the targeted grammatical roles not only in simple sentences, but also *embedded* clauses; this form of generalization is a defining criterion of *strong systematicity* (Hadley, 1994). For instance, a noun that only occurred as a subject of a simple sentence in training may occur as an object of an embedded clause in the generalization set:

(1) a. TRAINING: A **hedgehog** ate the cake.
    b. GENERALIZATION: A girl said that Emma called the **hedgehog**.

While some primitives appear in the training set in the context of a sentence, others only occur in isolation. We express common noun meanings as unary predicates (*shark* $\rightarrow$ $\lambda x.\text{shark}(x)$, proper noun meanings as constants (*Emma* $\rightarrow$ Emma), and verb meanings as n-ary predicates with thematic role specifications (*like* $\rightarrow$ $\lambda x.\lambda y.\lambda e.\text{like.agent}(e, y)$ AND $\text{like.theme}(e, x)$) (see Appendix H for more details). The training set contains these primitives as isolated words, but not as a part of a sentence; by contrast, the generalization set includes examples that require interpreting these primitives in context (e.g., *The shark smiled*).

3.2 Novel Combination of Modified Phrases and Grammatical Roles

Phrases with a modifier, such as an NP modified by a prepositional phrase (PP), can occupy the same grammatical roles as unmodified phrases. For example, just like [*the cat*]$_{NP}$, the phrase [[*the cat*]$_{NP}$ [*on the mat*]$_{PP}$]$_{NP}$ is an NP, and can occupy the same syntactic positions. Children acquiring language are most likely not exposed to modifiers in every possible syntactic position that the modified element may occur, yet learn a context-free phrasal modification rule (e.g., NP $\rightarrow$ NP PP) rather than a rule localized to a specific grammatical role (e.g., NP$_{obj}$ $\rightarrow$ NP PP). To test for generalization to modifiers in an unseen grammatical role, our training set includes only examples with PP modifiers within object NPs, and the generalization set contains PP modifiers within subject NPs. We note that this is a simplification of the generalization problem that humans may encounter; see Appendix H for a further discussion.

3.3 Deeper Recursion

The ability to derive an infinite number of expressions from a finite set of building blocks is a defining characteristic of human linguistic competence (Hauser et al., 2002). Human language achieves this property by allowing certain phrase types to be nested within a phrase of the same type. In [*Mary knows that* [*John knows* [*that Emma cooks*]$_{CP}$]$_{CP}$]$_{CP}$, clauses (CP) are nested inside other clauses. Our dataset includes two types of recursive constructions that allow arbitrary depths of nesting: sentential complements (nested CPs) and nominal PP modifiers (nested PPs). The training set contains nestings of depth 0–2, where depth 0 is a phrase without nesting. The generalization set contains nestings of strictly greater depths (3–12).

3.4 Verb Argument Structure Alternation

Many English verbs participate in argument structure alternations (Levin, 1993). For instance, *break* can be used both as a transitive verb (*John broke the window*), and as an unaccusative verb, with its theme in the subject position (*The window broke*). Likewise, agent-patient verbs can passivize; *John broke the window* can be passivized to *The window was broken*, or with an optional agent *by*-phrase, *The window was broken by John*. These alternation patterns are not restricted to particular lexical items, and humans can often apply such alternations to verbs that have only been observed in one of the forms. To illustrate, a person told that *I floosed the cat* means “I fed the cat twice” would immediately be able to interpret *The cat was floosed* (though see Section 7 for a caveat).

COGS contains alternation patterns that humans have been shown in experiments to generalize to nonce verbs: active-passive (Brooks and Tomasello, 1999), transitive-intransitive (unaccusative and object-omitted transitives; Ono and Budwig 2006; Hu et al. 2007; Kline and Demuth 2014), and the alternation between double-object and prepositional-phrase datives (Conwell and Demuth, 2007). For several verbs, we include only one of the alternating forms (e.g., active) in the training set, and only the other form (e.g., passive) in the generalization set.

3.5 Verb Class

In English, the semantic role of the argument of a verb with a single argument depends on the identity of the verb; the surface syntax of the sentence is not enough to determine its interpretation. For instance, *froze* in the sentence *The lake froze* is an unaccusative verb, which takes a theme (or patient) as its grammatical subject, whereas in *The dog smiled*, *smiled* is an unergative verb that takes an agent as its grammatical subject. Inspired by this property, we include in our generalization set combinations of verbs and NPs, which all occur separately in the training set, but such that the NPs never appear as the thematic role specified by the verb in the training set. For instance, the training set contains a sentence with *cobra* as an agent subject (2a), and sentences with unaccusative verbs (2b), and the generalization set contains examples in which *cobra* and *freeze* appear together (3). Correctly interpreting *cobra* as the theme, even though it only appears in the training set as an agent, requires sensitivity to the argument structure of *freeze*.

(2) TRAINING

a. A cobra helped a dog. →
cobra(x_1) AND help.agent(x_2,x_1) AND help.theme(x_2,x_4) AND dog(x_4)

b. The drink froze. →
*drink(x_1) AND freeze.theme(x_2,x_1)

(3) GENERALIZATION

The cobra froze. →
*cobra(x_1) AND freeze.theme(x_2,x_1)

4 Dataset Generation

Grammar and logical forms. We generated the constructions described in Section 3 using a Probabilistic Context-Free Grammar (PCFG; Appendix A). The types of sentences covered by this PCFG accounted for 70–80% of naturally-occurring English sentences, according to the analysis of five English corpora conducted by Roland et al. (2007). The semantic interpretation of a sentence follows deterministically from the PCFG rules, which were annotated with semantic class information needed to disambiguate ambiguous syntactic structures (Section 3.5).

Sentences were first mapped to the simplified logical formalism proposed by Reddy et al. (2017) using their codebase,[2] and then passed through several postprocessing steps (see Appendix C). The logical forms use indexed constants that express the existence of an entity or an event denoted by the predicate. For example, in (4), x_1 expresses the existence of an entity that is both a cat and an agent of a smiling event; x_2 expresses the existence of an event that is a smiling event.

(4) A cat smiled →
cat(x_1) AND smile.agent(x_2, x_1)

Our constants are named after indices of the phrasal head in the original sentence; in (4), the noun *cat* is in position 1, so the corresponding constant is x_1. This indexing scheme was adopted to avoid the need to select arbitrary constant names (e.g, x, y, z, . . .) as the number of entities and events in the expression grows.

Primitive exposure examples. Many generalization cases crucially rely on particular training examples. For instance, to apply the Subject → Object generalization to *hedgehog*, at least one example with *hedgehog* as subject must be included in the training set. Human learners only need to observe an item in a small number of distinct contexts before they can generalize to new contexts. For example, children of age 2 years and 11 months were able to produce in a passive construction a nonce verb they have only heard in an active transitive construction, after being exposed to 8 distinct usages of the construction (Brooks and Tomasello, 1999). Borovsky et al. (2010, 2012) further suggest that humans are even capable of single-shot learning of word meaning in context. We include in our training set a single example to generalize from ("primitive exposure example") per generalization case that requires it. In Appendix E.2 we report results on a version of COGS with 100 primitive exposure examples.

Training and generalization sets. We sampled 30,000 distinct sentences from our PCFG, exclud-

---

[2] `https://github.com/sivareddyg/udeplambda`

ing ones with duplicate nominals (e.g., *The **cat** saw a **cat***). These sentences were divided into training (80%; n = 24,000), development (10%; n = 3000), and test (10%; n = 3000) sets. We then added to the training set examples that specify the primitive meanings of 80 verbs and 60 nouns (including common and proper nouns). Separately, we generated primitive exposure examples (n = 15, see previous paragraph) to add to the training set. The resulting training set consists of 24,155 examples.

The out-of-distribution generalization set was constructed from separate PCFGs, each of which generates examples pertaining to a particular generalization case. For the Subject → Object generalization, for example, we generated sentences with *hedgehog* in the object position. We sampled 1000 examples of each of the 21 cases, for a total of 21,000 examples.

5 Experiments

We next analyze the performance on COGS of two widely-used models for language tasks: Long Short-Term Memory (LSTM; Hochreiter and Schmidhuber 1997) and Transformer (Vaswani et al., 2017), both in an encoder-decoder setup (Sutskever et al., 2014). Transformers have been quickly adopted in practical NLP systems (Storks et al., 2019), but the literature has reported mixed results on the benefit of Transformers over LSTMs in terms of linguistic generalization (Hupkes et al., 2020; van Schijndel et al., 2019). Our goals in these experiments are, first, to test whether strong NLP models are equipped with the compositional generalization abilities required by COGS, and second, to determine whether there exist substantial differences across the models we test, when the number of trainable parameters is controlled for.

5.1 Training Details

We trained LSTM and Transformer models on COGS only without any pretraining. We used cross-entropy loss, a batch size of 128, and early stopping when validation loss did not improve for five validation steps (step size = 500). All experiments were run five times with different random seeds, which determined the initial weights and the order of the training examples. Models were implemented using OpenNMT-py[3] (Klein et al., 2017).

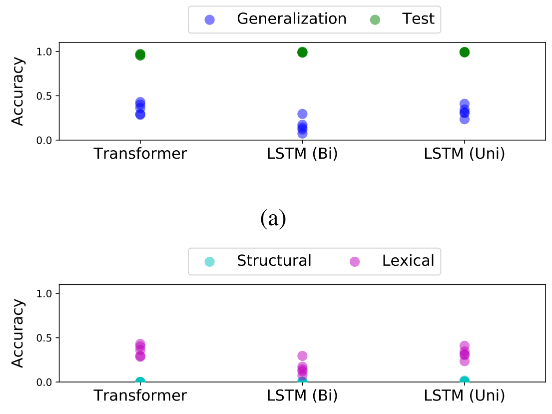
For the LSTM, we used a 2-layer encoder-decoder with global attention and a dot-product score function. The decoder followed an input-feeding approach (Luong et al., 2015). We tested both unidirectional and bidirectional LSTM encoders. The Transformer had a comparable number of parameters to the LSTMs (Transformer: 9.5M; BiLSTM: 10M; LSTM: 11M). It had 2 encoder and decoder layers, 4 attention heads, and a feed-forward dimension of 512. See Appendix D for additional training details.

5.2 Results

All architectures performed well on the development and test sets (Table 2), with little variability across runs (Figure 2a, green dots). By contrast, generalization accuracy was low across the board, and was characterized by much higher variance (blue dots). Transformers and unidirectional LSTMs of a comparable size did not substantially differ in their average accuracy, whereas bidirectional LSTMs performed comparatively worse.

Model	Dev.	Test	Gen.
Transformer	0.96	0.96	**0.35** (± 0.06)
LSTM (Bi)	0.99	0.99	0.16 (± 0.08)
LSTM (Uni)	0.99	0.99	0.32 (± 0.06)

Table 2: Average accuracy of tested models. Only standard deviation greater than 0.01 is shown.



(a)

(b)

Figure 2: (a) Accuracy on COGS. An output sequence is considered correct only if it exactly matches the gold sequence. Each dot represents a model trained with a different random seed. (b) Accuracy by generalization type (lexical or structural).

Accuracy on each generalization case greatly fluctuated across different runs of the same model,

Case	Training	Generalization	Accuracy Distribution
Subject → Object (common noun)	*Subject* A **hedgehog** ate the cake.	*Object* The baby liked the **hedgehog**.	Object → Subject (common noun)	*Object* Henry liked a **cockroach**.	*Subject* The **cockroach** ate the bat.	Object → Subject (proper noun)	*Object* Mary saw **Charlie**.	*Subject* **Charlie** ate a donut.	Primitive → Object (proper noun)	*Primitive* **Paula**	*Object* The child helped **Paula**.	Depth generalization: PP modifiers	*Depth 2* Ava saw the ball **in the bottle on the table**.	*Depth 3* Ava saw the ball **in the bottle on the table on the floor**.	Active → Passive	*Active* Emma **blessed** William.	*Passive* A child **was blessed**.	
Table 3: Accuracy on COGS by generalization case. Each dot represents a single run of the model.

except for the cases where accuracy was close to zero (see examples in Table 3, and see Appendix F for full results). The only exception to the trend was the Active → Passive case (but not vice versa) in the Transformer model, where all runs of the model achieved close to 100% accuracy. The majority of the LSTMs' predictions were structurally correct even when they did not exactly match the expected output, suggesting that Active → Passive is one of the least challenging cases in our generalization set (see Appendix G.1 for an error analysis).

5.2.1 Lexical vs. Structural Generalization

Some of the COGS generalization cases require *lexical* generalization: a primitive needs to be interpreted in a structure which, while not itself novel, did not occur with that primitive in training. This is the case for Object → Subject: the training set does contain examples of the structure [NP [V NP]$_{VP}$] (Figure 3a), and the generalization concerns the particular NP that has never been observed in the first NP position. This contrasts with cases requiring *structural* generalization, where the structure of the sentence is itself novel. This is the case, for instance, for the structure [[NP PP]$_{NP}$ [V NP]$_{VP}$]—a PP modifier on the subject—which appears in the generalization set but not in training (Figure 3b).

The depth generalizations and the generalization of modifiers across grammatical roles require structural generalization; all such cases had zero or near-zero accuracies, whereas models performed better on lexical generalization (Figure 2b). This discrepancy suggests that composition of structures is more challenging to both Transformers and LSTMs.

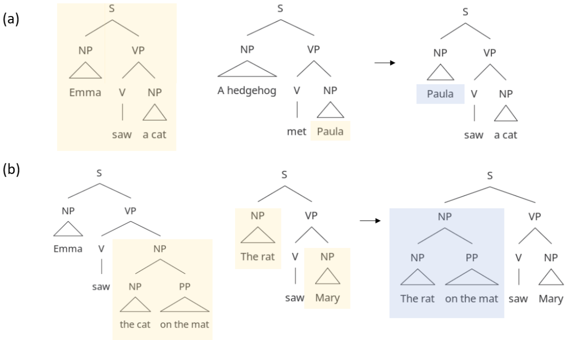

Figure 3: (a) Lexical generalization: a novel combination of a familiar primitive and a familiar structure. (b) Structural generalization: a novel combination of two familiar structures.

Successful depth generalization cases. Depth generalization with PP modifiers was the only case of structural generalization on which some models achieved nonzero accuracy. All of the successful examples were cases of depth 3, the smallest unseen depth tested. The success cases also had shorter output lengths, with a maximum length of 120 tokens. This was within the range of output lengths seen during training (the longest training example included 153 tokens), which may account for the somewhat higher accuracy on these cases.

Failure to generalize structurally or failure to produce novel labels? It is known that neural models find it challenging to produce labels they have not seen during training (Gandhi and Lake, 2019). Handling this problem is a necessary part of solving depth generalization, since each of the outputs of the depth generalization cases, such as (5b) below, contains more constants than the training outputs, such as the output of (5a):

(5) a. Depth 1: The **cat liked** that the **dog saw** the **mouse**. *(5 index-taking items)*

b. Depth 3: The **cat liked** that the **dog liked** that the **mouse liked** that the **girl saw** the **rat**. *(9 index-taking items)*

As discussed in Section 3, we used index-based labels for constants precisely to help models with this issue of producing novel elements, by grounding the labels to the indices. Specifically, the 5 index-taking items in (5a) are labeled x_1, x_2, x_5, x_6 and x_8 instead of being assigned arbitrary labels such as $x, y, z \ldots$. However, even with such non-arbitrary labels, the model still needs to learn that a word at index i relates to the output string 'i'.

While this problem of novel symbols is indeed an issue that the models need to handle during depth generalization, the pattern of errors suggest that the low accuracy is not purely due to this issue. In fact, only 0.5% of all depth generalization errors were cases where the structural form of the outputs were correct with only the indices being incorrect. More frequently, the models produced an end-of-sentence token too early (90.3% of all depth generalization errors), or produced sequences that were superfluously long (3% of errors contained more than 1000 tokens—more than twice as longer than the maximum gold output length: 480). This implies that models struggle with handling longer and deeper sequences than those observed during training, independently of their inability to produce novel labels. While output length likely contributed to the difficulty of our depth generalization cases—even in the in-domain test set, the average length of correct answers was 43 tokens, compared to 83 for incorrect answers—deeply nested structures imposed additional challenges. On the test set examples with output length greater than 95, LSTM models and Transformer models had 68% and 13% accuracy, respectively. Their PP modifier depth generalization accuracy was much lower (LSTM: 2%; BiLSTM and Transformer: near 0%).

5.2.2 Levels of Embedding

Our depth generalization set contains examples with embedding depths 3–12. However, it is likely that humans would find deeply embedded structures difficult to interpret. Given this potential difficulty for humans, is our depth generalization a fair challenge to pose? Comprehensibility of 3–5 degrees of embedding is attested in the literature; Blaubergs and Braine (1974) showed that humans can understand 3–5 levels of right-branching CP embedding, and Karlsson (2010) observed that 3–5 levels of right-branching PP and CP embeddings do occur in corpora. In the case of the models we tested, they almost completely failed on generalization to any levels of embedding, *including* depths 3–5 that humans should be able understand (Table 4). We discuss the issue of generalization to depths greater than 5 in Appendix H.

Model	All	3–5	6–12
Transformer	0.00	0.00	0.00
LSTM (Bi)	0.00	0.01	0.00
LSTM (Uni)	0.01	0.03	0.00

Table 4: Accuracy on depths 3–5 and depths 6–12.

5.2.3 Model Size / Number of Exposure Examples

In follow-up experiments, we found that increasing the number of parameters of the Transformer model five fold did not improve performance. If anything, variability was higher and mean accuracy was lower (see Appendix E.1). By contrast, increasing the number of exposure examples per primitive from one to 100 led to a significant improvement in generalization for all three models, though this increase was only applicable to lexical generalization cases (see Appendix E.2).

6 Comparison to Related Work

Our aggregate results in Table 2 are in line with recent work that has documented a significant discrepancy between neural models' excellent performance within distribution and their degraded performance out of distribution (Johnson et al., 2017; Lake and Baroni, 2018; Hupkes et al., 2020).

Our finding of poor generalization to deeper nested structures aligns with the results of Hupkes et al. (2020). Given that deeper structures also tend to be longer than shallower ones, this finding also relates to the difficulty of generalization to longer sequences. One illustrative example is the poor performance of LSTMs on a SCAN split that requires generalizing from shorter to longer sequences. While several models have made significant improvements over other SCAN splits, progress on the length split remains minimal (Li et al., 2019; Lake, 2019; Gordon et al., 2020).

The most similar work to ours is Compositional Freebase Questions (CFQ; Keysers et al. 2020), a synthetic dataset designed to test for compositional generalization in SQL parsing. COGS differs from CFQ in two main ways. First, compared to sentences with a SQL mapping, which are limited to questions and imperatives, the semantic representation used in COGS significantly extends the variety of expressions that can be assigned an interpretation. Second, in CFQ, challenging splits are defined by a similar primitive distribution but different distributions of the composed forms (“compound divergence”). This can lead to a training and test split that is not characterized by any principled linguistic difference. Following a stronger definition of compositionality, the generalization set in COGS includes combinations of primitives and syntactic roles that are novel (occurred zero times in training), without concern for matching the distribution of primitives across training and testing.

Our work is related to but distinct from work that tests language models for systematic syntactic generalization (Gulordava et al., 2018; Marvin and Linzen, 2018, *i.a.*). Unlike our work, the language modeling setup does not directly evaluate the *meaning* that the model assigns to a sentence.

7 Constraints on Generalization

To reach full adult linguistic competence, human learners not only need to be able to make abstraction-based generalizations, but also need to learn how to constrain them. For example, the verb *donate* takes a recipient *to*-PP (*Emma donated the book to the museum*) but does not allow double-object alternation (**Emma donated the museum the book*). How constraints as such could be learned has been discussed in linguistics under the banner of the projection problem (Baker, 1979). COGS focuses on evaluating computational models' ability to make systematic generalizations, but not on evaluating the ability to constrain them. For this reason, COGS only includes examples to which generalizations are applicable (e.g., dative verbs that alternate). This is a simplification; in natural language, generalizations are not applicable across-the-board, and are modulated by a multitude of morphophonological, syntactic and semantic factors. In the case of the dative alternation, properties such as animacy and definiteness are involved (Bresnan and Ford, 2010). Thus, evaluating constraints on generalization requires a detailed characterization of factors that govern individual generalization cases, as well as a formalism capable of expressing these factors, which we leave to future work.

8 Conclusion

We have proposed COGS, a challenge set for compositional generalization, which uses a synthetic sentence-to-logical-form mapping task that approximates meaning interpretation in English. When tested on COGS, both Transformers and LSTMs performed poorly on the generalization set, with high variability across runs, while their performance on the in-domain test set was consistently near-perfect. Furthermore, the models found structural generalization much more challenging compared to lexical generalization. Our results suggest that achieving high generalization accuracy on COGS is beyond the capacity of models that we tested, and COGS can therefore motivate the development of new computational models.

What architecture would be needed to solve COGS? For structural generalization cases, the results of Bowman et al. (2015); Evans et al. (2018) and McCoy et al. (2019) suggest that tree-structured models may provide a better inductive bias. In particular, Bowman et al. (2015) showed that tree-structured neural networks generalized to longer sequences. For lexical generalization cases, the RNN-based model from Gordon et al. (2020) that implements permutation equivariance may help, considering that it was able to solve all primitive generalizations in SCAN.

A PCFG

Our PCFG assigns uniform probability (about 5%) to each frame (e.g., transitive verb with both subject and object, transitive verb with only subject, passivized transitive with subject only, passivized transitive with subject and agent *by*-phrase...) except for CP embedding constructions, whose probability was increased to about 8% to match their distribution in natural corpora.[4] Syntactically ambiguous verb subcategories are distinguishable by distributional information; for instance, unaccusative verbs appear with both animate and inanimate subjects, whereas unergatives and object-omitted transitives only appear with animate subjects. Object-omitted transitives always have a transitive counterpart, whereas unergatives do not alternate. The verb subtypes also have distinct primitive logical forms, and primitive logical forms of some verbs were provided as part of the training set. The grammar assigns Zipfian probability distribution (inverse rank-frequency distribution) over lexical items in each noun and verb subcategory.[5] This was done in order to ensure that all possible grammatical patterns that a lexical item could appear in were sampled by the PCFG and included in our dataset, for at least the top most frequent items in the class (e.g., both forms of the object omission alternation are sampled for the most frequent verb).

The types of sentences generated by our PCFG are as follows. Sentence type names are taken from Roland et al. (2007).

- Simple Intransitive
- *To* Infinitive Verb Phrase
- Sentential Complement
- Simple Transitive
- Ditransitive
- Passive

When calculating the % covered by our grammar in Section 4, we collapsed Sentential Complement with Complementizer and Sentential Complement without Complementizer.

B Selection of Lexical Items

We selected the 403 common nouns in our lexical inventory from the MacArthur-Bates Communicative Development Inventories (Fenson et al., 2007) and the British National Corpus (Leech et al., 2001). 100 proper nouns were selected from top baby names of 2019 in the United States according to the United States Social Security Administration. In selecting the verbs, we referred to Levin (1993) and Kipper-Schuler (2005). There were 113 unique verbs and 6 verb types, with some overlapping verbs across verb types (e.g., *like* with NP and CP arguments). The list of verb types are as follows:

- Verbs that take NP arguments that allow direct object omission (e.g., *eat*)
- Verbs that take NP arguments that do not allow direct object omission (e.g., *find*)
- Subject control verbs that take infinitival arguments (e.g., *try*)
- Verbs that take CP arguments (e.g., *say*)
- Unaccusative verbs (e.g., *freeze*)
- Unergative verbs (e.g., *sleep*)
- Dative verbs (e.g., *give*)

5 common nouns, 3 proper nouns and 7 verbs used as primitive exposure examples were selected at random.

C Logical Form Postprocessing

We applied several postprocessing steps to the simplified logical forms of Reddy et al. (2017). The changes induced by our postprocessing steps are as follows:

- Skolem constants are named x_i instead of i, where i is the 0-based index of the head of the phrase denoted by the constant.
- Event predicates triggered by nominals are removed for simplicity.
- The final form is conjunctive, where the conjuncts are sorted by the subscript of the Skolem constants (i.e., the order of the conjuncts are deterministic).

---

[4] The assigned probabilities did not necessarily translate into the proportion in the generated dataset, since there were post-generation filtering mechanisms such as removing duplicate entries.

[5] This is a simplification, since not all synctactic categories or category subtypes are expected to follow a Zipfian frequency distribution (Piantadosi, 2014).

Expression: *John ate the cookie.*

- Definite and indefinite descriptions are formally distinguished. Refer to Appendix H for the exact distinction and linguistic implications.

See Table 5 for a comparison between logical forms.

D Training Details

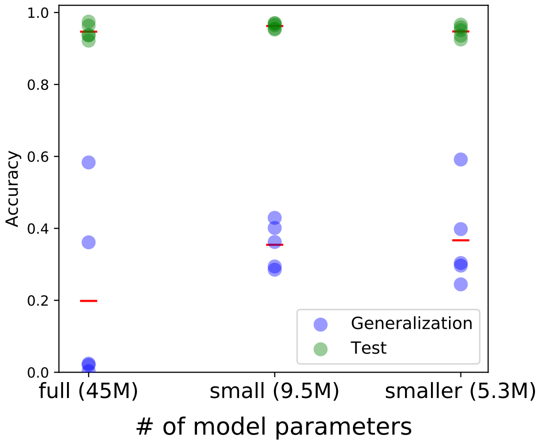
LSTM. We used a 2-layer LSTM encoder-decoder with global attention and a dot-product score function. The decoder followed an input-feeding approach (Luong et al., 2015). We tested both unidirectional and bidirectional encoders. We used inputs of dimension 512 and two hidden layers of dimension 512 (256 for model with bidirectional encoders so that the input dimension of the decoder stays constant across models after concatenating forward and backward states, and the number of parameters in each model remains comparable). A dropout of 0.1 was applied after the embedding layer and after each hidden layer except for the last. Following Lake and Baroni (2018), we used the Adam optimizer, and clipped gradients with a norm larger than 5.0. The training time for each model was around 3 to 4 hours on a single NVIDIA K80 GPU.

Transformer. Our Transformer model had 2 encoder and decoder layers, 4 attention heads, and a feedforward dimension of 512. Other hyperparameter settings not discussed here followed Vaswani et al. (2017) as closely as possible. The training time for each model was around 1 to 2 hours on a single NVIDIA K80 GPU.

E Additional experiments

E.1 Effect of Transformer Model Size

The results we report in the body of the paper are from a Transformer with 9.5M parameters. How does the number of parameters affect the Transformer’s success on COGS? Figure 4 compares the performance of three Transformer models of varying size (large: 45M, small: 9.5M, smaller: 4.5M). The number of parameters did not a have large impact on test set accuracy; all runs of all models achieved higher than 90% accuracy. On the other hand, model size did affect generalization. Perhaps surprisingly, the average across 5 runs of the large model was *lower* than those of smaller models; however, this average result is hard to interpret given the very high variance in accuracy across runs of the the largest Transformer.



# Params.	Dev.	Test	Gen.
45M	0.95	0.95	0.20 (± 0.26)
9.5M	0.96	0.96	0.35 (± 0.06)
5.3M	0.95	0.95	0.37 (± 0.14)

Figure 4: The effect of Transformer model size on generalization and test set accuracy.

E.2 Effect of Number of Distinct Exposure Examples per Primitive

COGS includes a single exposure example for each primitive (one-shot generalization). To test whether a larger number exposure examples help generalization, we repeated our experiments with a version of COGS training set in which the number of exposure examples was increased to 100. All models benefited from the greater number of exposure examples (Table 6). Note that some of the cases, such as Object-Modifying PP → Subject-Modifying PP, did not require primitive exposure examples, and are therefore identical across the 1-shot and 100-shot settings (for the detailed breakdown by case, see Table 7).

Model	# Exposure examples	Dev.	Test	Gen.
Transformer	1	0.96	0.96	**0.35**
	100	0.94	0.94	**0.63**
LSTM (Bi)	1	0.99	0.99	0.16
	100	0.99	0.99	0.50
LSTM (Uni)	1	0.99	0.99	0.32
	100	1.00	1.00	0.54

Table 6: Effect of number of exposure examples per primitive on accuracy.

F Results by Case

Table 7 lists the full results on each generalization case.

G Detailed Error Analysis

G.1 Active → Passive: Systematicity of Errors in LSTMs vs. Transformers

As discussed in Section 5.2, the Active → Passive generalization was a case in which Transformers performed near-perfectly, whereas LSTMs did not. However, an error analysis revealed that the errors made by LSTMs were more systematic than those of Transformers.

The majority of LSTMs' errors were structurally correct; only 0.3% (7/2591) of the unidirectional LSTM errors and 0.5% (14/2773) of the bidirectional LSTM errors had a different structure from the gold output. LSTMs often replaced the target passive verb with a different one (6), misused a thematic role (7), or misused an index (8). These types of errors have equivalent structure to the correct output, and have the same number of tokens as the correct output.

(6) A balloon was blessed. →
GOLD: balloon(x_1) AND bless.theme(x_3,x_1)
LSTM: balloon(x_1) AND inflate.theme(x_3,x_1)

(7) The book was blessed by a girl. →
GOLD: *book(x_1) AND bless.theme(x_3,x_1) AND bless.agent(x_3,x_6) AND girl(x_6)
LSTM: *book(x_1) AND bless.theme(x_3,x_1) AND send.recipient(x_3,x_6) AND girl(x_6)

(8) A rose was blessed by the baby. →
GOLD: *baby(x_6) ; rose(x_1) AND bless.theme(x_3,x_1) AND bless.agent(x_3,x_6)
LSTM: *baby(x_5) ; rose(x_1) AND bless.theme(x_3,x_1) AND bless.agent(x_3,x_6)

By contrast, the Transformer's errors in the Active → Passive generalization, despite being much fewer in number, had incorrect structure (79.6% of all errors; 39/49). The pattern in the total of 49 errors made by Transformer models in aggregate included omission of whole conjunct, spurious indices, not producing an output, using a numbered constant in place of a proper noun, etc. The following example shows a Transformer output with multiple errors—the model misinterpreted *tool* as a binary predicate and misindexed the theme argument:

(9) The tool was blessed by the girl. →
GOLD: *tool(x_1) ; *girl(x_6) ; bless.theme(x_3,x_1) AND bless.agent(x_3,x_6)

TRANSFORMER: *tool(x_1) ; *girl(x_6) ; tool(x_3,x_1) AND bless.theme(x_3,x_6)

Some Transformer runs produced more systematic errors than others, despite having similar accuracy on the Active → Passive generalization. For example, some runs mostly made the error of using the wrong verb as in (6). Others made more idiosyncratic errors with mixed patterns.

One possible reason for the high performance on the Active → Passive case is that our training data included both passive constructions with and without the agent *by*-phrase (e.g., both *The book was seen* and *The book was seen by Emma*). In these two constructions, the logical form of the former is a prefix of the logical form of the latter:

(10) The book was seen (by Emma). →
NO BY: ***book(x_1) AND see.theme(x_3,x_1)**

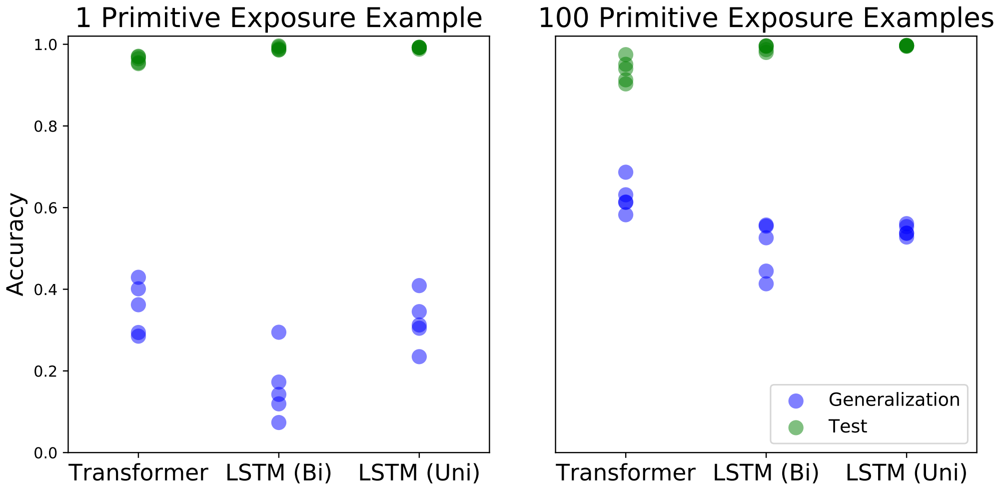


Figure 5: Accuracy on COGS with a different number of exposure examples. Each dot represents a model trained with a different random weight initialization.

WITH BY: ***book**(x_1) **AND**
see.theme(x_3,x_1) AND
see.agent(x_3,Emma)

Since these two types of passive constructions were sampled with equal probability, performance on the Active → Passive case may have benefited from more exposures to examples relevant to forming the passive construction.

G.2 More General Error Patterns

The LSTMs' erroneous outputs were more systematic, and closer to the correct outputs, in other generalization cases as well. The average token-level edit distance between errors and correct answers across all generalization cases, only considering error cases, were 11 and 14 tokens for bidirectional and unidirectional LSTMs, compared to 42 tokens for Transformers. Furthermore, Transformers frequently produced ill-formed logical forms; for example, they often failed to close the final parenthesis (11). In fact, ending the logical form with anything other than a right parenthesis is ill-formed (12). This type of error accounted for 12% of all Transformer errors, while only 0.5% of bidirectional and unidirectional LSTM errors were ill-formed in this way.

(11) Paula packed. →
GOLD: pack.agent(x_1, Paula)
TRANSFORMER: pack.agent(x_1, Paula

(12) Emma appreciated the hedgehog. →
GOLD: *hedgehog(x_3) ;
appreciate.agent(x_1,Emma) AND
appreciate.theme(x_1,x_3)
TRANSFORMER: *

G.3 Common vs. Proper Nouns

Table 3 shows that even for the same type of targeted generalization (e.g., Object → Subject, Primitive → Object), the variant that used proper nouns (13) was more challenging than the variant using common nouns (14).

(13) Training: The creature grew **Charlie**. →
*creature(x_1) AND grow.agent(x_2, x_1)
AND grow.theme(x_2, **Charlie**)
Generalization: **Charlie** ate a cookie. →
eat.agent(x_1,**Charlie**) AND
eat.theme(x_1,x_3) AND cookie(x_3)

(14) Training: Henry liked **a cockroach**. →
like.agent(x_1, Henry) AND
like.theme(x_1,x_3) **AND cockroach**(x_3)
Generalization: **The cockroach** ate the bat. → ***cockroach**(x_1) **AND** *bat(x_4)
AND eat.agent(x_2,x_1) AND
eat.theme(x_2,x_4)

What is the source of this discrepancy? As can be seen from the above examples, common and proper nouns are formally distinct in both the source sentence and the target logical form. Translating a common noun requires conjoining a unary predicate (cockroach(x_n)), and placing the predicated constant (x_n) in appropriate event predicates. On the other hand, translating a proper requires placing the nominal constant (Charlie) inside appropriate event predicates. Given the lower complexity of (symbolic) steps required for translating proper nouns, the lower accuracy is surprising. While we do not have a definite explanation for this discrepancy, one possibility is that it is due to a frequency effect; our dataset overall contained more common nouns than proper nouns, in terms of both type and token frequency.

The discrepancy in accuracy between common and proper nouns indicates that performance is sensitive to seemingly minor formal differences in cases that require the same type of generalization, echoing the discrepancy between the *jump* and *turn left* primitive splits of SCAN that were originally observed by Lake and Baroni (2018).

H Linguistic Commentary

Semantic representation. Our semantic representation is based on a Neo-Davidsonian view of verbal arguments (Parsons, 1990), in which verbs specify an event argument, and thematic roles link non-event arguments to the event. Definite descriptions that are not proper names are marked with an asterisk, standing in place of the standard ι notation. The asterisk expressions appear to the leftmost of the logical form to avoid nesting of predicated expressions. They are not conjoined to the logical form but separated with a ;, because ι expressions are of type *e* rather than *t*. The logical form with the asterisk expression (e.g., The cat ran: *cat(x_1) ; run.agent(x_2, x_1) should be semantically equivalent to one that contains a nested ι expression ($\exists e$. run.agent(e, ιx.cat(x)), if ι is scopally inert. This may not necessarily be the case for definite descriptions in intensional semantics; for instance under modals. See the discussion of Kaplan (1989) in Wolter (2019) for more details.

Representation of primitive meanings. Primitives in our dataset take the following form:

- Common noun: *shark* → λa.shark(a)
- Proper noun: *Emma* → Emma
- Verb: *like* → $\lambda a.\lambda b.\lambda e$.like.agent($e, a$) $\wedge$ like.theme(e, b)

where λ is written as 'LAMBDA' and $\wedge$ is written as 'AND'. Primitive meanings are not skolemized because they are not existentially quantified. We used the letters *e, a, b* to distinguish variables from skolem constants (x_n). Verbs that are compatible with agents specify an agent as an argument in their primitive meanings for simplicity, rather than following the external argument analysis of Kratzer (1996).

Recursive structures tested. Whether unbounded recursion should be considered as a part of machinery that governs language is a debated issue, the evidence against being the significantly degraded human parsing performance on multiply-nested structures (Christiansen and Chater, 1999). In our dataset, we only included structures that are traditionally thought of as recursive, but does not necessitate recursion as an intrinsic mechanism because they can be implemented by a Finite State Machine (Christiansen, 1992).

Testing generalization to arbitrary depths. Our depth generalization sets test generalization to 3-12 degrees of embedding in right-branching structures. However, human processing of embedded structures degrades over levels of embedding (Blaubergs and Braine, 1974) and attestation of embeddings greater than depth 5 is rare (Karlsson, 2010). Given this limitation in humans, should the inability to handle generalization to our generalization set, and furthermore *arbitrary* depths of embedding be viewed as a flaw of the system? Our position is that is should. According to Chomsky's notion of competence versus performance, there is no reason to view English sentences with embedding depths greater than 5 to be ungrammatical, even if human memory limitations make such sentences difficult to understand. Computational models that we tested are not restricted by the same memory limitations and therefore should not fail to process such sentences on the same grounds. Any such failure would be diagnostic of a discrepancy between what the model has learned and the correct way to perform the task, as defined by English grammar. A detailed comparison of computational models and human subjects' performance on this subset of COGS would be an interesting follow-up work that would shed light on both human and machine generalization. We predict that models' behavior will differ from that of humans, since the models' accuracy at depth 3 was already close to zero, whereas we expect that humans will display degraded but still reasonable understanding of depth 3 PP/CP embeddings.

PP attachment ambiguity. Our grammar does not generate VP-modifying PPs (the only PP verbal dependents are recipient *to*-phrases, which are always arguments rather than modifiers). Therefore, all PP modifiers in our dataset should strictly have an NP-attachment reading, although for human readers VP-attachment readings could sometimes be more prominent based on the lexical content of the sentences. All modifications are nested rather than sequential: *The cat ate [the cookie [on the mat [beside the table]]]* rather than *The cat ate [the cookie [on the mat] [beside the table]].*

Selectional preference. Words have selectional preference, a tendency to semantically constrain other words that they appear with. For instance, verbs such as *sing, walk* are likely to take animate subjects. Our grammar only implements a simplified version of selectional preference: namely the animacy of the NP arguments based on verb type (e.g., subjects of unergatives are animate). In reality, selectional preference is much more complex and highly verb-specific; for instance the theme of *eat* should be something that is edible. The simplification of selectional preference results in semantic infelicity in some of the generated sentences. This should not create any difficulty in constructing a valid form-meaning mapping if models are trained from scratch, but may cause problems if models pretrained on real language data are tested.

Generalization of PP modification. Our PP modifier generalization set (Section 3.2) requires generalizing PPs that modify NPs in the object position to NPs in the subject position, without having seen any subject modification. We note that this may be a stronger generalization problem than what humans may actually encounter based on the following two observations. First, it is true that PP modifiers in the subject position are much less frequent than PP modifiers in the object position in child-directed speech, but subject-modifying PPs are not absent from it: according to our analysis of the Epochs corpus of Perfors et al. (2011), PP modification on the subject of a declarative sentence occurred only 13 times whereas PP modification on the object occurred over 100 times. Second, there exist many [NP PP] fragments that are not full sentences (e.g., *a disk from a game*) in the corpus. It is still likely that PP modification does not occur in all possible syntactic positions that can be occupied by an NP—for instance, in the subject position of a depth 2 embedded CP—and to interpret such sentences structural generalization would be required. Nevertheless, whether humans would be able to generalize modifiers in one syntactic position in the total absence of observing modifiers in other syntactic positions (or as fragments) remains to be tested, and is part of our future work.

# Exposure Contexts	Case	Transformer	LSTM (Bi)	LSTM (Uni)
1	Subject → Object (common noun)	0.31	0.05	0.18

Abstract

Negation is underrepresented in existing natural language inference benchmarks. Additionally, one can often ignore the few negations in existing benchmarks and still make the right inference judgments. In this paper, we present a new benchmark for natural language inference in which negation plays an important role. We also show that state-of-the-art transformers struggle making inference judgments with the new pairs.

1 Introduction

Natural language understanding remains an elusive goal except in limited scenarios. It is arguably the ultimate problem in natural language processing: to empower machines to understand language as generated by humans. The state of the art has seen tremendous progress in recent years, and has moved from symbolic representations (Bos et al., 2004; Artzi and Zettlemoyer, 2013) to distributional representations often learned from massive datasets (Devlin et al., 2019). Recognizing entailments (Dagan et al., 2006), identifying paraphrases (Das and Smith, 2009), determining semantic textual similarity (Agirre et al., 2012), and sentiment analysis (Pang and Lee, 2008) are but a few problems that require natural language understanding to a lesser or greater degree.

There are many benchmarks targeting the problems above, and they usually cast them as classification problems. A couple of popular evaluation platforms, GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019), aggregate benchmarks for some of the problems above and provide a single score for many tasks under the umbrella of natural language inference. State-of-the-art models are close to or even surpass human performance (Wang et al., 2019). This fact, however, is true only when evaluating models and humans with existing benchmarks. Indeed, researchers have pointed out weaknesses in benchmarks suggesting that we are evaluating models with examples that are much simpler than what humans are capable of (Section 3). Source text selection, annotation artifacts (Gururangan et al., 2018), and asking annotators—either experts or crowd workers—to write examples as opposed to retrieving real examples from previously generated language are a few of the culprits.

In this paper, we investigate the role of negation in a core natural language understanding task: natural language inference—in its most basic form, determining whether a *text* entails a *hypothesis*. Recognizing entailments has many applications including question answering (Trivedi et al., 2019), summarization (Pasunuru et al., 2017) and machine translation evaluation (Padó et al., 2009).

Negation relates an expression e to another expression with a meaning that is in some way opposed to the meaning of e (Horn and Wansing, 2017), thus it plays an important role in natural language understanding. Additionally, negation is ubiquitous in regular English texts: approximately 25% of English sentences contain negation depending on the domain and genre (Section 4). Despite these facts, negation is underrepresented and mostly irrelevant in existing benchmarks—one can literally disregard the negations and still make correct inference judgments in popular datasets. The work presented here addresses these shortcomings and makes the following contributions:[1]

1. We show that negation is underrepresented and often irrelevant in existing benchmarks.
2. We create new benchmarks for natural language inference in which negation plays a critical role to make inference judgments.
3. We demonstrate that state-of-the-art trans-

---

November 16–20, 2020. ©2020 Association for Computational Linguistics

formers trained with the original benchmarks are not robust when negation is present.

4. We provide empirical evidence that transformers may be unable to learn the intricacies of negation in the most challenging benchmark, which includes longer texts from many genres.

2 Background

The task of natural language inference or recognizing textual entailment consists in determining whether a *hypothesis* is true given a *text*. The original task considers two labels: entailment or no_entailment (Dagan et al., 2006), and a newer formulation considers three labels: entailment, contradiction or neutral (Giampiccolo et al., 2007). For example, the *text* "A person on a horse jumps over an airplane" entails *hypothesis* "A person is outdoors, on a horse," contradicts "A person is at a diner, ordering an omelette," and is neutral with respect to "A person is training his horse for a competition." We work with three existing benchmarks: a collection of RTE datasets (Dagan et al., 2006; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009), SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018). The RTE datasets are smaller (5,767 text-hypothesis pairs) than SNLI and MNLI (569,033 and 431,997 pairs). MNLI is more challenging than RTE and SNLI: texts are longer and were selected from 10 genres including fiction and non-fiction as well as conversation transcripts. On the other hand, the texts in SNLI were selected from image captions. The hypotheses in SNLI and MNLI were crowdsourced, i.e., manually generated by non-experts.

Tables 2 and 4 show examples in the RTE, SNLI and MNLI benchmarks. We work with the formatted versions of these datasets in the GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) benchmarks for convenience.

3 Previous Work

Previous work has revealed weaknesses with the benchmarks we work with and that adversarial examples can break models for many natural language processing tasks. Adversarial examples consist of arguably trivial modifications to inputs that trick computational models. Some of them include misspellings (Pruthi et al., 2019), syntactically controlled paraphrases (Iyyer et al., 2018), lexical substitutions (Alzantot et al., 2018), and more elaborate substitutions (Ribeiro et al., 2018). More recently, Ribeiro et al. (2020) propose CHECKLIST, a task-agnostic strategy for testing NLP models. Their strategy can be used to identify which linguistic capabilities a model lacks. For example, they show that commercial systems for sentiment analysis are not robust when negation is present.

Regarding natural language inference, Poliak et al. (2018) show that models taking into account only hypotheses significantly outperform majority baselines, and Gururangan et al. (2018) discuss annotation artifacts, e.g., negation cues (not, never, etc.) are a strong indicator of contradictions. Glockner et al. (2018) show that models trained with SNLI fail to resolve new pairs that require simple lexical substitution, e.g., *holding a saxophone* contradicts *holding an electric guitar*. Naik et al. (2018) conclude that models are not robust to negation, but their only test is concatenating the tautology "and false is not true" to hypotheses. Wallace et al. (2019) introduce universal triggers and show that concatenating negation cues to SNLI hypotheses decreases accuracy to almost zero when the gold label is entailment or neutral.

The task of identifying paraphrases consists in determining whether two sentences have the same meaning, and can be casted—at least from a definitional perspective—as recognizing bidirectional entailments. Pruthi et al. (2019) show that computational models underperform in MRPC (Dolan et al., 2004) with adversarial misspellings, and Kovatchev et al. (2019) present a qualitative analysis of 11 state-of-the-art models (overall accuracies: 68–84%). When negation is present, however, accuracies drop to 33% (6 models) 67% (4 models) and 1% (1 model). Finally, Zhang et al. (2019) present a dataset for paraphrase identification including adversarial sentence pairs that are not paraphrases but have high word overlap. The new pairs helps training models robust to word scrambling.

The aforecited works do not investigate the role of negation in depth. Regarding paraphrase identification, previous work only has shown that models underperform with negation. Regarding natural language inference and negation, previous work considers negations only in the hypotheses—not the texts. Additionally, they only work with unrealistic negations that do not require models to do anything but ignore the negations. Indeed, they concatenate tokens including negations cues that are label-preserving and unrelated to the original texts and hypotheses. Unlike them, we (a) show

Table 1: Percentage of sentences containing negation in general-purpose English corpora (reviews, conversations, Wikipedia, books and OntoNotes) and existing natural language inference benchmarks (also in English). Negation is underrepresented in RTE and SNLI.

that existing benchmarks do not properly account for negation in terms of frequency and difficulty, (b) create new benchmarks that require understanding negations, and (c) show that state-of-the-art models trained with existing corpora struggle with the new pairs including negation, and that the issue persists even if we fine-tune models with the new pairs in the most challenging benchmark, MNLI.

4 Negation in English and Natural Language Inference Benchmarks

Negation is pervasive in English (Morante and Sporleder, 2012), although there is limited empirical evidence from previous work (Councill et al., 2010; Elkin et al., 2005). In order to conduct a large-scale analysis and compare how often negation is present in English and existing natural language inference benchmarks, we employ a negation cue detector using a Bi-LSTM neural architecture with an additional CRF layer (Hossain et al., 2020). Trained and tested with CD-SCO, a corpus publicly available (Morante and Blanco, 2012), it obtains 0.92 F1. The supplemental materials provide more details regarding the architecture of the negation cue detector and the negation cues it detects.

Table 1 details the percentage of sentences with at least one negation in several large general-purpose English corpora. We work with online reviews (Wan et al., 2019; Maas et al., 2011), conversations (Chang et al., 2019), Wikipedia (50,000 pages with at least 20 views), 500 books from Project Gutenberg (Lahiri, 2014), and OntoNotes (Hovy et al., 2006) as released by Pradhan et al. (2011). The percentage of sentences containing negation is high: it ranges from 8.69% to 29.92% in all corpora, and is over 17% in all but Wikipedia. We note that negation is pervasive across domains and genres, including informal texts such as online reviews and both oral and written conversations (22.64–29.92%). Perhaps surprisingly, the percentage is very high in books (28.45%).

Table 1 also presents the percentage of sentences with negation in the three natural language inference benchmarks. Negation is clearly underrepresented in all of them except MNLI. These percentages do not invalidate the benchmarks. They show, however, that SNLI and RTE do not account for intricate linguistic phenomena such as negations. The reason for the low percentage in SNLI is that it uses texts from picture captions (Section 3), and captions describe pictures with affirmative statements (see examples in Tables 2 and 4).

The Role of Negation in Existing Natural Language Inference Benchmarks We conduct a manual qualitative analysis in order to (a) characterize the negations in RTE, SNLI and MNLI, and (b) assess how critical negation is to solve the few text-hypothesis pairs that include at least one negation in these benchmarks. We conduct the analysis with 100 text-hypothesis pairs containing negation from each benchmark (300 pairs total). From a linguistic perspective, most negations:

- are particles (no, not, n't, etc.) whose only function is to indicate negation (RTE: 62%, SNLI: 60%, MNLI: 84%),
- grammatically modify a verb (RTE: 62%, SNLI: 55%, MNLI: 81%), and
- scope over the main predicate (RTE: 52%, SNLI: 53%, MNLI: 62%).

These percentages are roughly uniformly distributed across labels.

In addition to looking at the negation cues in isolation, we also analyze the role of negation in making judgments. The first key distinction is whether dropping the negation changes the inference judgment (entailment or no_entailment in RTE; and entailment, neutral or contradiction in SNLI and MNLI). If it does not, we say the negation is ***unimportant*** (*important* otherwise). The

	Example
RTE	1) T: Mr Lopez Obrador, who lost July's presidential election by less than one percentage point, declared himself Mexico's "legitimate" president. H: Mr Lopez Obrador didn't loose the presidential election in July.
	2) T: If toxic waste containg cyanide is not disposed of properly, it may drain into ponds, streams, sewers, and reservoirs. H: Leaks into environment are caused by bad disposal of toxic waste containing cyanide.
	3) T: Toshiba has produced a fuel cell with no moving parts. H: Toshiba has no moving parts.
SNLI	4) T: A fighter jet plane is landed outside. H: The fighter jet plane is not moving.
	5) T: A man with no shirt on is performing with a baton. H: A man is doing things with a baton.
	6) T: A homeless man carries a sign that says "hungry". H: The man does not have a home.
MNLI	7) T: It was summertime the air conditioner was on the door was closed and i couldn't knock because i had to hold the jack with the other hand i finally with my elbow rang the doorbell and mother came to the door. H: The wintertime is when the air conditioning was on, I couldn't ring the doorbell because it was frozen.
	8) T: It runs advertisements for its supporters at the top of shows and strikes business deals with MCI, TCI, and Disney, but still insists it's not commercial. H: It runs ads for its supporters at shows and strikes business deals, but insists it is not commercial.

Table 2: Examples of the few text-hypothesis pairs that contain negation in the three natural language inference corpora we work with (RTE, SNLI and MNLI). Negation cues are underlined, and we have made minimal edits to some examples so that they fit within the width of the table.

second key distinction is whether the negation is ***aligned***, i.e., whether there is a semantic *alignment* between what is negated in the text (or hypothesis) and a chunk of the hypothesis (or text). We further identify ***negated alignments***, i.e., alignments in which the alignment is also *negated*.

Table 2 exemplifies this classification with the three benchmarks. Regarding SNLI, the negation in the hypothesis of Example (4) is important: *landed* entails *not moving*, at least according to the SNLI annotators, who were describing pictures thus (presumably) couldn't really tell if the plane was (a) completely stopped or taxiing after landing (and thus still moving). The negation in the text of Example (5), however, is unimportant: *A man with no shirt on is performing with a baton* entails *A man is doing things with a baton* regardless of whether the man has a shirt. Simply put, the negation plays no role in making the correct inference judgment. In Examples (4) and (6), the negations align but in Example (5), the negation does not align. Specifically, the alignments of the negations in the text and hypothesis of Example (6) are *negated*: *homeless* aligns with *does not have a home*, and both are negated. The alignment of the negation in the hypothesis of Pair (4), on the other hand, is not negated: *not moving* aligns with *landed*, and the latter is not negated. The categorization of the negations in text-hypothesis pairs from RTE and MNLI examples is as follows:

- RTE. The negation in the hypothesis of Example (1) is important, and it aligns but the alignment is not negated (*didn't loose* – lost). In Example (2), the negation in the text falls under the same categories: important and aligned, and the alignment is not negated (*not disposed of properly – bad disposal*). In Example (3), on the other hand, the negations are unimportant and aligned, in fact, there is an identical (and negated) alignment (*no moving parts* in both the text and hypothesis).
- MNLI. The negation in the text of Example (7), *I couldn't knock*, is unimportant and not aligned. Indeed, the first clause in both the text and hypothesis, which do not contain negation, are sufficient to solve the pair: *the air conditioning being on in wintertime* is not entailed by *the air conditioning being on in summertime*. The negation in the hypothesis of Example (7), however, is also unimportant but aligned (*I couldn't ring the doorbell – my elbow rang the doorbell*), although the alignment is not negated. This negation is unimportant for the same reason: one can make the correct inference judgment disregarding the negation altogether. The negations in Example (8) are similar to the ones in Example (3): unimportant and aligned, although this time the alignments are almost identical (*it's not commercial – it is not commercial*).

	RTE			SNLI				MNLI			
	E	¬E	All	E	C	N	All	E	C	N	All
% unimportant	77	75	76	38	24	93	48	78	24	83	52
% aligned	25	17	20	62	76	17	55	39	76	23	53
w/ negation	15	4	10	25	0	13	10	26	2	9	8

Table 3: Analysis of the few negations in the text-hypothesis pairs from the three natural language inference corpora we work with (RTE: 7.16% of pairs, SNLI: 1.19%, MNLI: 22.63%; Table 1). E stands for entailment, ¬E for no_entailment, C for contradiction and N for neutral. Many negations are unimportant, i.e., one can ignore them and still make the correct inference judgment.

Table 3 presents the analysis of the role of negation based on these categories. First, we note that one can often ignore negations without consequences: 76% of negations are unimportant in RTE, 48% in SNLI and 52% in MNLI. In RTE, negations are unimportant in text-hypothesis pairs regardless of the inference judgment (75-76%). In SNLI and MNLI, however, negations are almost always unimportant in neutral text-hypothesis pairs (93% in SNLI and 83% in MNLI), and they tend to be unimportant when the text entails the hypothesis (78% in MNLI and 38% in SNLI). Second, we note that few negations *align* in RTE (entailment: 25%, no_entailment: 17%), but about half of them align in SNLI and MNLI (55% and 53%). The percentage of aligned negations heavily depends on the inference judgment in SNLI and MNLI, and in RTE to a lesser degree (entailment is 50% more likely). More interestingly, whether the alignment is negated is a clear sign of the inference judgment. In RTE, the alignments are rarely negated in no_entailment pairs (4% overall, 23.5% of aligned pairs), but that is not the case with entailment pairs (15% overall, 60% of aligned pairs). In SNLI, the differences are larger: 40.3% of aligned pairs labeled *entailment* are negated. We observe a similar pattern in the negations from MNLI: alignments are rarely negated in contradictions (2.6% of aligned pairs), and most alignments are negated in entailment pairs (66.7% of aligned pairs).

5 A Benchmark for Natural Language Understanding with Negation

We create new benchmarks in which negation plays an important role for natural language inference. The starting points are the original benchmarks, more specifically, we selected at random 500 text-hypothesis pairs from RTE, SNLI and MNLI (1,500 text-hypothesis pairs total). We work with pairs from the training and development splits as GLUE and SuperGLUE do not include gold labels for some test splits. Then, we follow three steps for each of the selected original pairs. In the remaining of the paper, we use T and H to refer to texts and hypotheses in RTE, SNLI and MNLI.

1. Add negation manually to the main verb in T and H to obtain T_{neg} and H_{neg}.
2. Generate three new pairs automatically by combining the elements in the original pair (T and H) and the results of Step (1) (T_{neg} and H_{neg}). This results in the following pairs: T_{neg}-H, T-H_{neg} and T_{neg}-H_{neg}.
3. Manually annotate the pairs from Step (2) using the labels from the original benchmarks (RTE: entailment or no_entailment; SNLI and MNLI: entailment, contradiction or neutral).

These steps result in 4,500 new pairs and their judgments (3 per original pair, 1,500 from each RTE, SNLI and MNLI). Note that the negations are rather simple—adding *not* to the main verb, and adding auxiliaries and fixing verb tense if needed—but are realistic in the sense that the resulting texts and hypotheses follow proper English grammar. Additionally, the new pairs including negation are not more difficult than the original pairs except for the presence of negation. In particular, they do not require additional lexical inference and the overall topic described does not change.

Table 4 exemplifies the new pairs with negation. While negating the main verb (Step 1) is a relatively straightforward step, note that annotating the three new pairs including negation (Step 3) requires more attention from annotators. In other words, the inference judgment for the original T-H pair does not unequivocally indicate the inference judgment for the three new pairs that include negation. Indeed, the two examples generated from RTE in Table 4 show that when the original text entails the

	Original pair	New pair w/ negation
RTE	T: Tropical Storm Debby is blamed for several deaths across the Caribbean. H: A tropical storm has caused loss of life.	T$_{neg}$: Tropical Storm Debby is not blamed for several deaths across the Caribbean. H$_{neg}$: A tropical storm has not caused loss of life.
	Judgments: T-H: entailment, T$_{neg}$-H: no_entailment, T-H$_{neg}$: no_entailment, T$_{neg}$-H$_{neg}$: entailment	
	T: Dr. Pridi was forced into exile, and Field Marshal Pibul again assumed power. H: Pibul was a field marshal.	T$_{neg}$: Dr. Pridi was not forced into exile, and Field Marshal Pibul again assumed power. H$_{neg}$: Pibul was not a field marshal.
	Judgments: T-H: entailment, T$_{neg}$-H: entailment, T-H$_{neg}$: no_entailment, T$_{neg}$-H$_{neg}$: no_entailment	
SNLI	T: Two people are working on computers. H: Two people are near the computers.	T$_{neg}$: Two people are not working on computers. H$_{neg}$: Two people are not near computers.
	Judgments: T-H: entailment, T$_{neg}$-H: neutral, T-H$_{neg}$: contradiction, T$_{neg}$-H$_{neg}$: neutral	
	T: Young man walking dog. H: The man is walking his cat.	T$_{neg}$: Young man is not walking dog. H$_{neg}$: The man is not walking his cat.
	Judgments: T-H: contradiction, T$_{neg}$-H: neutral, T-H$_{neg}$: entailment, T$_{neg}$-H$_{neg}$: neutral	
MNLI	T: The lot upon which it is built had been vacant. H: The lot had been vacant.	T$_{neg}$: The lot upon which it is built had not been vacant. H$_{neg}$: The lot had not been vacant.
	Judgments: T-H: entailment, T$_{neg}$-H: contradiction, T-H$_{neg}$: contradiction, T$_{neg}$-H$_{neg}$: entailment	
	T: Thursday's judge, the Honorable Charles Adams of the Coconino County Superior Court, agreed, but highly discouraged self-representation. H: Self-representation was encouraged by the Honorable Charles Adams.	T$_{neg}$: Thursday's judge, the Honorable Charles Adams of the Coconino County Superior Court, did not agree, but highly discouraged self-representation. H$_{neg}$: Self-representation was not encouraged by the Honorable Charles Adams.
	Judgments: T-H: contradiction, T$_{neg}$-H: contradiction, T-H$_{neg}$: entailment, T$_{neg}$-H$_{neg}$: entailment	

Table 4: Examples of original pairs and new pairs generated after we manually introduce negation. Note that we (a) generate three new pairs after combining texts and hypotheses with and without negation (T-H is the original pair), and (b) manually annotate inference judgments for the three new pairs.

hypothesis, the three new text-hypothesis pairs may receive different inference judgments (in particular the judgments for T$_{neg}$-H and T$_{neg}$-H$_{neg}$ are the opposite). The same is true across text-hypothesis pairs including negation and generated from different natural language inference benchmarks. For example, the text entails the hypothesis in the first examples shown from SNLI and MNLI, but the three new pairs including negation receive different judgments: neutral, contradiction and neutral; and contradiction, contradiction and entailment). The second examples created from SNLI and MNLI show the same phenomenon but with an original T-H pair labeled contradiction.

Annotation Process and Agreements. Three annotators and an additional adjudicator did the annotations described above in two phases.

In the first phase, the three annotators added negation to the main verbs of texts and hypotheses (Step 1). After a short training session, we decided to have only one annotator add negation in each original pair as the task is relatively straightforward. Any issues in this phase were detected during Phase 2. Text-hypothesis pairs with issues were discarded (only 5%) and additional pairs were collected to account for the discarded pairs (and still have 1,500 text-hypothesis pairs including negation and generated from each of the three benchmarks, 4,500 new text-hypothesis pairs in total).

In the second phase, the three annotators read the new pairs including negation (automatically generated in Step 2: T$_{neg}$-H, T-H$_{neg}$ and T$_{neg}$-H$_{neg}$) and manually labeled them with inference judgments (Step 3). In this phase, each pair was annotated by two annotators independently, and the adjudicator resolved any disagreements. We calculated inter-annotator agreement prior to adjudication using Cohen's κ (Cohen, 1960). κ coefficients were 0.85 (RTE), 0.81 (SNLI) and 0.72 (MNLI). κ coefficients between 0.6 and 0.8 are considered substantial, and between 0.8 and 1.0 nearly perfect (Artstein and Poesio, 2008).

	RTE		SNLI			MNLI		
	%E	%¬E	%E	%C	%N	%E	%C	%N
T_{neg}-H	19.8	80.2	6.0	32.0	62.0	11.8	45.8	42.4
T-H_{neg}	9.0	91.0	21.4	41.0	37.6	24.0	47.6	28.4
T_{neg}-H_{neg}	34.4	65.6	22.2	8.0	69.8	38.6	14.4	47.0
All	21.1	78.9	16.5	27.0	56.5	24.8	35.9	39.3

Table 5: Label distribution in the new text-hypothesis pairs including negation depending on the source pairs they were generated from (RTE, SNLI or MNLI). Unlike the authors of the original benchmarks, we do not artificially force a uniform distribution. The pairs generated from MNLI, which are the longest and the only ones from many genres, are the most balanced (majority baseline accuracy: 39.3%).

	RTE			SNLI				MNLI			
	E	¬E	All	E	C	N	All	E	C	N	All
% unimportant	52	56	56	17	24	61	42	12	19	63	43
% aligned	76	60	62	78	76	42	59	84	84	42	61
w/ negation	52	10	17	28	0	2	5	48	3	7	14

Table 6: Analysis of the negations in the text-hypothesis pairs in the new benchmarks. E stands for entailment, ¬E for no_entailment, C for contradiction and N for neutral. Some negations are unimportant, but the percentage of important negations in the new text-hypothesis pairs is higher than those in the original corpora (Table 3).

Label Distributions. The original RTE, SNLI and MNLI benchmarks contain, by design, text-hypothesis pairs with roughly uniform judgment distributions. Thus, the majority baseline obtains roughly 50% accuracy in RTE (2 labels) and 33% in SNLI and MNLI (3 labels).

Our new benchmarks including negation do not have a uniform judgment distribution (Table 5), although the pairs generated from MNLI are close (entailment: 24.8%, contradiction: 35.9%, and neutral: 39.3%). We acknowledge that the label distribution in the new pairs generated from RTE (majority baseline: 78.9%) and, to a certain degree, SNLI (majority baseline: 56.5%) are not as challenging as the label distributions in the original pairs. As we shall see in Section 6, however, our experiments show that the ones from MNLI are a challenge for state-of-the-art transformers.

The Role of Negation. Table 6 presents the analysis of the role of negation in the new benchmarks using the categories presented in Section 4. We analyze 100 text-hypothesis pairs generated from each original benchmark (RTE, SNLI and MNLI). There are less unimportant negations in our new benchmarks than in the original corpora (Table 3). While many negations in the new pairs generated from RTE are unimportant (entailment: 52%, no_entailment: 56%), few negations in the pairs generated from SNLI and MNLI are unimportant, especially when the text entails or contradicts the hypothesis (SNLI: 17% and 24%, MNLI: 12% and 19%). Unsurprisingly, the percentage of aligned negations is higher in our corpus due to the steps we use to introduce negation, especially with in the new pairs generated from RTE (62% vs. 20%).

6 Experiments and Results

In order to assess whether state-of-the-art systems can solve the task of natural language inference when negation is present, we experiment with three state-of-the art transformers: BERT (Devlin et al., 2019), XLNet (Yang et al., 2019) and RoBERTa (Liu et al., 2019). We use the implementation and pretrained models by Wolf et al. (2019), and tune them to solve each benchmark. The supplemental materials provide details about (a) the hyperparameter settings we use to fine-tune these transformers, and (b) other implementation decisions.

We conduct two experiments. First, we assess whether these transformers tuned with the original train splits in RTE, SNLI and MNLI are capable of solving our new benchmarks including negation (Section 6.1). Second, we investigate if tuning with the new text-hypothesis pairs including negation improves the results (Section 6.2).

Test pairs	RTE				SNLI				MNLI			
	MB	[1]	[2]	[3]	MB	[1]	[2]	[3]	MB	[1]	[2]	[3]
Original												
dev	52.7	75.8	69.9	66.1	33.8	91.6	90.6	89.9	35.5	87.9	86.7	83.2
dev$_{neg}$	51.2	78.1	73.2	63.4	54.4	91.7	90.3	89.4	50.2	88.0	86.7	83.0
New w/ neg.												
T$_{neg}$-H	80.2	70.8	69.0	65.2	62.0	46.4	39.8	32.6	45.8	66.2	63.8	65.6
T-H$_{neg}$	91.0	51.4	44.2	39.2	41.0	63.6	67.4	58.8	47.6	70.4	69.8	62.4
T$_{neg}$-H$_{neg}$	65.6	65.4	69.6	68.4	69.8	45.8	47.2	41.8	47.0	63.6	65.4	63.6
All	78.9	62.5	60.9	57.6	56.5	51.9	51.5	44.4	39.3	66.7	66.3	63.9

Table 7: Results obtained with state-of-the-art models trained with the original training split for each benchmark and evaluated with (a) the original development split (dev), (b) pairs in the original development split containing negation (dev$_{neg}$), and (c) the new pairs containing negation. MB stands for the majority baseline, [1] for RoBERTa (Liu et al., 2019), [2] for XLNet (Yang et al., 2019) and [3] for BERT (Devlin et al., 2019).

Train pairs	RTE			SNLI			MNLI		
	[1]	[2]	[3]	[1]	[2]	[3]	[1]	[2]	[3]
Original	64.4	61.1	59.3	52.0	53.1	43.3	64.0	64.4	63.8
+ 70% new w/ neg.	88.2	87.3	83.8	75.3	74.2	69.1	67.3	70.4	66.4

Table 8: Results obtained testing with 30% of the new text-hypothesis pairs containing negation and training with either (a) the original train split from each benchmark or (b) the original train split from each benchmark and 70% of the new pairs containing negation. [1] stands for RoBERTa (Liu et al., 2019), [2] for XLNet (Yang et al., 2019) and [3] for BERT (Devlin et al., 2019). None of the transformers benefit from training with a portion of the pairs that include negation when tested with MNLI, which contains longer and more diverse text-hypothesis pairs.

6.1 Training with Existing Benchmarks

Can transformers solve the new text-hypothesis pairs including negation if trained with existing benchmarks? No, they cannot (Table 7). Indeed, the three transformers obtain worse results with the new pairs including negation, especially with SNLI (≈50% drop with the three transformers). These results might be unsurprising with SNLI and RTE since the original text-hypothesis pairs included few negations (1.19% and 7.16%, Table 1). The pattern is also true, however, with MNLI: we observe relative drops ranging from 23.0 to 24.2% despite 22.63% of text-hypothesis contain a negation in MNLI (Table 1). Comparing with the results obtained with the majority baseline, we observe that the transformers do not learn to solve pairs with negation unless they are tuned with pairs including negation (Section 6.2). Indeed, all of them obtain worse results than the majority baseline in RTE and SNLI, but not in MNLI.

We make a couple additional observations from the results in Table 7. First, the transformers solve the few text-hypothesis pairs including negation in the original benchmarks (dev$_{neg}$) as good (SNLI, MNLI) or better (RTE) than all pairs (dev). In other words, as our analysis of the role of negation in existing benchmarks points out (Section 4), negations do not bring additional complexity in these benchmarks. Second, RoBERTa and XLNet obtain roughly the same results with the new pairs including negation, but BERT falls slightly behind.

6.2 Fine-Tuning with New Pairs Containing Negation

Can transformers solve the new text-hypothesis pairs including negation if retrained with some of the new pairs including negation? Only to a certain degree: with SNLI, they benefit but underperform with respect to the original pairs; and with MNLI, they only benefit slightly.

In order to investigate whether the transformers can learn to make inference judgments when negation must be considered, we divide the new text-hypothesis pairs containing negation into training (70%) and test (30%) splits. Table 8 shows the results obtained with the new test split and the three transformers trained with (a) the training split in the original benchmarks and (b) the training split in the original benchmarks combined with the training split with pairs containing negation. We observe that the transformers only learn to solve the new pairs including negation in the latter training scenario, but only partially. Indeed, we only observe a large improvement (59.3–64.4% vs. 83.8–88.2%) with the new pairs generated from RTE, which are also the only pairs that obtain higher accuracies than the original development split (83.8–88.2% vs. 66.1–75.8%). With the new pairs generated from SNLI, there is a substantial improvement after fine-tuning (43.3–53.1% vs. 69.1–75.3%) but the three transformers still obtain substantially worse results than with the original development split (69.1–75.3% vs. 89.9–91.6%). Finally, the transformers only benefit marginally from fine-tuning with the new pairs including negation and generated from MNLI (63.8–64.4% vs. 66.4–70.4%). Similar to the results obtained with pairs generated from SNLI, the transformers obtain substantially worse results than with the original development split in MNLI (66.4–70.4% vs. 83.2–87.9%). These results lead to the conclusion that natural language inference when negation is present remains an unsolved challenge.

7 Conclusions

Negation is ubiquitous in English and critical to understand language and make inferences, as it denies or inverts meaning. Despite these facts, negation is underrepresented in some natural language inference benchmarks (RTE and SNLI). Additionally, one can ignore negation and still make the correct inference judgment with many text-hypothesis pairs in existing natural language inference benchmarks (RTE, SNLI and MNLI).

In this paper, we have presented a new benchmark of text-hypothesis pairs containing negation (4,500 pairs). We generate and annotate these pairs after systematically adding negation to the main verb of the texts and hypotheses—either one or both—from RTE, SNLI and MNLI thus they are as difficult to solve as the original pairs except for the presence of negation. State-of-the art transformers trained with the original training splits from RTE, SNLI and MNLI obtain much worse results results with the new benchmark than with the original pairs—including the few original text-hypothesis pairs that do contain negation. In addition, our experimental results show that transformers struggle even after fine-tuning with new pairs containing negation.

A Identifying Negations

In order to identify negations in general English corpora as well as natural language inference corpora (RTE, SNLI, and MNLI, Section 4 in the paper), we develop a negation cue detector that consists of two-layer Bidirectional Long Short-Term Memory network with a Conditional Random Field layer (BiLSTM-CRF). This architecture (Figure 1) is similar to the one proposed by Reimers and Gurevych (2017). We train and evaluate the model with CD-SCO, a corpus of Conan Doyle stories with negation annotations (Morante and Daelemans, 2012; Morante and Blanco, 2012). CD-SCO includes common negation cues (e.g., never, no, n't), as well as prefixal (e.g., impossible, unbelievable) and suffixal negation (e.g., motionless).

We map each token in the input sentence to its 300-dimensional pre-trained GloVe embedding (Pennington et al., 2014). In addition, we extract token level universal POS tags using spaCy (Honnibal and Montani, 2017) and leverage another embedding (300-dimensional) to encode them. Embedding weights for universal POS are learned from scratch as part of the training of the network. We concatenate the word and POS embeddings, and feed them to the BILSTM-CRF architecture (size of cell state: 200 units). The learnt representations from the 2-layer BiLSTM are fed to a fully connected layer with ReLU activation function (Nair and Hinton, 2010). Finally, the CRF layer yields the final output.

We use the following labels to indicate whether a token is a negation cue: S_C (single-token negation cue, e.g., never, not), P_C (prefixal negation,

Hyperparameter	RTE			SNLI			MNLI		
	[1]	[2]	[3]	[1]	[2]	[3]	[1]	[2]	[3]
Batch size	16	8	8	32	32	32	32	32	32
Learning rate	2e-5	2e-5	2e-5	1e-5	1e-5	1e-5	2e-5	2e-5	2e-5
Epochs	10	50	50	3	3	3	3	3	3
Weight decay	0.0	0.0	0.0	0.1	0.1	0.1	0.0	0.0	0.0

Table 9: Hyperparameters for fine-tuning the state-of-the-art systems on RTE, SNLI, and MNLI. [1] stands for RoBERTa (Liu et al., 2019), [2] for XLNet (Yang et al., 2019) and [3] for BERT (Devlin et al., 2019).

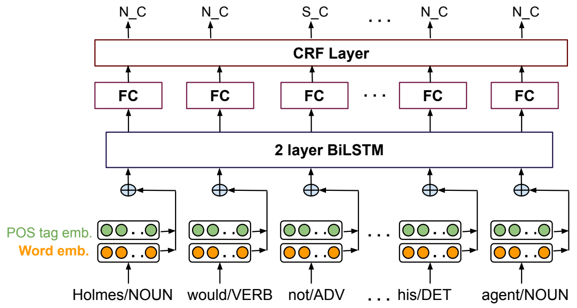

Figure 1: The BiLSTM-CRF architecture to identify negation cues. The input is a sentence. Each token is the concatenation of the word and its universal part-of-speech tag. The model outputs a sequence of labels indicating negation presence (S_C, P_C, SF_C or N_C). The example input sentence is "Holmes/NOUN would/VERB not/ADV listen/VERB to/ADP such/ADJ fancies/NOUN ,/PUNCT and/CCONJ I/PRON am/VERB his/DET agent/NOUN."

e.g., inconsistent), SF_C (suffixal negation, e.g., emotionless), and N_C (not a cue).

Training details. We merge the train and development instances from CD-SCO, and use 85% of the result as training and the remaining 15% as development. We evaluate our cue detector with the original test split from CD-SCO. We use the stochastic gradient descent algorithm with RMSProp optimizer (Tieleman and Hinton, 2012) for tuning weights. We set the batch size to 32, and the dropout and recurrent dropout are set to 30% for the LSTM layers. We stop the training process after the accuracy in the development split does not increase for 20 epochs, and the final model is the one which yields the highest accuracy in the development accuracy during the training process (not necessarily the model from the last epoch). Evaluating with the test set yields the following results: 92.75 Precision, 92.05 Recall, and 92.40 F1. While not perfect, the output of the cue detector is reliable, and an automatic detector is the only way to count negations in large corpora. The code is available at `https://github.com/mosharafhossain/negation-cue`.

The neural model has nearly 4.3 million parameters and takes 30 minutes on average to train on a CPU machine (Intel(R) Xeon(R) CPU E5-2680 v4 @ 2.40GHz) with 64 GB of RAM.

B Fine-tuning Hyperparameters for State-of-the-Art Systems

For all the Transformer models, we set the maximum sequence length to 128. We use the Hugging Face implementation and pretrained models (Wolf et al., 2019). We work with the default settings for most of the hyperparameters except a few used to fine-tune to each benchmark. Table 9 shows the fine-tuned hyperparameters for the 3 transformers. Also, we use the base architectures for all the transformers (12-layer, 768-hidden, 12-heads).

On the Sentence Embeddings from Pre-trained Language Models

Abstract

Pre-trained contextual representations like BERT have achieved great success in natural language processing. However, the sentence embeddings from the pre-trained language models without fine-tuning have been found to poorly capture semantic meaning of sentences. In this paper, we argue that the semantic information in the BERT embeddings is not fully exploited. We first reveal the theoretical connection between the masked language model pre-training objective and the semantic similarity task theoretically, and then analyze the BERT sentence embeddings empirically. We find that BERT always induces a non-smooth anisotropic semantic space of sentences, which harms its performance of semantic similarity. To address this issue, we propose to transform the anisotropic sentence embedding distribution to a smooth and isotropic Gaussian distribution through normalizing flows that are learned with an unsupervised objective. Experimental results show that our proposed BERT-flow method obtains significant performance gains over the state-of-the-art sentence embeddings on a variety of semantic textual similarity tasks. The code is available at `https://github.com/bohanli/BERT-flow`.

1 Introduction

Recently, pre-trained language models and its variants (Radford et al., 2019; Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019) like BERT (Devlin et al., 2019) have been widely used as representations of natural language. Despite their great success on many NLP tasks through fine-tuning, the sentence embeddings from BERT without fine-tuning are significantly inferior in terms of semantic textual similarity (Reimers and Gurevych, 2019) – for example, they even underperform the GloVe (Pennington et al., 2014) embeddings which are not contextualized and trained with a much simpler model. Such issues hinder applying BERT sentence embeddings directly to many real-world scenarios where collecting labeled data is highly-costing or even intractable.

In this paper, we aim to answer two major questions: (1) why do the BERT-induced sentence embeddings perform poorly to retrieve semantically similar sentences? Do they carry too little semantic information, or just because the semantic meanings in these embeddings are not exploited properly? (2) If the BERT embeddings capture enough semantic information that is hard to be directly utilized, how can we make it easier without external supervision?

Towards this end, we first study the connection between the BERT pretraining objective and the semantic similarity task. Our analysis reveals that the sentence embeddings of BERT should be able to intuitively reflect the semantic similarity between sentences, which contradicts with experimental observations. Inspired by Gao et al. (2019) who find that the language modeling performance can be limited by the learned anisotropic word embedding space where the word embeddings occupy a narrow cone, and Ethayarajh (2019) who find that BERT word embeddings also suffer from anisotropy, we hypothesize that the sentence embeddings from BERT – as average of context embeddings from last layers[1] – may suffer from similar issues. Through empirical probing over the embeddings, we further observe that the BERT sentence embedding space is semantically non-smoothing and poorly defined in some areas, which makes it hard to be used directly through simple similarity metrics such as dot

---

[1] In this paper, we compute average of context embeddings from last one or two layers as our sentence embeddings since they are consistently better than the [CLS] vector as shown in (Reimers and Gurevych, 2019).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9119–9130,
November 16–20, 2020.

product or cosine similarity.

To address these issues, we propose to transform the BERT sentence embedding distribution into a smooth and isotropic Gaussian distribution through normalizing flows (Dinh et al., 2015), which is an invertible function parameterized by neural networks. Concretely, we learn a flow-based generative model to maximize the likelihood of generating BERT sentence embeddings from a standard Gaussian latent variable in a *unsupervised* fashion. During training, only the flow network is optimized while the BERT parameters remain unchanged. The learned flow, an invertible mapping function between the BERT sentence embedding and Gaussian latent variable, is then used to transform the BERT sentence embedding to the Gaussian space. We name the proposed method as *BERT-flow*.

We perform extensive experiments on 7 standard semantic textual similarity benchmarks without using any downstream supervision. Our empirical results demonstrate that the flow transformation is able to consistently improve BERT by up to 12.70 points with an average of 8.16 points in terms of Spearman correlation between cosine embedding similarity and human annotated similarity. When combined with external supervision from natural language inference tasks (Bowman et al., 2015; Williams et al., 2018), our method outperforms the sentence-BERT embeddings (Reimers and Gurevych, 2019), leading to new state-of-the-art performance. In addition to semantic similarity tasks, we apply sentence embeddings to a question-answer entailment task, QNLI (Wang et al., 2019), directly without task-specific supervision, and demonstrate the superiority of our approach. Moreover, our further analysis implies that BERT-induced similarity can excessively correlate with lexical similarity compared to semantic similarity, and our proposed flow-based method can effectively remedy this problem.

2 Understanding the Sentence Embedding Space of BERT

To encode a sentence into a fixed-length vector with BERT, it is a convention to either compute an average of context embeddings in the last few layers of BERT, or extract the BERT context embedding at the position of the [CLS] token. Note that there is no token masked when producing sentence embeddings, which is different from pretraining.

Reimers and Gurevych (2019) demonstrate that such BERT sentence embeddings lag behind the state-of-the-art sentence embeddings in terms of semantic similarity. On the STS-B dataset, BERT sentence embeddings are even less competitive to averaged GloVe (Pennington et al., 2014) embeddings, which is a simple and non-contextualized baseline proposed several years ago. Nevertheless, this incompetence has not been well understood yet in existing literature.

Note that as demonstrated by Reimers and Gurevych (2019), averaging context embeddings consistently outperforms the [CLS] embedding. Therefore, unless mentioned otherwise, we use average of context embeddings as BERT sentence embeddings and do not distinguish them in the rest of the paper.

2.1 The Connection between Semantic Similarity and BERT Pre-training

We consider a sequence of tokens $x_{1:T} = (x_1, \ldots, x_T)$. Language modeling (LM) factorizes the joint probability $p(x_{1:T})$ in an autoregressive way, namely $\log p(x_{1:T}) = \sum_{t=1}^{T} \log p(x_t|c_t)$ where the context $c_t = x_{1:t-1}$. To capture bidirectional context during pretraining, BERT proposes a masked language modeling (MLM) objective, which instead factorizes the probability of noisy reconstruction $p(\bar{x}|\hat{x}) = \sum_{t=1}^{T} m_t \, p(x_t|c_t)$, where $\hat{x}$ is a corrupted sequence, $\bar{x}$ is the masked tokens, m_t is equal to 1 when x_t is masked and 0 otherwise. The context $c_t = \hat{x}$.

Note that both LM and MLM can be reduced to modeling the conditional distribution of a token x given the context c, which is typically formulated with a softmax function as,

$$p(x|c) = \frac{\exp \mathbf{h}_c^\top \mathbf{w}_x}{\sum_{x'} \exp \mathbf{h}_c^\top \mathbf{w}_{x'}}. \tag{1}$$

Here the context embedding $\mathbf{h}_c$ is a function of c, which is usually heavily parameterized by a deep neural network (e.g., a Transformer (Vaswani et al., 2017)); The word embedding $\mathbf{w}_x$ is a function of x, which is parameterized by an embedding lookup table.

The similarity between BERT sentence embeddings can be reduced to the similarity between BERT context embeddings $\mathbf{h}_c^T \mathbf{h}_{c'}$[2]. However, as

---

[2] This is because we approximate BERT sentence embeddings with context embeddings, and compute their dot product (or cosine similarity) as model-predicted sentence similarity. Dot product is equivalent to cosine similarity when the em-

shown in Equation 1, the pretraining of BERT does not explicitly involve the computation of $\mathbf{h}_c^T \mathbf{h}_{c'}$. Therefore, we can hardly derive a mathematical formulation of what $\mathbf{h}_c^\top \mathbf{h}_{c'}$ exactly represents.

Co-Occurrence Statistics as the Proxy for Semantic Similarity Instead of directly analyzing $\mathbf{h}_c^T \mathbf{h}'_c$, we consider $\mathbf{h}_c^\top \mathbf{w}_x$, the dot product between a context embedding $\mathbf{h}_c$ and a word embedding $\mathbf{w}_x$. According to Yang et al. (2018), in a well-trained language model, $\mathbf{h}_c^\top \mathbf{w}_x$ can be approximately decomposed as follows,

$$\begin{aligned} \mathbf{h}_c^\top \mathbf{w}_x &\approx \log p^*(x|c) + \lambda_c \qquad (2) \\ &= \text{PMI}(x, c) + \log p(x) + \lambda_c. \qquad (3) \end{aligned}$$

where $\text{PMI}(x, c) = \log \frac{p(x,c)}{p(x)p(c)}$ denotes the pointwise mutual information between x and c, $\log p(x)$ is a word-specific term, and λ_c is a context-specific term.

PMI captures how frequently two events co-occur more than if they independently occur. Note that co-occurrence statistics is a typical tool to deal with "semantics" in a computational way — specifically, PMI is a common mathematical surrogate to approximate word-level semantic similarity (Levy and Goldberg, 2014; Ethayarajh et al., 2019). Therefore, roughly speaking, it is semantically meaningful to compute the dot product between a context embedding and a word embedding.

Higher-Order Co-Occurrence Statistics as Context-Context Semantic Similarity. During pretraining, the semantic relationship between two contexts c and c' could be inferred and reinforced with their connections to words. To be specific, if both the contexts c and c' co-occur with the same word w, the two contexts are likely to share similar semantic meaning. During the training dynamics, when c and w occur at the same time, the embeddings h_c and x_w are encouraged to be closer to each other, meanwhile the embedding h_c and $x_{w'}$ where $w' \neq w$ are encouraged to be away from each other due to normalization. A similar scenario applies to the context c'. In this way, the similarity between h_c and $h_{c'}$ is also promoted. With all the words in the vocabulary acting as hubs, the context embeddings should be aware of its semantic relatedness to each other.

Higher-order context-context co-occurrence could also be inferred and propagated during pretraining. The update of a context embedding h_c could affect another context embedding $h_{c'}$ in the above way, and similarly $h_{c'}$ can further affect another $h_{c''}$. Therefore, the context embeddings can form an implicit interaction among themselves via higher-order co-occurrence relations.

2.2 Anisotropic Embedding Space Induces Poor Semantic Similarity

As discussed in Section 2.1, the pretraining of BERT should have encouraged semantically meaningful context embeddings implicitly. Why BERT sentence embeddings without finetuning yield unsatisfactory performance?

To investigate the underlying problem of the failure, we use word embeddings as a surrogate because words and contexts share the same embedding space. If the word embeddings exhibits some misleading properties, the context embeddings will also be problematic, and vice versa.

Gao et al. (2019) and Wang et al. (2020) have pointed out that, for language modeling, the maximum likelihood training with Equation 1 usually produces an anisotropic word embedding space. "Anisotropic" means word embeddings occupy a narrow cone in the vector space. This phenomenon is also observed in the pretrained Transformers like BERT, GPT-2, etc (Ethayarajh, 2019).

In addition, we have two empirical observations over the learned anisotropic embedding space.

Observation 1: Word Frequency Biases the Embedding Space We expect the embedding-induced similarity to be consistent to semantic similarity. If embeddings are distributed in different regions according to frequency statistics, the induced similarity is not useful any more.

However, as discussed by Gao et al. (2019), anisotropy is highly relevant to the imbalance of word frequency. They prove that under some assumptions, the optimal embeddings of non-appeared tokens in Transformer language models can be extremely far away from the origin. They also try to roughly generalize this conclusion to rarely-appeared words.

To verify this hypothesis in the context of BERT, we compute the mean ℓ_2 distance between the BERT word embeddings and the origin (i.e., the mean ℓ_2-norm). In the upper half of Table 1, we observe that high-frequency words are all close to

---

beddings are normalized to unit hyper-sphere.

Rank of word frequency	$(0, 100)$	$[100, 500)$	$[500, 5\text{K})$	$[5\text{K}, 1\text{K})$
Mean ℓ_2-norm	0.95	1.04	1.22	1.45
Mean k-NN ℓ_2-dist. $(k = 3)$	0.77	0.93	1.16	1.30
Mean k-NN ℓ_2-dist. $(k = 5)$	0.83	0.99	1.22	1.34
Mean k-NN ℓ_2-dist. $(k = 7)$	0.87	1.04	1.26	1.37
Mean k-NN dot-product. $(k = 3)$	0.73	0.92	1.20	1.63
Mean k-NN dot-product. $(k = 5)$	0.73	0.91	1.19	1.61
Mean k-NN dot-product. $(k = 7)$	0.72	0.90	1.17	1.60

Table 1: The mean ℓ_2-norm, as well as their distance to their k-nearest neighbors (among all the word embeddings) of the word embeddings of BERT, segmented by ranges of word frequency rank (counted based on Wikipedia dump; the smaller the more frequent).

the origin, while low-frequency words are far away from the origin.

This observation indicates that the word embeddings can be biased to word frequency. This coincides with the second term in Equation 3, the log density of words. Because word embeddings play a role of connecting the context embeddings during training, context embeddings might be misled by the word frequency information accordingly and its preserved semantic information can be corrupted.

Observation 2: Low-Frequency Words Disperse Sparsely We observe that, in the learned anisotropic embedding space, high-frequency words concentrates densely and low-frequency words disperse sparsely.

This observation is achieved by computing the mean ℓ_2 distance of word embeddings to their k-nearest neighbors. In the lower half of Table 1, we observe that the embeddings of low-frequency words tends to be farther to their k-NN neighbors compared to the embeddings of high-frequency words. This demonstrates that low-frequency words tends to disperse sparsely.

Due to the sparsity, many "holes" could be formed around the low-frequency word embeddings in the embedding space, where the semantic meaning can be poorly defined. Note that BERT sentence embeddings are produced by averaging the context embeddings, which is a convexity-preserving operation. However, the holes violate the convexity of the embedding space. This is a common problem in the context of representation learining (Rezende and Viola, 2018; Li et al., 2019; Ghosh et al., 2020). Therefore, the resulted sentence embeddings can locate in the poorly-defined areas, and the induced similarity can be problematic.

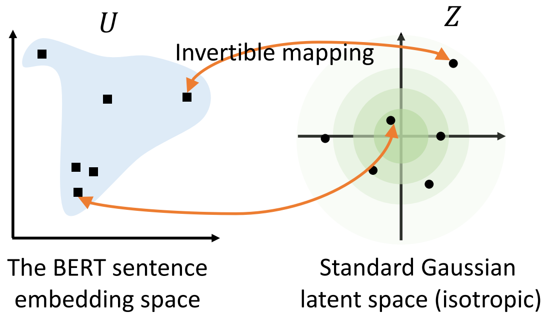

Figure 1: An illustration of our proposed flow-based calibration over the original sentence embedding space of BERT.

3 Proposed Method: BERT-flow

To verify the hypotheses proposed in Section 2.2, and to circumvent the incompetence of the BERT sentence embeddings, we proposed a calibration method called BERT-flow in which we take advantage of *an invertible mapping from the BERT embedding space to a standard Gaussian latent space*. The invertibility condition assures that the mutual information between the embedding space and the data examples does not change.

3.1 Motivation

A standard Gaussian latent space may have favorable properties which can help with our problem.

Connection to Observation 1 First, standard Gaussian satisfies isotropy. The probabilistic density in standard Gaussian distribution does not vary in terms of angle. If the ℓ_2 norm of samples from standard Gaussian are normalized to 1, these samples can be regarded as uniformly distributed over a unit sphere.

We can also understand the isotropy from a singular spectrum perspective. As discussed above, the anisotropy of the embedding space stems from the imbalance of word frequency. In the literature of traditional word embeddings, Mu et al. (2017)

discovers that the dominating singular vectors can be highly correlated to word frequency, which misleads the embedding space. By fitting a mapping to an isotropic distribution, the singular spectrum of the embedding space can be flattened. In this way, the word frequency-related singular directions, which are the dominating ones, can be suppressed.

Connection to Observation 2 Second, the probabilistic density of Gaussian is well defined over the entire real space. This means there are no "hole" areas, which are poorly defined in terms of probability. The helpfulness of Gaussian prior for mitigating the "hole" problem has been widely observed in existing literature of deep latent variable models (Rezende and Viola, 2018; Li et al., 2019; Ghosh et al., 2020).

3.2 Flow-based Generative Model

We instantiate the invertible mapping with flows. A flow-based generative model (Kobyzev et al., 2019) establishes an invertible transformation from the latent space $\mathcal{Z}$ to the observed space $\mathcal{U}$. The generative story of the model is defined as

$$\mathbf{z} \sim p_{\mathcal{Z}}(\mathbf{z}), \mathbf{u} = f_\phi(\mathbf{z})$$

where $\mathbf{z} \sim p_{\mathcal{Z}}(\mathbf{z})$ the prior distribution, and $f : \mathcal{Z} \to \mathcal{U}$ is an invertible transformation. With the change-of-variables theorem, the probabilistic density function (PDF) of the observable x is given as,

$$p_{\mathcal{U}}(\mathbf{u}) = p_{\mathcal{Z}}(f_\phi^{-1}(\mathbf{u}))\ |\det \frac{\partial f_\phi^{-1}(\mathbf{u})}{\partial \mathbf{u}}|$$

In our method, we learn a flow-based generative model by maximizing the likelihood of generating BERT sentence embeddings from a standard Gaussian latent latent variable. In other words, the base distribution $p_{\mathcal{Z}}$ is a standard Gaussian and we consider the extracted BERT sentence embeddings as the observed space $\mathcal{U}$. We maximize the likelihood of $\mathcal{U}$'s marginal via Equation 4 in a fully *unsupervised* way.

$$\max_\phi \mathbb{E}_{\mathbf{u}=\text{BERT(sentence)},\text{sentence}\sim\mathcal{D}} \log p_{\mathcal{Z}}(f_\phi^{-1}(\mathbf{u})) + \log\ |\det \frac{\partial f_\phi^{-1}(\mathbf{u})}{\partial \mathbf{u}}|, \tag{4}$$

Here $\mathcal{D}$ denotes the dataset, in other words, the collection of sentences. Note that during training, only the flow parameters are optimized while the BERT parameters remain unchanged. Eventually, we learn an invertible mapping function f_ϕ^{-1} which can transform each BERT sentence embedding $\mathbf{u}$ into a latent Gaussian representation $\mathbf{z}$ without loss of information.

The invertible mapping f_ϕ is parameterized as a neural network, and the architectures are usually carefully designed to guarantee the invertibility (Dinh et al., 2015). Moreover, its determinant $|\det \frac{\partial f_\phi^{-1}(\mathbf{u})}{\partial \mathbf{u}}|$ should also be easy to compute so as to make the maximum likelihood training tractable. In our experiments, we follows the design of Glow (Kingma and Dhariwal, 2018). The Glow model is composed of a stack of multiple invertible transformations, namely *actnorm*, *invertible* 1×1 *convolution*, and *affine coupling layer*[3]. We simplify the model by replacing affine coupling with additive coupling (Dinh et al., 2015) to reduce model complexity, and replacing the invertible 1×1 convolution with random permutation to avoid numerical errors. For the mathematical formula of the flow model with additive coupling, please refer to Appendix A.

4 Experiments

To verify our hypotheses and demonstrate the effectiveness of our proposed method, in this section we present our experimental results for various tasks related to semantic textual similarity under multiple configurations. For the implementation details of our siamese BERT models and flow-based models, please refer to Appendix B.

4.1 Semantic Textual Similarity

Datasets. We evaluate our approach extensively on the semantic textual similarity (STS) tasks. We report results on 7 datasets, namely the STS benchmark (STS-B) (Cer et al., 2017) the SICK-Relatedness (SICK-R) dataset (Marelli et al., 2014) and the STS tasks 2012 - 2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016). We obtain all these datasets via the SentEval toolkit (Conneau and Kiela, 2018). These datasets provide a fine-grained gold standard semantic similarity between 0 and 5 for each sentence pair.

Evaluation Procedure. Following the procedure in previous work like Sentence-BERT (Reimers and Gurevych, 2019) for the STS task, the predic-

Table 2: Experimental results on semantic textual similarity **without** using NLI supervision. We report the Spearman's rank correlation between the cosine similarity of sentence embeddings and the gold labels on multiple datasets. Numbers are reported as $\rho \times 100$. ↑ denotes outperformance over its BERT baseline and ↓ denotes underperformance. Our proposed BERT-flow method achieves the best scores. Note that our BERT-flow use *-last2avg* as default setting. $*$: Use NLI corpus for the unsupervised training of flow; supervision labels of NLI are NOT visible.

tion of similarity consists of two steps: (1) first, we obtain sentence embeddings for each sentence with a sentence encoder, and (2) then, we compute the cosine similarity between the two embeddings of the input sentence pair as our model-predicted similarity. The reported numbers are the Spearman's correlation coefficients between the predicted similarity and gold standard similarity scores, which is the same way as in (Reimers and Gurevych, 2019).

Experimental Details. We consider both BERT$_{\text{base}}$ and BERT$_{\text{large}}$ in our experiments. Specifically, we use an average pooling over BERT context embeddings in the last one or two layers as the sentence embedding which is found to outperform the [CLS] vector. Interestingly, our preliminary exploration shows that averaging the last two layers of BERT (denoted by *-last2avg*) consistently produce better results compared to only averaging the last one layer. Therefore, we choose *-last2avg* as our default configuration when assessing our own approach.

For the proposed method, the flow-based objective (Equation 4) is maximized only to update the invertible mapping while the BERT parameters remains unchanged. Our flow models are by default learned over the full target dataset (train + validation + test). We denote this configuration as *flow (target)*. Note that although we use the sentences of the entire target dataset, learning flow does not use any provided labels for training, thus it is a purely *unsupervised* calibration over the BERT sentence embedding space.

We also test our flow-based model learned on a concatenation of SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018) for comparison (*flow (NLI)*). The concatenated NLI datasets comprise of tremendously more sentence pairs (SNLI 570K + MNLI 433K). Note that "flow (NLI)" does not require any supervision label. When fitting flow on NLI corpora, we only use the raw sentences instead of the entailment labels. An intuition behind the flow (NLI) setting is that, compared to Wikipedia sentences (on which BERT is pretrained), the raw sentences of both NLI and STS are simpler and shorter. This means the NLI-STS discrepancy could be relatively smaller than the Wikipedia-STS discrepancy.

We run the experiments on two settings: (1) when external labeled data is unavailable. This is the natural setting where we fine-tune the pretrained BERT with the unsupervised flow-based objective (Equation 4) on raw text. (2) we first fine-tune both BERT and BERT-flow models on the SNLI+MNLI textual entailment classification task in a siamese fashion (Reimers and Gurevych, 2019). For BERT-flow, we further optimize the invertible mapping with the unsupervised objective to map the BERT embedding space to a Gaussian space. This setting is to compare with the state-of-the-art results which utilize NLI supervision (Reimers and Gurevych, 2019). We denote the two different models as BERT-NLI and BERT-NLI-flow respectively.

Results w/o NLI Supervision. As shown in Table 2, the original BERT sentence embeddings

Table 3: Experimental results on semantic textual similarity *with* NLI supervision. Note that our flows are still learned in a *unsupervised* way. InferSent (Conneau et al., 2017) is a siamese LSTM train on NLI, Universal Sentence Encoder (USE) (Cer et al., 2018) replace the LSTM with a Transformer and SBERT (Reimers and Gurevych, 2019) further use BERT. We report the Spearman's rank correlation between the cosine similarity of sentence embeddings and the gold labels on multiple datasets. Numbers are reported as $\rho \times 100$. ↑ denotes outperformance over its BERT baseline and ↓ denotes underperformance. Our proposed BERT-flow (i.e., the "BERT-NLI-flow" in this table) method achieves the best scores. Note that our BERT-flow use *-last2avg* as default setting. $*$: Use NLI corpus for the unsupervised training of flow; supervision labels of NLI are NOT visible.

(with both BERT$_{\text{base}}$ and BERT$_{\text{large}}$) fail to outperform the averaged GloVe embeddings. And averaging the last-two layers of the BERT model can consistently improve the results. For BERT$_{\text{base}}$ and BERT$_{\text{large}}$, our proposed flow-based method (BERT-flow (target)) can further boost the performance by 5.88 and 8.16 points on average respectively. For most of the datasets, learning flows on the target datasets leads to larger performance improvement than on NLI. The only exception is SICK-R where training flows on NLI is better. We think this is because SICK-R is collected for both entailment and relatedness. Since SNLI and MNLI are also collected for textual entailment evaluation, the distribution discrepancy between SICK-R and NLI may be relatively small. Also due to the much larger size of the NLI datasets, it is not surprising that learning flows on NLI results in stronger performance.

Results w/ NLI Supervision. Table 3 shows the results with NLI supervisions. Similar to the fully unsupervised results before, our isotropic embedding space from invertible transformation is able to consistently improve the SBERT baselines in most cases, and outperforms the state-of-the-art SBERT/SRoBERTa results by a large margin. Robustness analysis with respect to random seeds are provided in Appendix C.

4.2 Unsupervised Question-Answer Entailment

In addition to the semantic textual similarity tasks, we examine the effectiveness of our method on unsupervised question-answer entailment. We use Question Natural Language Inference (QNLI, Wang et al. (2019)), a dataset comprising 110K question-answer pairs (with 5K+ for testing). QNLI extracts the questions as well as their corresponding context sentences from SQUAD (Rajpurkar et al., 2016), and annotates each pair as either *entailment* or *no entailment*. In this paper, we further adapt QNLI as an unsupervised task. The similarity between a question and an answer can be predicted by computing the cosine similarity of their sentence embeddings. Then we regard *entailment* as 1 and *no entailment* as 0, and evaluate the performance of the methods with AUC.

As shown in Table 4, our method consistently improves the AUC on the validation set of QNLI. Also, learning flow on the target dataset can produce superior results compared to learning flows on NLI.

Method	AUC
$\text{BERT}_{\text{base}}$-NLI-last2avg	70.30
$\text{BERT}_{\text{base}}$-NLI-flow (NLI*)	72.52 (↑)
$\text{BERT}_{\text{base}}$-NLI-flow (target)	76.17 (↑)
$\text{BERT}_{\text{large}}$-NLI-last2avg	70.41
$\text{BERT}_{\text{large}}$-NLI-flow (NLI*)	74.19 (↑)
$\text{BERT}_{\text{large}}$-NLI-flow (target)	**77.09** (↑)

Table 4: AUC on QNLI evaluated on the validation set. $*$: Use NLI corpus for the unsupervised training of flow; supervision labels of NLI are NOT visible.

Method	Correlation
$\text{BERT}_{\text{base}}$	47.29
+ SN	55.46
+ NATSV ($k = 1$)	51.79
+ NATSV ($k = 10$)	60.40
+ SN + NATSV ($k = 1$)	56.02
+ SN + NATSV ($k = 6$)	63.51
$\text{BERT}_{\text{base}}$-flow (target)	**65.62**

Table 5: Comparing flow-based method with baselines on STS-B. k is selected among $1 \sim 20$ on the validation set. We report the Spearman's rank correlation ($\times 100$).

4.3 Comparison with Other Embedding Calibration Baselines

In the literature of traditional word embeddings, Arora et al. (2017) and Mu et al. (2017) also discover the anisotropy phenomenon of the embedding space, and they provide several methods to encourage isotropy:

Standard Normalization (SN). In this idea, we conduct a simple post-processing over the embeddings by computing the mean $\boldsymbol{\mu}$ and standard deviation $\boldsymbol{\sigma}$ of the sentence embeddings $\mathbf{u}$'s, and normalizing the embeddings by $\frac{\mathbf{u}-\boldsymbol{\mu}}{\boldsymbol{\sigma}}$.

Nulling Away Top-k Singular Vectors (NATSV). Mu et al. (2017) find out that sentence embeddings computed by averaging traditional word embeddings tend to have a fast-decaying singular spectrum. They claim that, by nulling away the top-k singular vectors, the anisotropy of the embeddings can be circumvented and better semantic similarity performance can be achieved.

We compare with these embedding calibration methods on STS-B dataset and the results are shown in Table 5. Standard normalization (SN) helps improve the performance but it falls behind nulling away top-k singular vectors (NATSV). This means standard normalization cannot fundamentally eliminate the anisotropy. By combining the two methods, and carefully tuning k over the validation set, further improvements can be achieved. Nevertheless, our method still produces much better results. We argue that NATSV can help eliminate anisotropy but it may also discard some useful information contained in the nulled vectors. On the contrary, our method directly learns an invertible mapping to isotropic latent space without discarding any information.

Similarity	Edit distance	Gold similarity
Gold similarity	-24.61	100.00
BERT-induce similarity	-50.49	59.30
Flow-induce similarity	-28.01	74.09

Table 6: Spearman's correlation ρ between various sentence similarities on the validation set of STS-B. We can observe that BERT-induced similarity is highly correlated to edit distance, while the correlation with edit distance is less evident for gold standard or flow-induced similarity.

4.4 Dicussion: Semantic Similarity Versus Lexical Similarity

In addition to semantic similarity, we further study lexical similarity induced by different sentence embeddings. Specifically, we use edit distance as the metric for lexical similarity between a pair of sentences, and focus on the correlations between the sentence similarity and edit distance. Concretely, we compute the cosine similarity in terms of BERT sentence embeddings as well as edit distance for each sentence pair. Within a dataset consisting of many sentence pairs, we compute the Spearman's correlation coefficient ρ between the similarities and the edit distances, as well as between similarities from different models. We perform experiment on the STS-B dataset and include the human annotated gold similarity into this analysis.

BERT-Induced Similarity Excessively Correlates with Lexical Similarity. Table 6 shows that the correlation between BERT-induced similarity and edit distance is very strong ($\rho = -50.49$), considering that gold standard labels maintain a much smaller correlation with edit distance ($\rho = -24.61$). This phenomenon can also be observed in Figure 2. Especially, for sentence pairs with edit distance ≤ 4 (highlighted with green), BERT-induced similarity is extremely correlated to edit distance. However, it is not evident that gold standard semantic similarity correlates with edit distance. In other words, it is often the case where the semantics of a sentence can be dramatically

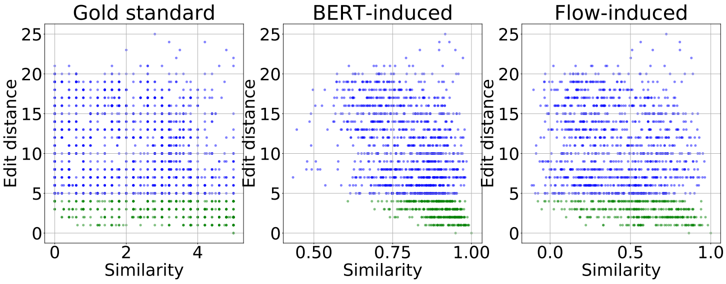

Figure 2: A scatterplot of sentence pairs, where the horizontal axis represents similarity (either gold standard semantic similarity or embedding-induced similarity), the vertical axis represents edit distance. The sentence pairs with edit distance ≤ 4 are highlighted with green, meanwhile the rest of the pairs are colored with blue. We can observed that lexically similar sentence pairs tends to be predicted to be similar by BERT embeddings, especially for the green pairs. Such correlation is less evident for gold standard labels or flow-induced embeddings.

changed by modifying a single word. For example, the sentences "I like this restaurant" and "I dislike this restaurant" only differ by one word, but convey opposite semantic meaning. BERT embeddings may fail in such cases. Therefore, we argue that the lexical proximity of BERT sentence embeddings is excessive, and can spoil their induced semantic similarity.

Flow-Induced Similarity Exhibits Lower Correlation with Lexical Similarity. By transforming the original BERT sentence embeddings into the learned isotropic latent space with flow, the embedding-induced similarity not only aligned better with the gold semantic semantic similarity, but also shows a lower correlation with lexical similarity, as presented in the last row of Table 6. The phenomenon is especially evident for the examples with edit distance ≤ 4 (highlighted with green in Figure 2). This demonstrates that our proposed flow-based method can effectively suppress the excessive influence of lexical similarity over the embedding space.

5 Conclusion and Future Work

In this paper, we investigate the deficiency of the BERT sentence embeddings on semantic textual similarity, and propose a flow-based calibration which can effectively improve the performance. In the future, we are looking forward to diving in representation learning with flow-based generative models from a broader perspective.

Acknowledgments

The authors would like to thank Jiangtao Feng, Wenxian Shi, Yuxuan Song, and anonymous reviewers for their helpful comments and suggestion on this paper.

A Mathematical Formula of the Invertible Mapping

Generally, flow-based model is a stacked sequence of many invertible transformation layers: $f = f_1 \circ f_2 \circ \ldots \circ f_K$. Specifically, in our approach, each transformation $f_i : x \to y$ is an additive coupling layer, which can be mathematically formulated as follows.

$$y_{1:d} = x_{1:d} \tag{5}$$

$$y_{d+1:D} = x_{d+1:D} + g_\psi(x_{1:d}). \tag{6}$$

Here g_ψ can be parameterized with a deep neural network for the sake of expressiveness.

Its inverse function $f_i^{-1} : y \to x$ can be explicitly written as:

$$x_{1:d} = y_{1:d} \tag{7}$$

$$x_{d+1:D} = y_{d+1:D} - g_\psi(y_{1:d}). \tag{8}$$

B Implementation Details

Throughout our experiment, we adopt the official Tensorflow code of BERT [4] as our codebase. Note that we clip the maximum sequence length to 64 to reduce the costing of GPU memory. For the NLI finetuning of siamese BERT, we folllow the settings in (Reimers and Gurevych, 2019) (epochs = 1, learning rate = $2e-5$, and batch size = 16). Our results may vary from their published one. The authors mentioned in `https://github.com/UKPLab/sentence-transformers/issues/50` that this is a common phenonmenon and might be related the random seed. Note that their implementation relies on the Transformers repository of Huggingface[5]. This may also lead to discrepancy between the specific numbers.

Our implementation of flows is adapted from both the official repository of GLOW[6] as well as the implementation fo the Tensor2tensor library[7]. The hyperparameters of our flow models are given in Table 7. On the target datasets, we learn the flow parameters for 1 epoch with learning rate $1e-3$. On NLI datasets, we learn the flow parameters for 0.15 epoch with learning rate $2e-5$. The optimizer that we use is Adam.

In our preliminary experiments on STS-B, we tune the hyperparameters on the dev set of STS-B. Empirically, the performance does not vary much with regard to the architectural hyperparameters compared to the learning schedule. Afterwards, we do not tune the hyperparameters any more when working on the other datasets. Empirically, we find the hyperparameters of flow are not sensitive across the datasets.

C Results with Different Random Seeds

We perform 5 runs with different random seeds in the NLI-supervised setting on STS-B. Results with standard deviation and median are demonstrated in Table 8. Although the variance of NLI finetuning is not negligible, our proposed flow-based method consistently leads to improvement.

Method	**Spearman's ρ**
BERT-NLI-large	77.26 ± 1.76 (median: 78.19)
BERT-NLI-large-last2avg	78.07 ± 1.50 (median: 78.68)
BERT-NLI-large-last2avg + flow-target	81.10 ± 0.55 (median: 81.35)

Abstract

Despite the subjective nature of many NLP tasks, most NLU evaluations have focused on using the majority label with presumably high agreement as the ground truth. Less attention has been paid to the distribution of human opinions. We collect **ChaosNLI**, a dataset with a total of 464,500 annotations to study **C**ollective **H**um**A**n **O**pinion**S** in oft-used **NLI** evaluation sets. This dataset is created by collecting 100 annotations per example for 3,113 examples in SNLI and MNLI and 1,532 examples in αNLI. Analysis reveals that: (1) high human disagreement exists in a noticeable amount of examples in these datasets; (2) the state-of-the-art models lack the ability to recover the distribution over human labels; (3) models achieve near-perfect accuracy on the subset of data with a high level of human agreement, whereas they can barely beat a random guess on the data with low levels of human agreement, which compose most of the common errors made by state-of-the-art models on the evaluation sets. This questions the validity of improving model performance on old metrics for the low-agreement part of evaluation datasets. Hence, we argue for a detailed examination of human agreement in future data collection efforts, and evaluating model outputs against the distribution over collective human opinions.[1]

1 Introduction

Natural Language Understanding (NLU) evaluation plays a key role in benchmarking progress in natural language processing (NLP) research. With the recent advance in language representative learning (Devlin et al., 2019), results on previous benchmarks have rapidly saturated. This leads to an explosion of difficult, diverse proposals of tasks/datasets for NLU evaluation, including Natural Language Inference (e.g., SNLI, MNLI and ANLI) (Bowman et al., 2015; Williams et al., 2018; Nie et al., 2020), Grounded Commonsense Inference (Zellers et al., 2018), Commonsense QA (Talmor et al., 2019), Social Interactions Reasoning (Sap et al., 2019), Abductive Commonsense Reasoning (αNLI) (Bhagavatula et al., 2020), etc.

One common practice followed by most of these recent works is to simplify the evaluation of various reasoning abilities as a classification task. This is analogous to asking objective questions to a human in educational testing. This simplification not only facilitates the data annotation but also gives interpretable evaluation results, based on which behaviors of the models are studied and then weaknesses are diagnosed (Sanchez et al., 2018).

Despite the straightforwardness of this formalization, one assumption behind most prior benchmark data sourcing is that there exists a single prescriptive ground truth label for each example. The assumption might be true in human educational settings where prescriptivism is preferred over descriptivism because the goal is to test humans with well-defined knowledge or norms (Trask, 1999). However, it is not true for many NLP tasks due to their pragmatic nature where the meaning of the same sentence might differ depending on the context or background knowledge.

Specifically for the NLI task, Manning (2006) advocate that annotation tasks should be "natural" for untrained annotators, and the role of NLP should be to model the inferences that humans make in practical settings. Previous work (Pavlick and Kwiatkowski, 2019) that uses a graded labeling schema on NLI, showed that there are inherent disagreements in inference tasks. All these discussions challenge the commonly used majority "gold-label" practice in most prior data collections and evaluations.

Intuitively, such disagreements among humans

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9131–9143,
November 16–20, 2020.

should be allowed because different annotators might have different subjective views of the world and might think differently when they encounter the same reasoning task. Thus, from a descriptive perspective, evaluating the capacity of NLP models in predicting not only individual human opinions or the majority human opinion, but also the overall distribution over human judgments provides a more representative comparison between model capabilities and 'collective' human intelligence.

Therefore, we collect **ChaosNLI**, a large set of **C**ollective **H**um**A**n **O**pinion**S** for examples in several existing (English) NLI datasets, and comprehensively examine the factor of human agreement (measured by the entropy of the distribution over human annotations) on the state-of-the-art model performances. Specifically, our contributions are:

- We collect additional 100 annotations for over 4k examples in SNLI, MNLI-matched, and αNLI (a total of 464,500 annotations) and show that when the number of annotations is significantly increased: (1) a number of original majority labels fail to present the prevailing human opinion (in 10%, 20%, and 31% of the data we collected for αNLI, SNLI, and MNLI-matched, respectively), and (2) large human disagreements exist and persist in a noticeable amount of examples.
- We compare several state-of-the-art model[2] outputs with the distribution of human judgements and show that: (1) the models lack the ability to capture the distribution of human opinions[3]; (2) such ability differs from the ability to perform well on the old accuracy metric; (3) models' performance on the subset with high levels of human agreement is substantially better than their performance on the subset with low levels of human agreement (almost close to solved versus random guess, respectively) and shared mistakes by the state-of-the-art models are made on examples with large human disagreements.
- We argue for evaluating the models' ability to predict the distribution of human opinions and discuss the merit of such evaluation with respect to NLU evaluation and model calibration. We also give design guidance on crowd-sourcing such collective annotations to facilitate future studies on relevant pragmatic tasks.

The **ChaosNLI** dataset and experimental scripts are available at `https://github.com/easonnie/ChaosNLI`

2 Related Work

Uncertainty of Annotations. Past discussions of human disagreement on semantic annotation tasks were mostly focused on the uncertainty of individual annotators and the noisiness of the data collection process. These tasks include word sense disambiguation (Erk and McCarthy, 2009; Jurgens, 2013), coreference (Versley, 2008), frame corpus collection (Dumitrache et al., 2019), anaphora resolution (Poesio and Artstein, 2005; Poesio et al., 2019), entity linking (Reidsma and op den Akker, 2008), tagging and parsing (Plank et al., 2014; Alonso et al., 2015), and veridicality (De Marneffe et al., 2012; Karttunen et al., 2014). These works focused on studying the ambiguity of annotations, how the design of the annotation setup might affect the inter-annotator-agreement, and how to make the annotations reliable. However, we consider the disagreements and subjectivity to be an intrinsic property of the populations. Our work discusses the disagreements among a large group of individuals, and further examines the relation between the annotation disagreement and the model performance.

Disagreements in NLI Annotations. Our work is significantly inspired by previous work that reveals the "inherent disagreements in human textual inference" (Pavlick and Kwiatkowski, 2019). It employed 50 independent annotators for a "graded" textual inference task, yielding a total of roughly 19,840 annotations, and validates that disagreements among the annotations are reproducible signals. In particular, in their work, the labeling schema is modified from 3-way categorical NLI to a graded one, whereas our study keeps the original 3-way labeling schema to facilitate a direct comparison between old labels and new labels, and focuses more on giving an in-depth analysis regarding the relation between the level of disagreements among humans and the state-of-the-art model performance.

Graded Labeling Schema. Some previous work attempts to address the issues with human disagreements by modifying or re-defining the evaluation task with a more fine-grained ordinal or even real-value labeling schema rather than categorical labeling schema (Zhang et al., 2017; Pavlick and

---

[2] We test models including BERT, RoBERTa, XLNET, ALBERT, DistilBERT, and BART.

[3] We measure the Jensen-Shannon Distance (JSD) and the Kullback–Leibler (KL) divergence between model softmax outputs and the estimated distribution over human annotations.

Kwiatkowski, 2019; Chen et al., 2019) to reduce the issues of ambiguity. Our work is independent and complementary to those by providing analysis on general language understanding from a collective distribution perspective.

3 Data Collection

Our goal is to gather annotations from multiple annotators to estimate the distribution over human opinions. Section 3.1 and 3.2 state some details of the collection. More importantly, Section 3.3 explains the challenges of such data collection and how our designs ensure data quality.

3.1 Dataset and Task

ChaosNLI provides 100 annotations for each example in three sets of existing NLI-related datasets. The first two sets are a subset of the SNLI development set and a subset of MNLI-matched development set, in which the examples satisfy the requirement that their majority label agrees with only three out of five individual labels collected by the original work (Bowman et al., 2015; Williams et al., 2018).[4] The third set is the entire αNLI development set introduced in Bhagavatula et al. (2020). To simplify the terminology, we denote SNLI, MNLI-m and αNLI portion of the ChaosNLI as ChaosNLI-S, ChaosNLI-M, and ChaosNLI-α, respectively.

3.2 Annotation Interface

To collect multiple labels for each example, we employed crowdsourced workers from Mechanical Turker with qualifications. The annotation interface is implemented using the ParlAI[5] (Miller et al., 2017) framework. The collection is embodied in a multi-round interactive environment where at each round annotators are instructed to do one single multi-choice selection. This reduces the annotators' mental load and helps them focus on the human intelligence tasks (HITs). The compressed versions of instructions are shown in Figure 1. Screenshots of Turker interfaces are attached in Appendix A.

3.3 Quality Control

Collecting the "soft-label" for examples based on plausible human opinions is difficult because we need to enforce that each annotator will genuinely try their best on the work to avoid errors caused by carelessness. We can not denoise the data by collecting more annotations and aggregating them with majority voting, nor can we use the inter-annotator agreement to measure data quality.

Natural Language Inference (NLI)

Given a context, a statement can be either:

- Definitely correct (Entailment); or
- Definitely incorrect (Contradiction); or
- Neither (Neutral).

Your goal is to choose the correct category for a given pair of context and statement.
An automatic detector will estimate your annotation accuracy on this task. If your estimated accuracy is **too low**, you might be **disqualified**.
If you feel **uncertain** about some examples, just choose the best category you believe the statement should be in.

Examples:
Context: *A guitarist is playing in a band.*
Statement: *Some people are performing.*
Answer: *The statement is* ***definitely correct****.*

Abductive Natural Language Inference (αNLI)

Given two observations (**O-Beginning** and **O-Ending**), and two hypotheses (**H1** and **H2**), your goal is to choose one of the hypotheses that is more likely to cause **O-Beginning** to turn into **O-Ending**.
An automatic detector will estimate your annotation accuracy on this task. If your estimated accuracy is **too low**, you might be **disqualified**.
If you feel **uncertain** about some examples, just choose the best category you believe the statement should be in.

Examples:
O-Beginning: *Jenny cleaned her house and went to work, leaving the window just a crack open.*
H1: *A thief broke into the house by pulling open the window.*
H2: *Her husband went home and close the window.*
O-Ending: *When Jenny returned home she saw that her house was a mess.*
Answer: H1*.*

Figure 1: Mechanical Turker instructions (compressed) for NLI and αNLI.

To this end, we select a set of examples , which exhibit high human agreement for a single label, to rigorously test and track the performance of each annotator. We call them ***the set of unanimous examples***. To obtain such set, we sampled examples from SNLI, MNLI, and αNLI training set, then crowdsourced 50 annotations for each of them, and finally selected those whose human agreement is indeed high (majority>95%). Throughout the collection process, we employ the following three mechanisms to ensure label quality:

On-boarding test. Every annotator needs to pass an on-boarding test before they can work on any real example. The test includes five easy examples pre-selected from ***the set of unanimous examples***. If they fail to give the correct selection for any of them, they will be prevented from working on any example. The mechanism tests whether the annotator understands the task.

---

[4] All the examples in SNLI and MNLI development and test set come with 5 labels and the ground truth labels are defined by majority label in all previous studies. Here, we intentionally choose to label examples with a low level of human agreement in SNLI and MNLI to highlight the factor of human disagreement. Both datasets are in English.

[5] `https://parl.ai/`

Training phase. After passing the on-boarding test, each annotator will be given 10 to 12 examples from ***the set of unanimous examples*** to be further annotated. For each example, if an annotator gives a label that is different from the pre-collected legitimate label, the annotator will be prompted with the correct label and told to keep concentrating on the task. If the accuracy of an annotator on training examples is below 75%, the annotator will be disallowed to proceed. This training mechanism further helps the annotators get familiar with the task.

Performance tracking. After the training phase, annotators will be given real examples. For each example to be annotated, there will be 10% chance that the example is sampled from ***the set of unanimous examples***. Again, for such examples, if an annotator gives a label that is different from the pre-collected legitimate label, the annotator will be prompted with the correct label and told to keep concentrating on the task. If the accuracy of an annotator on those examples is below 75% or if the annotator gives four consecutive incorrect labels, the annotator will be blocked. This mechanism tracks the performance of each annotator and guarantees that each annotator is capable and focused when working on any examples.

Table 1 shows that on-boarding test filters more than half of the turkers. Figure 2 shows that the average accuracy of a single Turker on ***the set of unanimous examples*** improves as the annotators have completed more examples and converges at around 92%.[6] The observations indicate that our filtering mechanisms are rigorous and help improving and keeping annotator concentrate during the collection task. The design gives guidelines for future work on how to ensure data quality where normal inter-annotator-agreement measures are not applicable.

3.4 Other Details

The entire collection takes about one month to complete over 464K annotations. The mean/median time a turker spent on each example ranges from 10 to 20 seconds as shown in Table 1 (and we pay up to $0.5 on average per HIT of ten examples). We observe high variance in the time/example across turkers (including over-estimation due to breaks), hence the median estimate is more reliable. We had a large set of qualified turkers for our final annotations. The total time of one month is largely attributed to the rigorous quality control mechanism via careful on-boarding qualification tests and quality monitoring.

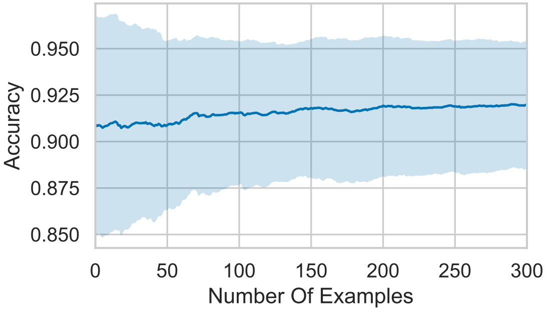

Figure 2: The accuracy range of the annotators on the NLI training and hidden *unanimous examples* as they annotated their first 300 examples.

Data	QFR (%)	FR (%)	#Turkers	Time (sec)
ChaosNLI-α	7.4	1.3	1,903	18.7 / 12.7
ChaosNLI-S	39.9	14.1	1,639	15.9 / 10.1
ChaosNLI-M	39.9	14.1	1,744	21.2 / 13.3

Table 1: MTurk statistics on the three datasets. 'QFR' or Qualification Fail Rate refers to the failure rate of the onboarding qualification test. 'FR' or Filter Rate refers to the ratio of Turkers who got blocked (during training phase and performance tracking described in Section 3.3) because their performance on the *unanimous examples* set are too low. SNLI and MNLI-m shared the same onboarding test and the same *unanimous examples* set, therefore their numbers are the same. The '#Turkers' column denotes the final set of filtered turkers that contributed to the released annotations. The last column 'Time' refers to the mean / median time spent by Turkers per example in seconds.

4 Analysis of Human Judgements

Statistics. We collected 100 new annotations for each example in the three sets described in Section 3.1. Table 2 shows the total number of examples in the three sets and the percentage of cases where the new majority label is different from the old majority label (based on 5 annotations for SNLI and MNLI and 1 annotation for αNLI in their original dataset, respectively). Since we only collected labels for subsets of SNLI and MNLI-m, we also include the size of the original SNLI and MNLI-m development sets and the change-of-label ratio with respect to the original sets. The findings suggest that the old labels fail to present the genuine majority labels among humans for a noticeable amount

---

[6] This is comparable to the accuracy of a majority voting over 5 aggregated annotations in previous work (Nangia and Bowman, 2019).

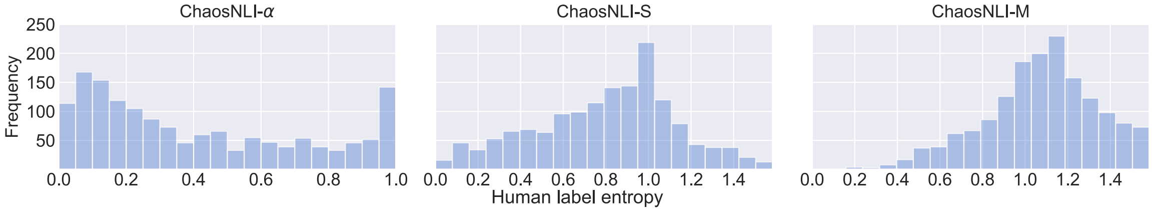

Figure 3: Histogram of entropy of estimated distribution over human annotations on ChaosNLI-α, ChaosNLI-S, ChaosNLI-M.

Data	# Examples	Change rate (%)
ChaosNLI-α	1,532	10.64
ChaosNLI-S	1,514 (10k)	24.97 (3.78)
ChaosNLI-M	1,599 (10k)	31.77 (5.08)

Table 2: Data Statistics. '# Examples' refers to the total number of examples. 'Change rate' refers to the percentage that the old majority label is different from the new majority label. The number in the parentheses shows the size of the entire original SNLI and MNLI-m development set and the percentage of label changes with respect to the entire set.

(10%, 25%, and 30% for ChaosNLI-α, ChaosNLI-S, and ChaosNLI-M, respectively) of the data. The label statistics for individual datasets can be found in Appendix D.

Examples. Table 3 and Table 4 show some collected NLI examples that either have low levels of human agreements or have different majority labels as opposed to the old ground truth labels. We can see that the resultant labels we collected not only provide more fine-grained human judgements but also give a new majority label that is better at presenting the prevailing human opinion. Moreover, there indeed exist different but plausible interpretations for the examples that are of low-level of human agreements and the discrepancy is not just noise but presents the distribution over human judgements with "higher resolutions". This is consistent with the finding in Pavlick and Kwiatkowski (2019).

Entropy Distribution. To further investigate the human uncertainty in our collected labels, we show the histogram of the entropy of label distribution for ChaosNLI-α, ChaosNLI-S and ChaosNLI-M in Figure 3. The label distribution is approximated by the 100 collected annotations. The entropy is calculated with $\mathbf{H}(\mathbf{p}) = -\sum_{i \in \mathcal{C}} p_i \log(p_i)$ and $p_i = \frac{n_i}{\sum_{j \in \mathcal{C}} n_j}$, where $\mathcal{C}$ is the label category set and n_i is the number of labels for category i. The entropy value gives a measure for the level of uncertainty or agreement among human judgements, where high entropy suggests low level of agreement and vice versa.

The histogram for the ChaosNLI-α shows a distribution that is similar to a U-Shaped distribution. This indicates that naturally occurring examples in ChaosNLI-α are either highly certain or uncertain among human judgements. In ChaosNLI-S and ChaosNLI-M, the distribution shows only one apparent peak; and the distribution for ChaosNLI-M is slightly skewed towards higher entropy direction. As described in Section 3.1, ChaosNLI-S and ChaosNLI-M are subsets of SNLI and MNLI-m development that are of low-level of human agreements, it could be expected that the majority of naturally occurring SNLI and MNLI data would also have low entropy, which will form another peak around the beginning of the x-axis resulting a U-like shape similar to ChaosNLI-α.[7]

5 Analysis of Model Predictions

In Section 4, we discussed the statistics and some examples for the new annotations. The observation naturally raises two questions regarding the development of NLP models: (1) whether the state-of-the-art models are able to capture this distribution over human opinions; and (2) how the level of human agreements will affect the performance of the models. Hence, we investigate these questions in this section. Section 5.1 and 5.2 state our experimental choices. Section 5.3 discusses the results regarding the extent to which the softmax distributions produced by state-of-the-art models trained on the dataset reflects similar distributions over human annotations. Section 5.4 demonstrate the surprising influence of human agreements on the model performances.

---

[7] In our pilot study, we collected 50 labels for 100 examples of SNLI where all five original annotators agreed with each other, the average entropy of those is 0.31. The average entropy of examples on ChaosNLI-S is 0.80.

Context	**Hypothesis**	**Old Labels**	**New Labels**	**Source**	**Type**

Table 3: Examples from ChaosNLI-S and ChaosNLI-M development set. 'Old Labels' is the 5 label annotations from original dataset. 'New Labels' refers to the newly collected 100 label annotations. Superscript indicates the frequency of the label.

Observation-1	Sadie was on a huge hike.
Observation-2	Luckily she pushed herself and managed to reach the peak.
Hypothesis-1	Sadie almost gave down mid way.
Hypothesis-2	Sadie wanted to go to the top.
Old Label	Hypothesis-2
New Labels	**Hypothesis-1**$^{(58)}$ Hypothesis-2$^{(42)}$
Observation-1	Uncle Jock couldn't believe he was rich.
Observation-2	Jock lived the good life for a whole year, until he was poor again.
Hypothesis-1	He went to town and spent on extravagant things.
Hypothesis-2	Jock poorly managed his finances.
Old Label	Hypothesis-1
New Labels	Hypothesis-1$^{(48)}$ **Hypothesis-2**$^{(52)}$

Table 4: Examples from the collected ChaosNLI-α development set. The task asks which of the two hypothesis is more likely to cause **Observation-1** to turn into **Observation-2**. Superscript indicates the frequency of the label. Majority labels were marked in bold.

5.1 Models and Setup

Following the pretraining-then-finetuning trend, we focus our experiments on large-scale language pretraining models. We studied BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), and RoBERTa (Liu et al., 2019) since they are considered to be the state-of-the-art models for learning textual representations and have been used for a variety of downstream tasks. We experimented on both the base and the large versions of these models, in order to analyze the parameter size factor. Additionally, we include BART (Lewis et al., 2020), ALBERT (Lan et al., 2019), and DistilBERT (Sanh et al., 2019) in the experiments. ALBERT is designed to reduce parameters of BERT by cross-layer parameter sharing and decomposing embedding. DistilBERT aims to compress BERT with knowledge distillation. BART is a denoising autoencoder for pretraining seq-to-seq models.

For NLI, we trained the models on a combined training set of SNLI and MNLI which contains over 900k NLI pairs. We used the best hyper-parameters chosen by their original authors. For αNLI, we trained the models on αNLI training set (169,654 examples). The hyper-parameters for αNLI were tuned with results on αNLI development set. Details of the hyper-parameters are in Appendix B.

5.2 Evaluation and Metrics

As formulated in Equation 4, we used the 100 collected annotations for each example to approximate the human label distributions for each example. In order to examine to what extent the current models are capable of capturing the collective human opinions, we compared the human label distributions with the softmax outputs of the neural networks following Pavlick and Kwiatkowski (2019).

We used Jensen-Shannon Distance (JSD) as the primary measure of the distance between the softmax multinomial distribution of the models and the distributions over human labels because JSD is a metric function based on a mathematical definition (Endres and Schindelin, 2003). It's symmetric and bounded with the range [0, 1], whereas the Kullback–Leibler (KL) divergence (Kullback and Leibler, 1951; Kullback, 1997) does not have these two properties. We also used KL as a complementary measure. The two metrics are calculated as:

$$\text{KL}\left(\mathbf{p}\|\mathbf{q}\right) = \sum_{i \in C} p_i \log\left(\frac{p_i}{q_i}\right) \quad (1)$$

$$\text{JSD}\left(\mathbf{p}\|\mathbf{q}\right) = \sqrt{\frac{1}{2}\left(\text{KL}\left(\mathbf{p}\|\mathbf{m}\right) + \text{KL}\left(\mathbf{q}\|\mathbf{m}\right)\right)} \quad (2)$$

where $\mathbf{p}$ is the estimated human distribution, $\mathbf{q}$ is model softmax outputs, and $\mathbf{m} = \frac{1}{2}(\mathbf{p} + \mathbf{q})$.

5.3 Main Results

Table 5 reports the main results regarding the distance between model softmax distribution and estimated human label distribution. In addition to the models, we also show the results for the chance baseline (the first row) and the results for estimated

Table 5: Model Performances for JSD, KL, and Accuracy on majority label. ↓ indicates smaller value is better. ↑ indicates larger value is better. For each column, the best values are in bold and the second best values are underlined. “-b” and “-l” in the Model column denote “-base” and “-large”, respectively.

human performance (the last row). The chance baseline gives each label equal probability when calculating the JSD and KL measures. The accuracy of the chance baseline directly shows the proportion of the examples with the majority label in a specific evaluation set. To estimate the human performance, we employed a new set of annotators to collect another 100 labels for a set of randomly sampled 200 examples on ChaosNLI-α, ChaosNLI-S and ChaosNLI-M, respectively. For a better estimation of ‘collective’ human performance, we ensure that the new set of annotators employed for estimating human performance is disjoint from the set of annotators employed for the normal label collection.[8] In what follows, we discuss the results.

Significant difference exists between model outputs and human opinions. The most salient information we can get is that there are large gaps between model outputs and human opinions. To be specific, the estimated collective human performance gives JSD and KL scores far below 0.1 on all three sets. However, the best JSD achieved by the models is larger than 0.2 and the best KL achieved by the models barely goes below 0.5 across the table. The finding can be somewhat foreseeable since none of the models are designed to capture collective human opinions and suggests room for improvement.

Even chance baseline is hard to beat. What is more surprising is that a number of these state-of-the-art models can barely outperform and sometimes even perform worse than the chance baseline w.r.t. JSD and KL scores. On ChaosNLI-M, all the models yield similar JSD scores to the chance baseline and are beaten by it on KL. On ChaosNLI-α, BERT-base performs worse than the chance baseline on JSD and the scores of KL by all the models are way higher than that of the chance baseline. This hints that capturing human label distribution is a common *blind spot* for many models.

There is no apparent correlation between the accuracy and the two divergence scores. On both ChaosNLI-S and ChaosNLI-M, DistilBERT gives the best KL scores despite the fact that it obtains the lowest accuracy on the majority label. BERT-base gives the best JSD while having the second lowest accuracy on ChaosNLI-M. RoBERTa-large gives the highest accuracy on ChaosNLI-S and ChaosNLI-M, and the second highest accuracy on ChaosNLI-α but it only obtains the lowest JSD on ChaosNLI-α. The best JSD score on ChaosNLI-α is achieved by BART but it fails to give the best accuracy. This hints that the ability required to model the distribution of human labels differs from that required to predict the majority label and perform well on the accuracy metric.

Large models are not always better. Direct comparison between base and large models for BERT, XLNet, and RoBERTa reveals that large models cannot beat base models on ChaosNLI-α and ChaosNLI-M on KL scores. Moreover, on

---

[8] The estimation of collective human performance can also be viewed as calculating the JSD and KL between two disjoint sets of 100 human opinions.

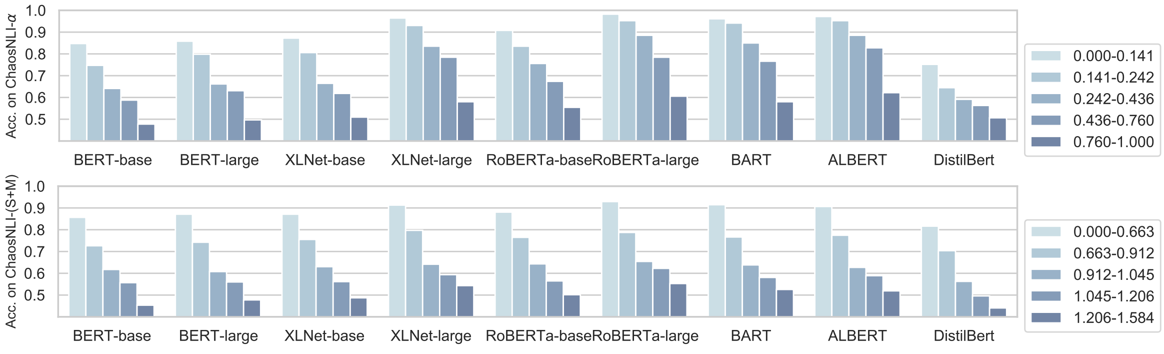

Figure 4: Accuracy on different bins of data points whose entropy values are within specific quantile ranges.

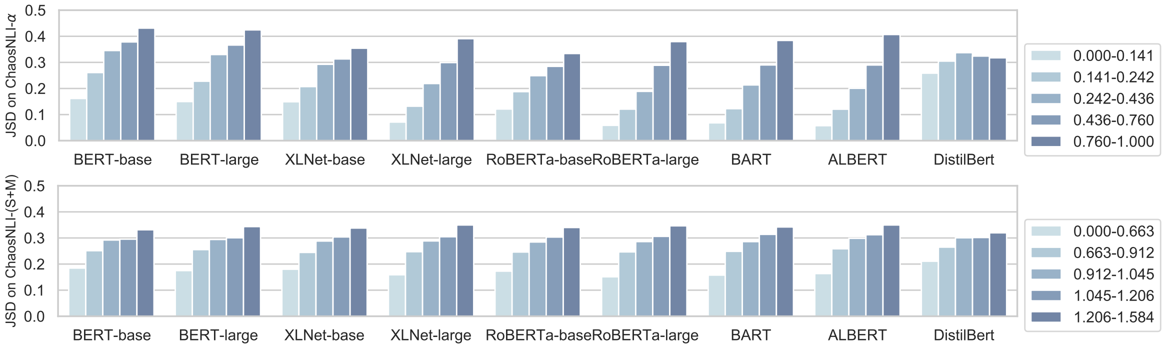

Figure 5: JSD on different bins of data points whose entropy values are within specific quantile ranges.

ChaosNLI-M, all the large models give higher JSD scores than the base models. However, all the large models achieve higher accuracy than their base model counterparts on all three evaluation sets. This observation suggests that modeling the collective human opinions might require more thoughtful designs instead of merely increasing model parameter size.

5.4 The Effect of Agreement

To study how human agreements will influence the model performance, we compute the entropy of the human label distribution (by Equation 4) for each data point. Then, we partition ChaosNLI-α and the union of ChaosNLI-S and ChaosNLI-M using their respective entropy quantiles as the cut points. This results in several bins with roughly equal numbers of data points whose entropy lies in a specific range. Figure 4 and 5 shows the accuracy and the JSD of the models on different bins.[9] We observe that:

- Across the board, *there are consistent correlations between the level of human agreements and the accuracy of the model*. This correlation is positive, meaning that all models perform well on examples with a high level of human agreements while struggle with examples having a low level of human agreements. Similar trends also exists in JSD.
- Accuracy downgrades dramatically (from 0.9 to 0.5) as the level of human agreements decrease.
- The model barely outperforms and sometimes even under-performs the chance baseline on bins with the lowest level of human agreements. For both αNLI and NLI, the accuracy of most models on the bin with the lowest level of human agreements does not surpass 60%.

These results reveal that most of the data (which often compose the majority of the evaluation set) with a high level of human agreement have been solved by state-of-the-art models, and most of the common errors on popular benchmarks (like αNLI, SNLI, and MNLI) lie in the subsets where human agreement is low. However, because of the low human agreement, the model prediction will be nothing more than a random guess of the majority opinion. This raises an important concern that whether improving or comparing the performance

---

[9] Model JSD performances are similar to the accuracy performances where all the models obtain worse results at the bins with higher entropy range. One exception is the JSD of DistilBert on ChaosNLI-α. This might due to the fact that DistilBert is highly uncertain in its prediction and tend to give even distribution for each label yielding similar results to the chance baseline.

on this last missing part of the benchmarks is advisable or useful.

6 Discussion & Conclusion

While common practice in natural language evaluation compares the model prediction to the majority label, Section 5.4 questions the value of continuing such evaluation on current benchmarks as most of the unsolved examples are of low human agreement. To address this concern, we suggest NLP models be evaluated against the collective human opinion distribution rather than one opinion aggregated from a set of opinions, especially on tasks which take a descriptivist approach[10] to language and meaning, including NLI and common sense reasoning. This not only complements prior evaluations by helping researchers understand whether model performance on a specific data point is reliable based on its human agreement, but also makes it possible to evaluate models' ability to capture the whole picture of human opinions. Section 5.3 shows that such ability is missing from current models and potential room for improvement is huge.

It is also important to note that the level of human agreement is an intrinsic property of a data point. Section 5.4 demonstrates that such a property can be an indicator of the difficulty of the modeling. This hints at the connections between human agreements and uncertainty estimation or calibration (Guo et al., 2017) where machine learning models are required to produce the confidence value of their predictions, leading to important benefits in real-world applications.

In conclusion, we hope our data and analysis inspire future directions such as explicit modeling of collective human opinions; providing theoretical supports for the connection between human disagreement and the difficulty of acquiring language understanding in general; exploring potential usage of these human agreements; and studying the source of the human disagreements and its relations to different linguistic phenomena.

A Annotation Interface

Figure 6 and 7 show the screenshots for NLI and αNLI collection, respectively.

B Hyperparameters

For SNLI and MNLI, we used the same hyperparameters chosen by their original respective authors. For αNLI, we tuned batch size, learning rate and the number of epoch. For BERT, XLNet, and RoBERTa, we only searched parameters for large models and the base models use the same hyperparameters based on the results of the large ones. Table 8 shows the details.

C Training Size and Trajectory

Figure 8 show the training trajectory and the changes of the accuracy and JSD of RoBERTa-large on four bins as the training data gradually increased in log space. The plots reveal that the accuracy of the models converges faster given fair amount of training data on bins with a high level of human agreements.

D Label Statistics

Labeling statistics can be found in Table 7. It is worth noting that there is a shift of majority labels from neutral to entailment in MNLI-m. We assume the difference might be due to multi-genre nature of the MNLI dataset, and collecting more intuitive and concrete reasons for such an observation from a cognitive or linguistic perspective will be important future work.

E Other Details

Our neural models are trained using a server with a Intel(R) Xeon(R) CPU E5-2630 v4 @ 2.20GHz (10 cores) and 4 NVIDIA TITAN V GPUs. Table 6 shows the urls where we downloaded external resources.

Abstract

Neural language models are often trained with maximum likelihood estimation (MLE), where the next word is generated conditioned on the ground-truth word tokens. During testing, however, the model is instead conditioned on previously generated tokens, resulting in what is termed *exposure bias*. To reduce this gap between training and testing, we propose using optimal transport (OT) to match the sequences generated in these two modes. An extension is further proposed to improve the OT learning, based on the structural and contextual information of the text sequences. The effectiveness of the proposed method is validated on machine translation, text summarization, and text generation tasks.

1 Introduction

Natural language generation is an essential component of many NLP applications, such as machine translation (Bahdanau et al., 2015), image captioning (You et al., 2016), text summarization (See et al., 2017), dialogue systems (Vinyals and Le, 2015), and machine comprehension (Nguyen et al., 2016). Generating human-like natural language is typically cast as predicting a sequence of consecutive words in a recurrent manner. Maximum likelihood estimation (MLE) is commonly employed as the objective to train such text-generation models, maximizing the log-likelihood of producing the ground-truth tokens within a sentence or paragraph (Salakhutdinov, 2015). In Recurrent Neural Network (RNN) models, this is also known as Teacher-Forcing (TF) (Williams and Zipser, 1989), due to the use of ground-truth tokens for next-token prediction.

However, in the maximum likelihood paradigm, previous observed tokens are usually provided during training, giving rise to an issue termed *exposure bias* (Bengio et al., 2015): the ground-truth tokens seen by the model during training are not available at inference time. During inference, the model is required to use outputs from the last step instead of the unseen ground-truth, which is often referred to as Student-Forcing (SF). As a result, there is a discrepancy between training and inference, accumulating errors along the sequence-generation trajectory (Ranzato et al., 2016a).

This challenge has been addressed by incorporating model-generated text at training time. Bengio et al. (2015) proposed *scheduled sampling* (SS), where the training samples are systematically tampered with by replacing some of the ground-truth tokens with model-predicted tokens. Other works regard text generation as a sequential decision making problem, applying reinforcement learning (RL) techniques (Ranzato et al., 2016b; Bahdanau et al., 2017). In particular, quantitative evaluation metrics such as BLEU and ROGUE are used as sequence-level rewards for model-generated texts.

Despite the encouraging results reported, concerns have been raised w.r.t. the above strategies. Scheduled sampling is known to be statistically inconsistent and fails to address the fundamental issues (Huszár, 2015). RL solutions usually suffer from slow and unstable training due to the high variance of REINFORCE-based policy gradients; consequently, specific training techniques are often needed (Rennie et al., 2017; Liu et al., 2018). Additionally, the results from RL models often do not correlate well with human evaluations, as the rewards used are typically biased towards specific aspects of a language model (Wang et al., 2018).

On the other hand, recent developments in likelihood-free modeling techniques, most prominently the *generative adversarial networks* (GANs), tackle exposure bias in a more principled fashion (Lamb et al., 2016; Yu et al., 2017; Zhang et al., 2017; Li et al., 2017). GAN-based text models, however, suffer from a number of severe dif-

---

ficulties, including mode collapse, where generated text looks real but lacks necessary diversity (Zhu et al., 2018; Caccia et al., 2018). Additionally, the training of GAN-based models is often unstable, and model learning easily breaks down in the event of vanishing or exploding gradients (Arjovsky et al., 2017; Zhang et al., 2017). Therefore, existing adversarial methods may not be able to match sentences generated by student-forcing with ground-truth sentences.

To mitigate the challenges from the adversarial methods, we utilize a sequence-matching loss based on Optimal Transport (OT), which avoids a neural discriminator and delivers a smoother gradient for the generator. Recently, Chen et al. (2019) leverage OT loss based on a Teacher-Forcing scheme, however, it degenerates to word-level matching, making it difficult to capture temporal semantic information. In this work, in order to enable sequence-level matching, we instead propose an OT-based sequence-level training scheme to directly optimize the discrepancy loss between the ground-truth and free-running text samples. Further, we introduced various OT cost functions for loss calculation. The significance of this work is two-fold: firstly, this approach alleviates the exposure bias, boosting model performance at the inference stage by using a sequence-level objective between free-running output and reference. Secondly, with the use of OT, this approach provides a direct objective that is easy and robust to optimize, without biasing towards a specific, manually-defined metric.

Our work provides the following contributions: *i*) We introduce a novel method for text generation called Student-Forcing OT (SFOT), leveraging OT loss to improve long-term sequence sampling. *ii*) A new context-preserving OT approach is proposed to effectively match a text sequence with order information. *iii*) We examine the necessity of integrating OT with Student-Forcing via Imitation Learning. *iv*) The proposed models are robust demonstrated by extensive empirical evaluations on Neural Machine Translation (NMT), Text Summarization, and Neural Text Generation (NLG).

2 Student Forcing Optimal Transport

To reduce exposure bias, the output sequences of the generator in the teacher-forcing (training) and student-forcing (inference) stages should be indistinguishable. Therefore, we propose to use OT loss to measure sequence matching distance between the two stages, in conjunction with the maximum likelihood estimate.

2.1 Maximum Likelihood Estimate

We denote the training dataset as N sequence pairs $\mathcal{D} = \{\boldsymbol{x}_n, \boldsymbol{y}_n\}_{n=1}^N$, with output sequence $\boldsymbol{x} = [x_1, \cdots, x_T]$ and input sequence $\boldsymbol{y} = [y_1, \cdots, y_{T'}]$. Depending on the specific task, $\boldsymbol{y}$ may have different definitions. For *seq2seq* models like neural machine translation, $\boldsymbol{y}$ represents the source sequence, conditioned on which the target sequence $\boldsymbol{x}$ is generated. For language modeling tasks, $\boldsymbol{y}$ is empty, and $\boldsymbol{x}$ becomes the unconditionally generated sequence.

To generate a text sequence, neural language models (Mikolov et al., 2010) generate every token x_t conditioned on the previous tokens in an auto-regressive manner:

$$\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y}) = \sum_{t=1}^{T} \log p_{\boldsymbol{\theta}}(x_t|x_{<t}, \boldsymbol{y}) \quad (1)$$

where $\boldsymbol{\theta}$ are model parameters, and $x_{<t}$ indicates all tokens before t. Learning $\boldsymbol{\theta}$ is often performed with maximum likelihood estimation (MLE):

$$\mathcal{L}_{\text{MLE}} = \mathbb{E}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{D}}[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y})] \quad (2)$$

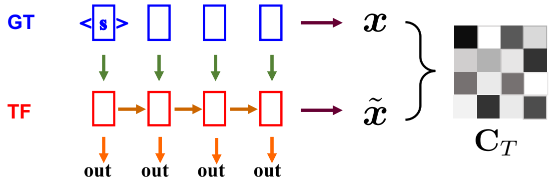
To facilitate MLE training, the *teacher-forcing* scheme is considered. The word tokens $x_{<t}$ from the ground-truth sequence are fed into (1) to generate the next token:

$$\tilde{\boldsymbol{x}} = [\tilde{x}_1, \cdots, \tilde{x}_T] \text{ with } \tilde{x}_t \sim p_{\boldsymbol{\theta}}(\tilde{x}_t|x_{<t}, \boldsymbol{y}) \quad (3)$$

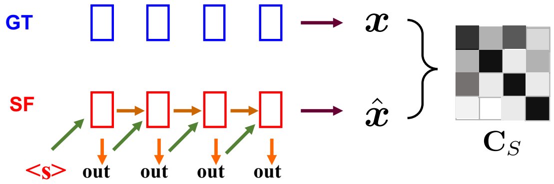
Learned neural language models are often evaluated using the *student-forcing* scheme. The previously generated word tokens of the model are conditioned to generate the next token:

$$\hat{\boldsymbol{x}} = [\hat{x}_1, \cdots, \hat{x}_T] \text{ with } \hat{x}_t \sim p_{\boldsymbol{\theta}}(\hat{x}_t|\hat{x}_{<t}, \boldsymbol{y}) \quad (4)$$

The difference between (3) and (4) reveals a gap between training and evaluation in the MLE method. To reduce the gap, a natural idea is to define a tractable function to measure the discrepancy between ground-truth and SF-generated text sequences, to regularize TF-based MLE learning.



(a) Teacher-Forcing OT



(b) Student-Forcing OT

Figure 1: Comparison of (a) teacher-forcing (TF) and (b) student-forcing (SF), where ⟨s⟩ is the start token. In (a), the ground-truth (GT) sequence $\boldsymbol{x}$ is compared with TF-generated sequence $\tilde{\boldsymbol{x}}$ to produce the cost matrix $\mathbf{C}_T$; In (b), the GT sequence $\boldsymbol{x}$ is compared with SF-generated sequence $\hat{\boldsymbol{x}}$ to produce the cost matrix $\mathbf{C}_S$.

2.2 Student Forcing Optimal Transport

We propose to use optimal transport (OT) to measure the discrepancy between the student-forcing generated sequence $\hat{\boldsymbol{x}}$ and the ground-truth sequence $\boldsymbol{x}$. Assuming there is an oracle/target distribution $\mu(\boldsymbol{x})$ to generate $\boldsymbol{x}$, our goal is to learn $\boldsymbol{\theta}$ such that the model distribution $p_{\boldsymbol{\theta}}(\hat{\boldsymbol{x}})$ matches $\mu(\boldsymbol{x})$. Formally, OT provides a distance metric between the two probability measures μ and p on a domain $\mathbb{X}$ (the sequence of word tokens):

$$\mathcal{R}_{\text{ot}}(\boldsymbol{x}, \hat{\boldsymbol{x}}) = \inf_{\gamma \in \Pi(\mu, p)} \mathbb{E}_{(\boldsymbol{x}, \hat{\boldsymbol{x}}) \sim \gamma}[c(\boldsymbol{x}, \hat{\boldsymbol{x}})], \tag{5}$$

where $\Pi(\mu, p)$ denotes the set of all joint distributions $\gamma(\boldsymbol{x}, \hat{\boldsymbol{x}})$ with marginals $\mu(\boldsymbol{x})$ and $p(\hat{\boldsymbol{x}})$. The function $c(\boldsymbol{x}, \hat{\boldsymbol{x}}) : \mathbb{X} \times \mathbb{X} \to \mathbb{R}$ defines the cost of moving $\hat{\boldsymbol{x}}$ to $\boldsymbol{x}$. Intuitively, OT provides a method of matching the sequence $\hat{\boldsymbol{x}}$ to $\boldsymbol{x}$ with the minimum cost, given μ, p and $c(\cdot, \cdot)$.

OT distance on discrete domains For discrete distributions μ, p on $\mathbb{X}$, we have $\mu = \sum_{i=1}^{T} \mathrm{u}_i \delta_{\mathbf{x}_i}$ and $p = \sum_{j=1}^{T} \mathrm{p}_j \delta_{\hat{\boldsymbol{x}}_j}$ with $\delta_{\mathbf{x}}$ the Dirac function centered on $\mathbf{x}$. The weight vectors $\mathbf{u} = \{\mathrm{u}_i\}_{i=1}^{T} \in \Delta^T$ and $\mathbf{p} = \{\mathrm{p}_i\}_{i=1}^{T} \in \Delta^T$ belong to the T-dimensional simplex, *i.e.*, $\sum_{i=1}^{T} \mathrm{u}_i = \sum_{j=1}^{T} \mathrm{p}_j = 1$, as both μ and p are probability distributions. Under such a setting, computing the OT distance is equivalent to solving the following network-flow problem (Luise et al., 2018):

$$\begin{aligned}\mathcal{R}_{\text{ot}}(\boldsymbol{x}, \hat{\boldsymbol{x}}) &= \min_{\mathbf{M} \in \Pi(\mathbf{u}, \mathbf{p})} \sum_{i=1}^{T} \sum_{j=1}^{T} \mathbf{M}_{ij} \cdot c(\boldsymbol{x}_i, \hat{\boldsymbol{x}}_j) \\ &= \min_{\mathbf{M} \in \Pi(\mathbf{u}, \mathbf{p})} \langle \mathbf{M}, \mathbf{C} \rangle \end{aligned} \tag{6}$$

where $\Pi(\mathbf{u}, \mathbf{p}) = \{\mathbf{M} \in \mathbb{R}_{+}^{T \times T} | \mathbf{M}\mathbf{1}_T = \mathbf{u}, \mathbf{M}^\top \mathbf{1}_T = \mathbf{p}\}$, $\mathbf{1}_T$ denotes a T-dimensional all-one vector, $\mathbf{C}$ is the cost matrix given by $\mathbf{C}_{ij} = c(\boldsymbol{x}_i, \hat{\boldsymbol{x}}_j)$, and $\langle \mathbf{M}, \mathbf{C} \rangle = \mathrm{Tr}(\mathbf{M}^\top \mathbf{C})$ represents the Frobenius dot-product. We refer to the minimizer $\mathbf{M}^*$ of (6) as *OT matching*.

Summarizing, our student-forcing optimal transport (SFOT) objective is:

$$\begin{aligned}\mathcal{L}_{\text{SFOT}} = \mathbb{E}_{(\boldsymbol{x}, \boldsymbol{y}) \sim \mathcal{D}}[&\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{y}) + \\ &\lambda \mathbb{E}_{\hat{\boldsymbol{x}} \sim p_{\boldsymbol{\theta}}(\hat{\boldsymbol{x}}|\boldsymbol{y})} \mathcal{R}_{\text{ot}}(\boldsymbol{x}, \hat{\boldsymbol{x}})]\end{aligned} \tag{7}$$

where λ is the weighting hyper-parameter that balances the MLE and OT losses. In practice, we only take one sample in student-forcing. Note that our SFOT objective considers $\mathcal{R}_{\text{ot}}(\boldsymbol{x}, \hat{\boldsymbol{x}})$. This is a key difference from Chen et al. (2019), where teacher-forcing is used in OT $\mathcal{R}_{\text{ot}}(\boldsymbol{x}, \tilde{\boldsymbol{x}})$. To note the difference, we refer to the method in Chen et al. (2019) as TFOT.

The exact minimization over $\mathbf{M}$ is generally computationally intractable (Arjovsky et al., 2017; Genevay et al., 2018). Hence we use the recently introduced Inexact Proximal point method for Optimal Transport (IPOT) (Xie et al., 2018) algorithm to approximate $\mathbf{M}^*$. The details of the IPOT algorithm are shown in Appendix A.1.

2.3 Cost Functions in SFOT

OT-matching quality largely depends on the cost function $c(\cdot, \cdot)$. In particular, there is flexibility in how we represent the elements to be transported, for which we outline two alternatives below.

Vanilla OT A natural choice for the cost distance is to use the word embeddings, denoted $\{\boldsymbol{h}_t^0\}_{t=1}^{T}$, as used by previous works:

$$c(\boldsymbol{x}_i, \hat{\boldsymbol{x}}_j) = 1 - \frac{\boldsymbol{h}_i^{0\top} \boldsymbol{h}_j^0}{\|\boldsymbol{h}_i^0\| \|\boldsymbol{h}_j^0\|}, \tag{8}$$

However, a word-embedding-based cost function only captures the token-to-token similarity. On the other hand, the semantics of words can be different in different positions or contexts. This inspires the proposal of two novel cost functions to improve text sequence matching in OT.

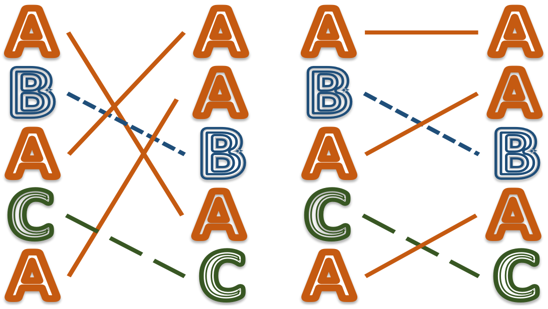


Figure 2: Illustration of the intuition of the proposed OT extensions. The goal is to match the sequence `ABACA` to the sequence `AABAC`. Left: traditional OT, where only the token information is considered; thus letter `A` in any positions of the two sequences can be aligned. Right: the proposed extensions of OT, where the *context* and *ordering* information help to eliminate undesirable alignment. In terms of the context, letter `A` will be matched to those that share a similar context {`A`, `B`} and {`A`, `C`}. In terms of ordering, letter `A` will be aligned to the letters with similar positions

.

Contextualized OT with Order-Preserving Regularizer Because the same word in different linguistic contexts may have different meanings, a cost function that cannot capture such variability may lead to undesirable matching results. While word embeddings $\{\boldsymbol{h}_t^0\}_{t=1}^T$ may be myopic, hidden representations $\{\boldsymbol{h}_t^\ell\}_{t=1}^T$ at higher layers ($\ell > 0$) of deep language models (*e.g.* LSTM (Hochreiter and Schmidhuber, 1997) or the Transformer (Vaswani et al., 2017)) often capture contextualized representations of the word in the sequence. Inspired by works on deep contextualized word representations (Peters et al., 2018; Devlin et al., 2018; Radford et al., 2018), we replace the word embeddings with $\{\boldsymbol{h}_t^\ell\}_{t=1}^T$ to represent the meaning of words inside the sequence. Then the cost function can be defined

$$c(\boldsymbol{x}_i, \hat{\boldsymbol{x}}_j) = 1 - \frac{{\boldsymbol{h}_i^l}^\top \boldsymbol{h}_j^l}{\|\boldsymbol{h}_i^l\| \|\boldsymbol{h}_j^l\|} \tag{9}$$

Figure 2 shows that the meaning of letter {`A`} can be less ambiguous when considering its local context {`B`, `A`} and {`C`, `A`}. This context information further helps eliminate the undesirable matching configurations. Otherwise, letter `A` can match to `A` of any position in the other sequence. Note that contextual information may implicitly capture relatively long-term dependency information compared with vanilla OT, and it can be perceived as a "soft" n-gram matching.

Algorithm 1 Student Forcing Optimal Transport

```
Input: Ground truth paired sequences $\mathcal{D} = \{\boldsymbol{x}_n, \boldsymbol{y}_n\}_{n=1}^N$
Initialize MLE model parameters $\theta$
while training do
    Draw samples $\{\boldsymbol{x}_n, \boldsymbol{y}_n\} \sim \mathcal{D}$
    Compute the outputs $\boldsymbol{h}$ of the model via teacher-forcing and $\hat{\boldsymbol{h}}$ via student-forcing
    Compute the cost matrix $\mathbf{C}$ based on the choice of cost function in (8), (10)
    Compute the OT Loss $\mathcal{R}_{\text{OT}}(\boldsymbol{x}, \hat{\boldsymbol{x}})$ defined in (6) via IPOT algorithm
    Update $\theta$ by optimizing $\mathcal{L}_{\text{SFOT}}$ defined in (7)
end while
```

We also consider an order-preserving regularizer for the contextualized OT, motivated by the fact that positional information of a token can be crucial in natural language understanding. For example, two sentences may have opposite meanings when the word order is changed: *"He hated it but then started loving it"* versus *"He loved it but then started hating it"*. Hence, it is desirable to have the transportation matrix concentrate to diagonal entries, by transporting the neighboring elements in one sequence into some other neighboring elements in another sequence with nearby temporal position (Su and Hua, 2018). Inspired by Albregtsen et al. (2008), we penalize the contextual cost function with *inverse difference moment* as

$$c_{\text{c}}(\boldsymbol{x}_i, \hat{\boldsymbol{x}}_j) = c(\boldsymbol{x}_i, \hat{\boldsymbol{x}}_j) - \frac{\beta}{(\frac{i}{T} - \frac{j}{T})^2 + 1} \tag{10}$$

where $\beta \geq 0$ is the weighting hyper-parameter for the order-preserving penalty. Figure 2 shows that when only considering the token-to-token similarity, the first letter `A` from the left sequence can be moved to any `A` in the right sequence. However, when considering the ordering penalty, letter `A` is aligned to the letters with similar position. SFOT is summarized in Algorithm 1.

Note that order-preserving regularization is only applied to contextualized OT, as requiring position-wise matching for the generated and target sentence may be too restrictive. Empirically, we observed adding the order-preserving regularizer to vanilla OT gives marginal improvement. However, since contextualized OT operates on a feature space, the position-wise matching is softened and can be naturally coupled with contextual cost function.

2.4 An Imitation Learning Interpretation of Student-Forcing

The sequential text generation process can be reformulated using Markov decision processes

(MDPs). Formally, an MDP $\mathcal{M} = \langle \mathcal{S}, \mathcal{A}, P_s, r \rangle$[1] defines a transition probability $P_s(\boldsymbol{s}'|\boldsymbol{s}, \boldsymbol{a})$ from state $\boldsymbol{s} \in \mathcal{S}$ to the next state $\boldsymbol{s}' \in \mathcal{S}$ after the agent takes an action $\boldsymbol{a} \in \mathcal{A}$; $r(\boldsymbol{s}, \boldsymbol{a})$ is an unknown reward function. To cast text generation as an MDP, we may consider the action as the selection of the next word x_t from the vocabulary, conditioned on the states of observed words $x_{<t}$, *i.e.*, $\boldsymbol{s}_t = x_{<t}$ and $\boldsymbol{a}_t = x_t$. At each time step t, the agent takes an action $\boldsymbol{a}_t$ at state $\boldsymbol{s}_t$ according to policy $\pi(\boldsymbol{a}_t|\boldsymbol{s}_t)$, and receives a reward $r(\boldsymbol{s}_t, \boldsymbol{a}_t)$. The conjunction of the generated word and the previous methods constitute the next state $\boldsymbol{s}_{t+1}$.

Imitation learning seeks to learn an optimal policy from demonstrations of an expert policy π_E. In language models, the training text plays the role of expert trajectories. This objective is formally:

$$\max_{r \in \mathbb{R}^{\mathcal{S} \times \mathcal{A}}} \min_{\pi \in \Pi} \; -H(\pi) + \mathcal{R}(\pi_E) - \mathcal{R}(\pi) \quad (11)$$

$$\text{with} \;\; \mathcal{R}(\pi) = \sum_{\boldsymbol{s}, \boldsymbol{a}} \rho_\pi(\boldsymbol{s}, \boldsymbol{a}) r(\boldsymbol{s}, \boldsymbol{a}).$$

where $\rho_\pi(\boldsymbol{s}, \boldsymbol{a})$ is the stationary joint distribution of $(\boldsymbol{s}, \boldsymbol{a})$ induced by the learning policy π; $H(\pi)$ is the entropy. Intuitively, the objective encourages that higher rewards are assigned to the expert policy π_E, while π is trained to mimic π_E.

Importantly, (11) suggests that each individual word of sentences that induces the distribution ρ_π should be fully generated by the learned language model π. In other words, at each time step, π generates a word using its own previously generated words. This is exactly the student-forcing scheme we employ for the proposed SFOT algorithm. This reveals the key difference with Chen et al. (2019), where teaching-forcing is employed. Since such an agent takes actions based on the partial expert trajectories, it will induce a biased occupancy measure. This results in a sub-optimal policy for text generation, even when the imitation learning objective (11) is optimized.

3 Related Work

Text Generation Natural Language Generation (NLG) is a challenging NLP task. Neural language models parameterized by autogressive architectures are widely used for NLG. To improve the global control ability of generated sentences, variational auto-encoders are considered for language generation (Bowman et al., 2016; Fu et al., 2019; Fang et al., 2019; Li et al., 2020a). Recently, GPT-2 (Radford et al., 2019) and GPT-3 (Brown et al., 2020) improve the generation fluency via pre-training on massive text corpus. All of them are trained with MLE using Teacher-Forcing, which are known to suffer from *exposure bias* in principle(Bengio et al., 2015). Several methods have been proposed to solve the problem, including (Shao et al., 2018; Zhang et al., 2019). Adversarial training techniques were also proposed (Yu et al., 2017; Zhu et al., 2018; Che et al., 2017; Lin et al., 2017; Guo et al., 2018; Chen et al., 2018; Li et al., 2020b; Yang et al., 2019; Zhang et al., 2018; Liang et al., 2018). However, adversarial-based NLG models can suffer from gradient vanishing and unstable training. Indeed, (Caccia et al., 2018) argues that a temperature sweeping approach on MLE can outperform GAN-based models. Our model further improves this work by adopting a principled sequence-matching loss via optimal transport and achieve state-of-the-art results on NLG tasks.

Optimal Transport Optimal transport is widely employed for a variety of NLP tasks, including document classification (Kusner et al., 2015), word embedding space alignment (Alvarez-Melis and Jaakkola, 2018), and generative adversarial networks (Chen et al., 2018). The most related work to ours is TFOT Chen et al. (2019). We discuss the difference between the proposed SFOT and TFOT as follows:

- *Strong empirical evidence on long sentences*. While the overall performance of SFOT is superior to TFOT only by a decent margin on standard datasets, we emphasize that the main advantage of SFOT is for long sentences. As shown in the break-down analysis (Figure 4), SFOT is significantly better than TFOT when sentence length is larger than 60. This highlights the critical contribution of this paper to addressing the exposure bias problem, which longer sentences usually suffer from.

- *Methodology novelty*. Besides the difference in SF decoding and TF decoding in two methods, we also propose a technique on "Contextualized OT with Order-Preserving Regularizer", which improves both SFOT and TFOT, as shown in Table 4. Note that, there is no order information used in TFOT, which de-

---

[1] The discount factor is set as one for simplicity

generates it to word embedding alignment instead of sequence matching. In contrast, the proposed technique can utilize sequence level, thus improving the performance.

- *Theoretical difference.* In Section 2.3, we provide theoretical justification on why SFOT can reduce exposure bias, while TFOT still suffers from it: TFOT is based on partial expert trajectories and induces a bias occupancy measure, while our proposed method SFOT uses previous self-generated words and can obtain an optimal policy.

Sequence matching Direct sequence matching has been explored widely in various machine learning tasks. Jaccard distance has been used to retrieve prototypes for sentence generation (Guu et al., 2018). Chernoff distance has been applied to image classification (Su et al., 2015). However, these distances assume each instance in the sequence is independent, ignoring temporal information. These distances consequently measure sequence alignment poorly, as they miss semantic relationships inside a sentence (*e.g.*cause and effect). Dynamic time warping (DTW) (Sakoe et al., 1990) and Connectionist Temporal Classification (CTC) (Graves and Jaitly, 2014) consider temporal information, and have been adopted widely in speech recognition. However, these losses preserve strict ordered alignment, and hence cannot be directly applied to text sequences.

4 Experiments

We perform experiments on neural machine translation (NMT), abstractive text summarization and unconditional natural language generation (NLG) tasks. Algorithms are implemented in Tensorflow and trained on an NVIDIA TITAN X GPU.

4.1 Neural Machine Translation

Two standard datasets are tested for NMT tasks: a small-scale English-Vietnamese corpus from the IWSLT 2015 Evaluation Campaign (Cettolo et al., 2015) and a large-scale English-German corpus from the WMT16 Evaluate Campaign[2]. Further details of the datasets and the experimental setup are shown in Appendix A.2.

We compare SFOT with a variety of methods: MLE (Luong et al., 2017), Scheudle Sampling (SS), TFOT and several RL-based models, *i.e.* RAML (Norouzi et al., 2016), SPG (Ding and Soricut, 2017), and MIXER (Ranzato et al., 2016b). The results are summarized in Tables 1 and 2. The proposed SFOT approach consistently improves upon MLE training and outperforms other models in all experimental setups. Besides the quantitative results, we observe that SFOT correctly maintains the information from the source side to make correct translations (Table 3). As can be seen from these examples, our model can better preserve information from the source and is less likely to transfer words incorrectly. Notice that most errors in the baseline models occur in the latter part of sequences, due to error accumulation from *exposure-bias*, which SFOT addresses by matching the free-running outputs to the ground-truth. In conjunction with the quantitative results presented above, these qualitative observations confirm that our model can generate more reliable translation for long sentences and address the *exposure-bias* problem.

Task	Algorithm	NT2012	NT2013

Table 2: DE-EN and EN-DE translation BLEU scores.

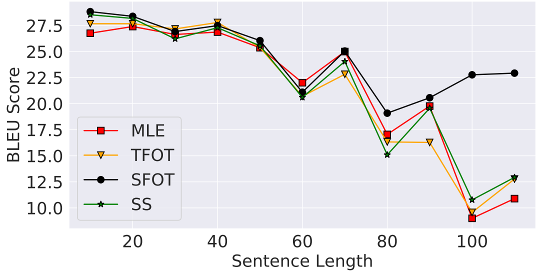

Figure 4: Translation quality as sentences become longer on NT2013 EN-VI.

faster in the early stages and finish with a higher final performance. However, TFOT has an unstable convergence trajectory, as it can degrade MLE training performance. SFOT by contrast is consistently better than MLE training, achieving the best BLEU score among the three models.

To further demonstrate SFOT's ability to address *exposure bias*, we follow Bahdanau et al. (2015) and group sentences of similar lengths together, computing a BLEU score per group on the test set. As errors accumulate in generation, longer sentences suffer more from *exposure bias* and have lower quality. Figure 4 shows that our model is more effective in handling long sentences: compared with other methods, SFOT is more robust for longer sentence lengths, indicating that matching the generated and ground-truth sentence in the sequence level may alleviate *exposure bias* for long-text generation.

Additionally, we compare different OT cost function variants in Table 4. We denote contextualized OT with order-preserving regularizer as -c. Contextualized OT improves translation quality when used with TFOT and SFOT. The improvements on both models indicate that contextualized representations with order preservation is capable of capturing more sentence semantic information.

4.2 Abstractive Text Summarization

We use a widely considered English Gigawords corpus (Graff et al., 2003) for the text-summarization task. Similar to NMT experiments, we use MLE as our baseline model and further compare SFOT with SS, TFOT, and several RL-based methods, *i.e.* RAML, SPG and MIXER. We evaluate the model performance using ROUGE (including -1, -2, -L) score (Lin, 2004), the most popular metric for summarization. Details of the datsetsets and the experimental setup are shown in Appendix A.3.

Summarization results are provided in Table 5. Consistent with our NMT results, SFOT outperforms all other methods, showing that the contextualized matching is capable of capturing semantic information essential for high-quality generation. Moreover, the superiority of SFOT over RL-based models demonstrates that the OT (sentence) matching is more robust than word/phrase matching in RL rewards.

4.3 Neural Language Generation

Following recent unconditional long text generation work (Caccia et al., 2018), we perform experiments on EMNLP2017 WMT News dataset[3]. All sentences are longer than 20, making the dataset appropriate for testing the *exposure bias* problem.

To evaluate the effectiveness of our model, we consider various baseline methods, including recent GAN-based text generation approaches, such as SeqGAN (Ramachandran et al., 2017), RankGAN (Lin et al., 2017), MaliGAN (Che et al., 2017), and LeakGAN (Guo et al., 2018), as well as an MLE-trained model using temperature sweep (Caccia et al., 2018). We apply SFOT with contextualized OT to improve the temperature-sweep MLE model. SS does not show significantly different results compared to the MLE model. For the evaluation metric, we follow the current protocol for NLG evaluation (Zhu et al., 2018) w.r.t. both quality and diversity. Specifically, the quality of the generation is measured with BLEU score (Papineni et al., 2002) and the diversity is evaluated with Self-BLEU (Zhu et al., 2018). Human evaluation is further considered to measure the quality of generation[4]. More details

---

MLE:	The Chinese leadership presented the decision of Sunday as a democratic breakthrough , because it gives Hong Kong citizens a direct right to vote , but the decision also makes it clear that the Chinese leadership maintains the **expiration of** a nomination committee closely controlled by Beijing .
TFOT:	The Chinese leadership presented Sunday ' s decision as a democratic breakthrough because it gives the citizens of Hong Kong a direct right to vote , but the decision also makes it clear that the Chinese leadership keeps the process firmly in the hands of a government -controlled Nomination Committee.
SFOT:	The Chinese leadership presented the decision on Sunday as a democratic breakthrough , because Hong Kong citizens have a direct electoral right , but the decision also makes it clear that the Chinese leadership remains firmly in hand with a nominating committee controlled by Beijing.

Table 3: Comparison of German-to-Enlish translation examples. For each example, we show the human translation (reference) and the translation from MLE, TFOT, and SFOT. We highlight the key phrase differences between reference and translation outputs in blue and red, and annotate translation errors in bold. In the first example, SFOT correctly maintains all the information in *"since winning in May election"* by translating to *"since his election victory in May"*, whereras MLE only generates *"in May"* and TFOT also misses *"winning"* in the reference. In the second example, SFOT successfully keeps the information *"Beijing"*, whereas MLE generates wrong words *"expiration of"* and TFOT changes *"Beijing"* to *"government"*.

Table 5: Results of text summarization on English Gigawords dataset.

of experiment setup are shown in Appendix A.4.

To reasonably select the best model along the temperature sweep, we are motivated by (Gu et al., 2019) and propose the BLEU-F1 score to evaluate the trade-off between the quality and diversity simultaneously, defined as

$$\text{BLEU-F1} = \frac{2 \times \text{BLEU} \times (\text{1-Self-BLEU})}{\text{BLEU} + (\text{1-Self-BLEU})} . \quad (12)$$

Figure 5 shows the BLEU-F1 score versus reverse temperature on MLE and SFOT. We observed that the best temperature for MLE model is $1/1.5$ and for SFOT is $1/1.4$. We further conduct analysis under these temperatures. Figure 5 also indicates that the SFOT model consistently improves the MLE model on the BLEU-F1 score.

We compare SFOT with the proposed strong baselines in Figure 6 and report human evaluation of generated quality in Table 6. We observe that SFOT has the highest generation quality in human evaluation. With better guided sequence-level semantics information, SFOT generates high-quality sentences at higher temperatures, compared with the MLE model. The MLE model decreases temperature to concentrate on generating *safe* words (with high probability); this avoids error accumulation by avoiding risky words. However, the model loses generation diversity when increasing temperature, as the model only focuses on *safe* words. SFOT obtains better quality at higher temperature, indicating SFOT can generate reasonable sequences on more risky words and hence

Method	SeqGAN	RankGAN	MaliGAN
Score	2.56 ± 0.49	2.89 ± 0.56	2.50 ± 0.46
Method	LeakGAN	MLE	SFOT
Score	3.45 ± 0.47	3.46 ± 0.42	3.54 ± 0.37

Table 6: Human evaluation of NLG on EMNLP news 2017 dataset. 100 generated sentences from each model are rated 1-5, with means and standard deviations reported. Real sentences were rated 4.21 ± 0.44.

can address *exposure bias* and gain more diversity in generation. We also observe that SFOT outperforms all text GANs in terms of quality-diversity trade-off and human evaluation. Under similar Self-BLEU score, SFOT significantly improves the quality of LeakGAN (Guo et al., 2018), the best GAN by BLEU metric.

5 Conclusions

We have introduced SFOT to mitigate exposure bias in text generation. The proposed model captures positional and contextual information of word tokens in OT matching. Experiments on neural machine translation, text summarization, and text generation have demonstrated the effectiveness of our SFOT algorithm, yielding improved performance over strong baselines on these tasks.

A.2 Neural Machine Translation Experiments

Dataset Two standard datasets are tested for NMT tasks. The first one is a small-scale English-Vietnamese corpus from the IWSLT 2015 Evaluation Campaign (Cettolo et al., 2015), which is a parallel corpus of TED-talks and contains 133K sentence pairs. We follow the pre-processing procedure in (Luong and Manning, 2015) by replacing words with frequencies less than 5 with ⟨unk⟩. As a result, our vocabulary reduces to 17K for English and 7.7K for Vietnamese. We use TED tst2012 as development set and TED tst2013 as the test set. For a large-scale dataset, we select an English-German corpus from the WMT16 Evaluate Campaign[5], which contains 4.5M sentence pairs. Newstest 2013 is used as the development set and Newstest 2015 is used as the test set. We conduct the sub-word tokenization on the corpus using the Byte Pair Encoding (BPE) method (Sennrich et al., 2015). Following Klein et al. (2017), we set the vocabulary size of both English and German to 32K.

Setup We use Google's Neural Machine Translation (GNMT) system (Wu et al., 2016) as our baseline MLE model, which follows the standard architecture and hyper-parameters[6] for fair comparison. All other models are built on top of with same network structure. We evaluate the model performance using BLEU scores (Papineni et al., 2002). We set OT weighting parameter $\lambda = 0.1$ and order-preserving penalty weighting parameter $\beta = 0.1$.

For English-Vietnamese translation tasks (*i.e.*, EN-VI or VI-EN), we follow the setup in (Sutskever et al., 2014; Luong et al., 2015b,a). We use one bidirectional LSTM layer with 512 hidden units as encoder and two-layer LSTM with 512 hidden units at each layer as decoder. The embedding dimension is set as 512. We follow the attention method described in (Luong et al., 2015a) and use dropout with probability 0.2 as suggested by (Zaremba et al., 2014). All parameters are initialized uniformly between $[-0.1, 0.1]$. We train the model for 12 epochs with 12 epochs using Stochastic Gradient Decent (SGD). For the first 8 epochs, we set learning rate as 1.0. After that, we anneal the learning rate at half at every epoch.

For English-German translation tasks (*i.e.*, EN-GE or GE-EN), we adopt a stacked LSTM with a 2-layer bidirectional of 1024 units as encoder and 4-layer LSTM with units 1024 as decoder. The embedding dimension is set to 1024. We adopt the attention used in (Wu et al., 2016). We train the model for 10 epochs. For the first 5 epochs, we set the learning rate as 1 and then halving the learning rate every half epoch.

A.3 Abstractive Text Summarization Experiments

We use a widely accepted English Gigawords corpus (Graff et al., 2003) for the text summariza-

---

[6] `https://github.com/tensorflow/nmt`

tion task. We follow the pre-process in (Rush et al., 2015). The dataset is sampled and split into train/dev/test set with size 200K/8K/2K.

A.4 Natural Language Generation Experiment

In the NLG experiment, 200K sentences are collected as the training set and 10K sentences as the test set. In the NLG experiment, we set OT weighting parameter $\lambda = 1$ and the order-preserving penalty weighting parameter is $\beta = 0.1$. Since input sequence $\boldsymbol{y}$ is empty in a language model, to better guide the student forcing output, we adopt schedule sampling with ratio 0.3 in our experiments. The samples generated by SFOT are presented in Table 7 .

So , this is a great way , but I'm not sure how to do that , he said .

When made an emergency landing , the driver who was also injured in the blast was arrested on suspicion of causing death .

The result is that the company's economic growth rate is rising by a substantial margin in November, which is even higher than a year ago .

It's really a big deal for us and we're going to get ready for the second game .

We feel like it's very hard to say that it's really going to be the next generation .

`j-guan19@mails.tsinghua.edu.cn`, `aihuang@tsinghua.edu.cn`

Abstract

Despite the success of existing referenced metrics (e.g., BLEU and MoverScore), they correlate poorly with human judgments for open-ended text generation including story or dialog generation because of the notorious one-to-many issue: there are many plausible outputs for the same input, which may differ substantially in literal or semantics from the limited number of given references. To alleviate this issue, we propose UNION, a learnable ***UN**referenced metr**I**c for evaluating **O**pe**N**ded story generation*, which measures the quality of a generated story without any reference. Built on top of BERT, UNION is trained to distinguish human-written stories from negative samples and recover the perturbation in negative stories. We propose an approach of constructing negative samples by mimicking the errors commonly observed in existing NLG models, including repeated plots, conflicting logic, and long-range incoherence. Experiments on two story datasets demonstrate that UNION is a reliable measure for evaluating the quality of generated stories, which correlates better with human judgments and is more generalizable than existing state-of-the-art metrics.

Leading Context Jack was at the bar.
Reference By Human He noticed a phone on the floor. He was going to take it to lost and found. But it started ringing on the way. Jack answered it and returned it to the owner's friends.
Sample 1 (Reasonable, B=0.29, M=0.49, U=1.00) On the way out he noticed a phone on the floor. He asked around if anybody owned it. Eventually he gave it to the bartender. They put it into their lost and found box.
Sample 2 (Reasonable, B=0.14, M=0.27, U=1.00) He had a drinking problem. He kept having more beers. After a while he passed out. When he waked up, he was surprised to find that he lost over a hundred dollars.
Sample 3 (Unreasonable, B=0.20, M=0.35, U=0.00) He was going to get drunk and get drunk. The bartender told him it was already time to leave. Jack started drinking. Jack wound up returning but cops came on the way home.

Table 1: Generated story samples given the same leading context from ROCStories (Mostafazadeh et al., 2016). **B** stands for BLEU (Papineni et al., 2002), **M** for MoverScore (Zhao et al., 2019), and **U** for UNION. A story can be reasonable even if it is dissimilar to the reference with a low BLEU score (B=0.14 in Sample 2), or unreasonable even if it has a large MoverScore (M=0.35 in Sample 3). In contrast, UNION is more reliable for evaluating story generation.

1 Introduction

Significant advances have been witnessed with neural encoder-decoder paradigm (Sutskever et al., 2014), transformer-based architecture (Vaswani et al., 2017) and large-scale pretraining models (Devlin et al., 2019; Radford et al., 2019) in a wide array of natural language generation (NLG) tasks including machine translation (Bahdanau et al., 2015), story generation (Fan et al., 2018; Guan et al., 2020), and many more. However, the research is increasingly hindered by the lack of effective evaluation metrics, particularly for open-ended text generation tasks such as story generation.

Since human evaluation is time-consuming, expensive, and difficult to reproduce, the community commonly uses automatic metrics for evaluation. Previous studies in conditional language generation tasks (e.g., machine translation) have developed several successful referenced metrics, which roughly quantify the lexical overlap (e.g., BLEU (Papineni et al., 2002)) or semantic entailment (e.g., MoverScore (Zhao et al., 2019)) between a generated sample and the reference. However, such referenced metrics correlate poorly with

---

human judgments when evaluating open-ended text generation (Liu et al., 2016) due to the one-to-many nature (Zhao et al., 2017), as illustrated in Table 1. Specifically, a generated sample can be reasonable if it is coherent to the given input, and self-consistent within its own context but not necessarily being similar to the reference in literal or semantics, as shown in Sample 2 and 3.

To address the one-to-many issue, unreferenced metrics are proposed to measure the quality of a generated sample without any reference. Kannan and Vinyals (2017) presented a learnable, unreferenced metric which measures the text quality by learning to distinguish human-written texts from generated samples. However, the discriminator-based metric can easily lead to over-fitting to specific data (Garbacea et al., 2019) or model bias since the quality of generated texts varies substantially across different NLG models. As a matter of fact, the *generalization or robustness* issue is critical for any learnable metrics.

Therefore, we propose UNION, a learnable ***UN**referenced metr**I**c for evaluating **O**pen-e**N**ded story generation*. UNION learns to distinguish human-written stories from negative samples auto-constructed by generating perturbations of human-written stories. It is trained without dependence on specific NLG models or any human annotation, making it more generalizable to distribution drift (Sellam et al., 2020) than the discriminator-based metric and those metrics which learn from human preference (e.g., Adem (Lowe et al., 2017)). To capture commonly observed issues in generated stories, such as repeated plots, conflicting logic, and inter-sentence incoherence, we adopt four negative sampling techniques to construct negative samples, including repetition, substitution, reordering, and negation alteration. In addition, we design an auxiliary reconstruction objective for UNION, which recovers the perturbation from a negative sample. This objective is shown to further improve the performance of UNION.

Our contributions are summarized as follows:
I. We propose a learnable unreferenced metric UNION for evaluating open-ended story generation to alleviate the one-to-many issue of referenced metrics. UNION does not depend on any output of NLG models or human annotation.
II. Extensive experiments[1] show that UNION correlates better with human judgments than state-of-the-art metrics, and is more generalizable to data drift (samples from different datasets) and quality drift (samples with different quality levels).

2 Related Work

Automatic evaluation is crucial for language generation tasks. We roughly divide existing metrics into referenced, unreferenced, and hybrid metrics, according to whether they rely on human-written references when calculating the metric score.

Referenced metrics usually measure how similar a generated text is to the reference text. Therefore, they are developed mainly for conditional language generation tasks such as machine translation and text summarization, where plausible outputs are largely limited within the semantics of input. Commonly used referenced metrics include word-overlap based (e.g., BLEU (Papineni et al., 2002), ROUGE (Lin, 2004)) and embedding based metrics (e.g., BertScore (Zhang* et al., 2020), MoverScore (Zhao et al., 2019)). However, referenced metrics are reported to correlate poorly with human judgments in open-ended generation tasks including open-domain dialog generation (Liu et al., 2016) and story generation, where the input contains only limited information for generation, and there are many plausible outputs for the same input, which can vary substantially in literal or semantics.

Unreferenced metrics measure the quality of a sample without any reference. The most classic unreferenced metric is *perplexity*, which measures how likely a sample is generated by a given language model trained on human-written texts. However, recent work has shown that natural language is rarely the most probable text (Holtzman et al., 2020), and perplexity is inadequate to measure quality (Hashimoto et al., 2019). Therefore, perplexity may not indicate the actual text quality well. Discriminator-based metric (Kannan and Vinyals, 2017) measures how easily a discriminator distinguishes the generated samples from human-written texts. However, training such a discriminator can be easily over-fitted to a specific dataset, thereby leading to poor generalization and low correlation with human judgments (Garbacea et al., 2019). In addition to the above point-wise metrics which score an individual sample, Semeniuta et al. (2019) proposed the Fréchet InferSent Distance (FID) to evaluate the model-level quality and diversity of generated samples, by computing the Fréchet dis-

---

[1] All the codes and data are available at `https://github.com/thu-coai/UNION`.

tance between the Gaussian distribution fitted to human text embeddings and that to generated sample embeddings. However, in real data, the distribution of embeddings may be far from Gaussian. Recently, Zhou and Xu (2020) proposed to evaluate sample-level quality by comparing a pair of samples, and further adopted a skill rating system to evaluate model-level quality based on the sample-level pair-wise comparison. However, it is unlikely to evaluate a single sample without access to its references.

Hybrid metrics combine referenced and unreferenced metrics. For open-domain dialog system evaluation, Lowe et al. (2017) proposed a learnable metric Adem to learn from the human-annotated score of a response given its post and ground truth. However, such a metric shows very poor generalization and is not robust to easy attacks such as simple word substitution or random word shuffle (Sai et al., 2019). Furthermore, RUBER and its variants (Tao et al., 2018; Ghazarian et al., 2019) evaluate a response by directly averaging a non-learnable referenced embedding similarity score and a learnable unreferenced post-response relatedness score that is learned by applying negative sampling without human annotations. However, merely measuring input-output relatedness is not sufficient for evaluating long text generation, as the intrinsic coherence and consistency within the generated text is a critical factor. Additionally, some metrics which learn from human preference achieve substantial results in conditional language generation, e.g., RUSE (Shimanaka et al., 2018) and BLEURT (Sellam et al., 2020). RUSE trained a regression model to score a reference-candidate pair using their sentence embeddings. And BLEURT used multiple automatic metrics (e.g., BLEU) as supervision signals for pretraining on synthetic data, and was fine-tuned on human judgments. However, BLEURT heavily relies on the quality of automatic metrics, but there are yet no such reliable metrics for open-ended text generation.

3 Methodology

UNION is expected to measure the overall quality of a generated story. In this section, we begin with common issues that can be observed in the output of NLG models. We then propose four negative sampling techniques based on the observations. Afterward, we introduce how UNION is trained and used for story evaluation. The overall paradigm of UNION is shown in Figure 1.

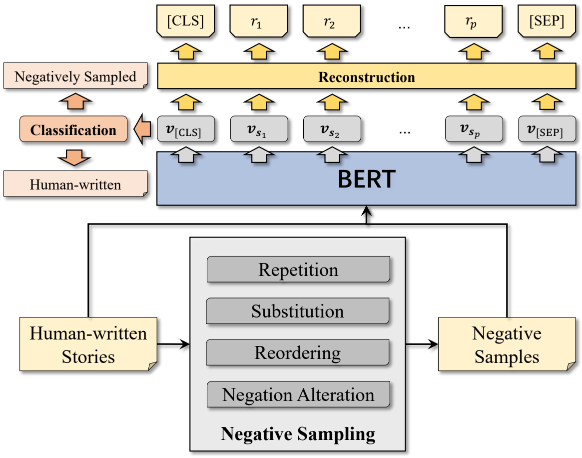

Figure 1: Overview of the UNION metric. UNION is trained to distinguish the human-written stories from the negative samples constructed by four negative sampling techniques, as well as to reconstruct the original human-written stories.

3.1 Empirical Observations

The key aspect of UNION is the construction of negative samples, which provides a range of lexical, syntactic, and semantic variations to simulate the errors made by NLG models. Therefore, we first present our empirical observations regarding the question *"What makes a story unreasonable for NLG models?"*.

We analyzed 381 unreasonable stories generated by various NLG models like Plan&Write (Yao et al., 2019) and fine-tuned GPT-2 (Radford et al., 2019) base on ROCStories (Mostafazadeh et al., 2016), and summarized four major types of errors, including **repeated plots** (repeating similar texts), **poor coherence** (with unrelated keywords or events but a reasonable main plot), **conflicting logic** (wrong causal or temporal relationship), and **chaotic scenes** (difficult to understand or with multiple previous errors). To facilitate understanding of the error types, we resorted to manual annotation of all the unreasonable stories. And seven annotators were hired for each story (see the full details in Section 4.2). In addition to the four error types, we also provide annotators with an option **Others**. We summarize the proportion of stories annotated with different error types in Table 2[2].

We can see that the four error types are the major issues of unreasonable stories, which provides

---

[2] Note that these human annotations are only used in test of UNION.

Type	**Repe**	**Cohe**	**Conf**	**Chao**	**Others**
Prop (%)	44.1	56.2	67.5	50.4	12.9

Table 2: Error type **Prop**ortions of 381 unreasonable stories, including **Repe**ated plots/poor **Cohe**rence/**Conf**licting logic/**Chao**tic scenes/**Others**.

rationales of constructing negative samples for evaluating generated stories. Besides, all the Spearman correlations between every two error types are less than 0.15 (p-value > 0.01), suggesting that different error types correlate weakly with each other. Furthermore, the stories annotated with 1/2/3/4 errors constitute 23.36%/36.48%/34.65%/4.46% of the annotated stories, respectively. Most of the unreasonable stories have more than one error, which motivates us to simultaneously apply multiple sampling techniques to construct negative samples.

3.2 Constructing Negative Samples

We construct negative samples to cover as many aforementioned issues of unreasonable stories as possible. Since using machine-generated texts as negative samples will easily lead to poor generalization (over-fitting to specific data or model bias (Garbacea et al., 2019)), we devise four negative sampling techniques to automatically construct a large number of negative samples from human-written stories as follows:

Repetition: Generating repetitive texts is commonly observed in many state-of-the-art NLG models (Fan et al., 2018; Radford et al., 2019), where the models focus repeatedly on what they have recently generated, particularly with maximum-likelihood based decoding strategies (Holtzman et al., 2020). To address the issue, we introduce lexical and sentence-level repetition to construct negative samples using two policies—we either repeat an N-gram (N=1,2,3,4) in a random sentence, or randomly select a sentence to repeat and remove the following sentence to keep the sentence number unchanged.

Substitution: The coherence of a story is mainly embodied through the relationship between keywords in the context (Clark et al., 2018; Guan et al., 2020). Therefore, we create incoherent samples by random keywords and sentence substitution, respectively at word level and sentence level. For word-level substitution, we replace random 15% keywords in a story with their corresponding antonyms (e.g., replace "deny" with "confirm"), otherwise with another random keyword sampled from all the keywords of the same part-of-speech (POS), according to the mention frequency. We use the commonsense knowledge base ConceptNet (Speer and Havasi, 2012)[3] for keyword recognition and antonym query. ConceptNet consists of commonsense triples like `(h, r, t)`, meaning that the head concept `h` has a relation `r` with the tail concept `t`, e.g., `(evaluation, IsA, judgment)`. We regard those words which are heads or tails in ConceptNet as keywords. And given an keyword, we look up those keywords as its antonyms with which have negated relations, including `Antonym`, `NotDesires`, `NotCapableOf`, and `NotHasProperty`. If no antonym is found for a keyword, we perform replacement with a random keyword of the same POS. And we adopt NLTK[4] for POS tagging.

For sentence-level substitution, we randomly replace a sentence in a story with another one sampled from the rest of stories in the dataset.

Reordering: Conflicting logic usually results from wrong causal relationship and temporal dependency in the context. Therefore, we randomly reorder the sentences in a story to create negative stories with conflicting plot.

Negation Alteration: Negation words such as "not" are crucial for language generation tasks because they may flip the semantics of a sentence, which is also an important cause of conflicting logic. We perform negation alteration by adding or removing negation words using rules for different types of verbs[5].

Since there may be multiple error types in a generated story, we apply different sampling techniques simultaneously to construct a negative sample. We first sample the number (n) of techniques from {1,2,3,4} with a distribution {50%, 20%, 20%, 10%}. We then sample a technique without replacement from {repetition, substitution, reordering, negation alteration} with a distribution {10%, 30%, 40%, 20%} until the total number of techniques (n) is reached. Last, we apply the sampled techniques on a human-written story to obtain a perturbated sample. A constructed example is shown in Table 3.

Leading Context Ken was out jogging one morning.
Reference By Human The weather was crisp and cool. Ken felt good and energetic. He decided to keep jogging longer than normal. Ken went several more miles out of his way.
Auto-Constructed Negative Sample The weather was crisp and cool *and cool.* Ken felt bad and energetic. **Ken DID NOT GO several more miles out of his way. He decided to keep jogging longer than normal**.

Table 3: An example of negative sample construction. The repeated bigram is in *italic*, the substituted keyword is underlined, the reordered sentences are indicated in **bold**, and the altered negation words are CAPITALIZED.

3.3 Modeling

Let $\{\boldsymbol{s}_n, \boldsymbol{r}_n, y_n\}_{n=1}^{N}$ denote the training dataset of size N for training the UNION metric, where $\boldsymbol{s}_n$ is a human-written story or an auto-constructed negative sample, $\boldsymbol{r}_n$ is the corresponding original story of $\boldsymbol{s}_n$. If $\boldsymbol{s}_n$ is a negative sample, $y_n = 0$, otherwise $y_n = 1$ where $\boldsymbol{s}_n$ is exactly the same as $\boldsymbol{r}_n$ in this case. $y_n \in \{0, 1\}$ indicates whether $\boldsymbol{s}_n$ is written by human. For better story understanding, we leverage BERT (Devlin et al., 2019) to obtain contextualized representations of the input. Given a story $\boldsymbol{s}_n = (s_1, s_2, \cdots, s_p)$ of length p (each s_i is a word), BERT outputs a sequence of contextualized vectors:

$$\boldsymbol{v}_{[\mathrm{CLS}]}, \boldsymbol{v}_{s_1}, \cdots, \boldsymbol{v}_{s_p}, \boldsymbol{v}_{[\mathrm{SEP}]} = \mathrm{BERT}(\boldsymbol{s}_n), \quad (1)$$

where $\boldsymbol{v}_{[\mathrm{CLS}]}$ and $\boldsymbol{v}_{[\mathrm{SEP}]}$ are the representation for the special tokens [CLS] and [SEP], respectively. We add a task-specific linear layer on top of the [CLS] vector to predict the UNION score, indicating the probability that $\boldsymbol{s}_n$ is written by human:

$$\hat{y}_n = \mathrm{sigmoid}(\mathbf{W}_c \boldsymbol{v}_{[\mathrm{CLS}]} + \mathbf{b}_c), \quad (2)$$

where $\mathbf{W}_c$ and $\mathbf{b}_c$ are trainable parameters. We use the cross entropy loss to optimize the prediction objective as follows:

$$\mathcal{L}_n^C = -y_n \log \hat{y}_n - (1 - y_n) \log (1 - \hat{y}_n). \quad (3)$$

In addition to the main prediction task, we devise an auxiliary reconstruction task which requires to reconstruct the corresponding human-written story $\boldsymbol{r}_n$ from perturbated story $\boldsymbol{s}_n$. Therefore, we add an additional linear layer at the last layer of BERT, which takes as input the vectors output from the last transformer block and computes a probability distribution over the entire vocabulary through a softmax layer, formally as follows:

$$P(\hat{r}_i | \boldsymbol{s}_n) = \mathrm{softmax}(\mathbf{W}_r \boldsymbol{v}_{s_i} + \mathbf{b}_r), \quad (4)$$

where $\hat{r}_i$ is the predicted i-th token, $\mathbf{W}_r$ and $\mathbf{b}_r$ are the parameters of the additional linear layer. Then the model is trained by minimizing the negative log-likelihood:

$$\mathcal{L}_n^R = -\frac{1}{p} \sum_{i=1}^{p} \log P(\hat{r}_i = r_i | \boldsymbol{s}_n), \quad (5)$$

where r_i is the i-th token in human-written story $\boldsymbol{r}_n$. The combined loss function $\mathcal{L}$ of the full model is computed as follows:

$$\mathcal{L} = \frac{1}{N} \sum_{n=1}^{N} (\mathcal{L}_n^C + \lambda \mathcal{L}_n^R), \quad (6)$$

where λ is an adjustable hyperparameter.

We fine-tune all the parameters of UNION on the training dataset, including the BERT and the two additional linear layers. In practical use, UNION can measure the quality of a new generated sample $\hat{\boldsymbol{s}}$ by taking $\hat{\boldsymbol{s}}$ as input to predict the corresponding score $\hat{y}$.

4 Experiment

We conducted extensive experiments to evaluate UNION on two story datasets. First, we compared UNION against existing text generation metrics. Then, we assessed its generalization on distribution drifts, including dataset drift and quality drift. Last, we measured the effect of each negative sampling technique with ablation studies.

4.1 Baselines

We compared UNION with the following three kinds of metrics as baselines:

Referenced metrics: sentence ***BLEU*** score (geometric mean of 1-gram up to 4-gram) (Papineni et al., 2002) to measure the lexical similarity between a candidate sample and its reference, and ***MoverScore*** (Zhao et al., 2019) to measure the semantic similarity.

Unreferenced metrics: ***Perplexity***[6] computed by the GPT-2 model (Radford et al., 2019), and a discriminative evaluator (***DisScore***) (Kannan and

---

[6] We take the minus of perplexity for all the following experiments to ensure a higher value means better quality.

Vinyals, 2017) that is trained based on BERT to distinguish generated samples from human-written stories.

Hybrid metrics: ***RUBER-BERT*** (Ghazarian et al., 2019) which improves the original RUBER (Tao et al., 2018) with contextualized embeddings from BERT, and the supervised metric ***BLEURT*** (Sellam et al., 2020) that is fine-tuned on human judgments after pretraining on large-scale synthetic data with multiple automatic metrics as supervision signals.

In addition, we also reported the performance of the referenced and unreferenced versions in RUBER-BERT, denoted as ***RUBER$_r$-BERT*** and ***RUBER$_u$-BERT***, respectively.

We set the parameters of UNION by following the uncased base version of Devlin et al. (2019): the transformer has 12 layers, 768 dimensional hidden states, and 12 attention heads. We used batch size 10, and learning rate 5e-5. The scale factor λ is set to 0.1. We directly used public pretrained parameters of BERT[7] or GPT-2[8] (base version) for all the baselines.

4.2 Data Preparation

We used two datasets for evaluation, ROCStories (**ROC** for short) (Mostafazadeh et al., 2016) and WritingPrompts (**WP**) (Fan et al., 2018). The ROC dataset contains 98,161 five-sentence human-written stories, with an average length of 49.4 words. To achieve better generalization performance, we followed Guan et al. (2020) to make delexilization by masking all the male/female/unknown names with placeholders [MALE]/[FEMALE]/[NEUTRAL], respectively.

The WP dataset consists of 303,358 stories paired with writing prompts collected from an online forum. The average length of the prompt/story is 28.4/734.5 respectively, much longer than those in ROC. Since it is still challenging for state-of-the-art NLG models to maintain a reasonable plot through the whole story, and hard to obtain acceptable annotation agreement in manual evaluation of long stories, we retained about 200 words (with correct sentence boundary) from the start and truncated the rest in WP for subsequent experiments.

We randomly selected 90%/5%/5% stories from both datasets for training/validation/test of UNION and learnable baseline metrics, and created the evaluation set for all the metrics by generating stories based on the test sets of the datasets with state-of-the-art story generation models. The story generation models include fusion convolutional seq2seq model (Fan et al., 2018), plan&write (Yao et al., 2019), fine-tuned GPT-2 (Radford et al., 2019), and knowledge-enhanced GPT-2 (Guan et al., 2020).

The data statistics are shown in Table 4. The number of negative samples for learning the metrics when necessary is the same as that of human-written stories on each dataset. Specifically, we created negative samples for DisScore by generating stories with above NLG models. For RUBER$_u$-BERT, a given leading context is appended by a randomly sampled continuation. All the stories in the evaluation set are manually labeled. In addition, we annotated another 400 stories in ROC and 200 in WP for training BLEURT[9]. Seven annotators were hired to judge the quality of each story with a binary score (1 for a reasonable story, and 0 otherwise). Furthermore, we asked annotators to label the error type of a story if it is labeled as unreasonable, including repeated plots, poor coherence, conflicting logic, chaotic scenes, and others. We resorted to Amazon Mechanical Turk (AMT) for annotation, and the average score of the seven annotators is treated as the final score. We provide the full details of the instruction for annotators in the supplementary file.

Split	Metrics	ROC	WP	NS
Train/ Validate	**Perplexity**	88,344/ 4,908	272,600/ 15,620	✗
	DisScore			✓
	RUBER$_u$			✓
	UNION			✓
	BLEURT	$360^\dagger/40^\dagger$	$180^\dagger/20^\dagger$	✗
Test	**All metrics**	$400^\dagger$	$200^\dagger$	N/A

Table 4: Data statistics. **RUBER$_u$** is short for **RUBER$_u$-BERT**. **NS** (Negative Sampling) means whether a metric requires negative samples for training/validation. † means the stories are generated by NLG models and manually annotated.

4.3 Correlation Results

Correlation analysis has been widely used to evaluate automatic metrics for language generation (Tao et al., 2018; Sellam et al., 2020). We employed UNION and other metrics to score the collected samples, and then calculated the Pearson (r),

---

[7] `https://github.com/google-research/bert`

[8] `https://github.com/openai/gpt-2`

[9] BLEURT is first initialized with the pretrained parameters (`https://github.com/google-research/bleurt`) and then fine-tuned on our annotated stories.

Metrics		ROC			WP		
		r	ρ	τ	r	ρ	τ
Referenced	**BLEU**	0.0299	0.0320	0.0231	0.1213	0.0941	0.0704
	MoverScore	0.1538*	0.1535*	0.1093*	0.1613	0.1450	0.1031
	RUBER$_r$-BERT	0.0448	0.0517	0.0380	0.1502	0.1357	0.0986
Unreferenced	**Perplexity**	0.2464*	0.2295*	0.1650*	-0.0705	-0.0479	-0.0345
	RUBER$_u$-BERT	0.1477*	0.1434*	0.1018*	0.1613	0.1605	0.1157
	DisScore	0.0406	0.0633	0.0456	0.0627	-0.0234	-0.0180
	Union	**0.3687***	**0.4599***	**0.3386***	**0.3663***	**0.4493***	**0.3293***
	-Recon	0.3101*	0.4027*	0.2927*	0.3292*	0.3786*	0.2836*
Hybrid	**RUBER-BERT**	0.1412*	0.1395*	0.1015*	0.1676	0.1664	0.1194
	BLEURT	0.2310*	0.2353*	0.1679*	0.2229*	0.1602	0.1180

Table 5: Correlation with human judgments on ROC and WP datasets. $r/\rho/\tau$ indicates the Pearson/Spearman/Kendall correlation, respectively. The best performance is highlighted in **bold**. The correlation scores marked with * indicate the result significantly correlates with human judgments (p-value<0.01).

Spearman (ρ) and Kendall (τ) correlation coefficients between model evaluation and human judgments. Pearson's r estimates linear correlation while Spearman's ρ and Kendall's τ estimate monotonic correlation, and τ is usually more insensitive to abnormal values than ρ. We used the standard statistical package `stats` in `SciPy`[10] for correlation calculation and significance test.

As summarized in Table 5, the referenced metrics correlate worse with human judgments, particularly for BLEU which is based on lexical similarity. Measuring the semantic similarity instead (MoverScore, RUBER$_r$-BERT) can improve the correlation but is still limited, indicating that referenced metrics are not competitive for evaluating open-ended language generation. Perplexity is ineffective on WP because the generated stories in the dataset are much longer and hence suffer from more serious repetition errors than those in ROC, which easily results in low perplexity (i.e., high minus perplexity) (Holtzman et al., 2020) but poor human judgment scores. Furthermore, Union outperforms other baselines including the supervised metric BLEURT by a large margin, which also demonstrates the advantage of unreferenced metrics. Besides, removing the reconstruction training objective (-Recon) leads to remarkably worse correlation, indicating that the auxiliary task further improves the performance of Union.

4.4 Generalization to Dataset and Quality Drift

It is extremely important for learnable metrics to deal with dataset drift and quality drift (Sellam et al., 2020). Specifically, a generalizable metric is expected to reliably evaluate outputs from different datasets even without re-training. Moreover, since the quality of generated samples can vary significantly across NLG models, a reliable metric should be able to evaluate samples of different quality levels. Therefore, we conducted experiments to assess the generalization ability of Union in this section.

Metrics	r	ρ	τ
Training: WP **Test**: ROC			
Perplexity	-0.0015	0.0149	0.0101
RUBER$_u$-BERT	-0.0099	-0.0162	-0.0110
BLEURT	0.1326*	0.1137*	0.0828*
Union	**0.1986***	**0.2501***	**0.1755***
-Recon	0.1704*	0.2158*	0.1523*
Training: ROC **Test**: WP			
Perplexity	0.0366	0.0198	0.0150
RUBER$_u$-BERT	0.1392	0.1276	0.0912
BLEURT	0.1560	0.1305	0.0941
Union	**0.2872***	**0.2935***	**0.2142***
-Recon	0.2397*	0.2712*	0.1971*

Table 6: Correlation results in the dataset drift setting where the metrics are trained on one dataset and then used for the other one.

To assess the generalization to dataset drift, we first trained the learnable metrics on ROC and then directly used them to evaluate generated stories from WP, and vise versa. Table 6 shows the Pearson correlation with human judgments in this setting. Compared with the results in Table 5, all the metrics trained on one dataset have remarkable drops in correlation when they are used for the other dataset because the two datasets are significantly different in length and topic. Nevertheless, Union performs more robustly than other metrics, with much bet-

---

-Repetition	0.3167 (↓**14%**)	0.4743 (↓**32%**)	0.5308 (↑3%)	0.4316 (↓6%)	0.6561 (↓3%)
-Substitution	0.3118 (↓**15%**)	0.7034 (↑1%)	0.4185 (↓**19%**)	0.4468 (↓2%)	0.5850 (↓**13%**)
-Reordering	0.2302 (↓**38%**)	0.6546 (↓6%)	0.5077 (↓1%)	0.3507 (↓**23%**)	0.5393 (↓**20%**)
-Negation Alteration	0.3304 (↓**10%**)	0.6665 (↓4%)	0.4987 (↓3%)	0.3946 (↓**14%**)	0.5176 (↓**23%**)

Table 7: Pearson correlation with different negative sampling techniques. The numbers in parentheses denote the number of stories. The error types include **Repe**ated plots, poor **Cohe**rence, **Conf**licting logic, and **Chao**tic scenes. The proportions in parentheses indicate the relative change with respect to UNION (the first row).

ter correlation with human judgments. Moreover, our method of constructing negative examples is generalizable to the two datasets.

To assess the generalization of UNION to quality drift, we created biased test sets from ROC by sampling stories of different quality levels with different probabilities. Specifically, the annotation score of each story ranges from 0 to 1 (i.e., $0, \frac{1}{7}, \frac{2}{7}, \cdots, 1$) since there are seven annotators for each sample. We then created 8 biased sets, indexed from 1 to 8 with variable I. For the I^{th} set, we sampled the stories whose annotation score is $\frac{k}{7}$ with a probability of $\frac{1}{|I-k|+1}$ where $k \in \{0, 1, \cdots, 7\}$. In this way, the 8 sets have different distributions of stories with different qualities[11], as shown in Figure 2 (left).

We then computed the Pearson correlation of different metrics with human judgments on the 8 sets. Results in Figure 2 (right) show that: **I.** UNION has higher correlation than other metrics on all the biased sets. **II.** UNION is more reliable and robust than other metrics, with much less variance. For instance, MoverScore performs much better on Set #1 (with more low-quality stories) than on Set #8 (with more high-quality stories). Interestingly, Perplexity performs much better on high-quality sets than on low-quality ones, because high-quality stories are closer to human-written stories from which a language model learns. **III.** The ablated UNION without the reconstruction objective has lower correlation and larger variance, indicating that the auxiliary task can improve the discriminative and generalization ability.

4.5 Ablation Studies

To understand the effect of each negative sampling technique, we conducted ablation tests on ROC dataset. Each time we ablated one technique of constructing negative samples, re-trained UNION on the constructed data, and evaluated it on five evaluation sets: all 400 samples, and four other sets where each contains 19 reasonable samples and other unreasonable samples of some error type. The error type of a story is decided if at least three of seven annotators annotate the same error type.

Table 7 shows the Pearson correlation results. UNION is remarkably better than its ablated version on the all-sample set, indicating the necessity of the four techniques for constructing negative samples. Reordering seems to be the most important technique, which agrees with our observation that conflicting logic is the major issue in existing story generation models. Furthermore, as expected, the correlation drops remarkably on the evaluation set of some error type if without the corresponding negative sampling technique. Interestingly, it is easier for UNION to evaluate repetitive/chaotic stories, which seem to be easier cases in story generation.

---

[11] We assume that the annotation score $\frac{k}{7}$ approximates the quality level.

5 Conclusion

We present UNION, an unreferenced metric for evaluating open-ended story generation. UNION is trained to distinguish human-written stories from auto-constructed negative samples and to recover the perturbation in negative samples. Extensive experiments show that UNION outperforms state-of-the-art metrics in terms of correlation with human judgments on two story datasets, and is more robust to dataset drift and quality drift. Results also show the effectiveness of the proposed four negative sampling techniques. As future work, we will explore the similar idea of designing unreferenced metrics for dialog generation.

Abstract

Despite recent advances in neural text generation, encoding the rich diversity in human language remains elusive. We argue that the sub-optimal text generation is mainly attributable to the imbalanced token distribution, which particularly misdirects the learning model when trained with the maximum-likelihood objective. As a simple yet effective remedy, we propose two novel methods, *F^2-Softmax* and *MefMax*, for a balanced training even with the skewed frequency distribution. *MefMax* assigns tokens uniquely to frequency classes, trying to group tokens with similar frequencies and equalize frequency mass between the classes. *F^2-Softmax* then decomposes a probability distribution of the target token into a product of two conditional probabilities of (i) frequency class, and (ii) token from the target frequency class. Models learn more uniform probability distributions because they are confined to subsets of vocabularies. Significant performance gains on seven relevant metrics suggest the supremacy of our approach in improving not only the diversity but also the quality of generated texts.

1 Introduction

Neural text generation is one of the extensively studied tasks of natural language processing (NLP), as it forms the basis for dialogue systems (Chen et al., 2017), machine translation (Chaudhary and Patel, 2018), and text summarization (Kryscinski et al., 2019). However, often monotonous or dull, texts generated from existing methods do not fully reflect the rich diversity and expression in human language (Welleck et al., 2020). In particular, models tend to overproduce words frequently appearing in the data, while hardly utilizing informative words (Dinan et al., 2020). Even pre-training techniques on large corpora fail to resolve the issue (Holtzman et al., 2019).

Possible causes for text degeneration have been illuminated, such as a defect specific to model architectures (Vig, 2018) or the discrepancy between training data and a true distribution (Holtzman et al., 2018; Jiang et al., 2019). Recently, the emphasis has been placed on investigating the flaws in the maximum likelihood objective (Holtzman et al., 2019). Concretely, the likelihood training pays little attention to the top ranks in terms of the target token probabilities (Welleck et al., 2020), or maximizing likelihood itself does not adequately reflect human language processing (Holtzman et al., 2019). Therefore, with the maximum likelihood-based training, models learn to produce tokens frequently appearing in the data more often.

We argue, however, that the primary reason behind the sub-optimal performance of the likelihood objective is essentially the imbalanced token distribution inherent in natural language. Natural language is extremely skewed in distribution, where the top hundred most frequently-used (top-100) words occupy nearly half of the total corpus (Fagan and Gençay, 2011) following the Zipf's law (Zipf, 1949). Training a classifier with the inherently imbalanced data on the maximum likelihood estimation (MLE) leads to biased classification boundaries in favor of majority classes (Khan et al., 2019). In other words, models play a difficult role in learning with the imbalanced label (i.e., token) distribution (He et al., 2008b).

We hypothesize that text generation can be enriched by balancing out the training data distribution. To this end, we introduce F^2-Softmax (Fig. 1(B), Section 3.2), which factorizes the probability distribution of the target token into a product of two conditional probabilities of (i) frequency class, and (ii) token from the target frequency class. It ensures training over balanced data, since the frequency classes are designed to have the distribution close to uniformity, and token distributions

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9167–9182,
November 16–20, 2020.

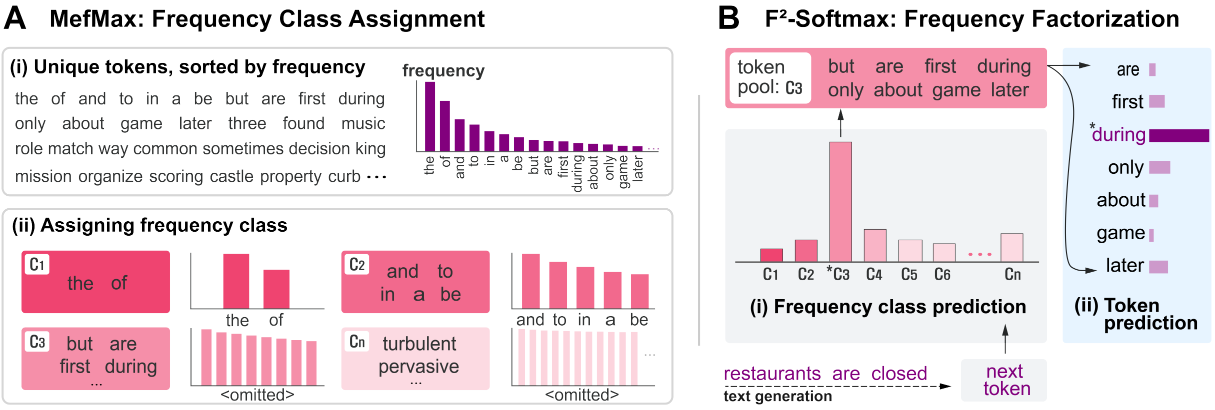

Figure 1: Illustrations for working mechanisms of the two proposed modules, MefMax and F^2-Softmax. (A) Once unique tokens are sorted by frequency, MefMax (Section 3.3) groups them to a set of frequency classes. The frequency distributions of the grouped tokens are more uniform than the distribution of the full vocabulary set. (B) With the frequency class assigned, token generation is decomposed into (i) predicting the frequency class, and (ii) generating the target token from the given frequency class.

within a class are confined to subsets of vocabularies grouped with similar frequencies. To this end, all unique tokens are assigned to a frequency class prior to the training, by our novel *mean efficiency maximization* (MefMax; Fig. 1(A), Section 3.3). MefMax evaluates and maximizes the class-labeling performance with the normalized entropy (i.e., efficiency), having the probability distributions to be learned as uniform as possible.

We conduct extensive performance evaluations on seven relevant metrics that quantify the diversity and quality of generated texts. In terms of the diversity of generated texts, our approach significantly outperforms not only the MLE baseline (Radford et al., 2019) but also other diversity-promoting alternatives (Welleck et al., 2020; Jiang et al., 2019). We also achieve state-of-the-art results on most of the quality performances.

2 Related Works

2.1 Diversity-promoting Text Generation

In the field of neural text generation, prior studies either take a training-based approach or a decoding-based approach to promote the diversity in the generated texts.

Training-based Approach. In dialogue generation, stimulating models to generate texts that share high mutual information with the contexts (Li et al., 2016) has shown to improve the diversity of output tokens by adding a maximum mutual information (MMI) constraint to the standard likelihood objective. Meanwhile, FACE (Jiang et al., 2019) dynamically weights the cross-entropy losses based on target token frequencies, to prevent excessive weight-updates of some frequently used words. In another line of works for language modeling, text diversity has been promoted by a learning-to-cooperate framework in which multiple discriminators cooperate to reach a common goal (Holtzman et al., 2018). Also, the unlikelihood training strategy penalizes repetition with auxiliary loss terms (Welleck et al., 2020). Such works are orthogonal to ours since F^2-Softmax focuses on decomposing the softmax function without employing an auxiliary loss or loss re-scaling.

Decoding-based Approach. One of the widely used decoding tactics for promoting the diversity and richness of texts is stochastic decoding. Top-k sampling stochastically samples the next token from the top-k candidates in the predicted probability distribution (Fan et al., 2018). Another pillar of stochastic decoding is nucleus sampling, which selects the next token from the top-p portion of the probability mass (Holtzman et al., 2019). Other studies include beam blocking (Paulus et al., 2017) in which the probabilities of tokens are set to zero if they were to create repeating n-grams, diverse beam search (Vijayakumar et al., 2018) which integrates dissimilarity terms into beam scores. Iterative beam search (Kulikov et al., 2019) enhances diverse beam search with multiple iterations of beam search with different search spaces. These techniques are agnostic about model architecture or training methods. Our approach can be harmonically combined with the above techniques.

2.2 Softmax Decomposition

Decomposing the softmax function has long been studied in language modeling. Goodman (2001) decomposed the softmax function using a two-level hierarchy. This idea was generalized to deeper hierarchies in a later study (Mnih and Hinton, 2009). Approaches to construct softmax hierarchies have followed, such as utilizing word clusters obtained from k-means algorithms (Le et al., 2011) or implementing Huffman coding with word frequencies (Mikolov et al., 2013). Furthermore, dynamic programming has been applied to obtain an optimal set of word classes with minimal computational costs for calculating the softmax function (Zweig and Makarychev, 2013). The same process has also been streamlined to fit into modern GPU environments (Grave et al., 2017). These techniques bear a resemblance to ours for the use of softmax decomposition. However, our goal is fundamentally different: we aim to balance the data distribution in training, whereas previous approaches share the primary goal of reducing computational costs.

2.3 Imbalanced Classification

That we assign tokens to classes of balanced distribution shares a similar goal with overcoming imbalanced classification in computer vision domains. One of the widely adopted techniques for imbalanced classification is re-sampling, which includes removing examples from the majority classes (under-sampling) and adding samples for the minority classes (over-sampling) (Buda et al., 2018). Techniques for over-sampling include interpolating samples from neighboring samples (Chawla et al., 2002) and adaptively synthesizing samples (He et al., 2008a). Cost-sensitive learning dynamically re-weights costs based on sample difficulties (Dong et al., 2017) or effective number of samples (Cui et al., 2018). Other studies for the data imbalance problem consider metric learning (Huang et al., 2016), knowledge transfer (Wang et al., 2017), and Bayesian estimation (Khan et al., 2019).

3 Methods

3.1 Maximum Likelihood

The goal of language modeling is to learn a model $\hat{p}(\mathbf{x})$ which best describes a joint probability distribution $p(\mathbf{x})$, where $\mathbf{x} = [x_1, \ldots, x_T]$ is a sequence of tokens and $x_i \in \mathcal{V}$ is a token from a vocabulary set. In an auto-regressive manner, $p(\mathbf{x})$ can be factorized into a product of conditional probabilities of tokens; $p(\mathbf{x}) = \prod_t p(x_t|\mathbf{x}_{<\mathbf{t}})$. A conventional approach for the training is to maximize log-likelihood of a sequence $\mathbf{x}$ as the following:

$$\mathcal{L}_{\text{MLE}}(\hat{p}, \mathbf{x}) = \sum_{t=1}^{T} \log \hat{p}(x_t|\mathbf{x}_{<t}). \tag{1}$$

3.2 F^2-Softmax

We propose to factorize the posterior $\hat{p}(x_t|\mathbf{x}_{<\mathbf{t}})$ into a product of two conditional probabilities:

$$\hat{p}_{(}x_t|\mathbf{x}_{<t}) = \hat{p}_1(c_t|\mathbf{x}_{<t}) \times \hat{p}_2(x_t|c_t, \mathbf{x}_{<t}), \tag{2}$$

where $c_t \in \mathcal{C}$ denotes a frequency class label assigned to the token x_t given the global frequency of the token in a corpus, belonging to a set of frequency classes $\mathcal{C}$. Following Eq. (2), the updated objective $\mathcal{L}_{F^2}(\hat{p})$ is then formulated as:

$$\begin{aligned}&\mathcal{L}_{F^2}(\hat{p}, \mathbf{x})\\&= \sum_{t=1}^{T}[\log \hat{p}_1(c_t|\mathbf{x}_{<t}) + \log \hat{p}_2(x_t|c_t, \mathbf{x}_{<t})].\end{aligned} \tag{3}$$

The objective is thus learning how to classify the target frequency of the token and selecting the exact token given the target frequency class. The factorized probabilities $\hat{p}_1(c_t|\mathbf{x}_{<t})$ and $\hat{p}_2(x_t|c_t, \mathbf{x}_{<t})$ are defined empirically using softmax functions:

$$\begin{aligned}\hat{p}_1(c_t|\mathbf{x}_{<t}) &= \frac{\exp(\mathbf{h}_{t-1} \cdot \mathbf{u}^{c_t})}{\Sigma_{m \in \mathcal{C}} \exp(\mathbf{h}_{t-1} \cdot \mathbf{u}^{m})}\\ \hat{p}_2(x_t|c_t, \mathbf{x}_{<t}) &= \frac{\exp(\mathbf{h}_{t-1} \cdot \mathbf{o}^{x_t})}{\Sigma_{n \in \mathcal{V}_{c_t}} \exp(\mathbf{h}_{t-1} \cdot \mathbf{o}^{n})},\end{aligned} \tag{4}$$

where $\mathbf{h}_{t-1}$ is a hidden state of the context $\mathbf{x}_{<t}$; $\mathbf{o}^i$ and $\mathbf{u}^j$ can be viewed as output embedding vectors for $i \in \mathcal{V}_{c_t}$ and $j \in \mathcal{C}$, respectively, while $\mathcal{V}_{c_t}$ is a subset of vocabularies assigned to the class c_t. Note that $\hat{p}_2(x_t|c_t, \mathbf{x}_{<t})$ is computed from the narrowed pool of tokens $\mathcal{V}_{c_t}$ rather than the full vocabularies set $\mathcal{V}$. Since classes are differentiated based on the token frequency, tokens with the same class have similar frequencies. It ensures within-class frequency distribution of tokens is closer to uniform than that of the full vocabulary set.

3.3 MefMax for Class Optimization

The more uniform a label distribution is, the less likely decision boundaries are biased in favor of frequent classes. Therefore, we aim to maximize the degree of uniformity of frequency distributions for both (i) tokens within each class and (ii) classes themselves (i.e., the sum of token frequencies within each class), to avoid the class imbalance problem (Buda et al., 2018) over the course of training. It is formalized as follows:

$$\mathcal{C}^{'} = \arg\max_{\mathcal{C}}[\mathcal{U}(\mathcal{C}) + \frac{1}{|\mathcal{C}|}\sum_{i \in \mathcal{C}} \mathcal{U}(\mathcal{V}_i)], \qquad (5)$$

where $\mathcal{U}$ is a function that measures the uniformity of the frequency distribution of a given set. While any tests of uniformity can be used as $\mathcal{U}$, we adopt *Shannon's entropy* (Shannon, 1948). The entropy is a decent proxy for measuring the uniformity (Dudewicz and Van Der Meulen, 1981).

Normalized Entropy. Since the number of samples affects the entropy, entropy cannot be directly used. To marginalize the effect of the sample size, we use *efficiency*, which is also known as the normalized entropy (Wijesekera and Dillon, 1997), defined as:

$$\mathcal{U}(\mathbf{k}) = -\sum_{k_i \in \mathbf{k}} \frac{p(k_i)\log(p(k_i))}{\log(|\mathbf{k}|)}. \qquad (6)$$

It is equivalent to the ratio of the entropy to the maximum entropy, if the data were perfectly uniform. By applying the efficiency to Eq. (5), our objective is to find a set of classes and their vocabularies such that their *mean efficiency* is maximized.

Greedy Approach. The remaining issue is the computational overhead since the cost for exploring all possible class boundaries grows exponentially with the vocabulary size, not to mention the challenge of finding the optimal number of classes. To improve computational efficiency, we employ a straightforward greedy mechanism. It is based on the assumption that the mean efficiency is maximized when each class has approximately the same total frequency size. This assumption allows us to reduce our objective to optimizing the number of classes. Given a sorted vocabulary set $\mathcal{V}'$ and a candidate number of classes K, we divide classes so that each class has the same $1/K$ of total frequency. The optimal number of classes is the one that maximizes the mean efficiency. Algorithm 1 shows the complete pseudo-code. Computation time is linear to the vocabulary size.

Algorithm 1 Pseudo-code for MefMax

```
Inputs : Array $\mathcal{V}'$ of length $n$ sorted by the decreasing order of token frequency
Outputs : Number of classes, class boundary tokens
$\mathcal{V}' \leftarrow \mathcal{V}'$ / sum($\mathcal{V}'$)          ▷ get relative frequencies
maxMeanEfficiency $\leftarrow 0$
maxClassNum $\leftarrow 1/\mathcal{V}'[0]$
for $K$ in [1, 2, ..., maxClassNum] do
    $B \leftarrow$ empty list          ▷ lists for candidate boundaries
    tar $\leftarrow 1/K$          ▷ target frequency
    cum, idx $\leftarrow 0, 0$          ▷ cumulative frequency & index
    while tar $\leq 1$ do          ▷ compute candidate boundaries
        cum $\leftarrow$ cum + $\mathcal{V}'$[idx++]
        if cum $\geq$ tar then
            tar $\leftarrow$ tar + $1/K$
            $B$.append(idx)
    meanEfficency $\leftarrow$ mean efficiency based on $B$
    if maxMeanEfficiency < meanEfficency then
        maxMeanEfficiency $\leftarrow$ meanEfficency
        $Out \leftarrow B$
return len($Out$), $Out$
```

3.4 Decoupled Decoding

For the decoding stage, we decouple $\hat{p}_1$ from $\hat{p}$ in Eq. (2) by first selecting a single frequency class from $\hat{p}_1$ and then generating the next token based on the selected class. For the target class $c_t = i$ sampled from the distribution $\hat{p}_1(c_t|\mathbf{x}_{<t})$, the probability for the next token is defined as:

$$\hat{p}^{'}(x_t|\mathbf{x}_{<t}) = \begin{cases} \hat{p}_2(x_t|c_t = i, \mathbf{x}_{<t}) & \text{if } x_t \in \mathcal{V}_i \\ 0 & \text{otherwise.} \end{cases} \qquad (7)$$

The target class can be sampled in both deterministic or stochastic manners, depending on decoding strategies. We found that the advantages of training balanced data distributions can be fully leveraged by sequentially performing tasks of frequency class prediction and token generation from the selected class.

4 Experiments

4.1 Training and Evaluation Details

In this section, experimental details are illustrated. Exact hyperparameter settings and data statistics are described in Appendix.

4.1.1 Datasets

Two datasets that differ in language and text types are selected for the implementations.

Wikitext-103 [1] is a collection of English articles extracted from Wikipedia. Containing more than

---

[1] `https://s3.amazonaws.com/research.metamind.io/wikitext/wikitext-103-v1.zip`

100 million words, it is widely regarded as a benchmark dataset for language modeling.

Melo-Lyrics is a Korean lyrics dataset we crawled from multiple music streaming websites, including Soribada[2], Genius[3], etc. Tokens in lyrics show a distribution largely different from general articles; for instance, repeated phrases are abundant in lyrics. Therefore it provides an additional unique angle for model evaluations and comparisons. It includes approximately 478 thousand songs with 51 million words in total.

4.1.2 Model Architecture

We use the Transformer (Vaswani et al., 2017), an architecture well-suited for neural text generation (Lewis et al., 2019; Welleck et al., 2020). Specifically, we apply the Transformer decoder used in the GPT-2 model (Radford et al., 2019). Input texts are tokenized with the byte pair encoding (Sennrich et al., 2016).

4.1.3 Baseline Models

For the baseline, we consider maximum likelihood estimation (MLE), a standard approach for text generation. Also compared are alternative models for promoting text diversities, including recently proposed FACE[4] (Jiang et al., 2019) and unlikelihood training[5] (UL) (Welleck et al., 2020). FACE improves text diversity by dynamically scaling losses, while the latter employs auxiliary losses.

4.1.4 Training

Training is carried out on a single GPU environment with 24GB of memory. We set all hyperparameters equal for all approaches by tuning them based on the validation losses of the MLE baseline for fair comparisons. We additionally optimize approach-specific hyperparameters of diversity-promoting baselines.

4.1.5 Generation

We generate texts for the evaluation by completing sequences from prefixes. Specifically, we batchify a test set, select the first 50 tokens from each batch as prefixes, and guide models to generate a continuation of 100 tokens from the prefixes. The experiments include both deterministic and stochastic decoding. We apply greedy search for deterministic decoding, and use top-k sampling for stochastic decoding.

4.1.6 Evaluation Metrics

From seven total quantitative metrics we adopt to evaluate our model, Perplexity (Bengio et al., 2003), KL-Divergence (Kullback, 1997), and MS-Jaccard (Alihosseini et al., 2019) are closely related to the *likelihood* of generated texts. The other four metrics, namely Self-BLEU (Zhu et al., 2018), Distinct-n (Li et al., 2016), Repetition (Holtzman et al., 2019), and Uniq (Welleck et al., 2020) measure the text *diversity*.

Perplexity quantifies the prediction difficulty over the next token. It is regarded as a general performance metric for text generation.

KL-Divergence measures the difference between two probability distributions. We use unigram distributions of the generated texts and the test data.

MS-Jaccard computes the similarity between the model's output and the ground truths by matching n-grams.

Self-BLEU evaluates the inter-text diversity by computing BLEU (Papineni et al., 2002) score for each generated text by regarding other outputs as reference.

Distinct-*n* quantifies the intra-text diversity based on distinct n-grams in each text.

Repetition examines whether texts are stuck in repetitive loops.

Uniq quantifies the richness of models using the number of unique generated tokens.

4.2 Quantitative Comparisons

In this section, we report the scores computed from fully-trained models on the two benchmarks, Wikitext-103 and Melo-Lyrics, compared against baselines. Table 1 shows the results of stochastic decoding, while the results of deterministic decoding are reported in Table 2.

4.2.1 Stochastic Decoding

Wikitext-103. The desired qualities we aim for a text generation model is to generate human-like texts with a wide spectrum of token choices. Coupled with top-k sampling, our F^2-Softmax achieves both goals by outperforming baselines with nearly all metrics compared, and closely approaching the human gold standard. As shown in Table 1(a), our model is particularly effective in capturing the token diversity in the corpus. Notably, F^2-Softmax

(b) Melo-Lyrics

Table 1: Quantitative comparisons of F^2-Softmax with baseline models. Top-*k* sampling strategy with the *k* size of 3 and 20 are used for Wikitext-103 and Melo-Lyrics, respectively, across all models. UL-token imposes a token-level penalty, and UL-token+seq considers both token- and sequence-level penalties. PPL, KLD, and Rep are abbreviated notations for perplexity, KL-Divergence, and Repetition, respectively. Numbers $n \in (1, 2, 3)$ in column headers under MS-Jaccard, Self-BLEU, and Distinct refer to n-grams. Boldface scores denote the performances closest to humans. F^2-Softmax outperforms compared baselines in most of the cases. Results on various *k* sizes are reported in Appendix.

significantly improves both Self-BLEU and Distinct performances, having relative gaps to the human gold standard of 3.4% and 3%, respectively. The performance gaps of the second-best scores are 6.5% (FACE) and 8.1% (UL-token+seq), respectively. A surprising result is that F^2-Softmax improves Rep performance by 50% over MLE, without an explicit penalty on repeating tokens. Another seminal contribution is the 30% relative increase in unique tokens used for the generation, from the previously state-of-the-art level of 10.6k to 15.7k, as shown by the Uniq metric. This level closely reflects the human use of 15.2k tokens.

In PPL, which reflects the likelihood of the generated texts, the diversity-promoting baselines tend to perform worse than MLE, presumably due to the trade-offs between the diversity and the likelihood of texts. In contrast, F^2-Softmax maintains the smallest performance drop on PPL. F^2-Softmax also improves KLD and MS-Jaccard by 59% and 19% over MLE, respectively, which are large margins compared to the other comparatives.

Melo-Lyrics. Significant performance gains of F^2-Softmax are also observed in lyrics generation in Table 1(b). The diversity-promoting baselines display severer degradation in PPL, KLD, and MS-Jaccard compared to the Wikitext-103 dataset. Especially, their repetition levels are significantly different from that of the ground truth data. We attribute this observation to the distinctive characteristics of lyrics, in which the same phrases are rhythmically repeated throughout the songs in the form of chorus or hook. Thus, for lyrics dataset, forcing models to discourage reusing previously used tokens may adversely affect the likelihood of the generated texts. Since F^2-Softmax helps models to diversify the output without an explicit regularization, models learn to generate well-thought-out tokens from the diversified token pool of 25.2k (Uniq), with state-of-the-art performances in KLD, MS-Jaccard, Self-BLEU, Distinct, and Rep.

4.2.2 Deterministic Decoding

In deterministic decoding, there is no clear method that outperforms the others in all of the metrics. For example, UL-token+seq exhibits the best performance in Distinct and Rep, while presenting the worst score in MS-Jaccard. Similarly, FACE improves Self-BLEU in exchange for performance loss on PPL and MS-Jaccard. Since we have seven metrics to compare, we conduct pair-wise evalu-

Metrics / Models	PPL	KLD	MS-Jaccard			Self-BLEU			Distinct			Rep	Uniq
			n=1	n=2	n=3	n=1	n=2	n=3	n=1	n=2	n=3

Table 2: Evaluation results on the greedy sampling. The abbreviations are the same as Table 1.

ations between the compared methods, in which a method outperforms the other when a majority of metrics record higher. Our approach beats compared methods seven out of eight times (Table 9). This result supports the supremacy of our approach regardless of the choice of decoding strategies.

However, deterministic decoding does not see the same amount of benefits obtained from stochastic decoding. We empirically find from our analyses that argmax operation in deterministic settings may harm the diversity when target class probabilities are nearly evenly distributed. We plan to delve deeper into our approach to improve our approach further.

4.3 Learning Balanced Distribution

The characteristic markers of monotonous texts are an overproduction of frequently used tokens and under-representation of rare tokens. To compare how models differentially generate tokens from frequent and rare tokens, we count the number of generated tokens corresponding to four defined categories of *frequent*, *medium*, *rare* and *very rare*. Tokens in each category are predefined from the Wikitext-103 training set. Fig. 2 plots the distribution results. MLE produces *frequent* tokens 34% more than human, while under-producing *rare* and *very rare* tokens by 40%. The unlikelihood training baselines (UL-token, UL-token+seq) improve the diversity against MLE, but their results are relatively far from the real distribution. FACE manages to regulate a disproportionate use of *frequent* tokens, but it fails to generate adequate amount of *very rare* tokens. Generation results of our F^2-Softmax are closest to the gold standard, with the differences in *frequent* and *rare* tokens falling within 6%.

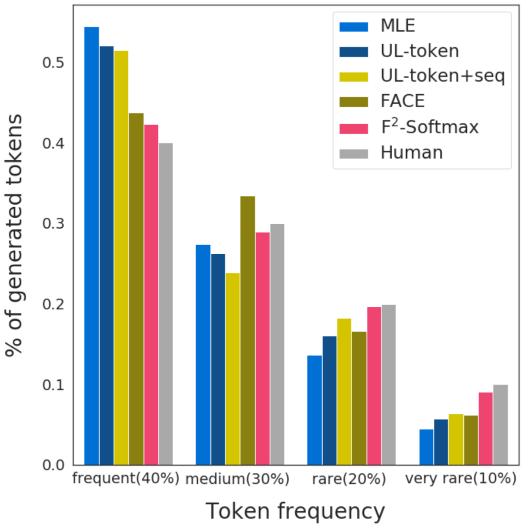

Figure 2: Frequency distribution comparisons on the Wikitext-103 test set. Tokens in each group are defined based on the frequency mass of the training set. Tokens occupying the top 40% of the frequency mass are assigned to *frequent*, while those corresponding to the bottom 10% are classified to *very rare*.

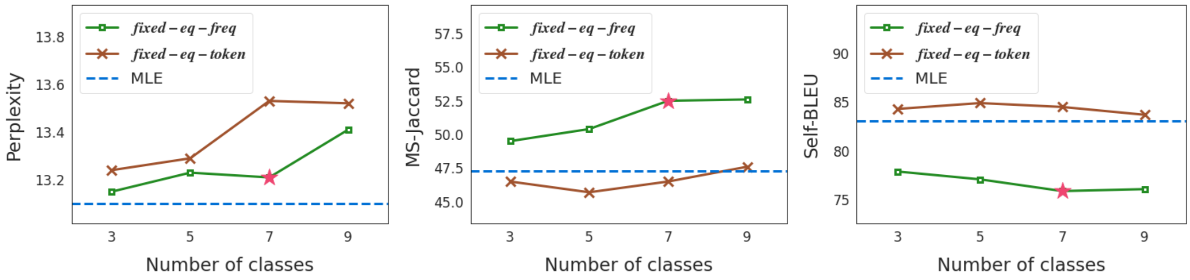
4.4 Ablation Studies

In this section, we justify the pivotal roles of MefMax (Section 3.3) and the decoupled decoding



(a) Perplexity (b) MS-Jaccard (c) Self-BLEU

Figure 3: Bigram performance on the Melo-lyrics test set with different numbers of classes. Green and brown lines indicate models with tokens are distributed based on frequency mass and token size, respectively. Blue dotted lines and star marks represent the MLE baseline and the choice of MefMax, respectively.

strategy (Section 3.4). In order to assess contributions toward the final performances, we conduct a series of ablation tests. Stochastic decoding is used for the ablation studies.

4.4.1 Ablation on MefMax

MefMax finds a desirable number of classes, intending to balance the frequency distribution of tokens between classes. Does MefMax help achieve better generation results than possible variants of class assignment? We answer this question by comparing the final performances against two simpler variants of MefMax. We name the first variant as *fixed-eq-token* in which tokens are distributed in *equal* numbers to a *fixed* number of classes. The second variant, *fixed-eq-freq*, also assumes a fixed number of classes, but tokens are assigned to minimize the difference in the frequency distribution between classes.

Fig. 3 presents the results. Clearly, *fixed-eq-freq* outperforms *fixed-eq-token*. It indicates that a decomposition of the softmax function without consideration of the data distribution (i.e., frequency distribution) aggravates both the likelihood and token diversity performances, regardless of the number of classes. For *fixed-eq-token*, we find that models tend to overclassify the target class to the first class, which contains most of the total frequency, having most tokens generated from a fraction of the total vocabulary. This finding also justifies the hypothesis that balanced data distribution is an important factor in text generation.

Assigning classes based on the frequency (i.e., *fixed-eq-freq*) continues to improve MS-Jaccard and Self-BLEU until the number of classes reaches the class choice of MefMax. With a larger number of classes than the choice, performances either plateau or decrease, demonstrating that MefMax is capable of selecting the optimal class size. Interestingly, perplexity significantly deteriorates when the number of classes exceeds the optimal number decided by MefMax.

Model	Decoupled Decoding	KLD	MSJ	SB	Uniq
F^2-Softmax	O	0.13	52.4	76.1	25.2k
	×	0.31	47.4	81.9	22.6k
MLE	×	0.34	47.3	83.1	22.4k

Table 3: Ablation study on the decoupled decoding. MSJ and SB stand for MS-Jaccard and Self-BLEU, respectively. Scores are measured on bigram level.

4.4.2 Ablation on Decoupled Decoding

Decoupled decoding formalized in Eq. (7) fully leverages the benefits of F^2-Softmax by sequentially performing the frequency class prediction and token generation tasks. Table 3 reports the results from an ablation test on the decoupled decoding. To ablate the decoupled decoding, we use a full posterior in Eq. (2). We observe significant performance gaps, meaning that the decoupled decoding is an indispensable component of our model. Notably, even without the decoupled decoding, our model maintains better performances than the MLE baseline.

4.5 Qualitative Comparisons

To further examine the generation quality, we sample texts from the trained models. Table 4 compares the generated texts from the same prefix. The results suggest that all trained models are capable of generating texts semantically coherent to the prefix. However, they differ in rare token usage patterns. While our F^2-Softmax exhibits the highest usage of rare tokens, we observe two issues from the base-

Model	**Texts**	**VR** (%)

Table 4: Generated texts on the Wikitext-103 test set. A prefix from the first batch was selected to avoid cherry-picking. **VR** denotes the ratio of *very rare* tokens (see Section 4.3 for the definition) against the text length. While all colored and bold-faced tokens indicate *very rare* tokens, **green** color denotes repeated tokens, and **red** color is reserved for non-pronoun words.

lines. The first is that models tend to repeat the same rare token across all sentences after its first appearance (MLE). The other issue is that generated rare tokens are mostly pronouns (UL-token-seq). Unlike the baselines, F^2-Softmax utilizes the broadest range of rare tokens with significantly less, but more likely, repetitions. Further, F^2-Softmax is shown to be adept at utilizing non-pronoun rare tokens, such as 'eccentric' or 'vanished'.

5 Conclusion

In this paper, we proposed F^2-Softmax, a simple but effective method for better learning the rich diversity in text. F^2-Softmax encourages models to diversify text generation by readjusting class formation and motivating models to learn a more balanced token distribution. Quantitative and qualitative analyses validate the diversity-promoting performances of our approach. Since it can be quickly adopted to replace the traditional likelihood objective, we believe in broader applicability of F^2-Softmax. Thus, future work involves extending the method to other related tasks, such as machine translation and text summarization, and investigating the potential gains from transfer learning.

A Datasets

A.1 Melo-Lyrics Data Collection

Few datasets have been publicly available for Korean text generation, and none of them has gained public consensus as a benchmark dataset, partly due to their small sample sizes. We collect lyrics data for three rationales. First, we test our model on a language other than English. Second, a large number of songs and lyrics are available. Lastly, lyrics show distributional characteristics at odds with Wikipedia. The crawling session was held between 5th July 2019 to 29th July 2019. After crawling enough data, we discarded those containing more than ten foreign language words, except for English. English was an exception since using English in Korean lyrics is natural and common. We also manually refined the lyrics by deleting noises, including advertisements and unnecessary meta-information about the lyrics writer transcriber. The remaining data consist of roughly 478 thousand lyrics with 51 million words. Indexed data can be downloaded from the url below[6]. We plan to release the raw data for research purposes only.

A.2 Data Statistics

The number of articles (songs) and containing words for training, test and validation phases are reported in Table 5.

	train	test	valid
# of articles	28,475	60	60
# of words	113,655,420	269,551	236,966

(a) Wikitext-103 dataset

	train	test	valid
# of songs	430,837	23,935	23,935
# of words	46,343,239	2,566,598	2,501,304

(b) Melo-Lyrics dataset

Table 5: Statistics on the datasets

B Hyperparameter Configurations

The detailed hyperparameters used are illustrated.

B.1 Model Hyperparamters

Table 6 reports the detailed list of model hyperparameters. The dropout and drop attention ratios are chosen from a set $\{0, 0.1\}$ based on validation losses. Sequence length is selected from a set $\{512, 1024\}$. We assigned 10,000 more vocabularies to training models on the Melo-Lyrics dataset, illuminating the characteristics of Korean language where words with varying forms may have similar meanings.

Dataset Hyperparameter	Wikitext-103	Melo-Lyrics
# of layers	12	
Hidden dimension	512	
Projection dimension	2048	
# of heads	8	
Head dimmension	64	
Dropout	0.1	
Drop attention	0	
Sequence length	1024	512
Vocabulary size	30,000	40,000
Total # of parameters	69.0M	76.5M

Table 6: Model hyperparameter settings

B.2 Training Hyperparamters

Dataset Hyperparameter	Wikitext-103	Melo-Lyrics
Batch size	8	16
Learning rate	0.0001	0.0002
Finetuning LR	0.00001	0.00002
Finetuning step	1500	1500
Gradient clipping	0.25	0.25
Weight decay	0.001	0
Optimizer	Adam	Adam
- β_1	0.9	0.9
- β_2	0.999	0.999
- ϵ	1e-8	1e-8

Table 7: Training hyperparameter settings

Table 7 shows the training configurations. The learning rate, gradient clipping norm, weight decay are selected from a set, $\{0.00005, 0.0001, 0.00015, 0.0002, 0.00025\}$, $\{0.25, 5.0\}$, $\{0, 0.001, 0.0001\}$, respectively. Batch sizes are chosen to accommodate the GPU memory constraint. We use default Adam configurations in PyTorch. Finetuning learning rate, selected from a set $\{0.00001, 0.00002\}$, is used to finetune UL-token-seq and FACE. Of the four variants of FACE, we use FACE-OPR, which reportedly performs best.

C Transfer Learning

Pre-trained language models are widely used for downstream applications by adapting them to domain-specific distributions. Significant gains can be realized if F-^{2} softmax is successfully applied to fine-tune pre-trained language models, as most

pre-trained language models are trained with standard softmax function. To validate our approach on transfer learning settings, we pre-train a language model on news datasets consisting of 10GB of articles and fine-tune the model on the Melo-Lyrics dataset. The results are shown in Table 8. The transferred model both increased the quality and diversity of the generation. However, the transferred model exhibits narrower vocabulary usage. We conjecture it is arisen by the vocabulary mismatch between datasets used for pre-training and fine-tuning. We plan to further investigate the vocabulary mismatch problem.

Abstract

The Data-to-Text task aims to generate human-readable text for describing some given structured data enabling more interpretability. However, the typical generation task is confined to a few particular domains since it requires well-aligned data which is difficult and expensive to obtain. Using partially-aligned data is an alternative way of solving the dataset scarcity problem. This kind of data is much easier to obtain since it can be produced automatically. However, using this kind of data induces the over-generation problem posing difficulties for existing models, which tends to add unrelated excerpts during the generation procedure. In order to effectively utilize automatically annotated partially-aligned datasets, we extend the traditional generation task to a refined task called Partially-Aligned Data-to-Text Generation (PADTG) which is more practical since it utilizes automatically annotated data for training and thus considerably expands the application domains. To tackle this new task, we propose a novel distant supervision generation framework. It firstly estimates the input data's supportiveness for each target word with an estimator and then applies a supportiveness adaptor and a rebalanced beam search to harness the over-generation problem in the training and generation phases respectively. We also contribute a partially-aligned dataset [1] by sampling sentences from Wikipedia and automatically extracting corresponding KB triples for each sentence from Wikidata. The experimental results show that our framework outperforms all baseline models as well as verify the feasibility of utilizing partially-aligned data.

1 Introduction

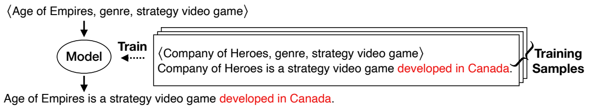

Figure 1: Illustration of the over-generation problem in the partially-aligned data-to-text generation task. In the training set, there is no KB triple corresponding to the text "*developed in Canada*". The model is likely to bind the text to existing triples incorrectly. As a result, during the testing or operational stage, the model is likely to overly generate this kind of excerpt for similar triples.

The Data-to-Text generation task focuses on generating human-readable text corresponding to some given structured data. For example, given the input knowledge base (KB) triple ⟨Company of Heroes, developer, Relic Entertainment⟩, the aim is to generate a text description such as "*Company of Heroes is developed by Relic Entertainment.*". In recent years, many works have been proposed to give impetus to the Data-to-Text generation task. For instance, Gardent et al. (2017a; 2017b) proposed the WebNLG task aiming at generating description text of the given KB triples. Novikova et al. (2017) proposed the E2E task aiming at generating restaurant reviews according to the given restaurant attributes. Lebret et al. (2016) proposed the WikiBio task in which the biography of each person is generated according to the given Wikipedia infobox.

These typical data-to-text generation tasks are confined to a few particular domains since it requires well-aligned data and text pairs which are difficult and costly to obtain. Specifically, it is required that each input data provides exactly the same information with the target text. This requirement makes the dataset difficult to build and confines the task to particular domains where such kind of data (WikiBio, E2E) or human-labeled data (WebNLG) are available. Using partially-aligned data is an alternative way of solving the dataset scarcity problem. Partially-aligned data do not re-

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9183–9193,
November 16–20, 2020. ©2020 Association for Computational Linguistics

quire that each part in the text is exactly aligned with a particular input KB triple. This kind of data is much easier to obtain with automatic methods. Consequently, it can handle much broader kinds of domains. However, it induces the over-generation problem[2]. As shown in Fig. 1, some parts ("*developed in Canada*") in the generated text for ⟨Age of Empires, genre, strategy video game⟩ have not been mentioned in the input KB triple. Essentially, it is because in the training set, such unrelated text exists in some training samples. During the training, it misleads the model to bind the text "*developed in Canada*" to some irrelevant KB triples. When similar triples exist in the testing, it is prone to adding some over-generated text which is actually unrelated to the given input data. Current generation models fail to be trained on such partially-aligned data due to lacking the tolerance of the over-generation problem.

In order to effectively utilize automatically annotated partially-aligned datasets for handling more domains, we extend the traditional generation task to a refined task called Partially-Aligned Data-to-Text Generation (PADTG). Like the traditional task, the PADTG task also requires generating text with respect to the given input data. However, for the training data, we only require that the given structured data contains partial information of the corresponding text. This task is more practical since it utilizes the partially-aligned data for training and thus considerably expands the application domains. However, due to such data's nature, successfully suppressing the over-generation problem is the critical point for proposing an effective model.

We propose a Distant Supervision Generation (DSG) framework to tackle the PADTG task. Our framework can deal with the challenging over-generation problem when training on the partially-aligned data. It firstly trains an estimator to calculate each word's supportiveness in the target sentence with respect to the input data, i.e. how likely the word is conveyed by the input triples. Then the framework employs a sequence-to-sequence (S2S) neural model to encode the input data and generates the description sentence accordingly. In the training procedure, a supportiveness adaptor is used to adapt the estimated supportiveness into the loss function while in the generation procedure, a rebalanced beam search is used to generate text augmented with the supportiveness scores.

To prepare the partially-aligned data, we build a new dataset called WITA from text sources, namely, Wikipedia and Wikidata. We propose a novel KB extractor to extract KB triples given a piece of text sampled from Wikipedia. The KB extractor firstly detects named entities with an entity detector. The triple retriever queries the Wikidata database to find the most matching triples corresponding to these entities. We filter the results with a matching score to remove unextractable sentences.

Our contributions can be summarized as follows. (1) We propose a new task, namely, partially-aligned Data-to-Text generation, which is more practical and extensible to more domains. (2) We propose a distant supervision generation framework that can tackle the challenges of the new task including the over-generation problem. (3) We contribute a sizeable partially-aligned dataset suitable for this task.

2 Method

2.1 Overview

Formally, we denote the input KB triples as $K = [\langle h_1, r_1, t_1\rangle, \cdots, \langle h_n, r_n, t_n\rangle]$, where h_i, r_i, t_i represent the ith head, relation, and tail respectively while n is the number of triples. The corresponding text is denoted as $T = [w_1, \cdots, w_m]$, in which w_i is the ith word in T and m is the sentence length. It should be noted that, in the task of Partially-Aligned Data-to-Text Generation (PADTG), T contains some information that K does not have. The target of the task is to train a model that generates text T' that exactly describes the KB triples in K.

Our proposed Distant Supervision Generation (DSG) framework contains four components, namely a Supportiveness Estimator (SE), a Sequence-to-Sequence Generator (S2SG), a Supportiveness Adaptor (SA), and a Rebalanced Beam Search (RBS). As illustrated in Fig. 2, in the SE training procedure, we first pre-train the SE component to estimate a supportiveness vector $s \in \mathbb{R}^m$ indicating whether each target word $w_i \in T$ is describing the input triples in K. It adopts the self-supervised mechanism that trains the model to maximize the margin between the target words' scores and negative sampled words' scores. Then, the pre-trained SE component is utilized to estimate a supportiveness vector s in both S2SG Training and S2SG Generation. In the S2SG training procedure, the S2SG model firstly calculates the generation

---

[2] Note that omission problem also happens in the Data-to-Text generation task, but it is not a major problem.

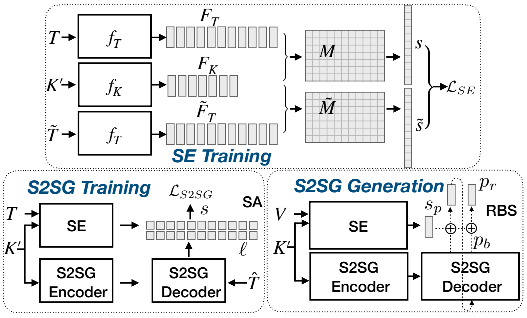

Figure 2: Distant Supervision Generation Framework.

loss ℓ. Then, SA combines ℓ with s to get a refined loss in which the loss is diminished if one target word has lower supportiveness. In the S2SG generation procedure, the RBS component combines s with the probability distribution of candidate words to obtain a better generation result.

2.2 Supportiveness Estimator

We concatenate the input KB triples word-by-word as $K' = [w_1^{h_1}, \cdots, w_{|h_1|}^{h_1}, w_1^{r_1}, \cdots, w_{|r_1|}^{r_1}, w_1^{t_1}, \cdots, w_{|t_1|}^{t_1}, \text{KBSEP}, w_1^{h_2} \;\cdots\cdots, w_{|t_n|}^{t_n}]$, in which h_j, r_j, t_j is the head, relation and tail entity of the jth triple. $w_i^{h_j}$ represents the ith word in the jth KB triple's head entity. $|h_j|$ stands for the word count of the jth head entity. KBSEP is a seperator between each triple.

Feature Extraction. In SE, a feature extraction component f_K is utilized to extract features for each word denoted as $F_K = f_K(K')$, in which $F_K \in \mathbb{R}^{d \times |K'|}$ is the extracted feature matrix for K'. d is the embedding dimension and $|K'|$ is the length of K'. Specifically, in the feature extraction component, K' is firstly embedded with an embedding layer as $K_1 = \text{emb}(K')$, $K_1 \in \mathbb{R}^{d \times |K'|}$. Then K_1 is sent into a normalization layer (Ba et al., 2016) as $K_2 = \text{NL}(K_1)$, $K_2 \in \mathbb{R}^{d \times |K'|}$. NL is defined as

$$\text{NL}(x) = \frac{\gamma(x - \mathbb{E}(x))}{\sqrt{\text{Var}(x) + \epsilon}} + \beta,$$

in which $\mathbb{E}$ and Var are mean and variance of the input x while γ and β are learnable parameters. ϵ is a small constant which is usually set to $1.0e-5$. K_2 is then sent into a combination of linear feedforward layers and a ReLU layer as $K_3 = \text{FW}_2(\text{ReLU}(\text{FW}_1(K_2)))$, $K_3 \in \mathbb{R}^{d \times |K'|}$, where FW_2 and FW_1 are linear feedforward layer while ReLU stands for the ReLU layer. Afterwards, the features representation is calculated as $F_K = \text{NL}(K_3)$. Similarly, the features for each word in the target text is denoted as $F_T = f_T(T)$, $F_T \in \mathbb{R}^{d \times m}$.

Supportiveness Vector. We calculate the supporting matrix as $M = F_K^T F_T$, $M \in \mathbb{R}^{|K'| \times m}$, in which $M_{i,j}$ represents the supportiveness of the ith word in K' that support for the jth word in T. The supportiveness score vector is aggregated from M as

$$s_j = \log \sum_{i=1}^{|K'|} \exp(M_{i,j}),$$

where s_j is the jth element of the vector $s \in \mathbb{R}^m$ and it stands for input K's supportiveness to the jth word.

Negative Sampling. In order to prevent the model from giving all words a high supportiveness score, we use the negative sampling method to sample some negative sentences. We denote the empirical distribution of the words in the target text as $P_{\mathcal{T}}$ in which $\mathcal{T}$ is the set of all target sentences. We sample words from $P_{\mathcal{T}}$ while avoiding sampling the same words in T. The sampling procedure can be denoted as $\tilde{w}_i \sim P_{\mathcal{T}}, \tilde{w}_i \notin T$. The negative sample is composed of $\tilde{w}_i$s as $\tilde{T} = [\tilde{w}_1, \cdots, \tilde{w}_m]$, where $\tilde{w}_i$ is the ith word in $\tilde{T}$ which has the same length as T. The negative sample $\tilde{T}$ will also be fed to the network in the same way as the original target T. The supportiveness score vector for the negative sample is denoted as $\tilde{s} \in \mathbb{R}^m$.

Optimization Target. The overall loss function consists of a margin loss, a word-consistent loss, and a concentration loss. The **margin loss** is defined as the margin between the supportiveness of the original text and that of the negative sample, which can be written as

$$\mathcal{L}_m = \sum_{i=1}^{\tilde{m}} \sigma(\tilde{s}_i) - \sum_{i=1}^{m} \sigma(s_i),$$

in which $\sigma(x) = 1/(1+e^{-x})$ is a sigmoid function. Minimizing $\mathcal{L}_m$ helps maximize the gap between the positive and the negative samples. The **word-consistent loss** is used to make the supportiveness from the same word in input KB larger than the supportiveness from different words. It is defined as

$$\mathcal{L}_w = -\sum_{i=1}^{m} \sum_{j=1}^{|K'|} \mathbb{1}(T_i = K'_j)[M_{i,j} - \log(\sum_{k=1}^{|K'|} \exp M_{k,j})].$$

It increases the supportiveness M_{ij} if the ith word in T and the jth word in K' are the same word. The

concentration loss is used to avoid one word in K' supporting too many words in T. It is denoted as

$$\mathcal{L}_c = \max_i \sum_{j=1}^{m} M_{i,j}.$$

If one word supports too many words, all its corresponding supportiveness will be penalized. The overall loss function is denoted as the weighted sum of these loss functions as

$$\mathcal{L}_{SE} = \mathcal{L}_m + \omega_w \mathcal{L}_w + \omega_c \mathcal{L}_c,$$

in which ω_w and ω_c are tunable hyper-parameters.

2.3 Sequence-to-Sequence Generator

We use the Transformer (Vaswani et al., 2017) structure as our S2S generator. The Transformer is an attention-based structure and is widely used in many tasks. It contains two major components, namely an encoder and a decoder. All of these components are built with several attention layers. The encoder firstly takes K' as input to generate the feature representation: $G_K = \text{Enc}(K')$. The decoder takes shifted target text $\hat{T}$ (shift last EOS tag to the beginning) as input and get the negative log-likelihood for each word in T as $\ell = \text{Dec}(\hat{T}, G_K)$, $\ell \in \mathbb{R}^{|T|}$, where Dec is the transformer decoder and $|T|$ is the length of T. We refer readers to Vaswani et al. (2017) for more technical details.

2.4 Supportiveness Adaptor

The supportiveness Adaptor adapts the supportiveness score to S2SG's output. We investigate three methods, namely, Hard Adaptor, Soft Adaptor, and Attention Adaptor.

Hard Adaptor. With the supportiveness scores, we can simply remove words that have low supportiveness. For each word w_i in the target sentence T, we use a uniform random number generator to generate a random number $r_i \in [0, 1]$. we ignore words in T if $r_i > s_i$ and copy it into T' otherwise. Then, T' is used instead of T in the training procedure.

Soft Adaptor. Since the hard adaptor directly removes words, it is easy to omit essential words and make the model generating unreadable text. We propose a soft adaptor to alleviate this issue. We use the original target text T as input. For the output negative log-likelihood loss vector ℓ, we combine it with the supportiveness vector s to modify the S2SG's loss as

$$\mathcal{L}_{S2SG} = \sum_{i=1}^{m} \ell_i s_i.$$

Attention Adaptor. Instead of using SE to estimate the supportiveness vector, attention adaptor directly aggregates the attention matrix as the supportiveness scores in our proposed DSG model. For each target word, it takes its max attention weight on each source word as the supportiveness score. We use maximization to aggregate the scores instead of considering all scores because all attention weights sum up to 1, and thus irrelevant words can also be assigned some attention. Using maximization aggregation avoids such irrelevant words. The supportiveness scores are then utilized in a similar way as the soft adaptor.

2.5 Rebalanced Beam Search

In the generation step, the supportiveness scores can also be utilized to help rebalance the final word probability distribution. We make a pseudo target sequence as $T_p = [1, 2, \cdots, |V|]$ which contains all words in vocabulary V. The supportiveness score $s_p \in \mathbb{R}^{|V|}$ for all words is calculated as the same procedure in training. In the traditional beam search, it outputs a probability $p_b \in \mathbb{R}^{|V|}$ over the whole vocabulary denoting the possibility for each token in the vocabulary to be chosen as the next word. We rebalance the probability with the supportiveness score vector as $p_r = p_b \cdot s_p^{\alpha}$ where α is a tunable hyper-parameter.

3 WITA: Our Partially-Aligned Dataset

We automatically harvest some partially-aligned data from Wikipedia and Wikidata and prepare a dataset called WITA. We select each Wikipedia article's first sentence from the 20190920 Wikipedia dump[3] as the target text. Then, we remove irrelevant tags and links with several predefined rules. We propose a KB extractor, as illustrated in Fig. 3, which can take the selected Wikipedia sentences and extract the corresponding KB triples. In the KB extractor, named entities are detected by an entity detector. The detected named entities are then combined into pairs by the Cartesian Product operation. The triples that mention these entity pairs are retrieved by a triple retriever that searches the corresponding KB triples from the Wikidata

Figure 3: Our proposed KB extractor for harvesting the partially-aligned data from Wikipedia and Wikidata.

database. We use an entity-recall based score to filter inappropriate sentences.

3.1 Entity Detector

We use three sub-detectors to recognize named entities and union them together. We first use a NER detector based on the spaCy[4]'s NER tool to recognize the named entities. Then we use the Noun detector based on spaCy's noun chunks recognition component to identify noun chunks. This detector is used because noun chunks have a high probability of being named entities. Finally, we use a linking detector, which is rule-based, to extract entities tagged with internal links. The detected entities for given sentence c is denoted as $E_c = [e_1, e_2, \cdots, e_p]$, while p is the entity number.

3.2 Triple Retriever

In order to quickly retrieve related triples for given named entities, we first store the Wikidata database in Elasticsearch[5]. We concatenate all possible variant names for an entity in Wikidata as the entity name. For example, *Steve Jobs*" has alternative names like "*Steven Paul Jobs*" and "*Steven Jobs*". The entity name is concatenated as "*Steve Jobs — Steven Paul Jobs — Steven Jobs*". In the Wikidata database, each triple contains a head, a relation and a tail entity and we denote the set of all the preprocessed triple as $\mathcal{D} = \{\langle h_i, r_i, t_i\rangle | \forall i\}$, where h_i, r_i, t_i are the head, relation and tail entity for the ith triple.

For given detected entities E_c, we make a list of named entity pairs by conducting a Cartesian Product as $C_e = \{\langle e_i, e_j\rangle | \forall e_i \in E_c, e_j \in E_c, e_i \neq e_j\}$. Afterwards, we query the Wikidata database to find a triple that matches the given named entity pair $\langle e_i, e_j\rangle \in C_e$ to make the head entity close to e_i while the tail entity close to e_j. It should be noted that the relation may be wrong, i.e. the matching triple describes a relation different from the one in the input sentence. But in reality, this probability is very small since most of the entity pairs only have one corresponding relation. For a given named entity pair $\langle e_i, e_j\rangle$, the query condition can be formally expressed as:

$$\begin{aligned}\widehat{\langle h, r, t\rangle} = \arg\max_{\langle h,r,t\rangle} d(g(e_i, h) + g(e_j, t)) + \\ (1-d)(g(e_j, h) + g(e_i, t)) \\ \text{s.t.}\ \ (1-d)M + l(e_i, h) \geqslant \kappa;\ \ dM + l(e_i, t) \geqslant \kappa; \\ (1-d)M + l(e_j, t) \geqslant \kappa;\ \ dM + l(e_j, h) \geqslant \kappa; \\ \langle h, r, t\rangle \in \mathcal{D};\quad d \in \{0, 1\},\end{aligned}$$

in which g is a single-term matching score[6] while l is the string similarity metric ranging from 0 to 1. M is a sufficiently large number and d is an integer. κ is a threshold preventing the retrieved head and tail being too different from e_1 and e_2. After we have retrieved entities for all sentences, we calculate a score based on entity-recall to filter wrongly extracted data-text pairs. entity-recall for KB triples and the corresponding text is defined as

$$\begin{aligned}r_e = \sum_{j=1}^{m} \mathbb{1}\{\sum_{i=1}^{n}[\mathbb{1}(w_j \in h_i) + \mathbb{1}(w_j \in r_i) + \\ \mathbb{1}(w_j \in t_i)] > 0\}/m,\end{aligned}$$

where m is the length of the sentence while n is the triple number. r_e indicates how much information in text has been covered by the retrieved triples.

Since WebNLG is the most similar task to our PADTG task among others, we compare the statistics of our WITA dataset with WebNLG in Table 1. It can be observed that (1) WITA is larger than the WebNLG dataset making it more practical. It can be easily extended to more domains. (2) WITA contains more relation types and entity types than that of WebNLG, indicating that our dataset involves more domains. (3) The vocabulary of the target sentences of WITA is much larger than that of WebNLG, which shows that our dataset is more challenging and more realistic. (4) The entity-recall score of WITA is lower than WebNLG. This is because WITA is automatically annotated and some information in the text is not contained in the KB triples. The low entity-recall score causes the over-generation problem and the specific value measures how serious the problem is.

4 Experiments

4.1 Experimental Setup

We split WITA into a training set, a development set, and a testing set of 50,000, 5,000, and 400 records respectively. For the purpose of evaluating the performance of the models, we ask human helpers to annotate the testing set sentences. The human helpers are asked to revise the input KB triples and the corresponding target sentences making them exactly consistent with each other. We use several evaluation metrics including BLEU (Papineni et al., 2002), ROUGE$_L$ (Lin, 2004), METEOR (Banerjee and Lavie, 2005), NIST (Doddington, 2002) and CIDEr (Vedantam et al., 2015) with the package provided by Novikova et al. (2017). We follow the default setting in ROUGE$_L$ where β is set to 1.2. We build our model based on the Transformer model (Vaswani et al., 2017; Ott et al., 2019) and use Byte Pair Encoding (BPE) (Sennrich et al., 2016) to build the subword dictionary. We use Fairseq (Ott et al., 2019) to build our model and keep all hyper-parameters for Transformer unchanged. We set $\kappa = 0.75$ from $\{0.1, 0.25, 0.5, 0.75, 0.9\}$ by extracting samples and ask human helper to evaluate. We use grid search to tune hyper-parameters on the development set and choose $\omega_w = 0.05$ from {0.02,0.05,0.1,0.2,0.5,1.0,2.0,5.0}, choose $\omega_c = 1.0$ from {0.02,0.05,0.1,0.2,0.5,1.0, 2.0,5.0} and choose $\alpha = 0.1$ from {0.02,0.05,0.1,0.2,0.5,1.0}. The model has 49M parameters and it takes 2.4 hours to train it on a NVIDIA TITAN RTX graphics card.

4.2 Comparison Models

We compare our full DSG model with the following baselines, state-of-the-art models, and ablations.

S2S utilizes the traditional S2S model (Sutskever et al., 2014; Cho et al., 2014) equipped with attention (Bahdanau et al., 2014; Luong et al., 2015) and copy (Gu et al., 2016) mechanism. It is recognised as the state-of-the-art model (Shimorina and Gardent, 2018) in the WebNLG (Gardent et al., 2017b) task.

S2ST utilizes the prevalent Transformer model (Vaswani et al., 2017; Ott et al., 2019) which outperforms the traditional S2S model in many generation tasks.

DSG-A utilizes the attention adaptor which adapts attention as the supportiveness scores in the loss.

DSG-H is almost the same as our DSG model. The only difference is that the supportiveness scores are adapted with hard adaptor while our DSG model uses the soft adaptor.

DSG w/o RBS is an ablation model. It removes the Rebalanced Beam Search component from our DSG model.

DSG w/o SA is an ablation model without the Supportiveness Adaptor. The supportiveness scores are only used by RBS in the generation phase. They are not adapted to the training loss.

4.3 Experimental Results

Main Results. The experimental results are shown in Table 2. It can be observed that our DSG model outperforms all comparison models in all metrics significantly and consistently, illustrating the effectiveness and consistentness of our framework. We can draw the following conclusions. (1) The superior performance of our DSG model shows that the supportiveness scores do help alleviate the over-generation problem. (2) The DSG-A model outperforms models without any adaptor. It fails to exceed the DSG model in all metrics. It shows attention can also be used to alleviate the over-generation problem but it performs not as good as our supportiveness scores. (3) The DSG model outperforms the DSG-H model illustrating that the soft adaptor is better than the hard adaptor. (4) The ablation experiments show that both the RBS and

	1-gram	2-gram	3-gram	4-gram	5-gram
S2ST	962	2,313	3,118	3,425	3,501
DSG-A	894	2,161	2,934	3,217	3,290
DSG-H	646	1,817	2,494	2,786	2,854
DSG	741	1,894	2,599	2,870	2,936

Table 3: N-gram statistics for over-generation error analysis.

	S2ST		DSG	
	BLEU	ROUGE$_L$	BLEU	ROUGE$_L$
10k	0.215	0.467	0.260	0.514
20k	0.383	0.631	0.421	0.659
30k	0.446	0.684	0.487	0.711
40k	0.500	0.719	0.518	0.728
50k	0.496	0.721	0.555	0.749

Table 4: Dataset size analysis.

the SA components contribute to alleviating the over-generation problem.

Specifically, the S2S model performs worse than other models. It shows that the Transformer based model works better in this task. This observation is consistent with the results observed in a lot of other similar tasks. The S2ST model performs worse than all other transformer-based models. The reason is that it suffers severely from the over-generation problem and is very likely to generate superfluous content in the generation procedure. The DSG-A model outperforms other models without any adaptor. This is because attention can also be regarded as a kind of supportiveness and it can be undoubtedly used to detect the over-generated words. However, since the purpose of the attention is to give weights to each input word, it is forced to assign weights to input words even no input data support the target word. As a result, it performs worse than our DSG model. Our DSG model with a soft adaptor outperforms the DSG-H model equipped with a hard adaptor. The reason is that when the hard adaptor is used, some words are directly ignored possibly resulting in generating an incoherent target sentence. Therefore, though it outperforms other models without any supportiveness adaption, it fails to exceed our proposed DSG model. The ablation experiment results show that both the RBS and SA components contribute to alleviating the over-generation problem. SA mainly focuses on alleviating the problem in the training phase while RBS focuses on solving it in the generation phase. They are all essential components of our model.

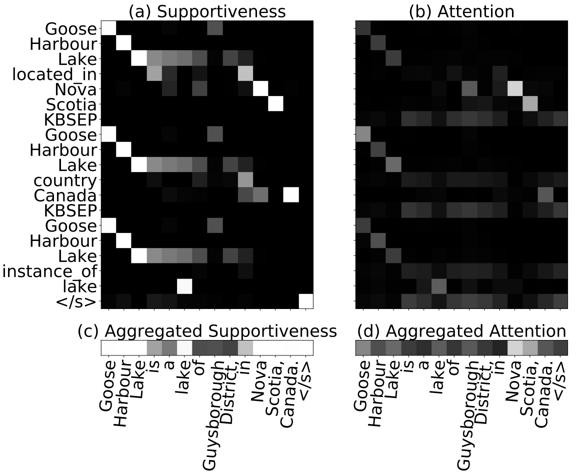

Figure 4: Comparision for supportiveness and attention. x-axis is the target text while y-axis is the given input KB triples. White stands for high score while black stands for low score. (a) and (b) show how each word in KB triples and text is aligned. (c) and (d) show the aggregated supportiveness and attention for each word in the target text.

Supportiveness Distribution Analysis. To give an intuitive understanding of how the supportiveness works and how it differs from the attention, we give an example comparing supportiveness distribution with the corresponding attention distribution. As shown in Fig. 4, it can be observed that both the supportiveness and the attention can capture the alignment relationship between words in the KB triples and words in the target sentence. The difference is that the aggregated supportiveness is high for correct words while the aggregated attention is not that significant for almost all words. The reason is that attention focuses on assigning weights to individual words with the weights summing to 1 while our proposed supportiveness score just focuses on deciding whether one word is correct or not. As a result, if one word is supported by many words in KB triples, our proposed supportiveness will be very high, while the attention may be relatively lower since its sum is fixed to 1. For example, three words "*Goose*" in the source sequence support the same word in the target text. The supportiveness for the word is very high while the attention is low since the three words in the source sequence dissipate the attention weight.

Over-Generation Error Analysis. In order to perform a quantitative analysis of the over-generation problem and show how it is mitigated by our model, we conduct an over-generation error analysis in which we count all over-generated n-gram words to measure how serious the problem

KB Triple	S2ST	DSG-H	DSG	Gold
⟨Four Crowned Martyrs, genre, sculptural group⟩, ⟨Nanni di Banco notable_work, Four Crowned Martyrs⟩	The Four Crowned Martyrs (also known as the Four Crowned Martyrs) is a sculptural group four by Nanni di Banco.	"Four Crowned Martyrs" a sculptural group Nanni di Banco.	Four Crowned Martyrs is a sculptural group by Nanni di Banco.	Four Crowned Martyrs is a sculptural group by Nanni di Banco.
⟨Newfoundland and Labrador Route 341, located_in, Newfoundland and Labrador⟩	Route 341 is a rural road in the Canadian province of Newfoundland and Labrador.	Route 341 a Canadian of Newfoundland and Labrador.	Route 341 is a settlement in Newfoundland and Labrador.	Route 341 is located in in Newfoundland and Labrador.
⟨Gaius Helen Mohiam, creator, Frank Herbert⟩, ⟨Gaius Helen Mohiam, instance_of, fictional character⟩, ⟨Dune universe, creator, Frank Herbert⟩, ⟨Dune universe, instance_of, fictional universe⟩, ⟨ Gaius Helen Mohiam, from_fictional_universe, Dune universe⟩	Gaius Helen Mohiam is a fictional character appearing in American comic books published by Frank Herbert.	Gaius Helen Mohiam is a fictional character created by Frank Herberfor the Dune univer.	Gaius Helen Mohiam is a fictional character in the Dune universe stationed by Frank Herbert.	Gaius Helen Mohiam is a fictional character in the Dune universe created by Frank Herbert.

Table 5: Case study. The red font stands for over-generated words while the blue underline indicates incoherent parts.

is. For generated sentences, we first remove all stopwords and check whether each of the remaining words appears in the given input KB triple. If it is not contained in the KB triple, we will count it as an over-generated word. The statistics are shown in Table 3. It can be observed that the DSG-H has minimal over-generated words. This is because it directly drops all the possible over-generated words in the training. It gets the lowest over-generated words count at the cost of making the result less human-readable and thus has lower scores in other metrics like BLEU, etc. Our proposed DSG model outperforms all other models without significantly losing readability indicating that our proposed framework directly helps alleviate the over-generation problem.

Dataset Size Analysis. In order to explore whether our framework is capable of working on small datasets, we conduct a dataset size analysis. The results are shown in Table 4. It can be concluded that as the data size increases, all the performance of models with or without supportiveness improve noticeably. It shows that increasing data size help improve the overall scores. On the other hand, models assembled with supportiveness scores always outperform models without it. It shows that our novel architecture alleviates the over-generation problem at all scales of data size.

Human Evaluation. We conduct a human evaluation to eval the generation performance. We sample 130 samples from each model's generated sentences and ask human helpers to give an overall score and a match score with respect to the target sentences ranging from 1 to 10. The results are illustrated in Table 6. It can be concluded from the experiment that the DSG model generates better sentences in the sense of humans.

	Overall	Match
S2ST	7.315	7.231
DSG-H	7.285	7.331
DSG	7.377	7.569

Table 6: Human evaluation.

Case Study. We provide a case study for several models. As shown in Table 5, The S2ST model is always generating text accompanied with over-generated content while our proposed DSG model alleviates this problem significantly and consistently. When comparing the DSG-H model with the DSG model, we can find that the DSG-H model can also avoid producing over-generated content. However, it tends to remove a lot of correct words making the sentence incoherent and unreadable. Take the last case for example: The S2ST model conveys that Gaius Helen Mohiam comes from an American comic book. However, the given input KB triple does not mention this fact. On the other hand, the DSG-H model produces " *... created by Frank Herberfor the Dune univer ...* " which is even not a human-readable sentence.

5 Related Works

During the past few years, many tasks have been proposed to generate human-readable text from the structured data. WebNLG (Gardent et al., 2017a,b; Ferreira et al., 2019) is proposed to describe KB triples sampled from DBPedia (Auer et al., 2007).

The E2E (Novikova et al., 2017; Dušek et al., 2020) task is proposed for generating restaurant reviews based on the given attributes. Lebret et al. (2016) propose the Wikibio task to generate people's biography based on given Wikipedia infobox. Fu et al. (2020a) propose to generate text based on event chains. Moreover, Liang et al. (2009) propose to generate weather reports for weather records and Wiseman et al. (2017), Chen and Mooney (2008) and Puduppully et al. (2019) propose to generate a match report according to the match briefing. All these datasets are restricted to a few domains where well-aligned data is happened to be available. No existing works are focusing on handling partially-aligned data. To solve the dataset scarcity problem, Fu et al. (2020c) propose to use dual learning to train generation models based on unaligned text and knowledge triples. The model generates text based on input triples and then predict the input triples with a dual extraction model. The two models are trained alternatively with dual learning. Although Cheng et al. (2020) proposed the ENT-DESC task aiming at generating better text description for a few entities by exploring the knowledge from KB, their focus is more on distilling the useful part from the input knowledge.

Text aligning has been studied for many years. Dyer et al. (2013) propose the Fast Align model which is a log-linear reparameterization of IBM Model 2. Legrand et al. (2016) propose a new score aggregation method to improve the alignment result. Moreover, attention-based models (Bahdanau et al., 2014) can also be recognized as a kind of alignment. However, these models focus on aligning source words to target words, and no existing models have been proposed to directly calculate supportiveness for generation tasks. In generation systems, Fu et al. (2020b) propose to dynamically align the current generation state with topics to improve the generation performance. However, it still can not directly align to the input source words.

6 Conclusions

In this work, we propose a new task, namely, partially-aligned Data-to-Text generation, in which we generate human-readable text based on automatically produced training data. This task is more practical and extensible to any domains. We propose a distant supervision generation framework that tackling the task. The experimental results show that our proposed model solves the over-generation problem effectively and outperforms all baseline models. Moreover, we contribute a partially-aligned dataset WITA produced by our novel automatically annotating framework which is suitable for this new task.

Abstract

Existing persona-grounded dialog models often fail to capture simple implications of given persona descriptions, something which humans are able to do seamlessly. For example, state-of-the-art models cannot infer that interest in hiking might imply love for nature or longing for a break. In this paper, we propose to expand available persona sentences using existing commonsense knowledge bases and paraphrasing resources to imbue dialog models with access to an expanded and richer set of persona descriptions. Additionally, we introduce *fine-grained* grounding on personas by encouraging the model to make a discrete choice among persona sentences while synthesizing a dialog response. Since such a choice is not observed in the data, we model it using a discrete latent random variable and use variational learning to sample from hundreds of persona expansions. Our model outperforms competitive baselines on the PERSONA-CHAT dataset in terms of dialog quality and diversity while achieving persona-consistent and controllable dialog generation.

1 Introduction

Persona-grounded dialog generation is a 'chit-chat' dialog setup where a dialog agent is expected to communicate based on a given profile (Zhang et al., 2018). Many recent works have focused on a popular benchmark dataset for this task: PERSONA-CHAT (Zhang et al., 2018) that provides personas as a set of sentences along with each dialog (example in Figure 1). However, a careful analysis of state-of-the-art (SOTA) models reveals that they often struggle to respond to contexts that do not closely match given persona sentences, even when the implications might be obvious to a human.

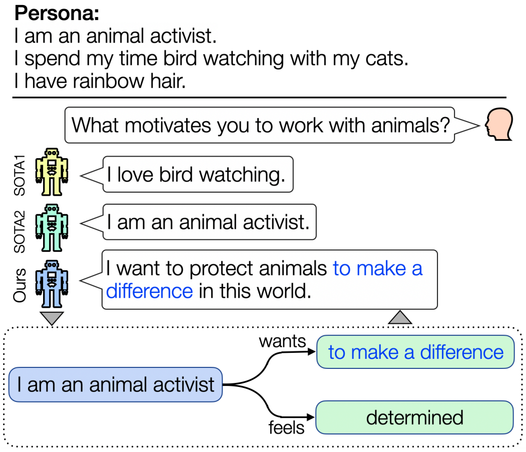

Figure 1: State-of-the-art models struggle to respond a user's query, where generating an engaging response depends on commonsense reasoning.

For example, in Figure 1, the user asks an *indirect* question to the bot related to one of its persona sentences: *I am an animal activist*. SOTA1, which concatenates all persona sentences with dialog history and finetunes a pre-trained generative model (e.g. GPT2) (Wolf et al., 2019), fails to infer implied commonsense from the dialog context and conditions on an incorrect persona. SOTA2, which separately selects a persona sentence given the dialog history (Lian et al., 2019) manages to choose the correct persona but merely copies it as the final response. Neither approach is in general capable of responding to context that goes beyond what is explicitly mentioned in the available persona sentences, which limits consistent and interesting conversation. The goal of our model is to understand that being 'an animal activist' may imply that the person wants 'to make a difference' via their activity towards animals and synthesizes a context-consistent and engaging response.

In this paper, we focus on making persona-grounded chatbots more consistent with personas and implicit dialog context. We present a framework to expand available persona sentences to their commonsense implications by using an existing

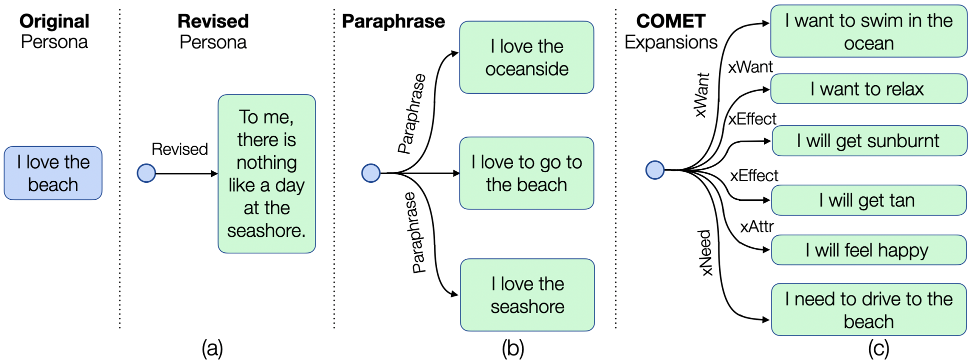

Figure 2: Expansions of an original persona via (a) human rewrite (2018), (b) paraphrase, and (c) COMET.

commonsense knowledge base or paraphrasing resources (see Section 3). We endow our dialog model with these expansions directly rather than requiring the model to learn them from scratch for being context-consistent. We find that expansions derived from a commonsense knowledge base are more useful to provide engaging contextual information compared to other expansion sources.

We further propose a **Com**mon Sense and **P**ersona **A**ligned **C**hatbot[1] (**COMPAC**) which models choices over the *expanded* persona set via a discrete latent random variable (See Section 4) as *fine-grained* persona grounding. Even though it is tractable to marginalize over all expansions, that would require a forward pass through the dialog generator for each outcome which is prohibitively slow during training. Instead, to accommodate hundreds of persona expansions, we train the model by optimizing a lower bound on the log-likelihood. We use amortized variational inference by approximating the true posterior using an inference network that eventually provides useful inductive bias. Particularly, we show that our Bayesian formulation for the fine-grained persona grounding was essential as simply providing expanded knowledge does not help the model generate better responses.

We also outperform competitive baselines in all dialog quality metrics as well as human evaluations which find COMPAC to be engaging and coherent. We demonstrate that COMPAC learns to be consistent with the dialog context with accurate persona grounding especially in the presence of commonsense expansions. Finally, we show that our model can reflect a change in response generation when a grounding persona is modified, indicating the possibility of controllable generation.

2 Persona Grounded Dialog

We use a popular benchmark dataset: PERSONA-CHAT (Zhang et al., 2018) for our persona-grounded dialog generation task. It contains 10,907 dialogs between pairs of speakers where each speaker follows their own persona; 968 dialogs are used for validation and 1,000 for testing. Each speaker is described by 3-5 persona sentences. (e.g. 'I love the beach', 'My mother is a medical doctor'). Out of 1,155 total unique personas, 100 are used for validation and 100 for testing.

The task of persona-grounded dialog generation is: given a dialog history H and grounding persona sentences S, we must predict the next utterance x (Summary of notations in Table 1). Hence a dialog model should maximize the likelihood $p(x|H, S)$. From the PERSONA-CHAT dataset, we use 131,438 utterances for training the dialog model, 15,602 for validation, and 15,024 for testing.

3 Persona Expansion

Persona sentences used in persona-grounded dialogs are instances of world events that often imply real-world consequences or richer information. For example, 'I love surfing' naturally implies that the person might be 'adventurous' or 'loves the outdoors'. Similarly, it also means that the person wants 'to go to the beach' regularly. Inferring these *expansions* from the original fact is non-trivial without additional commonsense knowledge.

Zhang et al. (2018) found evidence that having human written interpretations of a persona sentence via rephrasing often helps in providing novel information in persona grounding. While obtaining such expansions by manual rewriting is expensive, here we explore two automatic ways to generate them at scale and separately evaluate them on the downstream dialog modeling task.

---

[1] Code is available at – `https://github.com/majumderb/compac`.

3.1 COMET

COMET (Bosselut et al., 2019) is a framework that generates rich and diverse commonsense expansions of a given world event. It is a finetuned version of a pre-trained GPT2 (Radford, 2018) model on a pre-existing commonsense knowledge graph such as ATOMIC (Sap et al., 2019) that can generate novel nodes (events) and edges (relations), as seen in Figure 2c. Specifically, ATOMIC provides tuples that belong to nine relation types spanning over cause-effect interrelations between events: `oEffect`, `oReact`, `oWant`, `xAttr`, `xEffect`, `xIntent`, `xNeed`, `xReact`, and `xWant`—where a prefix '`x`' indicates an effect or cause on the person and '`o`' denotes the same on others. While we tried COMET finetuned on an alternative commonsense knowledge base (e.g.) ConceptNet, not all of the expansions were appropriate to describe a persona, mainly because we observe that persona sentences are *event*-like ('I love to go to the beach') as opposed to *concepts* such as 'beach'. For more details on COMET and ATOMIC we refer the reader to (Bosselut et al., 2019) and (Sap et al., 2019) respectively.

We use the COMET framework to generate expansions for each persona sentence along the nine relation types that ATOMIC provides. We obtain different samples while decoding via beam search from COMET for more diverse and unique expansions, as shown in Figure 2c. We preprocess these expansions to add suitable prefixes to make them similar to the original persona. For example, expansions relating to `xWant` and `xAttr` are prefixed with 'I want' and 'I am' respectively. For each persona sentence, we generate 5 expansions per relation, i.e., in total we will obtain $5 \times 9 = 45$ expansions per persona sentence.

3.2 Paraphrasing

To explore alternative sources for generating commonsense expansions beyond COMET, we consider paraphrasing persona sentences. Paraphrases of a sentence convey almost the same meaning to a listener as the original. Often paraphrases use synonymous phrases or manipulate word-syntax of the original sentence, which implicitly involves both context comprehension and world knowledge (Zeng et al., 2019). We obtain these in two ways:

Paraphrase Network To generate paraphrases at scale, we use an off-the-shelf paraphrasing system based on back-translation (Xie et al., 2019; Federmann et al., 2019) with pre-trained language translation models. We make use of `En-Fr` and `Fr-En` pre-trained translation models as the components for back-translation.[2] While we tried other language pairs, the `En-Fr` pair proved the most satisfactory based on qualitative analysis on 500 samples. We generate 5 paraphrases per persona sentence, which readily provides more lexical and syntactic variants as shown in Figure 2b.

Manual Paraphrasing To compare with other expansions, we reuse manually written revised versions of persona sentences provided with PERSONA-CHAT (Zhang et al., 2018) though these are limited to only one paraphrase per sentence. We call them **revised** for short (see Figure 2a).

4 Common sense and Persona Aligned Chatbot (COMPAC)

To infuse commonsense context in persona-grounded dialog generation, we imbue our dialog model with the expanded persona set instead of only original personas S. But these persona expansions lead to hundreds of new sentences as opposed to only a few given persona sentences which makes it infeasible to encode using a single transformer, as was done in prior works (Wolf et al., 2019). Additionally, encoding all persona sentences as a single text input leads to a lack of interpretability i.e., it is not clear which persona sentence was used by the model in generating a particular response.

Instead, we propose **COMPAC**: **Com**mon Sense and **P**ersona **A**ligned **C**hatbot that allows us to make a *fine-grained* choice of a persona sentence to generate the target response. Let C denote a list of expended personas, derived from S (including S itself). We further add a null persona $\varnothing$ in C considering that some utterances can purely condition on the dialog context. We are interested in modeling the conditional $p(x|H, C) = p(z|H, C)p(x|z, H, C)$ where $z \in \{1, 2, \ldots, |C|\}$ is a latent discrete random variable, unobserved in the data. Given the dialog history H, first we sample a particular persona sentence C_z from a *prior network* $p_\theta(z|H)$ (see Figure 3). Next, as depicted in Figure 3, the dialog response x is sampled from a *generator network* $p_\phi(x|H, C_z)$ by conditioning on the history H and chosen persona sentence C_z.

In the above described generative model, the latent variable z is a discrete random variable which

θ	Parameters for prior network $p_\theta(z\|H, C)$
ϕ	Parameters for generator network $p_\phi(x\|H, C_z)$
α	Parameters for inference network $p_\alpha(z\|x, H, C)$

Table 1: Summary of notation used in the paper

points to a single persona sentence. This decision was based on the observation that most dialog responses in the datasets under consideration are relevant to only one persona sentence. It is possible to allow for multiple persona sentences by defining z to pick a subset of $|C|$ persona sentences instead of picking a single sentence. We leave this as a possible future extension.

4.1 Persona Choice Prior

The dialog history H can hold cues regarding which persona sentence might be applicable given the context. For example, in Figure 3 the historical context suggests that 'following fashion trends' can be a consequence of 'being fashionable'.

We encode both the dialog history H and persona sentence C_k by averaging RoBERTa subword embeddings (Liu et al., 2019) as $e(H)$ and $e(C_k)$. We use an implementation from HuggingFace for RoBERTa[3] with `roberta-base` as the pretrained model. Then we parameterize the prior $p_\theta(z|H, C)$ as a log-linear model with the following features:

Dialog history We obtain $f_1(H, C_k)$: a scalar feature using a bilinear product $\langle e(H), e(C_k)\rangle$ to align the persona sentences with the dialog history.

Expansion types Each k-th persona expansion corresponds to an expansion type t_k. In the case of COMET, these types are the nine commonsense relations provided by ATOMIC (see Section 3.1). For paraphrased expansions, we annotate each as type `paraphrase` and the original persona sentences as `original`. We consider two additional features with expansion types: (a) $f_2(t_k)$ that represents a global preference over the relation type embedded via a type embedding layer; and (b) $f_3(t_k, H)$ that appends the expansion type embedding with dialog history encoding $e(H)$, followed by a linear layer to obtain a real-valued score for history-specific preference over the expansion type.

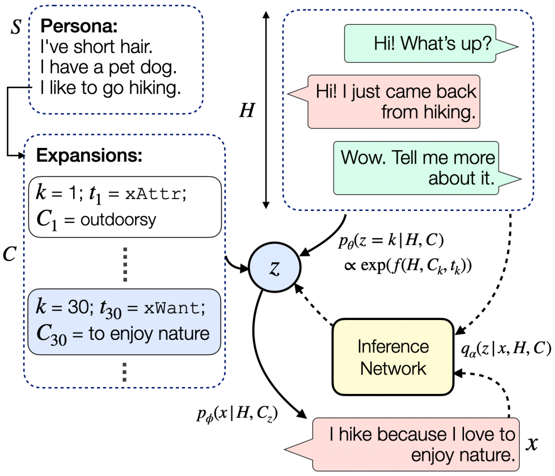

Figure 3: COMPAC samples a persona sentence from the prior and generates the response conditioned on the dialog context and sampled persona. The inference network is used only during training.

The dimension of the expansion type embedding was set to 5. Finally, the prior model can be represented concisely as $p_\theta(z = k|H, C) \propto \exp(f(H, C_k, t_k))$, where $f(H, C_k, t_k)$ is the sum $\lambda_1 * f_1(H, C_k) + \lambda_2 * f_3(t_k) + \lambda_3 * f_3(t_k, H)$ with λ_i's as trainable parameters.

4.2 Generator Network

Following prior work (Wolf et al., 2019), we use pre-trained GPT2 (Radford, 2018) (Transformer with 12 layers, 768 hidden size, 12 heads— `gpt2-small`[4]) to generate dialog responses given the dialog history H, with the selected persona sentence C_z prepended to it. In the case of C_z being the null persona, an empty string is prepended. We further append the target response x to the combined context $(C_z; H)$, and feed the sequence to GPT2, after tokenization. To distinguish between persona tokens, history tokens, and target response tokens, we use segment indicators—{`Persona`, `Speaker1`, `Speaker2`}—for which corresponding embeddings are learned via a separate segment embedding layer in the model. We add the segment embedding to the corresponding token embedding in the model input layer. To obtain the conditional likelihood $p_\phi(x|H, C_z)$, we only consider the target tokens for cross-entropy loss calculation.

---

[3] `https://huggingface.co/transformers/model_doc/roberta.html`

[4] `https://github.com/huggingface/transfer-learning-conv-ai`

Wolf et al. (2019) also leveraged incorrect responses given a dialog history from PERSONA-CHAT as negative samples in an auxiliary loss to encourage the correct candidate to obtain the highest likelihood compared to the incorrect ones. However, we did not find any improvement using this loss in COMPAC.

4.3 Learning and Inference

Our training data $\mathcal{D}$ consists of instances of dialog history H and ground truth dialog responses x. We train our model parameters θ and ϕ to maximize the likelihood of the target dialog response x given the dialog history: $\log p(x|H, C; \theta, \phi)$ totalled over $\mathcal{D}$. Since the discrete random variable z is unobserved in the training data, we must marginalize over z to compute the desired likelihood $p(x|H; \theta, \phi)$:

$$\log p(x|H; \theta, \phi) = \log \mathbb{E}_{z \sim p_\theta(z|H)}[p_\phi(x|z, H)];$$

where we drop C from the conditionals for simplicity.

Inference Network Note that the number of persona expansions is typically in the range 150-250, and thus it is computationally expensive to marginalize over the entire selection space of z during training. We instead optimize a variational lower bound (ELBO) of $\log p(x|H; \theta, \phi)$ given as

$$\mathbb{E}_{z \sim q_\alpha(z|H)}[\log p_\phi(x|z, H)] \\ - KL(q_\alpha(z|x, H)||p_\theta(z|H)),$$

where we use the inference network $q_\alpha(z|x, H)$ to compute the approximate posterior (Kingma and Welling, 2014). In our initial experiments, we observe that using an inference network leads to better perplexity values than using samples from the prior.

The architecture of the inference network is similar to that of the prior network, a log-linear model. Along with the features related to dialog history and expansion types, we additionally include another scalar feature: a bilinear product $\langle x, C_k \rangle$ between the encoded persona and ground truth response x encoded with RoBERTa embeddings to align the persona choice according to the target utterance.

Optimization The parameters of the generator network (ϕ) and prior network (θ) can be trained directly via back-propagation. Since z is a discrete latent variable, we use REINFORCE (Williams, 1992) to train the inference network parameters α. However, the REINFORCE estimator often suffers from high variance. To reduce the variance, we found it useful to (1) use a moving average baseline (Zhao et al., 2011); and (2) regularize the prior network by penalizing the entropy of the output categorical distribution. To avoid KL mode collapse, we use KL-annealing (Bowman et al., 2016) where we linearly increase the weight of the KL term beginning from 0 to 1 as training progresses.

Decoding At decoding time, we first sample k from the prior $p_\theta(z|H, C)$, and then C_k is fed to the generator network. Following previous work (Wolf et al., 2019), we use nucleus sampling (Holtzman et al., 2020) (with $p = 0.95$) to decode the final response from the probabilities produced by the generator. We also found that high-temperature sampling from the prior often leads to more diverse generation.

5 Experiments

We conduct our experiments based on the following desiderata: (1) Do persona expansions help to generate high quality and diverse responses? (2) Does COMPAC achieve accurate persona grounding given a dialog context? (3) Does COMPAC enable persona-consistent and controllable generation? Hyperparameter details are in Appendix §A.

5.1 Baselines

To demonstrate the efficacy of COMPAC, we compare it with three competitive baselines on the PERSONA-CHAT dataset:

1. **Per-CVAE:** A CVAE model that exploits persona sentences for diverse generation with an external memory (Song et al., 2019b)
2. **LIC + KS:** The best performing transformer model (Lost in Conversation i.e., LIC) in terms of human evaluation in the ConvAI2 NeurIPS competition (Dinan et al., 2019a) combined with a knowledge-selection (KS) mechanism Lian et al. (2019) to achieve state-of-the-art results on PERSONA-CHAT;
3. **GPT2:** Finetuned GPT2 on PERSONA-CHAT just by concatenating all persona sentences along with dialog history (Wolf et al., 2019) to obtain the best automatic metric in the ConvAI2 competition.

System	PPL	BLEU-1	BLEU-2	D-1	D-2
Original					
Per-CVAE (2019b)	48.37	0.19	0.11	0.03	0.21
LIC + KS (2019)	30.50	0.18	0.07	0.07	0.24
GPT2 (2019)	21.46	1.42	0.78	0.05	0.11

Engagement	**90.5***	3.3	**87.4**	5.9	**97.6***	0.5	**86.5***	10.5	**81.5***	10.5	**62.1***	30.5
Relevance	**78.2***	4.8	**78.0***	7.7	**93.2***	1.8	**65.5***	18.5	**62.1**	15.6	32.8	**54.6***

Table 4: Pairwise comparison between responses generated by COMPAC vs. responses generated by other baselines (og: original, par: paraphrase) as well as the Gold response. All numbers are in percentages with **bold** indicates the highest. Ties are not shown. Entries with * denote significance with $p < 0.05$ from bootstrap tests on 1000 subsets of size 50.

A minimal version of COMPAC is also considered, **COMPAC-original**, which only uses the original persona, for a direct comparison with other model architectures that only use the original persona. Furthermore, to justify the choice of fine-grained persona grounding for an effective utilization of persona expansions, we also consider baseline versions of GPT2 trained with each of the expansion strategies: **GPT2-revised**, **GPT2-paraphase**, and **GPT2-COMET**. To show that COMPAC can work with persona expansions derived from various sources, we compare with versions of COMPAC trained with paraphrase-based expansions: **COMPAC-revised** and **COMPAC-paraphrase**. By default, COMPAC indicates it is trained with COMET expansions.

5.2 Comparison of Dialog Quality

We measure perplexity for language modeling performance, and BLEU-1 (Papineni et al., 2002) and BLEU-2 (Vedantam et al., 2015) scores between generated and gold utterances to measure the fidelity of the generated responses. Given our goal of generating engaging responses with novel information, we deem it important to consider the diversity in the generated responses which we measure using D-1 and D-2 (percentage of distinct uni- and bi-grams respectively) (Li et al., 2016).

Table 2 shows that COMPAC outperforms three competitive baselines when trained on the original persona in all quality metrics indicating the efficacy of our architecture. Moreover, when combined with persona expansions, we observe a modest 3-8 point decrease in perplexity and a large improvement in both BLEU and diversity scores which confirms that COMPAC successfully leverages the persona expansions to improve dialog quality. COMPAC trained with COMET expansions achieves the best performance both in terms of fidelity and diversity which shows that COMET expansions help the model to respond to implicit context with commonsense and to explore novel information. But with revised personas, we find that both COMPAC and GPT2 provide marginal performance gains, mirroring the observation from (Zhang et al., 2018). Finally we observe gradual degradation in performance when we trivially finetune GPT2 with paraphrase and COMET expansions. Note that GPT-2 could have implicitly learned to focus on a single persona attribute. However, the proposed COM-

PAC model performs better suggesting that fine-grained persona grounding acts as a useful inductive bias in effectively utilizing larger expansion sets.

5.3 Human Evaluation for Dialog Generation

Automatic evaluation of dialog systems is still notoriously unreliable (Liu et al., 2016; Novikova et al., 2017) and such systems should be evaluated by human users. Hence, we perform pairwise comparisons between responses generated our best system, COMPAC trained on COMET expansions, and responses generated by four strong baselines: GPT2, GPT2-COMET, COMPAC-original, COMPAC-paraphrase (the best COMPAC model with paraphrase expansions). We also consider the gold responses for comparison. We conduct a human evaluation with 100 test examples on three aspects critical for practical use: (1) **Fluency** measures whether the generated output is fluent (in English); (2) **Engagement** measures whether the generated response is engaging or interesting; and (3) **Relevance** measures whether the generated output is relevant with respect to the dialog history. More details of the evaluation are in Appendix §B.

Table 4 shows that human annotators found responses generated by COMPAC trained with COMET expansions more engaging as compared to responses from all the baselines as well as the gold responses by statistically significant margins. This confirms our hypothesis that COMET expansions were helpful in adding novel content. Human judges also found that despite a significant drop in perplexity, COMPAC was not more fluent than COMPAC-original and COMPAC-paraphrase with statistical significance, indicating similar language modeling performance. We find the inter-annotator agreement, as measured by Cohen's kappa (Cohen, 1960), for fluency, engagement, and relevance were 0.62, 0.71, and 0.73 respectively.

5.4 Fine-grained Persona Grounding

Next we want to investigate the extent of COMPAC's ability to ground the response generation with a fine-grained persona choice as a probing experiment. Specifically, we want to measure whether our model can choose a coherent persona from the available persona sentences given the dialog context. Note that in persona-grounded chitchat, not all utterances are tied to a personas and could be purely based on dialog context. We find that 44% of the time the model selects the null persona (∅) and conditions only on the dialog history. To assess the persona grounding for the remaining (56%) utterances, we perform (a) a persona entailment experiment, and (b) human evaluation.

System	Persona Entailment		Human
	Prior	Inference Network	eval.
Original			
COMPAC-original	25.5	79.3	–
Paraphrased			
COMPAC-revised	20.6	78.9	40.6
COMPAC-paraphrase	27.8	87.3	67.8
COMET			
COMPAC	**37.9**	**96.4**	**87.3**

Table 5: Assessment of persona grounding with and without inference network using the DNLI entailment set. Human evaluation (eval.) was conducted to measure the relevance when an expanded persona is chosen–all entries are statistically significant.

Persona Entailment We adapt the Dialogue Natural Language Inference (DNLI) dataset (Welleck et al., 2019) and collect persona-utterance pairs that belong to an *entailment* relation. This results in a subset of 4,613 utterances with associated ground truth persona sentences in our test set. Next, we obtain a persona sentence by performing argmax over the prior $p_\theta(z|H, C)$ as well as the inference network $q_\alpha(z|x, H, C)$ from our COMPAC models and calculate accuracy with the ground truth persona. For models that use expanded personas, we track the original persona from the retrieved expansion for accuracy calculation. Table 5 shows that COMPAC with COMET achieves the most accurate persona grounding suggesting that inference networks can approximate the true posterior better when a commonsense persona is available for grounding. In the case of the prior, a better entailment accuracy than random chance $(1/5)$ confirms our choice of the history-conditioned prior network rather than a uniform prior.

Human Evaluation Since DNLI does not entail expanded personas, we conduct a human evaluation to judge the relevance of a chosen persona *expansion* sampled from the inference network. Specifically, we ask: *Is this knowledge relevant to the given dialog history?*—with options as 'Yes', 'No', and 'Uncertain'—and with 100 examples (more in Appendix §B) for each COMPAC variant that uses expanded personas. The inter-annotator agreement, as measured by Cohen's kappa was 0.76. Again, Table 5 shows that models with COMET

System	Unigram Overlap Recall	Precision	F1	BERT Score
Original				
LIC + KS (2019)	10.4	34.2	15.3	–
CompAC-original	14.9	39.1	21.6	57.2
Paraphrased				
CompAC-revised	15.2	40.3	22.1	58.1
CompAC-paraphrase	17.8	42.2	25.1	72.9
COMET				
CompAC	**21.4**	**48.9**	**29.8**	**78.8**

Table 6: Conditional generation performance on the Persona-Chat test set to show the similarity between generated responses and grounding persona sentences. We omit GPT2-based models since they do not select a particular persona sentence for grounding.

Performance	Example
Presence of changed entity **86%**	**Changing the key entity** Before: My favorite color is red After: My favorite color is **green**
	Conversation: User: What is your favorite color? Bot: My favorite color is **green**
BERT score with unedited persona: 46.2 edited persona: **74.6**	**Swapping with another expansion** Before: I want to swim in the ocean After: I want to buy a beach **umbrella**
	Conversation: User: What do you do at beaches? Bot: I will buy an **umbrella** at the beach

Table 7: Controlled generation with edited persona

expansions can choose the most relevant persona sentence which corroborates our claim in persona entailment experiments. On average, we noticed that CompAC with COMET expansions prefers to choose expanded personas 87% of the time out of all non-null persona choices. This reduces to 62% in the case CompAC-paraphrase. In contrast, CompAC-revised tends to select an original persona over an expansion more often.

5.5 Controllable Generation

Controllable generation of persona-grounded dialog can help to generalize the dialog agent to newer persona details just by changing the grounding in the conditional generator. While controllable text generation with a desired attribute has gained interest recently (Dathathri et al., 2020; Kong et al., 2019), we investigate the possibility of controlling generation with a desired persona and measure the performance of the conditional generator. For this, we observe a set of knowledge overlap metrics—the unigram recall/precision/F1 scores–from Dinan et al. (2019b) and BERT score (Zhang et al., 2020) for semantic similarity between the generated responses and the persona retrieved. Table 6 shows that conditional generation is strongest when CompAC is trained with COMET suggesting commonsense expansions are more appropriate to the dialog context in influencing the response generation.

Next, we create a diagnostic dataset of 100 examples where we manually edit the persona by changing an entity in a persona sentence or swapping the selected persona expansion with another relevant one (See examples in Table 7) to directly measure controllability in response generation. We observe that CompAC can successfully reflect the entity-change in the generated response based on the change in the persona grounding 86% of the time. For a swapped persona expansion, we also see a higher BERT score (74.6) between the edited persona and newly generated response as opposed to a lower score (46.2) with the unedited persona. Together with the qualitative examples in Table 7 this suggests that CompAC supports controllable generation with contextually modified personas.

5.6 Qualitative Analysis

Table 3 shows responses from different models for a sample dialog context. Qualitatively, we find that CompAC with COMET expansions responds to the context with commonsense using novel content from a commonsense expansion (being Hindu → to learn about Hinduism), where other responses remain generic or incoherent. In Table 8, we illustrate responses generated by the CompAC model along with the underlying persona choice sampled from the prior network. Cases show that CompAC successfully chooses an original or an expanded persona sentence, as appropriate, but also defaults to the null persona ($\varnothing$) that leads to a bland response.

6 Related Works

Building personalized dialog agents has been a popular task recently, thanks to Zhang et al. (2018) who extensively studied the task with a new dataset Persona-Chat, later as a form of a challenge (Dinan et al., 2019a), where the dialog agent is seeded with a predefined persona in the form of multiple sentences of textual description, mirroring a casual human conversation which many times draws snippets from individual personal experiences and facts. Recent works focus on improving

Verdict	Persona	Dialog History	Persona Choice (z)	Response
Uses Original Persona	1. I'm the youngest of five. 2. I work at the hospital as a nurse. 3. I've pink hair.	What do you do for work?	I work at the hospital as a nurse.	I am a nurse.
Uses Expanded Persona	1. I just want to have fun with my friends. 2. I don't drink or do drugs or anything. 3. I am 19 and I cannot wait to move out of my parents home.	Are you enjoying life?	I just want to have fun with my friends → wants to have a party	Not really. I want to have a party.
Uses Improper Persona	1. I make a million dollars a year. 2. I'm married and have three kids. 3. I'm a baseball player.	I find it hard to support my family working at a bar. What about you?	Null persona (∅)	I enjoy my life.

Table 8: Examples showing correct and incorrect persona choices in various dialog contexts by COMPAC model. It shows that COMPAC is capable of choosing a correct persona sentence (original or expanded) but sometimes the prior network fails to sample an appropriate one (third case).

persona-grounded dialog generation performance (Wolf et al., 2019; Mazaré et al., 2018; Bao et al., 2019) as well as persona consistency in generated dialog (Welleck et al., 2019; Li et al., 2019; Song et al., 2019a). Bao et al. (2019) proposed a reinforcement-learning-based framework that promoting informativeness and persona-consistency via personal knowledge exchange. Xu et al. (2020) focused on using plausible topical keywords related to the available persona facts using a neural topic model to explore beyond the given knowledge, possibly closest to our work. We rather focus on obtaining commonsense implications of the given persona in the form of text snippets that are more expressive than topical keywords.

Persona-grounded dialog generation is a special case of knowledge-grounded dialog generation. Knowledge grounding in dialog has many real-world applications that are well-studied in recent literature (Zhou et al., 2018; Ghazvininejad et al., 2018; Dinan et al., 2019b; Lewis et al., 2019). In this work we use fine-grained grounding/selection on persona which performed better than encoding the entire persona for each response. Such fine-grained selection has been found useful in prior works on text generation such as dialog (Lian et al., 2019), image captioning (Jhamtani and Berg-Kirkpatrick, 2018; Wang et al., 2018), summarization (Gehrmann et al., 2018), etc. For dialog generation, a contextual knowledge selection that precedes the grounded dialog generation has been successfully applied in prior works (Parthasarathi and Pineau, 2018). Specifically, Zhao et al. (2017) and later Song et al. (2019b) proposed a conditional-VAE framework to learn latent context given the dialog history to guide knowledge selection.

Finally, few recent works focused on augmenting grounding with commonsense knowledge with successful applications in open-domain topical dialog generation (Ghazvininejad et al., 2018; Moon et al., 2019), story generation (Mao et al., 2019) and sarcasm generation (Chakrabarty et al., 2020). In this work, we extend this effort into persona-grounded dialog generation via augmenting grounding persona with commonsense knowledge.

7 Conclusion

In this work, we showed that expanding persona sentences with commonsense helps a dialog model to generate high-quality and diverse persona-grounded responses. Moreover, we found that *fine-grained* persona grounding is crucial to effectively condition on a large pool of commonsense persona expansions, which further provided additional controllability in conditional generation.

While our expansions are limited by the performance of COMET or paraphrase systems, we envision future work to train the dialog model end-to-end along with the expansion generation. As future work, we would like extend the prior network to sample more than one persona sentences by expanding the sample space of the discrete random variable to generate more interesting responses.

A Implementation Details

We obtain the PERSONA-CHAT dataset from ParlAI repository[5]. For COMET expansions, we use the code[6] released by the authors of COMET (Bosselut et al., 2019). We performed BPE tokenization with the GPT2Tokenizer[7].

Network architectures For the generator network, we use GPT2 (Transformer with 12 layers, 768 hidden size, 12 heads— `gpt2-small`[8]) following the state-of-the-art model (Wolf et al., 2019) from Conv-AI2 competition. Wolf et al. (2019) also leveraged incorrect responses given a dialog history from PERSONA-CHAT as negative samples in an auxiliary loss to encourage the correct candidate to obtain the highest likelihood compared to the incorrect ones. However, we did not find any improvement using this loss in COMPAC. COMPAC has total of 164 Million parameters whereas GPT2 based baseline has 124 Million parameters.

Hyperparameters Following (Wolf et al., 2019) we use history size 2 (i.e. 4 previous utterances). We use AdamW optimizer (Loshchilov and Hutter, 2017) and the learning rate was set at $6.25e-5$ with a linear decay of step size 10^{-1} per epoch. The baseline in REINFORCE was done with a discounted moving average with a ratio of 0.99. The REINFORCE loss coefficient was set at 0.8 and the language modeling loss coefficient was set to 1.0.

[7] `https://huggingface.co/transformers/model_doc/gpt2.html`

[8] `https://github.com/huggingface/transfer-learning-conv-ai`

Training Each model converged in 3 epochs on an average with batch size 4 in a TITAN X (Pascal) GPU that took 12 hours in total. While training, we only observe perplexity on the validation set to employ an early-stopping criteria.

B Evaluation

Automatic Evaluation During dialog quality evaluation, perplexity is measured by adapting the official evaluation protocol from the Conv-AI2 challenge[9].

To assess persona grounding, we use Dialogue Natural Language Inference (DNLI) dataset (Welleck et al., 2019) that has persona-utterances pairs under three classes—entailment, neutral, and contradiction. We gather all the entailment pairs including all splits that resulted in 44,000 persona-utterance pairs. Then we map with the PERSONA-CHAT test set to obtain 4,613 utterances associated with a ground truth persona.

For assessing conditional generation performance, we use BERT score from the publicly available repository[10].

Human Evaluation For human evaluation, we hired two Anglophone (Lifetime HIT acceptance $\% > 80$) annotators for every human-evaluated test generation. Figure 4 shows a sample question for a human judge for the pairwise comparison of a response generated by COMPAC and a response generated by a baseline for three aspects—fluency, engagement, and coherence.

While measuring persona grounding, we used a similar setup where we provided a dialog history and a sampled expansion and asked 'Is this knowledge relevant to the given dialog history?'— with three options —'Yes', 'No', and 'Uncertain' (See Figure 5). Similar to the previous human evaluation study, we hired two Anglophone (Lifetime HIT acceptance $\% > 80$) annotators for each question. We find the inter-annotator agreement, as measured by Cohen's kappa was 0.76.

C Generation Examples

Tables 9 to 12 present generations from COMPAC for sampled dialog histories with comparison across baselines.

Persona:
I've short hair.
I have a pet dog.
I like to go hiking.

User: Do you follow current fashion trends?
GPT2 (2019)**:** Yes. What about you?
COMPAC-original: I have a pet dog.
COMPAC-revised: I think you really need to go shopping.
COMPAC-paraphrase: I like shopping.
COMPAC: Yes, I prefer to be fashionable.

Table 9: Sample generations by different models.

Persona:
I just want to have fun with my friends.
I don't drink or do drugs or anything.
I am 19 and I cannot wait to move out of my parents home.

User: Are you enjoying life ?
GPT2 (2019)**:** Yes! What about you?
COMPAC-original: Hey yes! I don't drink.
COMPAC-revised: Yes. I like to go out with friends.
COMPAC-paraphrase: I don't want to be alone.
COMPAC: Not really. I want to have a party.

Table 10: Sample generations by different models.

Persona:
I've rainbow hair.
I am an animal activist.
I spend my time bird watching with my cats.

User: What motivates you to work with animals?
GPT2 (2019)**:** I love bird-watching.
COMPAC-original: I love bird-watching. What about you?
COMPAC-revised: I love animals.
COMPAC-paraphrase: I am in love with animals.
COMPAC: I want to protect animals to make a difference in this world.

Table 11: Sample generations by different models.

Persona:
I'm always wearing a hat.
I've a broken arm.
My friends are all skateboarders.

User: Do you skate? I do.
GPT2 (2019)**:** Yes. How about you?
COMPAC-original: I wear a hat.
COMPAC-revised: Yes. My friends are skateboarders.
COMPAC-paraphrase: That's great. My friends are skateboarders.
COMPAC: My friends and I go to the park for skateboarding.

Table 12: Sample generations by different models.

Instructions (Click to collapse)

This task requires basic English language understanding.

For each instance, you will have to read the dialog history between two people **A** and **B**, and observe the two alternative responses **R1** and **R2**. We expect you to compare the two alternatives on:

1) English language Fluency: Which comment is more fluent?

2) Engaging: Which response do you think is more engaging/interesting?

3) Relevance: Which response do you think is more relevant to the history?

1.
Dialog History:
A's turn: I teach some of them how to play piano. They welcome the structure.
B's turn: I bet they do. my mom is a dentist and sometimes volunteers at the clinic.
A's turn: Very nice. My dad was a professional violinist.

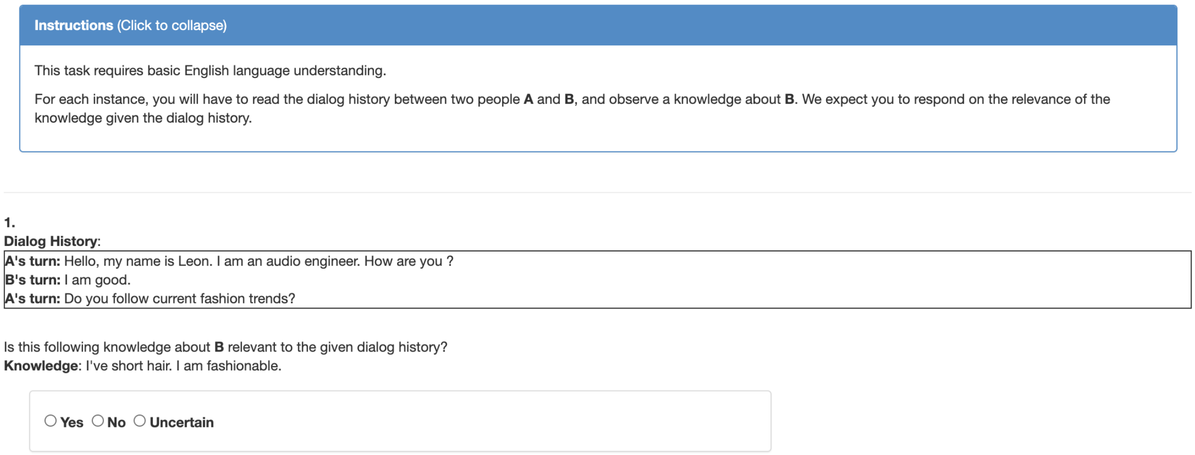
Alternatives for B's next turn:
Response R1: Wow! You have a family of musicians.
Response R2: My mom plays piano.

1.1 Considering English language fluency only, compare R1 and R2:
○ **R1 is better** ○ **Both have similar fluency** ○ **R1 is worse**

1.2 Which response do you think is more engaging/interesting?
○ **R1 is more engaging** ○ **Both have similar engagement level** ○ **R1 is less engaging**

1.3 Which response do you think is better in terms of relevance to the history?
○ **R1 is better** ○ **Both have similar fluency** ○ **R1 is worse**

Figure 4: Human evaluation for pairwise comparison between COMPAC and another baseline.



Instructions (Click to collapse)

This task requires basic English language understanding.

For each instance, you will have to read the dialog history between two people **A** and **B**, and observe a knowledge about **B**. We expect you to respond on the relevance of the knowledge given the dialog history.

1.
Dialog History:
A's turn: Hello, my name is Leon. I am an audio engineer. How are you ?
B's turn: I am good.
A's turn: Do you follow current fashion trends?

Is this following knowledge about **B** relevant to the given dialog history?
Knowledge: I've short hair. I am fashionable.

○ **Yes** ○ **No** ○ **Uncertain**

A Probabilistic End-To-End Task-Oriented Dialog Model with Latent Belief States towards Semi-Supervised Learning

Yichi Zhang[1], **Zhijian Ou**[1*], **Min Hu**[2], **Junlan Feng**[2]
[1] Speech Processing and Machine Intelligence Lab, Tsinghua University, Beijing, China
[2] China Mobile Research Institute, Beijing, China
`zhangyic17@tsinghua.org.cn`, `ozj@tsinghua.edu.cn`

Abstract

Structured belief states are crucial for user goal tracking and database query in task-oriented dialog systems. However, training belief trackers often requires expensive turn-level annotations of every user utterance. In this paper we aim at alleviating the reliance on belief state labels in building end-to-end dialog systems, by leveraging unlabeled dialog data towards semi-supervised learning. We propose a probabilistic dialog model, called the LAtent BElief State (LABES) model, where belief states are represented as discrete latent variables and jointly modeled with system responses given user inputs. Such latent variable modeling enables us to develop semi-supervised learning under the principled variational learning framework. Furthermore, we introduce LABES-S2S, which is a copy-augmented Seq2Seq model instantiation of LABES[1]. In supervised experiments, LABES-S2S obtains strong results on three benchmark datasets of different scales. In utilizing unlabeled dialog data, semi-supervised LABES-S2S significantly outperforms both supervised-only and semi-supervised baselines. Remarkably, we can reduce the annotation demands to 50% without performance loss on MultiWOZ.

1 Introduction

Belief tracking (also known as dialog state tracking) is an important component in task-oriented dialog systems. The system tracks user goals through multiple dialog turns, i.e. infers structured *belief states* expressed in terms of slots and values (e.g. in Figure 1), to query an external database (Henderson et al., 2014). Different belief tracking models have been proposed in recent years, either trained independently (Mrkšić et al., 2017; Ren et al., 2018; Wu et al., 2019) or within end-to-end (E2E) trainable dialog systems (Wen et al., 2017a,b; Liu and Lane, 2017; Lei et al., 2018; Shu et al., 2019; Liang et al., 2020; Zhang et al., 2020).

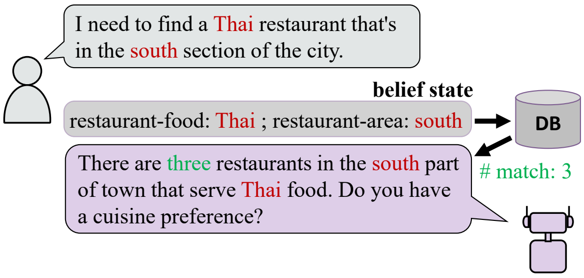

Figure 1: The cues for inferring belief states from user inputs and system responses. The system response reveals the belief state either directly in the form of word repetition (red), or indirectly in the form of the database query result (green) determined by the belief state.

Existing belief trackers mainly depend on supervised learning with human annotations of belief states for every user utterance. However, collecting these turn-level annotations is labor-intensive and time-consuming, and often requires domain knowledge to identify slots correctly. Building E2E trainable dialog systems, called E2E dialog systems for short, even further magnifies the demand for increased amounts of labeled data (Gao et al., 2020; Zhang et al., 2020).

Notably, there are often easily-available unlabeled dialog data such as between customers and trained human agents accumulated in real-world customer services. In this paper, we are interested in reducing the reliance on belief state annotations in building E2E task-oriented dialog systems, by leveraging unlabeled dialog data towards semi-supervised learning. Intuitively, the dialog data, even unlabeled, can be used to enhance the performance of belief tracking and thus benefit the whole dialog system, because there are cues from

user inputs and system responses which reveal the belief states, as shown in Figure 1.

Technically, we propose a latent variable model for task-oriented dialogs, called the **LA**tent **BE**lief **S**tate (LABES) dialog model. The model generally consists of multiple (e.g. T) turns of user inputs $u_{1:T}$ and system responses $r_{1:T}$ which are observations, and belief states $b_{1:T}$ which are latent variables. Basically, LABES is a conditional generative model of belief states and system responses given user inputs, i.e. $p_\theta(b_{1:T}, r_{1:T}|u_{1:T})$. Once built, the model can be used to infer belief states and generate responses. More importantly, such latent variable modeling enables us to develop semi-supervised learning on a mix of labeled and unlabeled data under the principled variational learning framework (Kingma and Welling, 2014; Sohn et al., 2015). In this manner, we hope that the LABES model can exploit the cues for belief tracking from user inputs and system responses. Furthermore, we develop LABES-S2S, which is a specific model instantiation of LABES, employing copy-augmented Seq2Seq (Gu et al., 2016) based conditional distributions in implementing $p_\theta(b_{1:T}, r_{1:T}|u_{1:T})$.

We show the advantage of our model compared to other E2E task-oriented dialog models, and demonstrate the effectiveness of our semi-supervised learning scheme on three benchmark task-oriented datasets: CamRest676 (Wen et al., 2017b), In-Car (Eric et al., 2017) and MultiWOZ (Budzianowski et al., 2018) across various scales and domains. In supervised experiments, LABES-S2S obtains state-of-the-art results on CamRest676 and In-Car, and outperforms all the existing models which do not leverage large pretrained language models on MultiWOZ. In utilizing unlabeled dialog data, semi-supervised LABES-S2S significantly outperforms both supervised-only and prior semi-supervised baselines. Remarkably, we can reduce the annotation requirements to 50% without performance loss on MultiWOZ, which is equivalent to saving around 30,000 annotations.

2 Related Work

On use of unlabeled data for belief tracking. Classic methods such as self-training (Rosenberg et al., 2005), also known as pseudo-labeling (Lee, 2013), has been applied to belief tracking (Tseng et al., 2019). Recently, the pretraining-and-fine-tuning approach has received increasing interests (Heck et al., 2020; Peng et al., 2020; Hosseini-Asl et al., 2020). The generative model based semi-supervised learning approach, which blends unsupervised and supervised learning, has also been studied (Wen et al., 2017a; Jin et al., 2018). Notably, the two approaches are orthogonal and could be jointly used. Our work belongs to the second approach, aiming to leverage unlabeled dialog data beyond of using general text corpus. A related work close to ours is SEDST (Jin et al., 2018), which also perform semi-supervised learning for belief tracking. Remarkably, our model is optimized under the principled variational learning framework, while SEDST is trained with an ad-hoc combination of posterior regularization and auto-encoding. Experimental in §6.2 show the superiority of our model over SEDST. See Appendix A for differences in model structures between SEDST and LABES-S2S.

End-to-end task-oriented dialog systems. Our model belongs to the family of E2E task-oriented dialog models (Wen et al., 2017a,b; Li et al., 2017; Lei et al., 2018; Mehri et al., 2019; Wu et al., 2019; Peng et al., 2020; Hosseini-Asl et al., 2020). We borrow some elements from the Sequicity (Lei et al., 2018) model, such as representing the belief state as a natural language sequence (a text span), and using copy-augmented Seq2Seq learning (Gu et al., 2016). But compared to Sequicity and all its follow-up works (Jin et al., 2018; Shu et al., 2019; Zhang et al., 2020; Liang et al., 2020), a feature in our LABES-S2S model is that the transition between belief states across turns and the dependency between system responses and belief states are well statistically modeled. This new design results in a completely different graphical model structure, which enables rigorous probabilistic variational learning. See Appendix A for details.

Latent variable models for dialog. Latent variables have been used in dialog models. For non task-oriented dialogs, latent variables are introduced to improve diversity (Serban et al., 2017; Zhao et al., 2017; Gao et al., 2019), control language styles (Gao et al., 2019) or incorporate knowledge (Kim et al., 2020) in dialog generation. For task-oriented dialogs, there are prior studies which use latent internal states via hidden Markov models (Zhai and Williams, 2014) or variational autoencoders (Shi et al., 2019) to discover the underlying dialog structures. In Wen et al. (2017a) and Zhao et al. (2019), dialog acts are treated as latent variables, together with variational learning and reinforcement learning, aiming to improve response generation. To the best of our knowledge, we are the first to model belief state as discrete latent variables, and propose to learn these structured representations via the variational principle.

3 Latent Belief State Dialog Models

We first introduce LABES as a general dialog modeling framework in this section. For dialog turn t, let u_t be the user utterance, b_t be the current belief state after observed u_t and r_t be the corresponding system response. In addition, denote c_t as the dialog context or model input at turn t, such as $c_t \triangleq \{r_{t-1}, u_t\}$ as in this work. Note that c_t can include longer dialog history depending on specific implementations. Let d_t be the database query result which can be obtained through a database-lookup operation given the belief state b_t.

Our goal is to model the joint distribution of belief states and system responses given the user inputs, $p_\theta(b_{1:T}, r_{1:T}|u_{1:T})$, where T is the total number of turns and θ denotes the model parameters. In LABES, we assume the joint distribution follows the directed probabilistic graphical model illustrated in Figure 2, which can be formulated as:

$$\begin{aligned}p_\theta(b_{1:T}, r_{1:T}|u_{1:T}) &= p_\theta(b_{1:T}|u_{1:T})p_\theta(r_{1:T}|b_{1:T}, u_{1:T})\\ &= \prod_{t=1}^{T} p_\theta(b_t|b_{t-1},c_t)p_\theta(r_t|c_t,b_t,d_t)\end{aligned}$$

where b_0 is an empty state. Intuitively, we refer the conditional distribution $p_\theta(b_t|b_{t-1},c_t)$ as the belief state decoder, and $p_\theta(r_t|c_t,b_t,d_t)$ the response decoder in the above decomposition. Note that the probability $p(d_t|b_t)$ is omitted as database result d_t is deterministically obtained given b_t. Thus the system response can be generated as a three-step process: first predict the belief state b_t, then use b_t to query the database and obtain d_t, finally generate the system response r_t based on all the conditions.

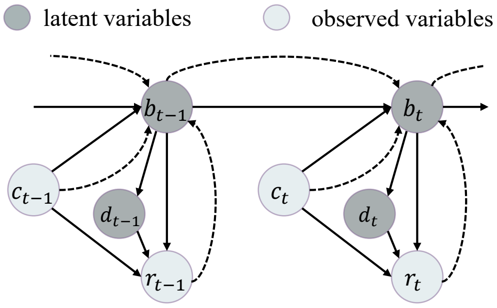

Figure 2: The probabilistic graphical model of LABES. Solid arrows describe the conditional generative model p_θ, and dash arrows describe the approximate posterior model q_ϕ. Note that we set $c_t \triangleq \{r_{t-1}, u_t\}$ in our model, and omit u_t from the graph for simplicity.

Unsupervised Learning

We introduce an inference model $q_\phi(b_t|b_{t-1}, c_t, r_t)$ (described by dash arrows in Figure 2) to approximate the true posterior $p_\theta(b_t|b_{t-1}, c_t, r_t)$. Then we can derive the variational evidence lower bound (ELBO) for unsupervised learning as follows:

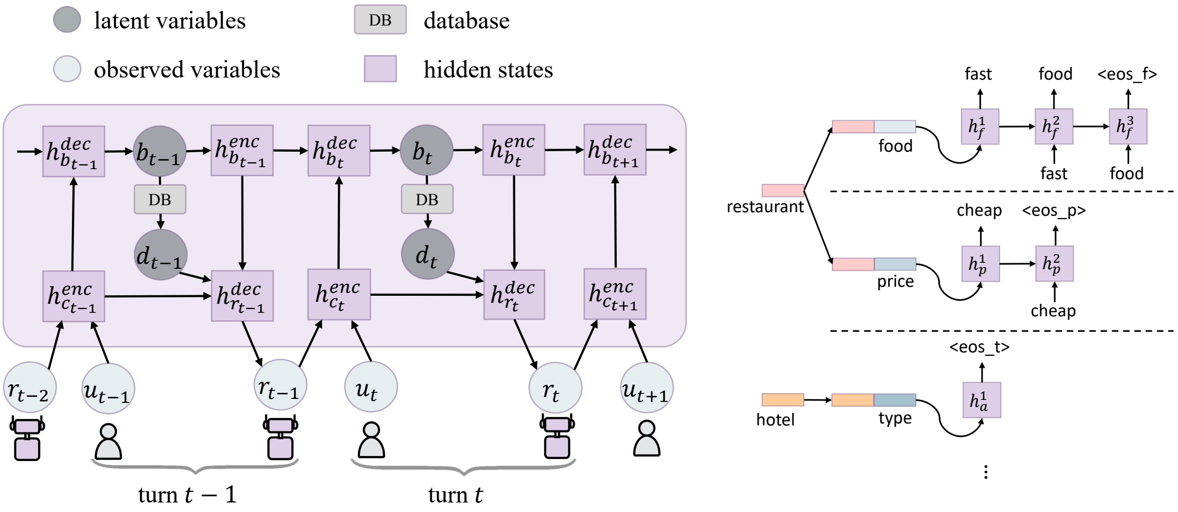
$$\begin{aligned}\mathcal{J}_{un} &= \mathbb{E}_{q_\phi(b_{1:T})}\left[\log \frac{p_\theta(b_{1:T}, r_{1:T}|u_{1:T})}{q_\phi(b_{1:T}|u_{1:T}, r_{1:T})}\right]\\ &= \sum_{t=1}^{T} \mathbb{E}_{q_\phi(b_{1:T})}\left[\log p_\theta(r_t|c_t, b_t, d_t)\right]\\ &\quad -\alpha \mathrm{KL}\left[q_\phi(b_t|b_{t-1}, c_t, r_t)\|p_\theta(b_t|b_{t-1}, c_t)\right]\end{aligned}$$

where

$$q_\phi(b_{1:T}) \triangleq \prod_{t=1}^{T} q_\phi(b_t|b_{t-1}, c_t, r_t)$$

and α is a hyperparameter to control the weight of the KL term introduced by Higgins et al. (2017).

Optimizing $\mathcal{J}_{un}$ requires drawing posterior belief state samples $b_{1:T} \sim q_\phi(b_{1:T}|u_{1:T}, r_{1:T})$ to estimate the expectations. Here we use a sequential sampling strategy similar to Kim et al. (2020), where each b_t sampled from $q_\phi(b_t|b_{t-1}, c_t, r_t)$ at turn t is used as the condition to generate the next turn's belief state b_{t+1}. For calculating gradients with discrete latent variables, which is non-trivial, some methods have been proposed such as using a score function estimator (Williams, 1992) or categorical reparameterization trick (Jang et al., 2017). In this paper, we employ the simple Straight-Through estimator (Bengio et al., 2013), where the sampled discrete token indexes are used for forward computation, and the continuous softmax probability of each token is used for backward gradient calculation. Although the Straight-Through estimator is biased, we find it works pretty well in our experiments, therefore leave the exploration of other optimization methods as future work.



(a) Overview of LABES-S2S.

(b) Structure of the belief state decoder.

Figure 3: (a) shows the computational graph of LABES-S2S. In (b), rectangles in different colors denote different word embeddings, and the embedding of domain names and slot names are concatenated as the initial input. Note that the same (i.e. weight-tied) decoder is shared across all slots. Decoding stops when a slot-specific end-of-sentence symbol is generated, which is possible to be the first output if the slot does not appear in the dialog.

Semi-Supervised Learning

When b_t labels are available, we can easily train the generative model p_θ and inference model q_ϕ via supervised maximum likelihoods:

$$\mathcal{J}_{sup} = \sum_{t=1}^{T}\Big[\log p_\theta(b_t|b_{t-1},c_t) + \log p_\theta(r_t|c_t,b_t,d_t) + \log q_\phi(b_t|b_{t-1},c_t,r_t)\Big]$$

When a mix of labeled and unlabeled data is available, we perform semi-supervised learning using a combination of the supervised objective $\mathcal{J}_{sup}$ and the unsupervised objective $\mathcal{J}_{un}$. Specifically, we first pretrain p_θ and q_ϕ on small-sized labeled data until convergence. Then we draw supervised and unsupervised minibatches from labeled and unlabeled data and perform stochastic gradient ascent over $\mathcal{J}_{sup}$ and $\mathcal{J}_{un}$, respectively. We use supervised pretraining first because training $q_\phi(b_t|b_{t-1},c_t,r_t)$ to correctly generate slot values and special outputs such as “dontcare” and end-of-sentence tokens as much as possible is important to improve sample efficiency in subsequent semi-supervised learning.

4 LABES-S2S: A Copy-Augmented Seq2Seq Instantiation

In the above probabilistic dialog model LABES, the belief state decoder $p_\theta(b_t|b_{t-1},c_t)$ and the response decoder $p_\theta(r_t|c_t,b_t,d_t)$ can be flexibly implemented. In this section we introduce LABES-S2S as an instantiation of the general LABES model based on copy-augmented Seq2Seq conditional distributions (Gu et al., 2016), which is shown in Figure 3(a) and described in the following. The responses are generated through two Seq2Seq processes: 1) decode the belief state given dialog context and last turn’s belief state and 2) decode the system response given dialog context, the decoded belief state and database query result.

Belief State Decoder

The belief state decoder is implemented via a Seq2Seq process, as shown in Figure 3(b). Inspired by Shu et al. (2019), we use a single GRU decoder to decode the value for each informable slot separately, feeding the embedding of each slot name as the initial input. In multi-domain setting, the domain name embedding is concatenated with the slot name embedding to distinguish slots with identical names in different domains (Wu et al., 2019).

We use two bi-directional GRUs (Cho et al., 2014) to encode the dialog context c_t and previous belief state b_{t-1} into a sequence of hidden vectors $h^{enc}_{c_t}$ and $h^{enc}_{b_{t-1}}$ respectively, which are the inputs to the belief state decoder. As there are multiple slots, and their values can also consist of multiple tokens, we denote the i-th token of slot s by $b^{s,i}_t$. To decode each token $b^{s,i}_t$, we first compute an attention vector over the encoder vectors. Then the attention vector and the embedding of the last decoded token $e(b_t^{s,i-1})$ are concatenated and fed into the decoder GRU to get the decoder hidden state $h_{b_t^{s,i}}^{dec}$, denoted as $h_{s,i}^{dec}$ for simplicity:

$$\begin{aligned} a_t^{s,i} &= \text{Attn}(h_{c_t}^{enc} \circ h_{b_{t-1}}^{enc}, h_{s,i}^{dec}) \\ h_{s,i}^{dec} &= \text{GRU}(a_t^{s,i} \circ e(b_t^{s,i-1}), h_{s,i-1}^{dec}) \\ \hat{h}_{s,i}^{dec} &= \text{dropout}\big(h_{s,i}^{dec} \circ e(b_t^{s,i-1})\big) \end{aligned}$$

where $\circ$ denotes vector concatenation. We use the last hidden state of the dialog context encoder as $h_{s,0}^{dec}$, and the slot name embedding as $e(b_t^{s,0})$. We reuse $e(b_t^{s,i-1})$ to form $\hat{h}_{s,i}^{dec}$ to give more emphasis on the slot name embedding and add a dropout layer to reduce overfitting. $\hat{h}_{s,i}^{dec}$ is then used to compute a generative score ψ_{gen} for each token w in the vocabulary $\mathcal{V}$, and a copy score ψ_{cp} for words appeared in c_t and b_{t-1}. Finally, these two scores are combined and normalized to form the final decoding probability following:

$$\begin{aligned} \psi_{gen}(b_t^{s,i} = w) &= v_w^{\mathsf{T}} \mathrm{W}_{\text{gen}} \hat{h}_{s,i}^{dec}, \quad w \in \mathcal{V} \\ \psi_{cp}(b_t^{s,i} = x_j) &= h_{x_j}^{enc\mathsf{T}} \mathrm{W}_{\text{cp}} \hat{h}_{s,i}^{dec}, \quad x_j \in c_t \cup b_{t-1} \\ p(b_t^{s,i} = w) &= \frac{1}{Z}\Bigg(e^{\psi_{gen}(w)} + \sum_{j:x_j = w} e^{\psi_{cp}(x_j)}\Bigg) \end{aligned}$$

where W_{gen} and W_{cp} are trainable parameters, v_w is the one-hot representation of w, x_j is the j-th token in $c_t \cup b_{t-1}$ and Z is the normalization term.

With copy mechanism, it is easier for the model to extract words mentioned by the user and keep the unchanged values from previous belief state. Meanwhile, the decoder can also generate tokens not appeared in input sequences, e.g. the special token "dontcare" or end-of-sentence symbols. Since the decoding for each slot is independent with each other, all the slots can be decoded in parallel to speed up.

The posterior network $q_\phi(b_t|b_{t-1}, c_t, r_t)$ is constructed through a similar process, where the only difference is that the system response r_t is also encoded and used as an additional input to the decoder. Note that the posterior network is separately parameterized with ϕ.

Response Decoder

The response decoder is implemented via another Seq2Seq process. After obtaining the belief state b_t, we use it to query a database to find entities that meet user's need, e.g. Thai restaurants in the south area. The query result d_t is represented as a 5-dimension one-hot vector to indicate 0, 1, 2, 3 and >3 matched results respectively. We only need the number of matched entities instead of their specific information as the input to the response decoder, because we generate delexicalized responses with placeholders for specific slot values (as shown in Table 4) to improve data efficiency (Wen et al., 2015). The values can be filled through simple rule-based post-processing afterwards.

Instead of directly decoding the response from the belief state decoder's hidden states (Lei et al., 2018), we again use the bi-directional GRU (the one used to encode b_{t-1}) to encode the current belief state b_t into hidden vectors $h_{b_t}^{enc}$. Then for each token r_t^i in the response, the decoder state $h_{r_{t,i}}^{dec}$ can be computed as follows:

$$\begin{aligned} a_t^i &= \text{Attn}(h_{c_t}^{enc} \circ h_{b_t}^{enc}, h_{r_{t,i}}^{dec}) \\ h_{r_{t,i}}^{dec} &= \text{GRU}(a_t^i \circ e(r_t^{i-1}) \circ d_t, h_{r_{t,i-1}}^{dec}) \\ \hat{h}_{r_{t,i}}^{dec} &= h_{r_{t,i}}^{dec} \circ a_t^i \circ d_t \end{aligned}$$

Note that dropout is not used for $\hat{h}_{r_{t,i}}^{dec}$, since response generation is not likely to overfit, compared to belief tracking in practice. We omit the probability formulas because they are almost the same as in the belief state decoder, except for changing the copy source from $c_t \cup b_{t-1}$ to $c_t \cup b_t$.

5 Experimental Settings

5.1 Datasets

We evaluate the proposed model on three benchmark task-oriented dialog datasets: the Cambridge Restaurant (CamRest676) (Wen et al., 2017b), Stanford In-Car Assistant (In-Car) (Eric et al., 2017) and MultiWOZ (Budzianowski et al., 2018), with 676/3031/10438 dialogs respectively. In particular, MultiWOZ is one of the most challenging dataset up-to-date given its multi-domain setting, complex ontology and diverse language styles. As there are some belief state annotation errors in MultiWOZ, we use the corrected version MultiWOZ 2.1 (Eric et al., 2019) in our experiments. See Appendix B for more detailed introductions and statistics.

5.2 Evaluation Metrics

We evaluate the model performance under the end-to-end setting, i.e. the model needs to first predict belief states and then generate response based on its own belief predictions. For evaluating belief tracking performance, we use the commonly used `joint goal accuracy`, which is the proportion of dialog turns where all slot values are correctly predicted. For evaluating response generation, we use `BLEU` (Papineni et al., 2002) to measure the general language quality. The response quality towards task completion is measured by dataset-specific metrics to facilitate comparison with prior works. For CamRest676 and In-Car, we use `Match` and `SuccF1` following Lei et al. (2018). For MultiWOZ, we use `Inform` and `Success` as in Budzianowski et al. (2018), and also a combined score computed through (`Inform`+`Success`)×0.5+`BLEU` as the overall response quality suggested by Mehri et al. (2019).

5.3 Baselines

In our experiments, we compare our model to various Dialog State Tracking (DST) and End-to-End (E2E) baseline models. Recently, large-scale pretrained language models (LM) such as BERT (Devlin et al., 2019) and GPT-2 (Radford et al., 2019) are used to improve the performance of dialog models, however in the cost of tens-fold larger model sizes and computations. We distinguish them from light-weighted models trained from scratch in our comparison.

Independent DST Models: For CamRest676, we compare to StateNet (Ren et al., 2018) and TripPy (Heck et al., 2020), which are the SOTA model without/with BERT respectively. For MultiWOZ, we compare to BERT-free models TRADE (Wu et al., 2019), NADST (Le et al., 2020b) and CSFN-DST (Zhu et al., 2020), and BERT-based models including TripPy, the BERT version of CSFN and DST-Picklist (Zhang et al., 2019).

E2E Models: E2E models can be divided into three sub-categories. The TSCP (Lei et al., 2018), SEDST (Jin et al., 2018), FSDM (Shu et al., 2019), MOSS (Liang et al., 2020) and DAMD (Zhang et al., 2020) are based on the copy-augmented Seq2Seq learning framework proposed by Lei et al. (2018). LIDM (Wen et al., 2017a), SFN (Mehri et al., 2019) and UniConv (Le et al., 2020a) are modular designed, connected through neural states and trained end-to-end. SimpleTOD (Hosseini-Asl et al., 2020) and SOLOLIST (Peng et al., 2020) are two recent models, which both use a single auto-regressive language model, initialized from GPT-2, to build the entire system.

Semi-Supervised Methods: First, we compare with SEDST (Jin et al., 2018) for semi-supervised belief tracking performance. SEDST is also a E2E dialog model based on copy-augmented Seq2Seq learning (see Appendix A for more details). Over unlabled dialog data, SEDST is trained through posterior regularization (PR), where a posterior network is used to model the posterior belief distribution given system responses, and then guide the learning of prior belief tracker through minimizing the KL divergence between them. Second, based on the LABES-S2S model, we compare our variational learning (VL) method to a classic semi-supervised learning baseline, self-training (ST), which performs as its name suggests. Specifically, after supervised pretraining over small-sized labeled dialogs, we run the system to generate pseudo belief states b_t over unlabeled dialogs, and then train the response decoder $p_\theta(r_t|b_t, c_t, d_t)$ in a supervised manner. The gradients will propagate through the discrete belief states by the Straight Through gradient estimator (Bengio et al., 2013) over the computational graph, thus also adjusting the belief state decoder $p_\theta(b_t|b_{t-1}, c_t)$.

6 Results and Analysis

In our experiments, we report both the best result and the statistical result obtained from multiple independent runs with different random seeds. Details are described in the caption of each table. The implementation details of our model is available in Appendix C. Results are organized to show the advantage of our proposed LABES-S2S model over existing models (§6.1) and the effectiveness of our semi-supervised learning method (§6.2).

6.1 Benchmark Performance

We first train our LABES-S2S model under full supervision and compare with other baseline models on the benchmarks. The results are given in Table 1 and Table 2.

As shown in Table 1, LABES-S2S obtains new SOTA joint goal accuracy on CamRest676 and the highest match scores on both CamRest676 and In-Car datasets. Its BLEU scores are also beyond or close to the previous SOTA models. The relatively low SuccF1 is due to that in LABES-S2S, we do not apply additional dialog act modeling and reinforcement fine-tuning to encourage slot token generation as in other E2E models.

Table 2 shows the MultiWOZ results. Among

Type	Model	CamRest676				In-Car		
		Joint Goal	Match	SuccF1	BLEU	Match	SuccF1	BLEU
DST	StateNet (Ren et al., 2018)	88.9	-	-	-	-	-	-

Table 2: Results on MultiWOZ 2.1. The model with the highest validation joint goal accuracy is shown as the best result, as similarly reported in prior work. The standard deviations for the statistical results are in Table 5 in the appendix. * denotes results obtained by our run of the open-source code.

all the models without using large pretrained LMs, LABES-S2S performs the best in belief tracking joint goal accuracy and 3 out of the 4 response generation metrics. Although the response generation performance is not as good as recent GPT-2 based SimpleTOD and SOLOLIST, our model is much smaller and thus computational cheaper.

6.2 Semi-Supervised Experiments

In our semi-supervised experiments, we first split the data according to a fixed proportion, then train the models using only labeled data (SupOnly), or using both labeled and unlabeled data (Semi) with the proposed variational learning method (Semi-VL), self-training (Semi-ST) and posterior regularization (Semi-PR) introduced in §5.3 respectively. We conduct experiments with 50% and 25% labeled data on CamRest676 and In-Car following Jin et al. (2018), and change the labeled data proportion from 10% to 100% on MultiWOZ. The results are shown in Table 3 and Figure 4.

In Table 3, we can see that semi-supervised learning methods outperform the supervised learning baseline consistently in all experiments for the two datasets. In particular, the improvement of Semi-VL over SupOnly on our model is significantly larger than Semi-PR over SupOnly on SEDST in most metrics, and Semi-VL obtains a joint goal accuracy of 1.3%∼3.9% higher over Semi-ST. These results indicate the superiority of our LABES modeling framework in utilizing unlabeled data over other semi-supervised baselines. Since LABES mainly improves modeling of belief states, it is more relevant to examine the belief tracking metrics such as joint goal accuracy and match rate (partly determined by the belief tracking accuracy).

Labeled Data	Model & Method	CamRest676				In-Car			
		Joint Goal	Match	SuccF1	BLEU	Joint Goal	Match	SuccF1	BLEU
50%	LABES-S2S + SupOnly	83.3	91.8	80.5	23.8	77.9	81.0	74.5	20.4
	LABES-S2S + Semi-ST	86.3	93.1	83.1	25.3	79.8	83.4	74.8	22.1

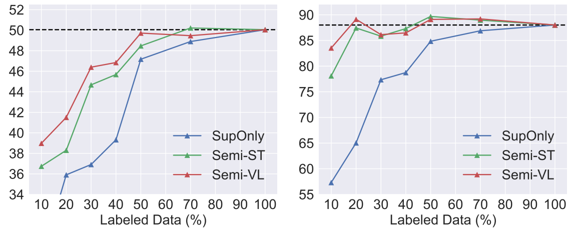
Table 3: *SupOnly* denotes training with only labeled data, and *Semi* denotes training with both labeled and unlabeled data in each dataset. ST, VL and PR denote self-training, variational learning and posterior regularization (Jin et al., 2018) respectively. Results of SEDST are obtained by our run of the open-source code. All the scores in this table are the mean from 5 runs.



(a) Joint Goal Accuracy (b) Combined Score

Figure 4: Performance of different methods w.r.t labeling proportion on MultiWOZ 2.1. The dash line corresponds to the baseline trained with 100% labeled data.

Note that Semi-VL and Semi-ST are fed with the same set of system responses, thus they obtain similar SuccF1 and BLEU scores in Table 3, which mainly measure the response quality.

The results on MultiWOZ shown in Figure 4 also support the above conclusions. From the plot of metric scores w.r.t labeling proportions, we can see how many labels can be reduced clearly. Our LABES-S2S model trained with Semi-VL obtains a joint goal accuracy of 49.47% and a combined score of 89.21 on only 50% of labeled data, which is very close to 50.05% and 88.01 obtained under 100% supervision. This indicates that we can reduce 50% of labels without losing performance, which results in reducing around 30,000 belief state annotations given the size of MultiWOZ. Moreover, it can be seen from Figure 4 that our Semi-VI can improve the belief tracking and response generation performance when labeling only 10% of dialogues, and the smaller amount of labels, the larger gain obtained by Semi-VI.

Dialog #586 in CamRest676	
	u_1: I am looking for an expensive restaurant that serves Russian food. b_1: {food: Russian, pricerange: expensive} r_1: There is no expensive restaurant that serves Russian food. Can I help you with anything else? u_2: Yes, do you have British type food ? b_2: {food: British, pricerange: expensive} r_2: Yes, there are 6 options. Does the part of town matter? u_3: I don't care.
Sup Only	b_3: {food: British, pricerange: expensive} r_3: [v.name] is located at [v.addr]. How else I can help you with?
Semi -VL	b_3: {food: British, pricerange: expensive, area: dontcare} r_3: [v.name] is a nice British restaurant in the [v.area] of town. Would you like their address?
Dialog #PMUL1329 in MultiWOZ	
	u_1: I need a train going to Bishops Stortford. b_1: {destination: Bishops Stortford} r_1: OK. Are you departing from Cambridge? u_2: Yes, that's why I'm requesting help from Cambridge towninfo.
Sup Only	b_3: {destination: Bishops Stortford} r_3: Where will you be departing from?
Semi -VL	b_3: {destination: Bishops Stortford, departure: Cambridge} r_3: I have [v.choice] trains that meet your criteria. What day would you like to travel?

Table 4: Comparison of two example turns generated by our model with supervised learning only (SupOnly) and semi-supervised variational learning (Semi-VL).

6.3 Case Study

We give two examples where the model trained with Semi-VL improves over the supervised-training-only baseline. In both examples, the user indicates his/her goal implicitly with a short reply. These rarely occurred corner cases are missed by the baseline model, but successfully captured after semi-supervised learning. Moreover, we can see that Semi-VL helps our model learn the cue word "British" which contributes to a more informative response in the first dialog, and in the second dialog, avoid the incoherent error caused by error propagation, thus improve the response generation quality.

7 Conclusion and Future Work

In this paper we are interested in reducing belief state annotation cost for building E2E task-oriented dialog systems. We propose a conditional generative model of dialogs - LABES, where belief states are modeled as latent variables, and unlabeled dialog data can be effectively leveraged to improve belief tracking through semi-supervised variational learning. Furthermore, we develop LABES-S2S, which is a copy-augmented Seq2Seq model instantiation of LABES. We show the strong benchmark performance of LABES-S2S and the effectiveness of our semi-supervised learning method on three benchmark datasets. In our experiments on MultiWOZ, we can save around 50%, i.e. around 30,000 belief state annotations without performance loss.

There are some interesting directions for future work. First, the LABES model is general and can be enhanced by, e.g. incorporating large-scale pre-trained language models, allowing other options for the belief state decoder and the response decoder such as Transformer based. Second, we can analogously introduce dialog acts $a_{1:T}$ as latent variables to define the joint distribution $p_\theta(b_{1:T}, a_{1:T}, r_{1:T}|u_{1:T})$, which can be trained with semi-supervised learning and reinforcement learning as well.

A Model Comparisons with Prior Work

In this section, we comment on the differences between our LABES-S2S model and Sequicity (Lei et al., 2018) in both models and learning methods. Note that SEDST (Jin et al., 2018) employs the same model structure as Sequicity. First, Figure 5 shows the difference in computational graphs between Sequicity/SEDST and LABES-S2S. For Sequicity/SEDST, b_t and r_t are decoded directly from the belief state decoder's hidden states $h_{b_t}^{dec}$, thus the conditional probability of r_t given b_t and the state transition probability between b_{t-1} and b_t are not considered[2]. In contrast, LABES-S2S model introduces an additional b_t encoder and uses the encoder hidden states $h_{b_t}^{enc}$ to generate system response and next turn's belief state, thus the conditional probability $p_\theta(r_t|b_t, c_t)$ and state transition probability $p_\theta(b_t|b_{t-1}, c_t)$ are well defined by two complete Seq2Seq processes.

Second, the difference in models can also be clearly seen from the probabilistic graphical model structures as shown in Figure 6. LABES-S2S is a conditional generative model where the belief states are latent variables. In contrast, Sequicity/SEDST do not treat the belief states as latent variables.

Third, the above differences in models lead to differences in learning methods for Sequicity/SEDST and LABES-S2S. Sequicity can only be trained on labeled data via multi-task supervised learning. SEDST resorts to an ad-hoc combination of posterior regularization and auto-encoding for semi-supervised learning. Remarkably, LABES-S2S is optimized under the principled variational learning framework.

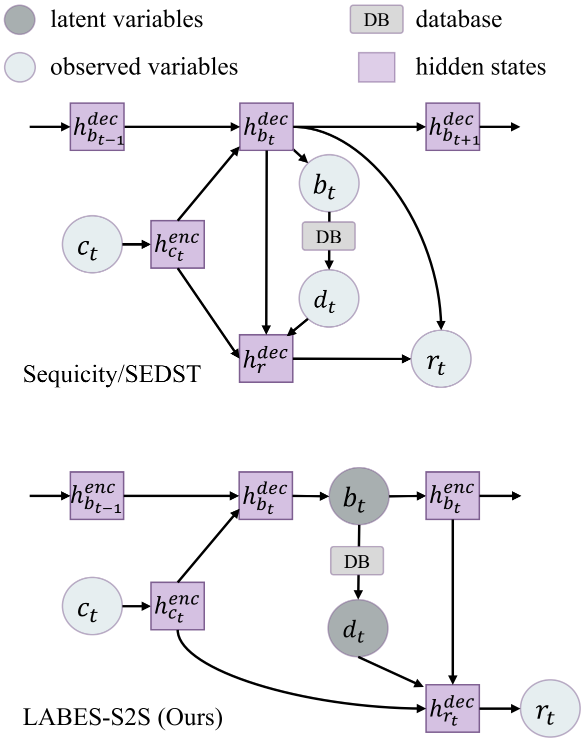

Figure 5: Comparison of computational graphs.

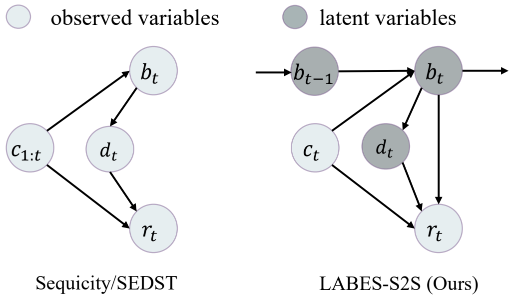

Figure 6: Comparison of probabilistic graphical model structures.

B Datasets

In our experiments, we evaluate different models on three benchmark task-oriented datasets with different scales and ontology complexities (Table 6). The Cambridge Restaurant (CamRest676) dataset (Wen et al., 2017b) contains single-domain dialogs where the system assists users to find a restaurant. The Stanford In-Car Assistant (In-Car) dataset (Eric et al., 2017) consists of dialogs between a user and a in-car assistant system covering three tasks: calendar scheduling, weather information retrieval and point-of-interest navigation. The MultiWOZ (Budzianowski et al., 2018) dataset is a large-scale human-human multi-domain dataset containing dialogs in seven domains including attraction, hotel, hospital, police, restaurant, train, and taxi. It is more challenging due to its multi-domain setting, complex ontology and diverse language styles. As there are some belief state annotation errors in MultiWOZ, we use the corrected version MultiWOZ 2.1 (Eric et al., 2019) in our experiments. We follow the data preprocessing setting in Zhang et al. (2020), whose data cleaning is developed based on Wu et al. (2019).

---

[2] Strictly speaking, the transition between belief states across turns and the dependency between system responses and belief states are modeled very weakly in Sequicity/SEDST, only owing to the copy mechanism. For simpliciy, we omit such relations in both Figure 5 and 6.

Model	Belief Tracking	Response Generation			
	Joint Goal	Inform	Success	BLEU	Combined
LABES-S2S (statistical)	50.05±0.92	76.89±1.51	63.30±2.35	17.92±0.35	88.01±2.10

#Req. Slot	7	11	38
#Values	99	284	4510

Table 6: Statistics of dialog datasets. Info and Req are shorthands for informable and requestable respectively.

C Implementation Details

In our implementation of LABES-S2S, we use 1-layer bi-directinonal GRU as encoders and standard GRU as decoders. The hidden sizes are 100/100/200, vocabulary sizes are 800/1400/3000, and learning rates of Adam optimizer are 3e^{-3}/3e^{-3}/5e^{-5} for CamRest676/In-Car/MultiWOZ respectively. In all experiments, the embedding size is 50 and we use GloVe (Pennington et al., 2014) to initialize the embedding matrix. Dropout rate is 0.35 and λ for variational inferece is 0.5, which are selected via grid search from $\{0.1, 0.15, 0.2, 0.25, 0.3, 0.35, 0.4, 0.45, 0.5\}$ and $\{0.1, 0.3, 0.5, 0.7, 1.0, 1.5\}$ respectively. The learning rate decays by half every 2 epochs if no improvement is observed on development set. Training early stops when no improvement is observed on development set for 4 epochs. We use 10-width beam search for CamRest676 and greedy decoding for other datasets. All the models are trained on a NVIDIA Tesla-P100 GPU.

The World is Not Binary:
Learning to Rank with Grayscale Data for Dialogue Response Selection

Abstract

Response selection plays a vital role in building retrieval-based conversation systems. Despite that response selection is naturally a learning-to-rank problem, most prior works take a point-wise view and train binary classifiers for this task: each response candidate is labeled either relevant (one) or irrelevant (zero). On the one hand, this formalization can be sub-optimal due to its ignorance of the diversity of response quality. On the other hand, annotating grayscale data for learning-to-rank can be prohibitively expensive and challenging. In this work, we show that grayscale data can be automatically constructed without human effort. Our method employs off-the-shelf response retrieval models and response generation models as automatic grayscale data generators. With the constructed grayscale data, we propose multi-level ranking objectives for training, which can (1) teach a matching model to capture more fine-grained context-response relevance difference and (2) reduce the train-test discrepancy in terms of distractor strength. Our method is simple, effective, and universal. Experiments on three benchmark datasets and four state-of-the-art matching models show that the proposed approach brings significant and consistent performance improvements.

1 Introduction

Building intelligent conversation systems (Shum et al., 2018; Kollar et al., 2018) is gaining more and more attention in recent years. A core module in such kind of conversation systems is response selection (Ritter et al., 2011; Hu et al., 2014; Wu et al., 2017; Tao et al., 2019): Identifying the best response from a set of possible candidates given a dialogue context, i.e., conversation history. For the response selection problem, the trendy practice is to build neural matching models (Ji et al., 2014; Wang et al., 2015; Xu et al., 2016; Wu et al., 2017; Zhou et al., 2018; Lu et al., 2019) for scoring the adequacy of individual response candidates in the dialogue context. Most prior works on this topic focus on fine-grained text encoding and better interactions between dialogue context and response candidates, typically via sophisticated and powerful matching networks (Wu et al., 2017; Zhou et al., 2018; Lu et al., 2019; Gu et al., 2019). Despite their differences, in almost all these previous works, the matching models are trained with binary classification objective. Each response in the training data is either labeled positive (i.e., a correct response to the dialogue context) or negative (i.e., an incorrect response). Often, the negative responses are automatically constructed by random sampling.

Dialogue Context Between Speakers A and B	**Relevance**
A: Would you please share some useful experience for improving spoken English? B: Sure! Watching English movies helped a lot. A: Agreed. I watched Friends many times. B: Me too! I bought the DVDs and they went broken due to my frequent use.	
Ground Truth	
G: Hah! Then your English should be very good!	+
Distractor Response During Training	
R1: Why didn't the British police come?	− − −
Distractor Responses in Real-world Scenario	
R2: It's said that a DVD can be preserved for decades.	−
R3: Friends is an American television sitcom.	−

Table 1: Dialogue context (conversation history) between Speakers A and B. R1 is a random sample used as a negative instance during training. R2 and R3 are real distractors during testing.

One limitation of the above training strategy is that this formalization downplays the nuance of fine-grained response quality; the matching model is only informed to predict a binary label, either correct or incorrect. However, the quality of possible response candidates may be quite diverse, thus

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9220–9229,
November 16–20, 2020.

letting the matching model be aware of which response candidates are more incorrect or less incorrect than others may more effectively increase the model capacity. Another limitation is that in real-world scenarios the matching models are often confronted with more difficult tasks: to select the best response from a set of strong response candidates instead of random ones. An example is given in Table 1. During training, the matching models are trained to distinguish the ground truth G and the randomly sampled response R1, where R1 shows little relevance to the dialogue context. Matching models trained on such training data have little experience to identify the ground-truth response G from a set of strong distractor responses such as R2 and R3. Intuitively, a good matching model should be able to not only distinguish good responses from random ones (usually totally irrelevant), as conveyed by the binary classification objective, but also capture the more subtle differences for competitive candidates.

One natural solution to the above problems is to collect grayscale data for training; if we consider the quality of all possible response candidates falls in the interval $[0, 1]$, the golden-truth and random responses usually cover the two endpoints only, and our goal is to obtain a list of grayscale responses locate in between 0 and 1. However, grayscale data are hard to obtain in reality owing to the expense of human annotation and the subjectivity of individual human annotators.

In this work, we propose to automatically construct grayscale data from standard dialogue datasets, where only golden dialogue context and response pairs are provided. To meet this goal, we resort to off-the-shelf retrieval algorithms and generation models. Our idea is inspired by the observation that, in most cases, the responses from retrieval models or generation models are better than randomly sampled ones but worse than the ground-truth response. We believe that this progressive relationship, such as "*ground truth* $>$ *retrieval* $>$ *random*", can be utilized for training a better matching model. Concretely, we propose a multi-level ranking objective to make full use of such relationships. Our multi-level ranking objective jointly combines multiple binary contrastive estimations. In addition, the grayscale data partly simulates the real-world response distractors and thus reduces the gap between training and testing, leading to a better distinguishing ability for strong response distractors.

Our method is simple, effective, and orthogonal to prior efforts for modeling designs. It can be conveniently implemented with most existing matching models. Experimental results on four state-of-the-art matching models and three benchmark datasets demonstrate that our new training approach leads to remarkable performance improvement consistently.

2 Background

Early research for response selection is devoted to single-turn conversations (Wang et al., 2013; Tan et al., 2015; Yan et al., 2016). Recently, researchers have started to study on multi-turn conversations (Lowe et al., 2015; Wu et al., 2017; Zhang et al., 2018). In the current literature, the task of response selection is formulated as follows. Given a dialogue dataset $\mathcal{D} = \{(c_i, r_i)\}$, where c_i represents a dialogue context, and r_i is the human-written ground-truth response. The goal is to build a matching model $s(\cdot, \cdot)$ from $\mathcal{D}$ so that $s(c, r)$ accurately measures the adequacy of a response candidate r for a dialogue context c.

Rapid progress has been made for building such matching models in recent years. Concretely, various neural architectures (Zhou et al., 2016; Wu et al., 2017; Zhou et al., 2018; Gu et al., 2019; Tao et al., 2019; Yuan et al., 2019) have been proposed for fine-grained text encoding and better dialogue context and response interactions modeling. To train such matching models, binary-labeled training sets are constructed (Lowe et al., 2015; Wu et al., 2017; Zhang et al., 2018): The human-written ground-truth response is designated as positive instances (labeled as 1), and a set of randomly sampled responses $\mathcal{N}_i$ are treated as negative ones (labeled as 0). The learning objective of $s(\cdot, \cdot)$ is then to maximize the following binary classification loss function:

$$\log s(c_i, r_i) + \mathbb{E}_{r^- \in \mathcal{N}_i} \log\left(1 - s(c_i, r^-)\right). \quad (1)$$

Different from previous works, our study questions the effectiveness of the binary-labeled training data and the corresponding binary classification objective. We argued that the binary classification paradigm is sub-optimal as most of the randomly sampled negative responses are distant from the corresponding positive responses in terms of matching degree, which could lead to serious drawbacks when some strong distractors are presented during

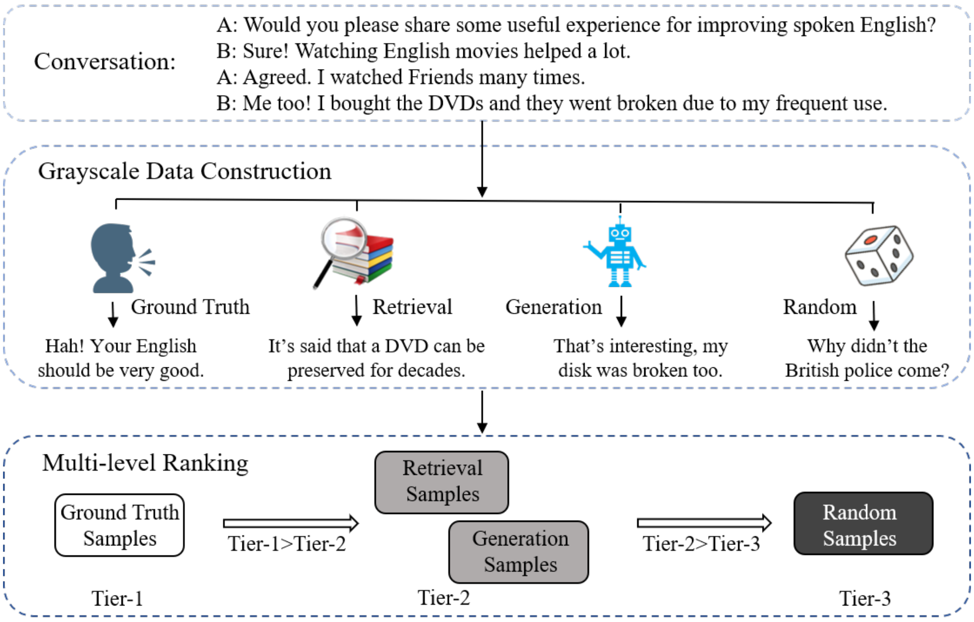

Figure 1: The illustration of our training approach. For each dialogue, we first extract a number of grayscale data from heterogeneous sources. Then, the multi-level ranking objective is applied to learn the progressive relationships between different responses.

testing (Zhou et al., 2018; Zhang et al., 2018). Our work starts with enriching the range of the negative sample set $\mathcal{N}_i$ in terms of response quality and leads to a simple but new learning strategy that aimed at capturing more fine-grained response quality differences.

3 Proposed Approach

3.1 Overview

Figure 1 depicts an overview of our approach. First, different responses are acquired from various sources, such as retrieval models, generation models, and random sampling. Then, the collected responses are sorted by estimated quality to form progressive relationships. Lastly, a multi-level ranking objective is designed to learn such relationships. We first present our methods for automatically constructing grayscale data in Section 3.2, followed by the multi-level ranking objective introduced in Section 3.3.

3.2 Grayscale Data Acquisition

Our goal is to construct a set of responses with diverse quality. Specifically, we construct three types of responses for each dialogue context and rank them in three tiers. It should be noted that our data acquisition only relies on standard dialogue datasets, which only provide human-to-human dialogue context and response pairs.

Zero & One First of all, the corresponding responses for dialogues context in the standard dialogue dataset are considered as our ground-truth responses. These human-written responses are often informative and relevant. As a result, the ground-truth samples are ranked as tier-1. Similar to previous work, we also utilize randomly sampled responses for contrastive estimation. The random responses are sampled from the responses of other dialogue contexts in the training data. We rank random responses as tier-3 because they often show little relevance to the dialogue context. The ground-truth responses and random responses constitute the "zero & one" binary training data used in the prior work.

Grayscale We now delve into describing the grayscale data construction procedures. We consider two types of frequently-used toolkits for automatic response generation to produce grayscale data, namely, the retrieval-based models and the generation-based models.

The retrieval-based models (Ji et al., 2014; Hu et al., 2014) directly copy an existing response from the training corpus when receiving a response request. Since the returning responses are always human utterances in real-world conversations, they are informative and grammatical. However, the response quality of such systems varies as it depends on the lexical similarity of the given dialogue context and those in the training corpus. Typically, the retrieval results are better than random responses because they are more or less relevant to the dialogue context. However, most retrieval results are worse than the ground truth. The retrieval results are ranked tier-2.

Specifically, we split the multi-turn dialogue into a series of single-turn input-response pairs. Then we index the input-response pairs with the BM25 algorithm (Robertson and Zaragoza, 2009). We retrieve response candidates using the last utterance of the dialogue context.

The generation-based models (Shang et al., 2015; Li et al., 2016) generate a new utterance from scratch after training. While those models have better generalization capacity in rare dialogue contexts, the generation responses tend to be universal and noninformative (e.g., I dont know, I think so etc.) (Li et al., 2016). Similar to the retrieval responses, the generation responses are usually better than the random responses but worse than the ground-truth responses. However, compared to retrieval models that merely rely on lexical overlapping, generation results can capture deeper semantic interactions. The different characteristics of retrieval and generation models make their results complement each other in terms of response quality, which we consider beneficial for training.

Specifically, we train a Seq2Seq model with the attention mechanism (Bahdanau et al., 2015) for response generation. We adopt the same corpus used in the retrieval model to train the generation model. The generation response is produced by feeding the dialogue context to a trained model.

Discussion on Extendibility Note that there can be many more sophisticated ways to construct the grayscale data. For example, one may employ the results from different retrieval models and/or generation models. Responses from different models can be further divided into sub-groups according to the relative strengths of the corresponding models. For instance, responses that are generated from more advanced and competent generation models (e.g., a model based on GPT2 (Radford et al., 2019)) can be considered better than those from less competent models (e.g., a vanilla seq2seq model). However, in this paper, we only showcase the results with basic retrieval and generation models for keeping our idea simple and neat. Nevertheless, this simple setting, as we will demonstrate, already leads to remarkable performance improvements.

3.3 Multi-Level Ranking Objectives

Our grayscale data acquisition provides ground for carrying out more principled and sufficient training paradigms. To make full use of the grayscale data, we propose multi-level ranking objectives. Unlike prior work that minimizes binary classification errors, our training objective better fits the learning-to-rank nature of response selection, that is, minimizes ranking errors of possible responses (Cao et al., 2007). Also, as the grayscale data exhibit various response quality, training with such data rather than random negatives better simulate testing environments.

We start formal descriptions with some notation: the training set can be re-organized as $\overline{\mathcal{D}} = \{(c_i, R_i)\}_{i=1}^{N}$, where c_i denotes the dialogue context and $R_i = \{r_i, e_i, g_i, \tilde{r}_i\}$ is the response set enhanced by grayscale data. Concretely, r_i, e_i, g_i, and $\tilde{r}_i$ refer to ground-truth responses, retrieval responses, generation responses, and random responses, respectively. We consider three ordered list as follows.

- *ground truth>retrieval>random* This ordered list considers the progressive relationships between ground-truth responses, retrieval responses, and random responses. We use margin ranking losses for implementation, the formula are given below:

  $$\begin{aligned}\mathcal{L}_{Ret} = &\max\{0, \mu - s(c, r_i) + s(c, e_i)\} \\ &+ \max\{0, \mu - s(c, e_i) + s(c, \tilde{r}_i)\}.\end{aligned}$$

  where μ is a hyperparameter and represent the minimum acceptable score margin between two tiers, and $s(\cdot, \cdot)$ is the matching score given by a matching model.

- *ground truth>generation>random* This ordered list considers the progressive relationships between ground-truth responses, generation responses, and random responses. The loss function is given below.

  $$\begin{aligned}\mathcal{L}_{Gen} = &\max\{0, \mu - s(c, r_i) + s(c, g_i)\} \\ &+ \max\{0, \mu - s(c, g_i) + s(c, \tilde{r}_i)\},\end{aligned}$$

- *ground truth>random*

  $$\mathcal{L}_{Ran} = \max\{0, \mu - s(c, r_i) + s(c, \tilde{r}_i)\},$$

  this loss function directly models the relationship between the ground-truth samples r_i and random samples $\tilde{r}_i$.

Our final training objective is an unite of all above. It models the integrated relationship between tiers "*ground truth*>*retrieval* & *generation*>*random*" and "*ground truth* > *random*" simultaneously:

$$\mathcal{L}_{Uni} = \mathcal{L}_{Ran} + \mathcal{L}_{Ret} + \mathcal{L}_{Gen}.$$

4 Experimental Setup

4.1 Datasets and Evaluation Metrics

We test on three benchmark datasets for multi-turn response selection.

Ubuntu Dialogue Corpus It consists of English multi-turn dialogues about technical support collected from the Ubuntu Forum (Lowe et al., 2015). The dataset contains 500K, 50K and 50K chat logs for training, validation, and test respectively. Each test dialogue is paired with 9 distractor responses. Following conventions, the response selection performance is evaluated by $R_n@k$ scores. $R_n@k$ is the recall rate at position k in n candidates.

Douban Conversation Corpus It consists of Chinese multi-turn daily conversations crawled from Douban group (Wu et al., 2017). The dataset contains 500K, 25K and 1K chat logs for training, validation, and test respectively. Each test dialogue is paired with 10 candidate responses. Following prior work, besides $R_n@k$ scores, we also report Mean Average Precision (MAP), Mean Reciprocal Rank (MRR) and the precision at position 1 (P@1).

E-commerce It consists of Chinese conversations between customers and customer service staff from Taobao (Zhang et al., 2018). The dataset sizes and settings is the same as Douban corpus. $R_n@k$ scores are commonly employed for evaluation.

4.2 Baseline Models

We compare with the following baseline models.

Single-turn Matching Models These models concatenate all context utterances together into one single long utterance then compute the matching scores between the long utterance and response candidates, including RNN (Lowe et al., 2015), CNN (Lowe et al., 2015), LSTM (Lowe et al., 2015), Bi-LSTM (Kadlec et al., 2015), Match-LSTM (Wang and Jiang, 2016) and MV-LSTM (Wan et al., 2016).

Multi-turn Matching Models These models aggregate the information of context utterances in more advanced ways, including DL2R (Yan et al., 2016), Multi-View (Zhou et al., 2016), DUA (Zhang et al., 2018), SMN (Wu et al., 2017), DAM (Zhou et al., 2018), IOI (Tao et al., 2019), and MSN (Yuan et al., 2019).

4.3 Implementation Details

For grayscale data construction, we train a seq2seq generation model and build a BM25 retrieval system using the training set for each dataset. We consider the top 100 responses from BM25 retrieval and the top 5 responses from seq2seq generation (via beam search) as the grayscale responses. To facilitate further research, we have made our collected grayscale data publicly available.[1] During training, we use these grayscale responses in a way adaptive to the training matching model. At each training epoch, ten different grayscale responses are used: the top 5 retrieval responses ranked by the current matching model and all 5 seq2seq generation responses. We experiment our new training approach on four latest state-of-the-art models as follows:

- SMN (Wu et al., 2017) interacts each utterance of a dialogue context with a response and then transforms interaction matrices into matching vectors with CNN. The matching vectors are finally mapped into a matching score with an RNN.
- DAM (Zhou et al., 2018) obtains matching vectors of text segments at different granularities with the stacked self-attention. The matching vectors are then distilled with the cross-attention and finally fused into a matching score via a single-layer perceptron.
- IOI (Tao et al., 2019) pairs each utterance of a context with a response via stacking multiple interaction blocks and then aggregates matching information from all the pairs as a matching score in an iterative fashion.
- MSN (Yuan et al., 2019) utilizes a multi-hop selector to select the relevant utterances as context and then matches the filtered context with the given response candidate to obtain a matching score.

Table 3: Ablation study of our approach on Douban datasets with SMN and DAM.

Specifically, we first pre-train a model with objective $\mathcal{L}_{ran}$ only then switch to $\mathcal{L}_{Uni}$. We find that such a treatment makes the training process more stable.

5 Results and Discussion

5.1 Experimental Results

The experimental results are listed in Table 2, where G-X indicates X with our grayscale enhanced training approach. We can see that our training approach significantly improves the performance of all four matching models in terms of various metrics. The improvements are consistent across different datasets and different models, indicating the university of our approach. Moreover, one interesting observation is that a less-accurate matching architecture with the proposed training approach can outperform a stronger matching architecture with the traditional training paradigm, e.g., G-IOI vs. MSN. This suggests that while the choice of learning objective is often overlooked, it could be decisive for building a competitive response selection model.

5.2 Effect of Different Grayscale Data

We then turn to conduct an ablation study for understanding the roles of different grayscale data in performance enhancement. We choose SMN as well as DAM as the baselines models. We train the models with three additional settings by removing either retrieval responses or generation responses and removing both of them.

The results are shown in Table 3, we can find that both retrieval data and generation data make irreplaceable contributions to the overall performance and the combination of both worlds makes the best results, which confirms our hypotheses that responses from heterogeneous sources complement each other. We can also find that the help from retrieval data has a greater influence than generation data when used alone. This can be attributed to that the seq2seq-based generation model tends to output general and dull responses. Such general responses are less informative than the retrieval data, thus can provide limited help for distinguishing the nuance of fine-grained response quality.

5.3 Effect of Multi-level Ranking Objectives

Next, we study the effect of the multi-level ranking objective (MRO). Recall that we adopt the MRO in order to make use of the progressive relationship in different tiers. However, a simpler alternative is to treat all grayscale data as negative samples and use the learning objective in Eq. 2. It can be regarded

Model	$P@1$	$R_{10}@1$	$R_{10}@2$	$R_{10}@5$
G-SMN	**0.443**	**0.271**	**0.439**	**0.781**
−*MRO*	0.410	0.244	0.416	0.766

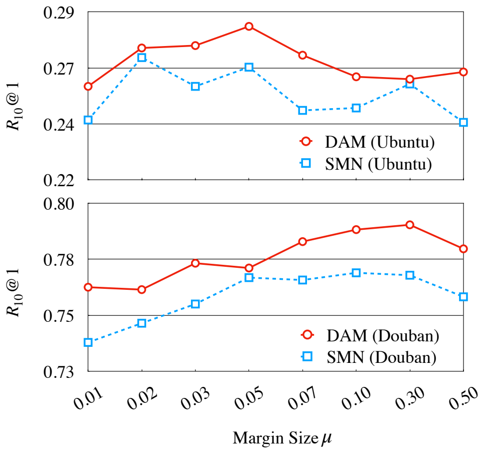

Figure 2: The effect of margin size.

as a simple data augmentation technique, enlarging the set of negative examples with retrieval and generation results. We implement such an idea to test whether the proposed MRO is necessary and quantify the benefit of the MRO.

As shown in Table 4, the performance of models trained without MRO falls behind those trained with MRO. Besides, the improvements of grayscale data without MRO are quite limited compared to the original counterparts without grayscale data. This indicates that the proposed multi-level ranking objective is essential for performance improvement.

5.4 Effect of Margin Size

The hyperparameter margin size (μ) denotes the minimum distance between two tiers in matching scores, which may affect the performance of a matching model. We conduct a series of sensitivity analysis experiments to study how the margin affects the performance of our training.[2] All models are evaluated in terms of $R_{10}@1$.

Referring to Figure 2, we can see that both SMN and DAM have a similar trend on Douban: the curves first increase and then drop as the margin increases. This is mainly because response candidates on Douban are of high relevance. When the margin is too large, matching models have no idea to handle strongly relevant distractors. However, when the margin is too small, matching models will become too sensitive and sometimes mistakenly give high scores for responses with less relevance to dialogue context. Results on Ubuntu show a completely different behavior: the performances grow in step with the margin. The reason may be that the response distractors of Ubuntu have relatively large margins in semantic and matching models need to make strong discrimination between the ground truth and other grayscale samples. As a result, models learned with the large margin can fit such data distribution.

5.5 Compatiblity with Co-teaching

We have noticed that Feng et al. (2019) adopts the co-teaching framework to train a robust matching model. From their experiment, the co-teaching framework with dynamic margins is proven to eliminate the effect from random sampled noisy responses effectively. We believe that our approach and co-teaching framework can benefit each other. Therefore, we combine our training approach with the co-teaching framework taking margins strategy as an instance to train the matching models.

From the results in Table 5, we can see that models trained with our approach outperform those trained with the co-teaching framework. More importantly, the SMN+CoT and DAM+CoT obtain further improvements after adding our multi-level ranking objectives. This demonstrates that our approach is compatible with the co-teaching framework and shows strong portability and practicability to act as a generalized approach.

5.6 Case Study

As shown in case 1 of Table 6, response 2 contains some irrelevant content about the comic “One Piece”, but it is still selected by DAM as the best response. In case 2, SMN selects the totally irrelevant response 2 as the best response, which may because this response has some overlapped words with the dialogue. These are consistent with the problem

---

[2] We also tried to use different margins for different pairs but the improvements are limited.

We copy the results of SMN+CoT and DAM+CoT from Feng et al. (2019) on Douban, and we supplement the results of two models trained with the co-teaching framework on Ubuntu.

Case 1 given by DAM	
A: 处女天蝎有异地的么? B: 国内异地,每天都好虐心哦,快5个月了也不知道能不能继续走下去。唉,不管怎么说还是加油吧,要分也是他甩我吧 A: 差不多都加油 B: 其实已经分开了,祝你们好运,加油 A: 哦,其实现实挺残酷的,希望我和他能坚持吧	A: Is there any long-distance relationship between Scorpio and Virgo people? B: We are in the same country but different cities, tortured every day. It has been almost five months, and I don't know if we can keep going. Anyway, I will try my best until he couldn't hold on any longer. A: We are all the same. Let's cheer up! B: We have already broken up. Good luck guys! Cheer up! A: Actually, the reality is cruel. Hope we can hold on.
Response 1 (*Ground Truth*): 呵呵,现实确实残酷! Response 2 (*Distractor*): 其实海贼已经是现实的一个逃脱了,坚持就会成真,这样的事其实在现实里吧多少是掺了假的	Response 1 (*Ground Truth*): Hoho, indeed the reality is grim! Response 2 (*Distractor*): One Piece is an escapism that persistence making dreams come true. However, it does not always happen in the real world.
Case 2 given by SMN	
A: 亚航特价票在哪里改名 B: 好像不用给钱哦,我也是抢的特价票,然后换名.你可以去问问先 A: 我是8月份买的 B: 具体的我也不太清楚了哦.但是改名应该是可以的吧.只要提供有效证件什么的	A: How can I change the passenger name of the discount ticket of AirAsia Airline? B: It seems to be free. I have once bought a discount ticket and then changed the passenger name. You can ask them first. A: I bought the ticket in this August. B: I am not sure about the details. But changing passenger name ought to be allowed as long as you provide valid identification.
Response 1 (*Ground Truth*): 这样子的啊,好的,谢谢楼主 Response 2 (*Distractor*): 我是说具体位置	Response 1 (*Ground Truth*): Ok, I see. Thank you! Response 2 (*Distractor*): I mean the details of location.

Table 6: Two cases from the test set of Douban are listed above, and both of them have Response 1 as a ground-truth response. Though each dialogue has ten candidates, we show only two of them due to space limitations. The dialogues are in Chinese (the left) and we also provide their translated version in English (the right).

introduced in Section 2 that these models may mistake the fuzzy-candidate with few improper details for the best response due to the gap between training and testing. In contrast, after adopting our training approach, the G-SMN and G-DAM correctly identify the improper content in the negative responses and successfully select response 1 as the best response.

6 Related Work

Some researchers also studied how to improve the performance of existing matching models with a better learning method. Wu et al. (2018) proposed to leverage a Seq2Seq model as a weak annotator to assign a score for each response candidate of the dialogue and learn matching models through the scores. Feng et al. (2019) introduced the co-teaching framework (Han et al., 2018) for eliminating the effect of training noises. The learning approach maintains two matching models and makes them teach each other. Li et al. (2019) attempted to neglect the effect of false negatives and trivial true responses by adopting four negative sampling strategies to choose negative samples during training dynamically. Different from those previous works, our approach makes use of grayscale data from heterogeneous sources and learns progressive quality relationships. In addition, our work enhances retrieval models with generation models, which is on par with recent attempts (Cai et al., 2019a,b) to strengthen generation models via retrieval models.

7 Conclusions

We presented a novel approach for training response selection models for multi-turn conversations. It automatically constructs different types of grayscale data and uses a multi-level ranking objective. The proposed approach can teach a matching model to capture fine-grained quality differences better and reduce the train-test discrepancy in distractor strength. Experimental results on three benchmark datasets and four state-of-the-art models demonstrated the effectiveness of the proposed training approach.

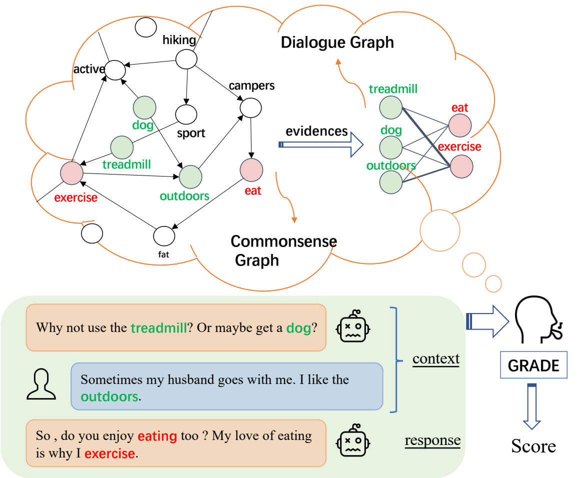
Abstract

Automatically evaluating dialogue coherence is a challenging but high-demand ability for developing high-quality open-domain dialogue systems. However, current evaluation metrics consider only surface features or utterance-level semantics, without explicitly considering the fine-grained topic transition dynamics of dialogue flows. Here, we first consider that the graph structure constituted with topics in a dialogue can accurately depict the underlying communication logic, which is a more natural way to produce persuasive metrics. Capitalized on the topic-level dialogue graph, we propose a new evaluation metric **GRADE**, which stands for **G**raph-enhanced **R**epresentations for **A**utomatic **D**ialogue **E**valuation. Specifically, GRADE incorporates both coarse-grained utterance-level contextualized representations and fine-grained topic-level graph representations to evaluate dialogue coherence. The graph representations are obtained by reasoning over topic-level dialogue graphs enhanced with the evidence from a commonsense graph, including k-hop neighboring representations and hop-attention weights. Experimental results show that our GRADE significantly outperforms other state-of-the-art metrics on measuring diverse dialogue models in terms of the Pearson and Spearman correlations with human judgements. Besides, we release a new large-scale human evaluation benchmark to facilitate future research on automatic metrics.



Why not use the treadmill? Or maybe get a dog?

Sometimes my husband goes with me. I like the outdoors.

So , do you enjoy eating too ? My love of eating is why I exercise.

Figure 1: An illustrative example of how our GRADE evaluates dialogue coherence by incorporating graph information on topic transitions from a commonsense graph. Topic keywords of the context and the response are highlighted in **green** and **red** respectively, which can be aligned to the corresponding nodes in the commonsense graph. The white nodes and all the edges in the commonsense graph are pieces of evidence that assist in constructing the dialogue graph. Taking advantage of such evidence, GRADE can better capture the topic transition dynamics between the context and the response, as shown in the thickness of edges in the dialogue graph.

1 Introduction

Coherence, what makes dialogue utterances unified rather than a random group of sentences, is an essential property to pursue an open-domain dialogue system aiming at conversing with humans. Although open-domain dialogue systems have achieved significant progress and performed much more human-like skills in recent years (Zhou et al., 2020; Adiwardana et al., 2020; Roller et al., 2020), automatically measuring dialogue coherence for state-of-the-art open-domain dialogue models is still an open and under-explored research problem attributing to the open-ended nature of dialogue (See et al., 2019).

Statistic-based automatic metrics, such as BLEU (Papineni et al., 2002), mostly rely on the degree of word overlap between a dialogue response and its corresponding gold response. However,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9230–9240,
November 16–20, 2020.

due to the ignorance of the underlying semantic of a response, they are biased and correlate poorly with human judgements in terms of response coherence (Liu et al., 2016). To overcome this issue, some learning-based metrics were proposed to train a coherence scoring model by considering the utterance-level semantics, such as ADEM (Lowe et al., 2017), RUBER (Tao et al., 2018), and BERT-RUBER (Ghazarian et al., 2019). However, a coherent real-world dialogue should be not only coherent among utterances but also smooth at topic transition. As shown in Figure 1, the topics inside a coherent dialogue are close to each other in the commonsense graph, which embodies a smooth topic transition. Although the above metrics have demonstrated higher correlations with human judgements than statistic-based metrics, they only model dialogue coherence at utterance level without explicitly considering the fine-grained topic transition dynamics of dialogue flows.

To address the above problems, we propose a new automatic metric for open-domain dialogue systems, named as **G**raph-enhanced **R**epresentation for **A**utomatic **D**ialogue **E**valuation (GRADE), which explicitly models topic transition dynamics by reasoning over dialogue graphs and incorporates them into utterance-level contextualized representations. As a result, our method can capture more accurate semantic transition information, thus measuring dialogue coherence in a more human-like manner.

Specifically, our GRADE consists of two semantic extraction branches. One branch deploys BERT (Devlin et al., 2019) to learn the coarse-grained utterance-level contextualized representations, while another learns the fine-grained topic-level graph representations by constructing topic-level dialogue graphs and applying a graph neural network on the graphs to model the topic transition dynamics. As to the dialogue graph construction, we determine nodes and edges by utilizing the evidence from the commonsense knowledge graph, ConceptNet (Speer et al., 2017), including k-hop neighboring representations and hop-attention weights. GRADE is trained in an unsupervised manner with data automatically generated by a negative sampling strategy considering both lexical and semantic aspects rather than random sampling adopted by previous works (Tao et al., 2018; Ghazarian et al., 2019). Experimental results show that GRADE significantly outperforms other state-of-the-art metrics in terms of the Pearson and Spearman correlations with human judgements and can generalize to unseen chit-chat datasets well.

Our contributions are summarized as follows:

- We propose GRADE, a novel automatic coherence metric for evaluating open-domain dialogue systems, which is the first attempt to introduce graph reasoning into dialogue evaluation.
- We demonstrate the effectiveness of incorporating graph information into dialogue evaluation. Extensive experiments show that GRADE has significantly stronger correlations with human judgements than other state-of-the-art metrics.
- We construct and release a new large-scale human evaluation benchmark with 11910 human annotations to the research community for encouraging future study on automatic metrics.

The code and data are available at `https://github.com/li3cmz/GRADE`.

2 Related Work

Automatic evaluation for open-domain dialogue systems is difficult since there are many appropriate responses for a dialogue context under the open-domain setting, known as the one-to-many problem (Zhao et al., 2017).

Initially, the statistic-based metrics in language generation tasks are adopted for dialogue evaluation, such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and ROUGE (Lin, 2004). These metrics use statistical rules to measure the surface similarity between generated responses and reference responses. For example, BLEU computes the geometric average of the n-gram precisions. However, they can not cope with the one-to-many problem and have weak correlations with human judgements (Liu et al., 2016).

In recent years, learning-based metrics have increasingly attracted interest from researchers. ADEM proposed by Lowe et al. (2017) achieves higher correlations with human judgements than the statistic-based metrics, which is trained with human-annotated data in a supervised manner. However, it is time-consuming and expensive to obtain large amounts of annotated data. To reduce the cost of obtaining annotated data, Tao et al. (2018) trained their metric RUBER with auto-constructed negative samples in an unsupervised manner.

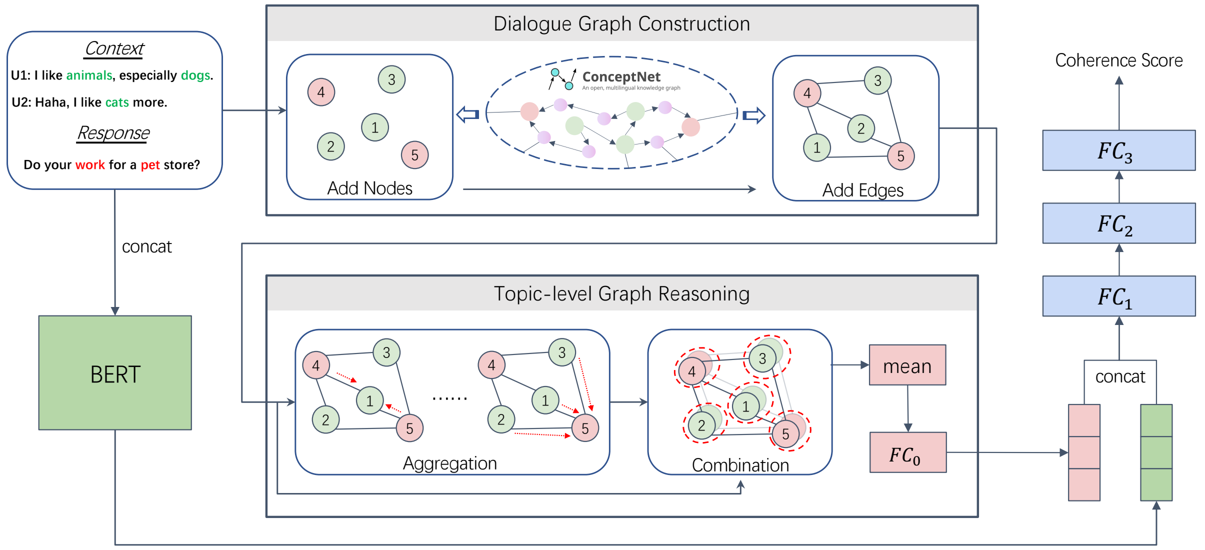

Figure 2: The architecture of GRADE consists of two semantic extraction branches. One branch encodes the context-response pair with BERT, while the other constructs a topic-level dialogue graph for the pair by utilizing the evidence from ConceptNet and performs reasoning over the constructed graph. The representations from the two branches are concatenated and fed into a MLP to compute the final coherence score. Note that the **green** and **red** nodes are corresponding to the keywords in the context and the response respectively.

With the advances of the pre-trained language model, BERT (Devlin et al., 2019) has been adopted for dialogue or NLG evaluation. Ghazarian et al. (2019) proposed BERT-RUBER, which outperforms RUBER significantly by incorporating BERT embeddings. BERTScore (Zhang et al., 2020) performs soft-overlap between candidate and reference sentences by using BERT embeddings directly without fine-tuning, and has been shown to correlate with human judgment robustly. Besides, Sellam et al. (2020) introduced BLEURT by further training regular pre-trained BERT with an elaborate pre-training scheme and fine-tuning on small amounts of rating data, which yields superior results.

Note that our model differs from the above learning-based metrics in two folds. First, our metric is trained with high-quality negative samples that are similar to the ground truths in both lexical and semantic aspects instead of randomly sampling. Second, different levels of representations are considered in our GRADE, especially the fine-grained topic-level graph representation.

3 GRADE Metric

In this paper, we focus on designing an evaluation metric that can automatically assess the coherence of responses produced by dialogue models. Formally, given a dialogue context $\boldsymbol{c} = \{c_1, \cdots, c_m\}$ and a response $\boldsymbol{r} = \{r_1, \cdots, r_n\}$, where each c_k is a token in the context and each r_k is a token in the response, our goal is to learn a function $f : (\boldsymbol{c}, \boldsymbol{r}) \rightarrow s$ that predicts the coherence score s.

As illustrated in Figure 2, our GRADE predicts a coherence score s between a context $\boldsymbol{c}$ and a response $\boldsymbol{r}$ in three steps: (1) producing the utterance-level contextualized representation $\boldsymbol{v}_c$ (Section 3.1); (2) generating the topic-level graph representation $\boldsymbol{v}_g$ (Section 3.2 and Section 3.3); (3) predicting the coherence score s based on $\boldsymbol{v}_c$ and $\boldsymbol{v}_g$ (Section 3.4). The training details of our GRADE is elaborated in Section 3.5.

3.1 Utterance-level Contextualized Encoding

We use BERT (Devlin et al., 2019) to encode the context $\boldsymbol{c}$ and the response $\boldsymbol{r}$. The pooled output feature of BERT is then taken as the utterance-level contextualized representation $\boldsymbol{v}_c$:

$$\boldsymbol{v}_c = BERT(\boldsymbol{c}, \boldsymbol{r}). \tag{1}$$

3.2 Dialogue Graph Construction

We construct a topic-level dialogue graph based on $\boldsymbol{c}$ and $\boldsymbol{r}$, denoted as $G = (V, E)$, where V is a set of topic nodes and E is a set of edges between topics. The details are described as follows.

Nodes. To determine the nodes in G, we first apply a rule-based keyword extractor that combines both TF-IDF and Part-Of-Speech features (Tang et al., 2019), to extract the keywords of $\boldsymbol{c}$ and $\boldsymbol{r}$. Then the keywords in $\boldsymbol{c}$ is the context-topic nodes of G, denoted as $V_c = \{t_1, t_2, ..., t_p\}$, while the keywords in $\boldsymbol{r}$ is the response-topic nodes of G, denoted as $V_r = \{t_{p+1}, t_{p+2}, ..., t_{p+q}\}$, where p and q are the numbers of keywords in the context $\boldsymbol{c}$ and the response $\boldsymbol{r}$ respectively. Therefore, $V = V_c \cup V_r$. After determining the nodes, we utilize ConceptNet to obtain node representations. Specifically, each topic node t_i is aligned to the corresponding node in ConceptNet and first initialized as $\boldsymbol{h}_i = CN(t_i) \in R^d, i \in [1, p+q]$, where $\boldsymbol{h}_i$ is the initial representation of the node t_i, CN means the ConceptNet Numberbatch embeddings[1], d is the dimension of each node representation. Furthermore, in order to preferably capture the topic relations in reality, $\boldsymbol{h}_i$ is updated with the representations of its k-hop neighbors in ConceptNet, named as k-hop neighboring representations:

$$\boldsymbol{h}_{\bar{\mathcal{N}}_i^k} = \frac{1}{|\bar{\mathcal{N}}_i^k|} \sum_{t_j \in \bar{\mathcal{N}}_i^k} CN(t_j), \tag{2}$$

$$\bar{\boldsymbol{h}}_i = \boldsymbol{h}_i + \sum_{k=1}^{K} (\boldsymbol{W}_k \boldsymbol{h}_{\bar{\mathcal{N}}_i^k} + \boldsymbol{b}), \tag{3}$$

where K is the maximum number of hops taken into account and is set as 2, $\bar{\mathcal{N}}_i^k$ is the k^{th} hop neighboring nodes of t_i in the ConceptNet graph, $\boldsymbol{W}_k$ and $\boldsymbol{b}$ are the weight matrix and bias vector respectively.

Edges. Since our goal is to predict a coherence score of a response based on a context, we only consider the edges between the context nodes V_c and the response nodes V_r. In other words, the edges only exist between each context-topic node V_c^i and each response-topic node V_r^j. Moreover, we consider G as a weighted undirected graph and assign a weight to each edge of G by heuristically using the hop information in the ConceptNet commonsense graph, named as hop-attention weights. Specifically, let the weighted adjacency matrix of G as $\boldsymbol{A}$, then the hop-attention weight of the edge between the nodes t_i and t_j (i.e., $\boldsymbol{A}[i][j]$) is determined by:

$$\boldsymbol{A}[i][j] = \frac{1}{\#hops(V_c^i, V_r^j))}, \tag{4}$$

where $\#hops(\cdot)$ indicates the shortest path between V_c^i and V_r^j over the ConceptNet graph. As a result, the distances between topic nodes are redefined and the nodes that are far away from each other will have low weight values. After determining the edges, we randomly deactivate a certain number of edges from G at each training step to prevent over-smoothing, and normalize the adjacency matrix A (Rong et al., 2020):

$$\bar{\boldsymbol{A}} = (\boldsymbol{D} + \boldsymbol{I})^{-1/2} (\boldsymbol{A} + \boldsymbol{I}) (\boldsymbol{D} + \boldsymbol{I})^{-1/2}, \tag{5}$$

where $\bar{\boldsymbol{A}}$ is the augmented normalized adjacency matrix, $\boldsymbol{D}$ is the corresponding degree matrix of $\boldsymbol{A}$ and $\boldsymbol{I}$ is the identity matrix.

3.3 Topic-level Graph Reasoning

We explicitly model the topic transition dynamics by reasoning over the constructed topic-level graph G via two steps: aggregation and combination (Hamilton et al., 2017).

In the first step, we apply the graph attention network(GAT) (Veličković et al., 2018) to aggregate neighboring information of each node t_i. The aggregated representation $\boldsymbol{z}_i^{(l)}$ at the layer l for the node t_i is formulated as follows:

$$\boldsymbol{z}_i^{(l)} = \sum_{j \in \mathcal{N}_i} \alpha_{ij} \mathbf{W}_l \boldsymbol{h}_j^{(l)}, \tag{6}$$

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{n \in \mathcal{N}_i} \exp(e_{in})}, \tag{7}$$

$$e_{ij} = \bar{\boldsymbol{A}}[i][j] * \rho \left(\boldsymbol{a}_l^T \left[\mathbf{W}_l \boldsymbol{h}_i^{(l)} \| \mathbf{W}_l \boldsymbol{h}_j^{(l)} \right] \right), \tag{8}$$

where $\boldsymbol{h}_i^{(0)} = \bar{\boldsymbol{h}}_i$, $\mathcal{N}_i$ is the neighboring nodes of t_i in the dialogue graph G, $W_l \in R^{d \times d}$ and $\boldsymbol{a}_l \in R^{2d}$ are learnable parameters, α_{ij} is the attention coefficient, ρ is LeakyReLU, and $\cdot^T$ represents transposition. Note that we scale the attention coefficients with the above augmented normalized adjacency matrix $\bar{\boldsymbol{A}}$, as shown in equation 8, so that the network will pay more attention to the nodes that are closer to t_i in the ConceptNet graph during the aggregation.

In the second step, the aggregated representation $\boldsymbol{z}_i^{(l)}$ is combined with the i^{th} node representation $\boldsymbol{h}_i^{(l)}$ to get the updated node representation $\boldsymbol{h}_i^{(l+1)}$:

$$\boldsymbol{h}_i^{(l+1)} = ELU\left(\mathbf{V}_l \boldsymbol{h}_i^{(l)} + \boldsymbol{z}_i^{(l)} \right), \tag{9}$$

where $V_l \in R^{d \times d}$ is the weight matrix to transform $\boldsymbol{h}_i^{(l)}$, and ELU represents an exponential linear unit (Clevert et al., 2016).

Finally, the topic-level graph representation $\boldsymbol{v}_g$ is obtained by:

$$\boldsymbol{v}_g = FC_0(mean(\{\boldsymbol{h}_i^{(L)} | i \in [1, p+q]\})), \tag{10}$$

---

[1] `https://github.com/commonsense/conceptnet-numberbatch`

where $\boldsymbol{h}_i^{(L)}$ is the i^{th} node representation at the last layer, $mean$ represents mean pooling and FC_0 is a fully-connected layer with a ELU activation.

3.4 Coherence Scoring

To compute the coherence score s, the contextualized representation $\boldsymbol{v}_c$ and the graph representation $\boldsymbol{v}_g$ are concatenated together and fed into a multi-layer perceptron(MLP) to transform the high-dimensional representation into a real number:

$$s = FC_3(FC_2(FC_1([\boldsymbol{v}_c; \boldsymbol{v}_g]))), \qquad (11)$$

where FC_1, FC_2 and FC_3 are three different fully-connected layers whose activation functions are ELU, ELU and sigmoid, respectively.

3.5 Training

Training Objective. Inspired by Tao et al. (2018), we train our GRADE in an unsupervised manner. Given a dataset $D = \{(\boldsymbol{c}_i, \boldsymbol{r}_i, \bar{\boldsymbol{r}}_i) | i \in [1, N]\}$, where $\boldsymbol{c}_i$ and $\boldsymbol{r}_i$ are a ground-truth context-response pair and $\bar{\boldsymbol{r}}_i$ is a false response for the context $\boldsymbol{c}_i$ selected by using negative sampling described in the next paragraph, then GRADE is trained to predict a higher score for each ground-truth response $\boldsymbol{r}_i$ than its corresponding false response $\bar{\boldsymbol{r}}_i$ by minimizing the following margin ranking loss:

$$\mathcal{L} = \frac{1}{N} \sum_{i=1}^{N} max(0, \bar{s}_i - s_i + m), \qquad (12)$$

where N is the size of the dataset, m is a margin value set as 0.1, s_i and $\bar{s}_i$ are the coherence scores of $\boldsymbol{r}_i$ and $\bar{\boldsymbol{r}}_i$ respectively in the i^{th} example.

Negative Sampling. Following Sato et al. (2020), we select the false response $\bar{\boldsymbol{r}}$ that is similar to the ground-truth response $\boldsymbol{r}$, instead of random sampling adopted in previous works (Tao et al., 2018; Ghazarian et al., 2019). Overall, we generate negative samples by two sampling methods: lexical sampling and embedding-based sampling. For lexical sampling, we use Lucene[2] to retrieve utterances that are related to the ground-truth response $\boldsymbol{r}$ from the training set, and select the middle one in the retrieved utterances as the false response $\bar{\boldsymbol{r}}$. For embedding-based sampling, we first randomly sample 1000 utterances and take the utterances with the top-5 cosine similarity against the ground-truth response $\boldsymbol{r}$.[3] The false response $\bar{\boldsymbol{r}}$ is then randomly selected from the top-5 utterances.

4 Experiments

4.1 Experimental Setup

Dialogue Models. We consider both retrieval-based and generation-based dialogue models to obtain diverse responses for metric evaluation so that the performance of the metrics can be assessed comprehensively. Specifically, we first deploy Transformer-Ranker and Transformer-Generator from the ParlAI platform (Miller et al., 2017), where the former is retrieval-based and the latter is generation-based. Besides, we also deploy two state-of-the-art dialogue models, BERT-Ranker (Jack Urbanek, 2019) and DialoGPT (Zhang et al., 2019) that can output more human-like responses than Transformer-Ranker and Transformer-Generator.

Baseline Metrics. We compare our GRADE with seven dialogue metrics, consisting of three statistic-based metrics: BLEU (Papineni et al., 2002) ROUGE (Lin, 2004) and METEOR (Banerjee and Lavie, 2005), four learning-based metrics: ADEM (Lowe et al., 2017), BERT-RUBER (Ghazarian et al., 2019), BERTScore (Zhang et al., 2020) and BLEURT (Sellam et al., 2020). Note that, for comparison, we only present the BLEU-4 results for BLEU metric, and ROUGE-L for ROUGE, BERTScore-F1 for BERTScore.

Datasets. We use the DailyDialog[4] (Li et al., 2017) dataset which contains high-quality open-domain conversations about daily life including diverse topics, to learn our GRADE. In addition, another two chit-chat datasets, ConvAI2[5] (Dinan et al., 2019) and EmpatheticDialogues[6] (Rashkin et al., 2019), are considered as unseen datasets to verify the transferability of the metrics. The details of the datasets are provided in Appendix A.

Implementation Details. We use $BERT_{BASE}$ for the utterance-level contextualized encoding. For the graph reasoning module, the GAT layer is set as 3 and the number of heads is 4, where both the input and output dimensions are 300. To train GRADE, we use Adam (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and set batch size as 16, learning rate as 2e-5. Our GRADE is implemented with a natural language processing toolkit, Texar-Pytorch (Hu et al., 2019).

Human Judgements. We collected human judge-

[6] `https://github.com/facebookresearch/EmpatheticDialogues`

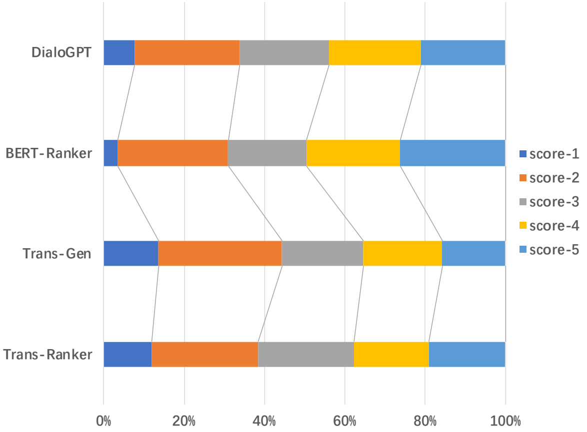

Figure 3: Score distributions of human judgements on the ConvAI2 dataset. Trans-Gen and Trans-Ranker refer to the Transformer-Generator and Transformer-Ranker dialogue models respectively.

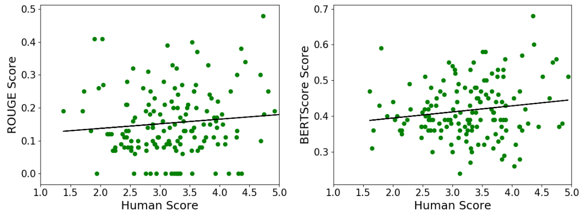
ments from Amazon Mechanical Turk (AMT). Each survey contained six questions, including five coherence questions and one attention check question. The submissions failed in the attention check are directly discarded. For each coherence question, workers were provided with a context-response pair and asked to assess the coherence between the context and the response on a scale of 1-5 (not coherent at all to very coherent). Each pair was assessed by 8 to 10 individual workers. In total, there are 1200 different pair and 11910 human annotations from 217 unique workers, as the final human judgements. As shown in Figure 3, the distributions of human judgements are balanced from score 1 to 5. Moreover, It also demonstrates that the dialogue models we selected are diverse in performance, which helps comprehensively assess the abilities of the metrics.

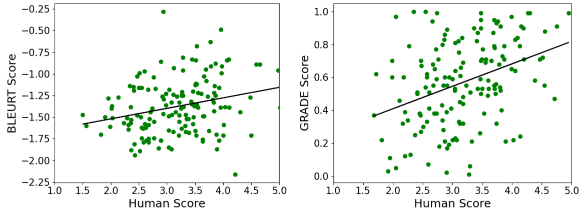
4.2 Experimental Results

DailyDialog Dataset. The test set results of the DailyDialog dataset are presented in Table 1. Overall, our GRADE obtains the highest correlations with human judgements in average. Although the Spearman value of GRADE on the Transformer-Ranker is lower than BLEURT which is trained on a very large-scale dataset, the averaged correlation result of GRADE is 1% higher than BLEURT. Besides, all the correlation results of GRADE are statistically significant with p-value <0.05, which is more reliable than the baselines.

Other Unseen Datasets. To verify the transferability of our GRADE, we further evaluate the human correlations of GRADE compared with other baselines on two unseen chit-chat datasets, ConvAI2 and EmpatheticDialogues. Results in Table 1 show that GRADE can easily adapt to other unseen datasets without any re-training and obtain more stable and higher correlations with human judgements than the baseline metrics. It is noteworthy that all Pearson and Spearman correlations of GRADE are statistically significant with p-value < 0.05, and most of them are with p-value < 0.01. Particularly, GRADE achieves a significant Pearson correlation of 0.606 and Spearman correlation of 0.617 for evaluating Transformer-Generator on the ConvAI2 dataset, bringing an improvement of 0.411 (Pearson) and 0.417 (Spearman) compared with BLEURT. Furthermore, Table 2 presents the correlation results of GRADE and other baselines for evaluating two state-of-the-art dialogue models, BERT-Ranker and DialoGPT. Our GRADE significantly outperforms the baseline metrics on human correlations, which shows that GRADE is better at evaluating the coherence of high-quality responses. Besides, Figure 4 illustrates the scatter plots against human judgements for DialoGPT on the ConvAI2 dataset. We can see that the scores predicted by GRADE are closer to the human scores than the baseline metrics, which intuitively shows the superiority of our GRADE.



(a) ROUGE (b) BERTScore



(c) BLEURT (d) GRADE

Figure 4: Score correlations between auto-metrics and human judgements, presented in a scatter plot form. Each point is associated with a context-response pair where the context is from the ConvAI2 dataset, and the response is generated by the DialogPT model.

4.3 Ablation Studies

We perform ablation studies[7] for the main components of GRADE to better analyze their relative contributions. The results are shown in Table 3.

Does the negative sampling strategy work? We

---

[7] For each ablation experiment, We run five times and take the averaged result since the results fluctuate over different runs (more details in Section 5).

Table 2: Correlations between auto-metrics and human judgements on the ConvAI2 dataset and two dialogue models, Bert-Ranker and DialoGPT, respectively.

first verify the effectiveness of our negative sampling strategy by replacing it with random sampling. As shown in Table 3, adopting the random sampling strategy hurts performance significantly with a 6.6% drop in average, which indicates the importance of our negative sampling strategy.

Does the graph work? To prove the contribution of our graph components, we perform three ablations respectively: 1) remove the entire graph branch of GRADE; 2) remove the k-hop neighboring representations used for initializing the node representations in the dialogue graph; 3) remove the hop-attention weights used for computing a weight for each edge in the dialogue graph. Consequently, the performance of GRADE decreased after removing the graph branch or one of the components in the graph branch.

How much graph information we need? Finally, we explore the number of k-hop neighboring representations needed for initializing the dialogue graph's nodes in two aspects: the maximum number of hops (refer to the K in Equation 3), and the number of neighboring nodes in the k^{th} hop (denoted as N_k, i.e., the number of nodes in $\bar{\mathcal{N}}_i^k$ in Equation 3). By comparing the results among the first row and the last three rows in Table 3, we confirm that incorporating both the 1^{st} hop and the 2^{nd} hop neighboring nodes brings the best performance. Furthermore, we also observe that considering too much graph information may result in relatively poor performance, as shown in the last row. Therefore, the final version of GRADE adopts the 2-hop neighboring representations where $N_1 = 10, N_2 = 10$.

Metric	Transformer-Ranker		Transformer-Generator		Average
	Pearson	Spearman	Pearson	Spearman	
Our GRADE ($N_1 = 10, N_2 = 10$)	**0.227** ±0.018	**0.162** ±0.015	**0.364** ±0.017	**0.372** ±0.018	**0.281** ±0.008

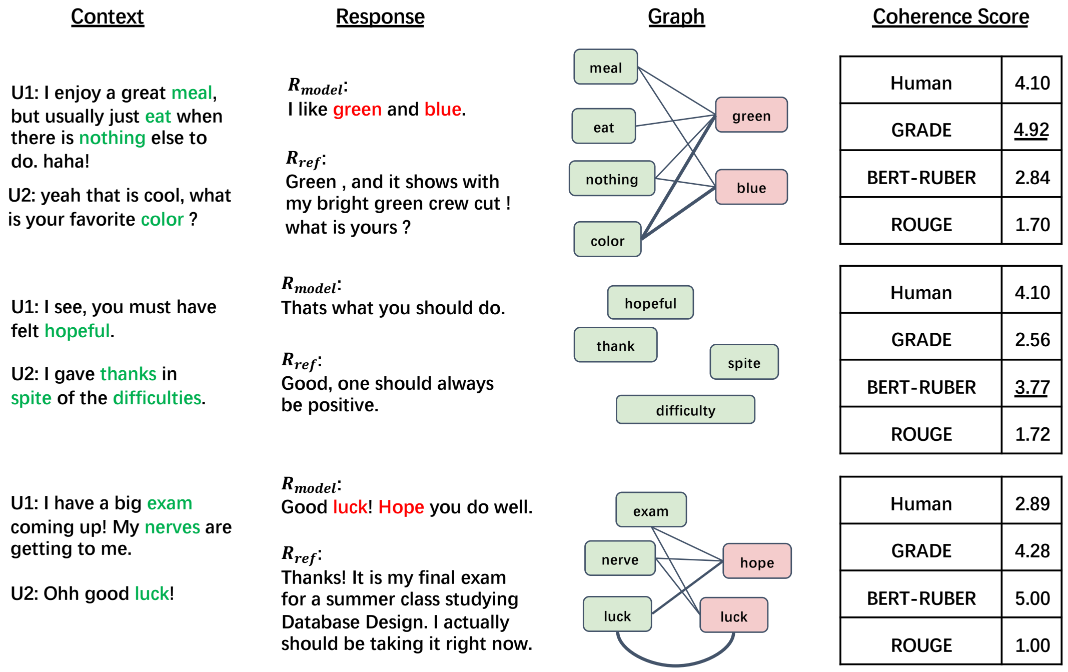
Table 3: Ablation results on the DailyDialog dataset, averaged across five random seeds, with standard deviations presented in gray color. N_1 and N_2 refer to the numbers of the 1^{st} and 2^{nd} hop neighboring nodes in ConceptNet, respectively. The symbol $\star$ indicates that three or more than three correlation results over the five random seeds are not statistically significant, namely, p-value > 0.05.



U1: I enjoy a great meal, but usually just eat when there is nothing else to do. haha!

U2: yeah that is cool, what is your favorite color ?

R_{model}:
I like green and blue.

R_{ref}:
Green , and it shows with my bright green crew cut ! what is yours ?

Human	4.10
GRADE	4.92
BERT-RUBER	2.84
ROUGE	1.70

U1: I see, you must have felt hopeful.

U2: I gave thanks in spite of the difficulties.

R_{model}:
Thats what you should do.

R_{ref}:
Good, one should always be positive.

Human	4.10
GRADE	2.56
BERT-RUBER	3.77
ROUGE	1.72

U1: I have a big exam coming up! My nerves are getting to me.

U2: Ohh good luck!

R_{model}:
Good luck! Hope you do well.

R_{ref}:
Thanks! It is my final exam for a summer class studying Database Design. I actually should be taking it right now.

Human	2.89
GRADE	4.28
BERT-RUBER	5.00
ROUGE	1.00

Figure 5: Visualization results of our GRADE, compared with two baseline metrics, ROUGE and BERT-RUBER. Keywords of the contexts and the model responses $\boldsymbol{R}_{model}$ are highlighted in **green** and **red** respectively. $\boldsymbol{R}_{ref}$ is the reference response. For comparison, the auto-metric scores are normalized to the range of human scores, i.e., [1,5].

4.4 Case Study

To more intuitively analyze the performance of our GRADE, three representative examples are shown in Figure 5. From the example in the first row, we can see that the score given by our metric is closer to the human score than the other two baseline metrics. However, in the second-row example, our metric performs poorly. The potential reason may be the lack of topics (i.e., keywords) in the model response, as illustrated in the graph that only contains context-topic nodes. As a result, the graph reasoning module in our GRADE fails to induce an appropriate graph representation, which harms the coherence scoring. Finally, the example in the last row shows a hard case that both our GRADE and the baseline metrics are failed to cope with. In this hard case, the topics of the model response are relevant to the dialogue context so that both our GRADE and BERT-RUBER, as learning-based metrics, deem that the response greatly matches the context. However, the truth is that the model response is more likely a response for the previous utterance **U1** rather than **U2**, which is hard for metrics to recognize.

5 Conclusion and Discussion

In this paper, we proposed GRADE (Graph-enhanced Representations for Automatic Dialogue Evaluation), a novel metric for dialogue coherence evaluation of open-domain dialogue systems. Empirical results show that GRADE has stronger correlations with human judgements and can generalize to other unseen chit-chat datasets. Besides, we also release a new large-scale human evaluation benchmark to facilitate future research on automatic metrics.

A limitation of GRADE is the inconsistency between the training objective (relative ranking) and the expected behavior (absolute scoring). Specifically, the ranking loss we adopted only requires good responses to be ranked higher than bad responses, which is a relatively loose constraint compared with the absolute scoring that humans do. Therefore, GRADE may deviate from the human scoring criterion and fail to quantify the dialogue responses accurately, and that the human correlation results fluctuate over different runs. Overall, to develop a dialogue metric that can quantify in a more human-like manner, it is critical to reducing the gap between the training objective and the model behavior we truly care about.

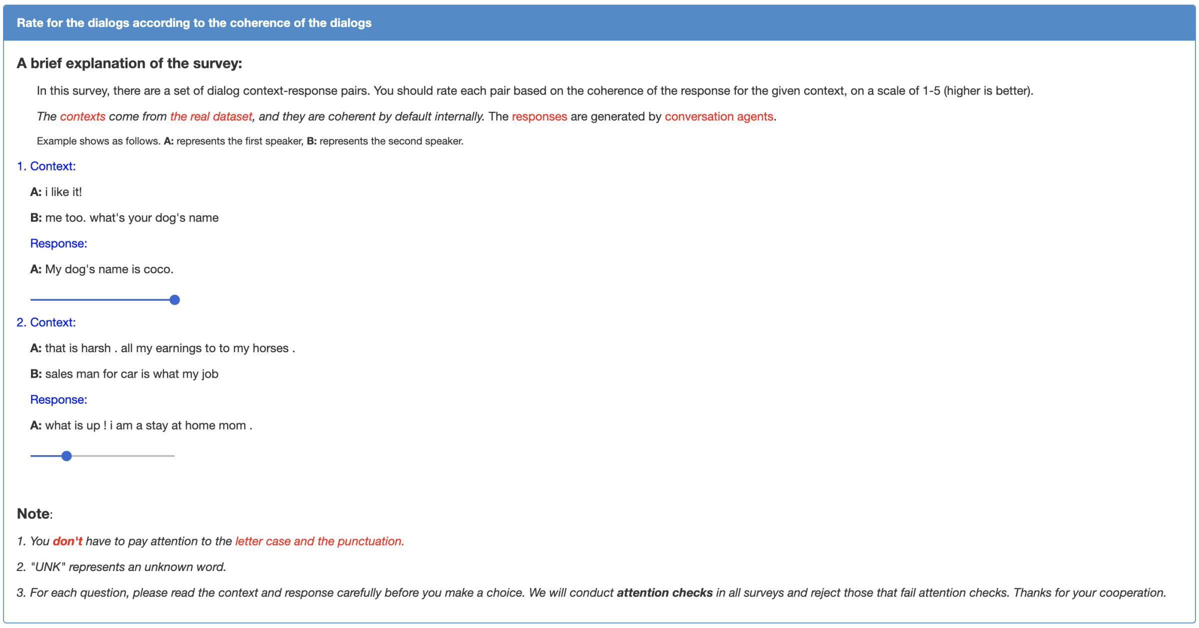
A Details of the Datasets

The detailed processing procedure of DailyDialog and the introduction of the other two unseen datasets are presented.

DailyDialog is a chit-chat dataset with strong annotations for topic, emotion and utterance act. It contains total 13,118 open-domain multi-turn dialogues. We use the initial split of DailyDialog where training/validation/test sets have 11,118/1,000/1,000 dialogues respectively. Next, we subdivide these dialogues into context-response pairs each of which is composed of a context $\boldsymbol{c}$ with length = 2 and a ground-truth response $\boldsymbol{r}$. Therefore, the processed training/validation/test sets now have 59264/6015/5705 pairs respectively. Then, for each context-response pair, we obtain two false responses $\bar{\boldsymbol{r}}_l$ and $\bar{\boldsymbol{r}}_e$ based on the lexical sampling and embedding-based sampling methods respectively, and get two tuples $(\boldsymbol{c}, \boldsymbol{r}, \bar{\boldsymbol{r}}_l)$, $(\boldsymbol{c}, \boldsymbol{r}, \bar{\boldsymbol{r}}_e)$. In total, there are 118528/12030/11410 tuples as our final data for training GRADE.



Rate for the dialogs according to the coherence of the dialogs

A brief explanation of the survey:

In this survey, there are a set of dialog context-response pairs. You should rate each pair based on the coherence of the response for the given context, on a scale of 1-5 (higher is better).

The contexts come from the real dataset, and they are coherent by default internally. The responses are generated by conversation agents.

Example shows as follows. **A:** represents the first speaker, **B:** represents the second speaker.

1. Context:

A: i like it!

B: me too. what's your dog's name

Response:

A: My dog's name is coco.

2. Context:

A: that is harsh . all my earnings to to my horses .

B: sales man for car is what my job

Response:

A: what is up ! i am a stay at home mom .

Note:

1. You ***don't*** *have to pay attention to the letter case and the punctuation.*

2. "UNK" represents an unknown word.

3. For each question, please read the context and response carefully before you make a choice. We will conduct ***attention checks*** *in all surveys and reject those that fail attention checks. Thanks for your cooperation.*

Figure 6: Screenshot of the survey's introduction on AMT for collecting the human judgements.

ConvAI2 is a chit-chat dataset based on the PersonaChat dataset (Dinan et al., 2019) for a NIPS 2018 competition. The dataset was collected by asking workers to chat with each other naturally with a given persona. The conversations cover a broad range of topics and frequently change during the conversations since both the speakers want to say out their persona information.

EmpatheticDialogues is a novel dataset of 25k conversations grounded in a wide range of emotions to facilitate training and evaluating dialogue systems. It has been verified that dialogue models trained on this dataset are perceived to be more empathetic by human evaluators.

Abstract

Medical dialogue systems are promising in assisting in telemedicine to increase access to healthcare services, improve the quality of patient care, and reduce medical costs. To facilitate the research and development of medical dialogue systems, we build large-scale medical dialogue datasets – MedDialog, which contain 1) a Chinese dataset with 3.4 million conversations between patients and doctors, 11.3 million utterances, 660.2 million tokens, covering 172 specialties of diseases, and 2) an English dataset with 0.26 million conversations, 0.51 million utterances, 44.53 million tokens, covering 96 specialties of diseases. To our best knowledge, MedDialog is the largest medical dialogue dataset to date. We pretrain several dialogue generation models on the Chinese MedDialog dataset, including Transformer, GPT, BERT-GPT, and compare their performance. It is shown that models trained on MedDialog are able to generate clinically correct and human-like medical dialogues. We also study the transferability of models trained on MedDialog to low-resource medical dialogue generation tasks. It is shown that via transfer learning which finetunes the models pretrained on MedDialog, the performance on medical dialogue generation tasks with small datasets can be greatly improved, as shown in human evaluation and automatic evaluation. The datasets and code are available at https://github.com/UCSD-AI4H/Medical-Dialogue-System

1 Introduction

Telemedicine refers to the practice of delivering patient care remotely, where doctors provide medical consultations to patients using HIPAA compliant video-conferencing tools. As an important complement to traditional face-to-face medicine practiced physically in hospitals and clinics, telemedicine has a number of advantages. First, it increases access to care. For people living in medically under-served communities (e.g., rural areas) that are in shortage of clinicians, telemedicine enables them to receive faster and cheaper care compared with traveling over a long distance to visit a clinician. Second, it reduces healthcare costs. In a study[1] by Jefferson Health, it is shown that diverting patients from emergency departments with telemedicine can save more than $1,500 per visit. Third, telemedicine can improve the quality of care. The study in (Pande and Morris, 2015) shows that telemedicine patients score lower for depression, anxiety, and stress, and have 38% fewer hospital admissions. Other advantages include improving patient engagement and satisfaction, improving provider satisfaction, etc. Please refer to (Wootton et al., 2017) for a more comprehensive review.

While telemedicine is promising, it has several limitations. First, it puts additional burden on physicians. In addition to practicing face-to-face medicine which already makes physicians very busy, physicians need to provide remote telemedicine consultations, which further increases the risk of physician burnout. Second, different from in-hospital patients, the progression of whose medical conditions can be easily tracked by clinicians, remote patients are difficult to track and monitor. To address such problems, there has been increasing research interest in developing artificial intelligence (AI) methods to assist in telemedicine. In particular, medical dialogue systems are being developed to serve as "virtual doctors". These "virtual doctors" are aimed to interact with patients via natural dialogues, asking about the medical conditions and history of patients and providing clinical advice. They can also proactively reach out to patients to ask about the progression of patients' conditions and provide timely interventions.

To build medical dialogue systems, a large collection of conversations between patients and doctors is needed as training data. Due to data privacy concerns, such data is difficult to obtain. The existing medical dialogue datasets (Xu et al., 2019; Yang et al., 2020) are limited in size or biased to certain diseases, which cannot adequately serve the purpose of training medical dialogue systems that can achieve doctor-level intelligence and cover many specialities in medicine.

To address the limitations of existing datasets, we build large-scale medical dialogue datasets – MedDialog – that contain 1) a Chinese dataset with 3.4 million conversations between patients and doctors, 11.3 million utterances, 660.2 million tokens, covering 172 specialties of diseases, and 2) an English dataset with 0.26 million conversations, 0.51 million utterances, 44.53 million tokens, covering 96 specialties of diseases. Both datasets cover almost all specialities in medicine, ranging from internal medicine to family medicine and covers a wide spectrum of diseases, including cancer, pneumonia, etc. To our best knowledge, they are the largest Chinese and English medical dialogue datasets to date. The data is open to the public. Each consultation starts with a description of medical conditions and history, followed by the conversation between doctor and patient. In certain consultations, doctors make diagnosis conclusions and give suggestions on treatment. The conversations have multiple turns.

On the Chinese MedDialog (MedDialog-CN) dataset, we train several dialogue generation models for the interested community to benchmark with. Generating a response given the conversation history can be formulated as a sequence-to-sequence (seq2seq) learning problem, where we use the Transformer (Vaswani et al., 2017) architecture to perform this task. Transformer consists of an encoder which embeds the conversation history and a decoder which generates the response. Both the encoder and decoder use self-attention to capture long-range dependency between tokens. In addition to training the Transformer on MedDialog-CN from scratch, we can pretrain the encoder and decoder on a corpora much larger than MedDialog-CN, then finetune them on MedDialog-CN. BERT-GPT (Wu et al., 2019; Lewis et al., 2019) is a pretrained model where the encoder is pretrained using BERT (Devlin et al., 2018) and the decoder is pretrained using GPT (Radford et al.). Besides the seq2seq formulation, dialogue generation can be formulated as a language modeling problem which generates the next token in the response conditioned on the concatenation of the already generated tokens in the response and the conversation history. GPT (Radford et al.; Zhang et al., 2019) is a pretrained language model based on Transformer decoder. BERT-GPT and GPT are finetuned on MedDialog-CN. We perform evaluation of these models using automatic metrics including perplexity, BLEU (Papineni et al., 2002a), Dist (Li et al., 2015), etc. The generated responses are clinically informative, accurate, and human-like.

We utilize the models trained on the large-scale MedDialog-CN dataset to improve performance in low-resource dialogue generation tasks where the dataset size is small. The study is performed on COVID-19 dialogue generation on the CovidDialog (Yang et al., 2020) dataset, which contains 1,088 dialogues and 9,494 utterances. The small size of this dataset incurs high risk of overfitting, if directly training the large-sized neural models on it. To alleviate this risk, we take the weights of dialogue generation models pretrained on MedDialog-CN and finetune the weights on CovidDialog. Human evaluation and automatic evaluation show that pretraining on MedDialog-CN can greatly improve the performance on CovidDialog and generate clinically meaningful consultations about COVID-19.

The major contributions of this paper are:

- We build large-scale medical dialog datasets – MedDialog, which contain 1) a Chinese dataset with 3.4 million conversations between patients and doctors, 11.3 million utterances, 660.2 million tokens, covering 172 specialties of diseases, and 2) an English dataset with 0.26 million conversations, 0.51 million utterances, 44.53 million tokens, covering 96 specialties of diseases. To our best knowledge, they are the largest of their kinds to date.
- We pretrain several dialogue generation models on the Chinese MedDialog dataset, including Transformer, BERT-GPT, and GPT, and compare their performance using automatic metrics.
- Through human evaluation and automatic evaluation, we show that the pretrained models on MedDialog-CN can significantly improve performance on medical dialogue generation tasks where the dataset size is small, via transfer learning.

The rest of this paper is organized as follows. Section 2 and 3 present the datasets and dialogue generation models (DGMs). Section 4 gives experimental results of developing DGMs on Chinese MedDialog and studies the transferability of DGMs trained on MedDialog-CN to other low-resource medical dialogue generation tasks. Section 5 reviews related works and Section 6 concludes the paper.

2 Related Works

There have been several works investigating medical dialogue generation. Wei et al. (Wei et al., 2018) built a task-oriented dialogue system for automatic diagnosis. The system detects the user intent and slots with values from utterances, tracks dialogue states, and generates responses. Xu et al. (Xu et al., 2019) developed a medical dialogue system for automatic medical diagnosis that converses with patients to collect additional symptoms beyond their self-reports and automatically makes a diagnosis. This system incorporates a medical knowledge graph into the topic transition in dialogue management. Xia et al. (Xia et al.) developed a reinforcement learning (RL) based dialogue system for automatic diagnosis. They proposed a policy gradient framework based on the generative adversarial network to optimize the RL model.

3 Datasets

Our MedDialog consists of a Chinese dataset and an English dataset, collected from different sources.

3.1 The Chinese MedDialog dataset

The Chinese MedDialog (MedDialog-CN) dataset contains 3.4 million Chinese dialogues (consultations) between patients and doctors. The total number of utterances is 11.3 million. Each consultation starts with the narration of patient' medical condition and history, including present disease, duration of the disease, allergies, medications, past diseases, etc. Then it follows with the multi-turn conversation between patient and doctor. In the conversation, there are cases that multiple consecutive utterances are from the same person (either doctor or patient) and these utterances were posted at different time points. For such cases, we combine the consecutive utterances from the same person into a single utterance. Optionally, at the end of the consultation, the doctor makes diagnosis and treatment suggestions to the patient. Table 1 shows statistics of the Chinese dataset. Figure 1 shows an exemplar consultation. The data is crawled from an online consultation website – haodf.com[2], which provides consultation service to patients. The dialogues cover 29 broad categories of specialties including internal medicine, pediatrics, dentistry, etc. and 172 fine-grained specialties including cardiology, neurology, gastroenterology, urology, etc. The consultations are conducted from 2010 to 2020.

# dialogues	3,407,494
# utterances	11,260,564
# tokens	660,171,367
Avg. # of utterances in a dialogue	3.3
Max # of utterances in a dialogue	198
Min # of utterances in a dialogue	2
Avg. # of tokens in an utterance	55.6
Max # of tokens in an utterance	6,935
Min # tokens in an utterance	1

Table 1: Statistics of the Chinese MedDialog dataset

3.2 The English MedDialog dataset

The English MedDialog (MedDialog-EN) dataset contains 0.26 million English consultations between patients and doctors. The total number of utterances is 0.51 million. Each consultation consists of two parts: (1) description of patient's medical conditions; (2) conversation between patient and doctor. The data is crawled from iclinic.com[3] and healthcaremagic.com[4], which are two online platforms of healthcare services, including symptom self-checker, video consultation, online chat with doctors, etc. The consultations cover 51 categories of communities including diabetes, elderly problems, pain management, etc. and 96 specialties including andrology, cardiology, nephrology, pharmacology, etc. The consultations were conducted from 2008 to 2020.Table 2 shows statistics of the English dataset.

3.3 Advantages of our datasets

To our best knowledge, MedDialog-CN and MedDialog-EN are the largest Chinese and English medical dialog dataset respectively. They have the following advantages.

- **Large number of conversations and utterances.** MedDialog-CN has about 3.4 mil-

MedDialog-EN	257,332	96

Table 3: Comparison with other datasets.

Table 3 shows a comparison of our datasets with several other medical dialogue datasets. The number of dialogs and diseases in our datasets are both much larger than those in other datasets.

4 Methods

We train several dialogue generation models on the Chinese MedDialog dataset for the interested research community to benchmark with. During training, given a dialogue containing a sequence of alternating utterances between patient and doctor, we process it into a set of pairs $\{(s_i, t_i)\}$ where the target t_i is a response from the doctor and the source s_i is the concatenation of all utterances (from both patient and doctor) before t_i. A dialogue generation model takes s as input and generates t. This problem can be formulated either as a sequence-to-sequence learning problem where the goal is to generate t conditioned on s via an encoder-decoder model, or as a language modeling problem which generates the i-th token t_i in t conditioned on the concatenation of the conversation history s and the already generated sequence $t_1, \cdots, t_{i-1}$ in the response before t_i via a language model.

4.1 Dialogue Generation as Sequence-to-Sequence Modeling

The problem of response generation can be formulated as a sequence-to-sequence (seq2seq) learning (Sutskever et al., 2014) problem: given the conversation history s, generate the response t. We use the Transformer (Vaswani et al., 2017) architecture for seq2seq modeling. Transformer consists of an encoder which embeds the input sequence into a latent space and a decoder which takes the embedding of the input sequence as input and generates the output sequence. Different from LSTM-based seq2seq models (Sutskever et al., 2014) which learn representations of a sequence of tokens in a recurrent manner and therefore suffer computational inefficiency due to their sequential nature, Transformer uses self-attention to capture the long-range dependency among tokens by calculating the similarity between each pair of tokens in the sequence. Self-attention avoids sequential computation and greatly facilitates parallel computation. A building block in Transformer contains the following modules: a self-attention sub-layer, a token-wise feed-forward sub-layer, residual connections (He et al., 2016) between sub-layers, and layer normalization (Ba et al., 2016). Both the encoder and decoder are composed of a stack of such building blocks. The encoder generates an encoding for each token in the input sequence. These encodings are fed into the decoder to generate the output sequence. To generate the token at position i, the decoder encodes the generated tokens from 1 to $i-1$ (like an encoder), calculates an attentional representation by performing attention between the encodings of input tokens and the encodings of output tokens $1, \cdots, i-1$, then feeds the attentional representation into a softmax layer to generate token i. Transformer learns the weights in the encoder and decoder by maximizing the conditional likelihood of responses conditioned on conversation histories.

4.2 Dialogue Generation as Language Modeling

Besides the sequence-to-sequence formulation, response generation can be formulated as a language modeling problem as well. Given the conversation history s, a language model defines the following probability on the sequence of tokens $t = t_1, \cdots, t_n$ in the response:

$$p(t|s) = p(t_1|s) \prod_{i=2}^{n} p(t_i|s, t_1, \cdots, t_{i-1}), \qquad (1)$$

where $s, t_1, \cdots, t_{i-1}$ denotes the concatenation of s and $t_1, \cdots, t_{i-1}$. GPT (Radford et al.) is a pretrained language model which uses the Transformer decoder to model the conditional probability $p(t_i|s, t_1, \cdots, t_{i-1})$ in Eq.(1), which first encodes the tokens in $s, t_1, \cdots, t_{i-1}$, then predicts t_i based on the encodings. GPT learns the weights of the decoder by maximizing the likelihood (defined based on Eq.1) on the responses in the training data.

Split	# Dialogs	# Utterances	# Pairs
Train	2,725,990	9,006,966	4,503,483
Validation	340,749	1,127,150	563,575
Test	340,755	1,126,448	563,224

Table 4: The split statistics of the Chinese MedDialog dataset.

4.3 Pretraining

Before training Transformer and GPT on the MedDialog-CN dataset, we can first pretrain them on general-domain text datasets which are much larger than MedDialog-CN, to get a good initialization of the weight parameters. BERT-GPT (Wu et al., 2019; Lewis et al., 2019) is a pretraining approach of Transformer, which uses BERT (Devlin et al., 2018) to pretrain the Transformer encoder and uses GPT to pretrain the Transformer decoder. Given a sequence of tokens, BERT randomly marks out some of them. The masked sequence is fed into the transformer encoder, which aims to recover the masked tokens. The weights in the encoder are learned by maximizing the accuracy of recovery. In BERT-GPT, the BERT encoder generates representation of the input sequence, which is then fed into the GPT decoder to generate the response.

5 Experiments

5.1 Experiments on the Chinese MedDialog dataset

5.1.1 Experimental Settings

We split the Chinese MedDialog dataset into a training set, a validation set, and a test set with a ratio of 0.8:0.1:0.1. The split was based on dialogues, not based on source-target pairs. The split statistics are summarized in Table 4. The models were built at the Chinese character level. The validation set was used for hyperparameter tuning. The training procedure was stopped when the validation loss stopped to decrease. For Transformer, the implementation by HuggingFace[5] was used, where the hyperparameters followed the default settings in the original Transformer (Vaswani et al., 2017). In

---

[5] https://github.com/huggingface/transformers

BERT-GPT, the BERT encoder and GPT decoder are Transformers with 12 layers. The hidden state size is 768. The optimization of weight parameters was performed using stochastic gradient descent, with a learning rate of 1e-4. The maximum length of input sequences was truncated to 400 and that of output sequences was truncated to 100. For GPT, the DialoGPT-small (Zhang et al., 2019) architecture was used, with 10 layers. We set the embedding size to 768 and the context size to 300. In layer normalization, the epsilon hyperparameter was set to 1e-5. In multi-head self-attention, we set the number of heads to 12. The weight parameters were learned with Adam (Kingma and Ba, 2014). The initial learning rate was set to 1.5e-4 and the batch size was set to 32. The learning rate scheduler was set to Noam, with 2000 warm-up steps. Top-k random sampling (Fan et al., 2018) with $k = 50$ was used for decoding in all methods. We evaluated the trained models using automatic metrics including perplexity, NIST-n (Doddington, 2002) (where n is the size of n-gram and is set to 4), BLEU-n (Papineni et al., 2002b) (where n is set to 2 and 4), METEOR (Lavie and Agarwal, 2007), Entropy-n (Zhang et al., 2018) (where n is set to 4), and Dist-n (Li et al., 2015) (where n is set to 1 and 2). Perplexity measures the language quality of the generated responses. The lower, the better. NIST, BLEU, and METEOR measure the similarity between the generated responses and groundtruth via n-gram matching. The higher, the better. Entropy and Dist measure the lexical diversity of generated responses. The higher, the better.

BERT-GPT is pretrained on Chinese corpus collected from the Large Scale Chinese Corpus for NLP[6]. The corpus includes Chinese Wikipedia containing 104 million documents, News containing 2.5 million news articles from 63,000 sources, Community QA containing 4.1 million documents belonging to 28 thousand topics, and Baike QA containing 1.5 million question-answering pairs from 493 domains. The total size of these datasets is 15.4 GB. GPT is pretrained on Chinese Chatbot Corpus[7] containing 14 million dialogues and 500k-Chinese-Dialog[8] containing 500K Chinese dialogues.

	Transformer	BERT-GPT	GPT
Perplexity	9.5	**8.2**	9.7
NIST-4	**0.39**	0.31	0.36
BLEU-2	4.9%	3.7%	**5.0%**
BLEU-4	0.9%	0.5%	**1.8%**
METEOR	**13.1%**	10.4%	12.1%
Entropy-4	13.5	**13.6**	**13.6**
Dist-1	**0.03%**	0.02%	0.02%
Dist-2	2.0%	**2.1%**	2.0%
Avg Len	27.9	27.3	28.3

Table 5: Performance on the MedDialog-CN test set.

5.1.2 Results

Table 5 shows the performance on the MedDialog-CN test set. From this table, we make the following observations. First, BERT-GPT achieves lower perplexity than Transformer. This is because BERT-GPT is pretrained on a large collection of corpora before being finetuned on MedDialog-CN. Pretraining enables the model to better capture the linguistic structure among words, which yields lower perplexity. Second, on machine translation metrics including NIST-4, BLEU-2, BLEU-4, and METEOR, BERT-GPT performs worse than Transformer. This indicates that Transformer is able to generate responses that have more overlap with the groundtruth. However, it is worth noting that the studies in (Liu et al., 2016) show that machine translation metrics are not reliable evaluation metrics for dialogue generation. Given the same conversation history, many responses are valid. A response should not be deemed as bad simply because it has little overlap with the response given by a doctor. Third, on diversity metrics, BERT-GPT and Transformer are on par, which indicates that they have similar capability in generating diverse responses. Fourth, compared with BERT-GPT, GPT has worse perplexity, better machine translation scores, and comparable diversity scores.

Figure 2 shows an example of generated responses on the MedDialog-CN test set. The response generated by BERT-GPT is clinically informative and accurate. It prescribes Ebastine and gives detailed instructions of taking this medication. Ebastine is a medication for treating eczema. The patient mentioned that his/her baby has eczema. So this prescription is clinically meaningful. The language quality of the response is also good. It is syntactically and semantically correct and smooth. The response generated by GPT is also good, but

Conversation history: 所谓的湿疹, 孩子从一周岁后起, 到换季的时候, 就周身发痒, 用手一抓破, 就一直是红色的, 水水的, 要过几长时间才会结痂, 留有黑色印迹. (Eczema. Since one year old, whenever changing seasons, the baby feels itchy all over the body. The pimples break when scratched. They are always red and swelling. It takes a long time to scab, leaving a black mark.)

Groundtruth response: 建议到江苏省皮肤病研究所就诊. (I suggest to visit the Dermatology Research Institute of Jiangsu Province.)

Transformer: 需要看到皮肤的形态才能给予具体建议. (I need to see the skin to give detailed suggestions.)

GPT: 如果是过敏性皮肤， 建议外用酮康唑乳膏. (If the skin is allergic, can take some Ketoconazole cream.)

BERT-GPT: 你去买一种依巴斯汀一天晚上吃一片试试看. (Can use Ebastine, one tablet every day at bedtime.)

Figure 2: An example of generated responses on the MedDialog-CN test set.

less specific. It believes the baby has a skin allergy issue, but does not pinpoint the exact issue as BERT-GPT does. The response generated by Transformer is less clinically informative. It does not give medical suggestions. But it asks for further information, which is also a valid response.

Figure 3 shows another example. The response generated by BERT-GPT is clinically accurate and concise. The language quality is great. The response generated by GPT is self-conflicting. It says "if there is no abnormality at the throat, you can take a laryngoscope test; if abnormal, you should take a laryngoscope test", which is semantically inconsistent. The response generated by Transformer prescribes two repetitive laryngoscope tests, which is clinically insensible.

5.2 Transfer to Other Datasets

In this section, we study how to use the models pretrained on MedDialog-CN to improve the performance on low-resource dialogue generation tasks where the dataset size is small. The target task is generating medical dialogues related to COVID-19 on the small-sized CovidDialog-Chinese (Yang et al., 2020) dataset. We finetune the MedDialog-pretrained models on CovidDialog-Chinese, and use the finetuned models to generate COVID-19-related dialogues.

5.2.1 Data

We use a Chinese dialogue dataset about COVID-19: CovidDialog-Chinese (Yang et al., 2020), for the experiments. This dataset has 1,088 patient-doctor dialogues about COVID-19, with 9,494 utterances and 406,550 tokens (Chinese characters) in total. Duplicated and incomplete dialogues were removed. The dialogues are multi-turn. The average number of utterances in a dialogue is 8.7. The utterances are reasonably long. The average number of tokens in an utterance is 42.8. Table 6 shows the statistics of this dataset.

Conversation history: 声音嘶哑, 几年了, 不时发作. (My voice is broken. In the past few years, it happens oftentimes.)

Groundtruth response: 手术方式: 门诊表麻电子喉镜下摘除(小息肉)或住院全麻支撑喉镜下显微镜下摘除(大息肉). (Surgery choices: outpatient, surface anesthetic, remove small polyps using electrolaryngoscope; inpatient, general anesthesia, remove large polyps using laryngoscope and microscope.)

Transformer: 建议到当地儿童医院进行喉镜检查, 然后到比较好的医院进行喉镜检查, 以便确诊和选择治疗. (I suggest to take a laryngoscope test at a local Children's hospital. Then take a laryngoscope test at a better hospital, to confirm and select the best way for treatment.)

GPT: 你好, 声音嘶哑原因较多, 不知你的是喉部还是咽喉部? 如果喉部没有异常, 建议做电子喉镜检查, 如果有异常, 应该做喉镜检查. *声带是指哪些部位的病变? (Hello. Broken voice can be caused by many things. Is your problem at the throat or pharynx? If there is no abnormality at the throat, you can take a laryngoscope test. If abnormal, you should take a laryngoscope test.

BERT-GPT: 您好， 建议先到当地医院做一个电子喉镜检查. (Hello. I suggest to take a laryngoscope test at a local hospital.)

Figure 3: Another example of generated responses on the MedDialog-CN test set.

# of dialogues	1,088

Table 6: Statistics of the CovidDialog-Chinese dataset.

5.2.2 Experimental settings

We split the CovidDialog-Chinese dataset into a training set, a validation set, and a test set with a ratio of 0.8:0.1:0.1. The split is based on dialogues. The split statistics are summarized in Table 7. Most hyperparameter settings follow those in Section 4.1, except the following: in optimization, the batch size was set to 8. We evaluate the trained models using automatic metrics including perplexity, NIST-4 (Doddington, 2002), BLEU-2, 4 (Pa-

Split	# Dialogs	# Utterances	# Pairs

Conversation history: 刚刚我坐公交车时候车里后面有人脱下口罩打喷嚏, 我有戴口罩, 普通口罩, 公交车里面还开着空调, 有没有危险? 和风险? (Just now, when I was taking a bus, someone took off his facial mask and sneezed. I was wearing an ordinary mask. The air conditioner in the bus was on. Is this risky?

Groundtruth response: 你们当地有没有确诊病例? (Are there confirmed cases in your city?)

Transformer without pretraining on MedDialog: 感谢您的信任, 病情资料我已详细阅读. (Thank you for your trust. I have read your medical record.)

Transformer with pretraining on MedDialog: 不舒服吗? (Are you feeling unconforable?)

GPT without pretraining on MedDialog: *我已, 我们在有是不是否是感染. 根据你现有的情况.

GPT with pretraining on MedDialog: 有可能性, 没有风险, 多饮水, 别太担心. (It is likely. No risk. Drink more water. Don’t worry too much.)

BERT-GPT without pretraining on MedDialog: 就是没有风险，可以保险点，但不一定要全部戴口罩. (No risk. Try to be careful, but it is not necessary to wear mask.)

BERT-GPT with pretraining on MedDialog: 你的年纪?目前的呼吸功能好吗?有没有胸部 CT 的报告? (How old are you? Is your breath OK? Do you have chest CT report?

Figure 4: An example of generated responses about COVID-19.

Conversation history: 不发烧, 就是锁骨中间不舒服, 有点想咳嗽, 躺下就会感觉好很多, 站起来就更想咳嗽一点, 没有痰, 没去过武汉, 没接触过武汉来的人. (No fever. It is kind of uncomfortable in the middle of clavicle. Have the feeling to cough. Feel much better when lying down. When I stand up, the feeling to cough becomes stronger. No phlegm. Didn’t visit Wuhan or contact people from Wuhan.

Groundtruth response: 发病前 14 天有没有接触湖北地区或者是疫情高发省份来的人? 或者是你所在的小区有没有疑似或者确诊病例? 发热咳嗽咽痛病人最好排除下冠状病毒. (Have you contacted people from Hubei or other provinces that have severe epidemic? Does your community have suspected or confirmed cases? If you have fever, cough, sore throat, it’s better to get a test.)

Transformer without pretraining on MedDialog: 你好, 我已经仔细研读了您的资料, 请您现在您现有没有接触史吧. (Hello. I have carefully read your record. Do you have a history of exposure?)

Transformer with pretraining on MedDialog: 请问您有咽喉疾病病史吗? (Do you have medical history of throat disease?)

GPT without pretraining on MedDialog: *你好, 不会的症状, 如果, 我就是新型冠状病毒感染有没有接触到感冒.好, 如果不客气, 也不会有感染, 我就是新型冠状病毒感染的症状?

GPT with pretraining on MedDialog: 从你提供的检查结果来看, 没有发现明显异常. 不发烧不咳嗽不腹泻, 不腹泻, 不考虑是新冠肺炎, 除非有新型冠状病毒感染, 还有说明书, 如果仅仅是普通的, 都没问题. (I didn’t see abnormality in the test results that you provided. If no fever, no cough, no diarrhea, no diarrhea, then it is unlikely to be COVID-19, unless infected by coronavirus. And manual. If ordinary, then there is no problem.)

BERT-GPT without pretraining on MedDialog: 咳嗽吗? 你好. 咳嗽考虑支气管炎, 建议口服莲花清瘟颗粒. (Do you cough. Hello. If having cough, it may be bronchitis. You can take some Lianhuaqingwen pills orally.)

BERT-GPT with pretraining on MedDialog: 感冒可能性大, 不过有些病毒或者细菌感染患者出现这种状况比较常见, 建议多喝水, 必要时去医院检查一下. (It is more likely to be cold. But people infected by virus or bacteria may have such conditions as well. Drink more water. Visit the hospital if necessary.

Figure 5: The second example of generated responses about COVID-19.

pineni et al., 2002b), METEOR (Lavie and Agarwal, 2007), Entropy-4 (Zhang et al., 2018), and Dist-1, 2 (Li et al., 2015). We also perform human evaluation. We randomly select 100 dialog examples and ask 5 undergraduate and graduate students to rate the generated responses in terms of informativeness, relevance, and human-likeness. Informativeness is about whether a response contains sufficient medical information such as explanations of diseases and suggestions for treatment. Relevance is about whether the content of a response matches with that of the conversation history. Human-likeness is about whether a response sounds like a human. The ratings are from 1 to 5. The higher, the better. The ratings from different annotators are averaged as the final results.

5.2.3 Results

Table 8 shows the automatic evaluation results achieved by different models, with or without pretraining (PT) on MedDialog-CN. From this table, we make the following observations. First, on Transformer, pretraining on MedDialog-CN improves results on all metrics. This demonstrates that pretraining on MedDialog-CN can improve performance on low-resource medical dialog generation tasks. Second, on GPT, pretraining on MedDialog-CN improves 5 of the 8 metrics. On BERT-GPT, pretraining on MedDialog-CN improves half of metrics. The reason that improvement on GPT and BERT-GPT is not as significant as that on Transformer is probably because these two models are already pretrained using other corpora. Therefore the value of pretraining on MedDialog-CN is diminishing. However, it is still useful to pretrain on MedDialog-CN to adapt these two models to the medical dialog domain.

Table 9 shows the human evaluation results on the test set of CovidDialog-Chinese. From this table, we can see that on all models, pretraining on MedDialog-CN improve relevance, informativeness, and human-likeness. This further demon-

	Transformer No-PT vs PT	GPT No-PT vs PT	BERT-GPT No-PT vs PT	Groundtruth vs BERT-GPT
Relevance	0.006	0.008	0.004	0.003
Informativeness	0.014	0.004	0.003	0.004
Human-likeness	0.009	0.001	0.031	0.036

Table 10: Significance tests on human evaluation results.

strates the effectiveness of pretraining. We perform significance tests between different methods based on the double-sided Student's t-test. The results are shown in Table 10. As can be seen, in most cases, the p-value is less than 0.015, demonstrating high statistical significance. For Transformer, GPT, and BERT-GPT, using pretraining (PT) on MedDialog-CN achieves significantly better performance than not using pretraining (No-PT).

Figure 4 shows an example of generating a doctor's response given the utterance of a patient. As can be seen, models pretrained on MedDialog-CN perform better than their unpretrained counterparts. For example, the response generated by GPT without pretraining on MedDialog-CN is not understandable by human. With pretraining on MedDialog-CN, it generates a much better response which gives medical advice. Figure 5 shows another example. Similarly, without MedDialog-pretraining, the response generated by GPT is not readable. With pretraining, the generated response is smooth and clinically informative.

6 Conclusions and Future Works

To facilitate the research and development of medical dialogue systems that can potentially assist in telemedicine, we build large-scale medical dialogue datasets – MedDialog – which contain 1) a Chinese dataset with 3.4 million conversations between patients and doctors, 11.3 million utterances, 660.2 million tokens, covering 172 specialties of diseases, and 2) an English dataset with 0.26 million conversations, 0.51 million utterances, 44.53 million tokens, covering 96 specialties of diseases. To our best knowledge, they the largest of their kind. We pretrain Transformer, GPT, and BERT-GPT on MedDialog-CN. The results show that the generated dialogues by these pretrained models are clinically meaningful and human-like. We use transfer learning to apply these pretrained models for low-resource dialogue generation. On a COVID-19 dialogue generation task where the dataset is small, human evaluation and automatic evaluation show that models pretrained on MedDialog-CN can effectively improve the quality of generated responses.

For future work, we will annotate medical entities in our datasets. Such annotations can facilitate the development of goal-oriented medical dialog systems.

An information theoretic view on selecting linguistic probes

Abstract

There is increasing interest in assessing the linguistic knowledge encoded in neural representations. A popular approach is to attach a diagnostic classifier – or "probe" – to perform supervised classification from internal representations. However, how to select a good probe is in debate. Hewitt and Liang (2019) showed that a high performance on diagnostic classification itself is insufficient, because it can be attributed to either "the representation being rich in knowledge", or "the probe learning the task", which Pimentel et al. (2020) challenged. We show this dichotomy is valid information-theoretically. In addition, we find that the methods to construct and select good probes proposed by the two papers, *control task* (Hewitt and Liang, 2019) and *control function* (Pimentel et al., 2020), are equivalent – the errors of their approaches are identical (modulo irrelevant terms). Empirically, these two selection criteria lead to results that highly agree with each other.

1 Introduction

Recently, neural networks have shown substantial progress in NLP tasks (Devlin et al., 2019; Radford et al., 2019). To understand and explain their behavior, a natural question emerge: how much linguistic knowledge is encoded in these neural network systems?

An efficient approach to reveal information encoded in internal representations uses diagnostic classifiers (Alain and Bengio, 2017). Referred to as "probes", diagnostic classifiers are trained on pre-computed intermediate representations of neural NLP systems. The performance on tasks they are trained to predict are used to evaluate the richness of the linguistic representation in encoding the probed tasks. Such tasks include probing syntax (Hewitt and Manning, 2019; Lin et al., 2019; Tenney et al., 2019a), semantics (Yaghoobzadeh et al., 2019), discourse features (Chen et al., 2019; Liu et al., 2019; Tenney et al., 2019b), and commonsense knowledge (Petroni et al., 2019; Poerner et al., 2019).

However, appropriate criteria for selecting a good probe is under debate. The traditional view that high-accuracy probes are better is challenged by Hewitt and Liang (2019), who proposed that the high accuracy could be attributed to either (1) that the representation contains rich linguistic knowledge, or (2) that the probe learns the task. To circumvent this ambiguity, they proposed to use the improvement of probing task performance against a control task (predicting random labels from the same representations), i.e., the "selectivity" criterion. Recently, Pimentel et al. (2020), challenged this dichotomy from an information theoretic viewpoint. They proposed to use an "information gain" criterion, which empirically is the reduction in cross entropy from a "control function task" probing from randomized representation.

In this paper, we show the "non-exclusive-or" dichotomy raised by Hewitt and Liang (2019) is valid information-theoretically. There is a difference between the original NLP model learning the task and the probe learning the task.

In addition, we show that the "selectivity" criterion and the "control function" criterion are comparably accurate. Pimentel et al. (2020) formulated their errors with the difference in a pair of KL divergences. We show that the error of the "selectivity" criterion (Hewitt and Liang, 2019), if measured from cross entropy loss, can be formulated in the difference in a pair of KL divergences as well. When randomizations are perfect, these two criteria differ by only constant terms.

Empirically, on a POS tag probing task on English, French and Spanish translations, we show that the "selectivity" and the "control function" criteria highly agree with each other. We rank experi-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9251–9262,
November 16–20, 2020.

ments with over 10,000 different hyperparameter settings using these criteria. The Spearman correlation of the Hewitt and Liang (2019) vs. Pimentel et al. (2020) criteria are on par with the correlations of "accuracy vs. cross entropy loss" – two very strong baselines.

Overall, we recommend using control mechanisms to select probes, instead of relying on merely the probing task performance. When randomization is done well, controlling the target or representations are equivalent.

2 Related work

Diagnostic probes were originally intended to explain information encoded in intermediate representations (Adi et al., 2017; Alain and Bengio, 2017; Belinkov et al., 2017). Recently, various probing tasks have queried the representations of, e.g., contextualized word embeddings (Tenney et al., 2019a,b) and sentence embeddings (Linzen et al., 2016; Chen et al., 2019; Alt et al., 2020; Kassner and Schütze, 2020; Maudslay et al., 2020; Chi et al., 2020).

The task of probing is usually formulated as a classifier problem, with the representations as input, and the features indicating information as output. A straightforward method to train a classifier is by minimizing cross entropy, which is the approach we follow. Note that Voita and Titov (2020) derived training objectives from minimum description lengths, resulting in cross entropy loss and some variants.

3 Information theoretic probes

3.1 Formulation

We adopt the information theoretic formulation of linguistic probes of (Pimentel et al., 2020), and briefly summarize as follows.

We want to probe true labels T from representations R. An ideal probe should accurately report the code-target mutual information $I(T;R)$, which is unfortunately intractable. We will write $I(T;R)$ in an alternative form.

Let $p(T \mid R)$ be the unknown true conditional distribution, and a diagnostic probe, according to the setting in literature (Alain and Bengio, 2017; Hewitt and Manning, 2019; Maudslay et al., 2020), is an approximation $q_\theta(T \mid R)$ parameterized by θ, then:

$$\begin{aligned} I(T;R) &= H(T) - H(T \mid R) \\ H(T \mid R) &= -\mathbb{E}_{p(T \mid R)} \log p(T \mid R) \\ &= -\mathbb{E}_{p(T \mid R)} \log \frac{p(T \mid R) q_\theta(T \mid R)}{q_\theta(T \mid R)} \\ &= -\mathbb{E}_p \log q_\theta - \mathbb{E}_p \log \frac{p}{q_\theta} \\ &= H(p, q_\theta) - \text{KL}(p \,\|\, q_\theta), \end{aligned}$$

where p and q_θ stand for $p(T \mid R)$ and $q_\theta(T \mid R)$ respectively. We also use $H(p, q_\theta) = -\mathbb{E}_p \log q_\theta$ to represent the cross entropy for simplicity.

3.2 The source of probing error

A valid dichotomy Traditionally, people use the cross entropy loss of the diagnostic probe $H(p, q_\theta)$ to approximate $I(T;R)$. We can derive a source of error by rewinding the above formulations:

$$H(p, q_\theta) = H(T) - I(T;R) + \text{KL}(p \,\|\, q_\theta)$$

The first term on RHS, $H(T)$, is independent of either R or θ. Therefore, a low cross entropy loss $H(p, q_\theta)$ can be caused by either of the two scenarios:

- High code-target mutual information $I(T;R)$, indicating the representation R contains rich information about the target T.
- Low KL-divergence between $p(T \mid R)$ and $q_\theta(T \mid R)$, indicating the probe learns the task.

The two scenarios exactly correspond to the dichotomy of Hewitt and Liang (2019).

A good probe To get a good probe, we want $H_{q_\theta}(T \mid R)$ to approximate $I(T;R)$ as much as possible. This means a good probe should minimize $\text{KL}(p \,\|\, q_\theta)$, as proposed by Pimentel et al. (2020).

However, empirically Pimentel et al. (2020) (as well as many previous articles) used the cross entropy loss $H_{q_\phi}(T \mid R)$ to select good probes, which is insufficient, as described above. Alternatively, Hewitt and Liang (2019) and Pimentel et al. (2020) proposed control tasks and control functions, respectively.

3.3 The control task

The control task (Hewitt and Liang, 2019) sets random targets for the probing task. Let us use $c(T)$ to indicate a "control function" applied on a token

v that originally has label T. The control function could nullify the information of the input, if necessary.

If we measure the difference between cross entropy in the control task and probing task $H(p(c(T) \mid R), q_{\theta_c}(c(T) \mid R)) - H(p(T \mid R), q_\theta(T \mid R))$, we can derive a form of error margin in their measurements[1]. Let us use a short-hand notations $H(p_c, q_{\theta_c}) - H(p, q_\theta)$ for clarity. Now, what does the diff between cross entropy on control task and probing task actually contains?

$$
\begin{aligned}
&H(p_c, q_{\theta_c}) - H(p, q_\theta) \\
&= (H(c(T)) - I(c(T); R) + \mathrm{KL}(p_c \,\|\, q_{\theta_c})) \\
&\quad - (H(T) - I(T; R) + \mathrm{KL}(p \,\|\, q_\theta)) \\
&= (H(c(T)) - H(T)) \\
&\quad - I(c(T); R) + I(T; R) \\
&\quad + (\mathrm{KL}(p_c \,\|\, q_{\theta_c}) - \mathrm{KL}(p \,\|\, q_\theta))
\end{aligned}
$$

We already knew that $H(T) = \text{Const}$. According the definition of control function, the output $c(T)$ would be independent of R. Then:

$$
\begin{aligned}
&H(c(T)) = \text{Const} \\
&p(c(T), R) = p(c(T))p(R) \\
&I(c(T); R) = \mathbb{E}\frac{p(c(T), R)}{p(c(T))p(R)} = \text{Const}
\end{aligned}
$$

Therefore:

$$
H(p_c, q_{\theta_c}) - H(p, q_\theta) = I(T; R) - \Delta_h
$$

where Δ_h is a short-hand notation for the measurement error in the *control task* criteria:

$$
\Delta_h = \mathrm{KL}(p \,\|\, q_\theta) - \mathrm{KL}(p_c \,\|\, q_{\theta_c}) + \text{Const} \qquad (1)
$$

When the probe fits the true distribution to a similar extent on both the control task and probing task, the error Δ_h would be small. Unfortunately, both KL terms are intractable.

3.4 The control function

Control function (Pimentel et al., 2020) introduces a random processor $\mathbf{c}(\cdot)$ on the representation R. To measure the information gain, they used an "information gain" criterion:

$$
\mathcal{G}(T, R, \mathbf{c}) = I(T; R) - I(T; \mathbf{c}(R))
$$

Noticing that mutual information terms are intractable, they approximated the objective with the difference between cross entropy in the control function task (we refer to as "control function" henceforth) and the probing task:

$$
\tilde{\mathcal{G}}(T, R, \mathbf{c}) = H(p_c, q_{\phi_c}) - H(p, q_\phi)
$$

To compute the error of this approximation, they reformulated the terms as following:

$$
\begin{aligned}
&\mathcal{G}(T, R, \mathbf{c}) \\
&\quad = H(T) - H(T \mid R) - H(T) + H(T \mid \mathbf{c}(R))
\end{aligned}
$$

The two $H(T)$ terms cancel out, then:

$$
\begin{aligned}
H(T \mid R) =& H(p(T \mid R), q_\phi(T \mid R)) \\
& - \mathrm{KL}(p(T \mid R) \,\|\, q_\phi(T \mid R)) \\
& = H(p, q_\phi) - \mathrm{KL}(p, q_\phi) \\
H(T|\mathbf{c}(R)) =& H(p(T \mid \mathbf{c}(R)), q_{\phi_c}(T \mid \mathbf{c}(R))) \\
& - \mathrm{KL}(p(T \mid \mathbf{c}(R)) \,\|\, q_{\phi_c}(T \mid \mathbf{c}(R))) \\
& = H(p_c, q_{\phi_c}) - \mathrm{KL}(p_c \,\|\, q_{\phi_c})
\end{aligned}
$$

Where we abbreviate similarly as we did for the control task. Specifically, we write ϕ for the probe parameters of control function to tell apart from θ in the control task.

Pimentel et al. (2020) showed that the error of their approximation, $\Delta_p = \mathcal{G}(T, R, \mathbf{c}) - \tilde{\mathcal{G}}(T, R, \mathbf{c})$, can be expressed as:

$$
\Delta_p = \mathrm{KL}(p \,\|\, q_\phi) - \mathrm{KL}(p_c \,\|\, q_{\phi_c}) \qquad (2)
$$

Again, when the probe fits the true distribution to a similar extent on both the target labels distribution and the probing task, the Δ_p will be small. Unfortunately, both KL terms are intractable too.

3.5 Control task vs control function

From Equations 1 and 2, we showed that the *selectivity* criterion of Hewitt and Liang (2019) and the *information gain* criterion of Pimentel et al. (2020), if both measured in cross entropy loss, have very similar errors in approximating information gains.

These errors, Δ_h and Δ_p respectively, appear in very similar forms[2]. The probes selected from these two criteria should be highly correlated to each other, and our experiments will confirm.

---

[1] Note that Hewitt and Liang (2019) used accuracy instead of cross entropy. We discuss cross entropy so as to compare the errors against the control function (Pimentel et al., 2020)

[2] When the two $c(\cdot)$ are ideal, Δ_h and Δ_p differ by only irrelevant terms – we include the derivations in Supplementary Material.

		train / dev / test	**(t_acc,f_ent)**	**(t_acc,t_ent)**	**(f_acc,f_ent)**
English	17	177k / 22k / 22k	0.1615	0.1334	0.1763
French	15	303k / 31k / 8k	0.0906	0.0606	0.1295
Spanish	16	341k / 33k / 11k	0.1360	0.0560	0.1254

Table 1: Spearman correlations between t_acc (the "selectivity" criterion (Hewitt and Liang, 2019)) and f_ent (the "gain" criterion (Pimentel et al., 2020)) are on par with two "accuracy vs. cross entropy" correlations.

4 Experiments

4.1 Setup

We use the same family of probes as Hewitt and Liang (2019) and Pimentel et al. (2020), multiple layers perceptrons with ReLU activations, to show the correlations of their "good probe" criteria (control task and control function, respectively).

Overall, we sweep the probe model hyperparameters with a unified training scheme on three tasks (probe, control task, control function). The control task (function) setting includes labels (embeddings) drawn from a uniform random sample once before all experiments. In each training, we follow the setting of (Hewitt and Liang, 2019). We save the model with the best dev loss, report the test set loss and accuracy, and average across 4 different random seeds.

Data We use the Universal Dependency (Zeman et al., 2019) dataset loaded with the Flair toolkit (Akbik et al., 2018). We examine three languages: English, French, and Spanish. For the probing task, we use POS with labels provided by SpaCy[3]. We use the embedding of multilingual BERT (mBERT) implemented by huggingface (Wolf et al., 2019). If a word is split into multiple word pieces, we average its representations.

4.2 The "good probes" are good for both

When measuring the qualities of probes using the "selectivity" (Hewitt and Liang, 2019) or "information gain" (Pimentel et al., 2020) criterion, we show that the rules-of-thumb for training good probes largely agree.

- Early stopping before 24,000 gradient steps (approximately 4 epochs) could inhibit probe quality, but longer training procedures do not improve the probe qualities considerably.
- Smaller probes are better in general, but exceptions exist. For example, when weight decay is set to 0, probes with one hidden layer and 40 hidden neurons are better in both criteria.
- A small weight decay is beneficial.

We include more descriptions, including comprehensive experiment configurations and plots in the Supplementary Material.

4.3 The high correlation between criteria

In addition to the qualitative correlations shown above, we compute the correlations between the two criteria over a grid-search style hyperparameter sweep of over 10,000 configurations. For each "probe, control task, control function" experiment set, we record the following four criteria:

- **t_acc**: Difference between probing task and control task accuracy. This is the "selectivity" criterion of Hewitt and Liang (2019).
- **f_ent**: Difference between control function and probing task cross entropy. This is the "gain" criterion of Pimentel et al. (2020).
- **t_ent**: Difference between the control task and the probing task cross entropy.
- **f_acc**: Difference between the probing task and control function accuracy.

We collect all experiments of each language according to these criteria, and use Spearman correlation to test three pairs of correlations. As is reported in Table 1, the (t_acc, f_ent) correlations are comparable to two strong baselines, (t_acc, t_ent) and (f_acc, f_ent), the correlations between measurements in accuracy and cross entropy losses.

5 Conclusion

When selecting probes that better approximate $I(T;R)$, we recommend measuring *with a control mechanism* instead of relying on the traditional cross entropy on probing task. We show both information-theoretically and empirically, that controlling the targets and representations are equivalent, as long as the control mechanism is randomized.

A Difference between the two criteria

In Section 3 we show that the error of the two criteria can both be written as difference between a pair of KL divergence (modulo a constant term). Here we further simplify the terms when we assume the control task and functions take perfectly random distributions (i.e., independent of the task and representations, respectively).

$$\begin{aligned}&\Delta_h - \Delta_p = \text{Const}+\\&\text{KL}(p(c(T)|R)\,\|\,q_{\theta_c}(c(T)|R)) - \text{KL}(p\,\|\,q_\theta)\\&-\text{KL}(p(T|c(R))\,\|\,q_{\phi_c}(T|c(R))) + \text{KL}(p\,\|\,q_\phi)\end{aligned}$$

When we use the same hyperparameter setting, $q_\theta(T \mid R)$ and $q_\phi(T \mid R)$ should be able to approximate $p(T \mid R)$ to the same extent, so $\text{KL}(p \,\|\, q_\theta)$ and $\text{KL}(p \,\|\, q_\phi)$ cancel out. Additionally, following the definitions of the control function and control tasks, we can simplify as follows:

$$\begin{aligned}&p(c(T)|R) = p(c(T)), q_{\theta_c}(c(T)|R) = q_{\theta_c}(c(T))\\&p(T|c(R)) = p(T), q_{\phi_c}(T|c(R)) = q_{\phi_c}(T)\end{aligned}$$

$$\begin{aligned}&\text{KL}(p(c(T)|R)\,\|\,q_{\theta_c}(c(T)|R)) = \mathbb{E}_{p(c(T))}\frac{p(c(T))}{q_{\theta_c}(c(T))}\\&\text{KL}(p(T|c(R))\,\|\,q_{\phi_c}(T|c(R))) = \mathbb{E}_{p(T)}\frac{p(T)}{q_{\phi_c}(T)}\end{aligned}$$

Therefore, the difference between errors of criteria of Hewitt and Liang (2019) and Pimentel et al. (2020) are:

$$\begin{aligned}\Delta_h - \Delta_p = \text{Const} - \text{KL}(p(T)\,\|\,q_{\phi_c}(T))\\+\,\text{KL}(p(c(T))\,\|\,q_{\theta_c}(c(T)))\end{aligned} \tag{3}$$

In short, these two criteria differ by terms dependent only on the randomization functions and the inherent distributions of task labels, i.e., irrelevant terms.

B Experiments details

Hewitt and Liang (2019) proposed some rules-of-thumb to select good probes, including a “simple probe” suggestion. We sweep the hyper parameters to test whether these rules also apply when measuring probe qualities using the control function (Pimentel et al., 2020).

Hyper-parameter ranges We sweep hyper parameters from the following ranges:

- Learning rate: $\{10^{-4}, 5 \times 10^{-5}, 3 \times 10^{-5}, 10^{-5}, 5 \times 10^{-6}, 3 \times 10^{-6}\}$
- Maximum gradient steps: $\{1500, 3000, 6000, 12000, 24000, 96000, \infty\}$. Their effects are shown in Figure 1.
- Weight decay: $\{0, 0.01, 0.1, 1.0\}$. Their effects are shown in Figures 2, 3 and 4. When sweeping weight decay, max gradient step is set to 24000.

In any configuration mentioned above, we run four experiments with random seeds 73, 421, 9973, 361091, and average the reported results (i.e., accuracy and loss).

Early stopping could inhibit probe quality Early stopping, if stopped before 24,000 gradient steps (approximately 4 epochs) may inhibit the quality of probes. In addition, we Figure 1 shows high correlation between the "selectivity" (Hewitt and Liang, 2019) and "information gain" (Pimentel et al., 2020) criteria.

Small weight decay is beneficial We find that smaller weight decays (e.g., 0.01) are more beneficial for probes than larger weight decays. While the two criteria rank the capacity of probes similarly, the most simple probes tend to stand out more distinctively with the "selectivity" criterion (Pimentel et al., 2020), as are shown on Figures 2, 3, and 4.

Smaller probes are not necessarily better We find that while smaller probes have higher "selectivity" and "information gain" for mBERT representations, probes with one hidden layer and 40-80 hidden neurons are better than more simplistic probes, as shown in Figures 5, 6 and 7. The plots show consistency between the two criteria. For example, larger models and more layers do not necessary lead to better results. Neither are the smallest probes with 0 hidden layers.

Note that we also swept hyperparameters for FastText, where probes with less parameters do not always outperform more complex probes in either accuracy, loss, selectivity, or information gain. Figures 8 and 9 illustrate these observations.

C Reproducibility

On a T4 GPU card, training one epoch takes around 20 seconds. Without setting maximum gradient steps, 98.6% of experiments finish within 400 epochs. We open source our codes at `https://github.com/SPOClab-ca/InfoProbe`.

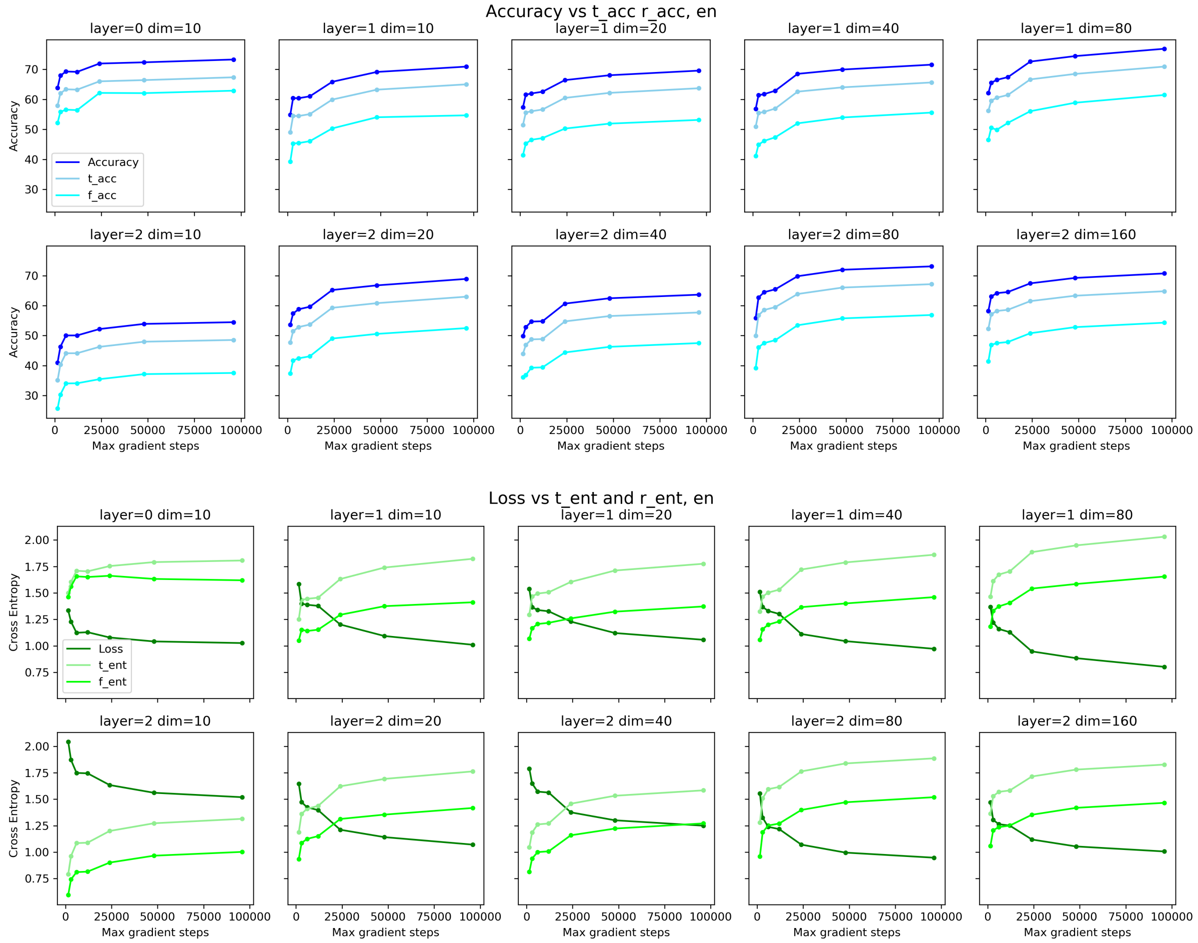

Figure 1: Max gradient step vs accuracy, t_acc, f_acc (blue) and loss, t_ent, f_ent (green) on English. The “t” refers to control task (Hewitt and Liang, 2019), and “h” refers to control function (Pimentel et al., 2020). In these set of experiments, we look for the best learning rate and zero weight decay in each configuration.

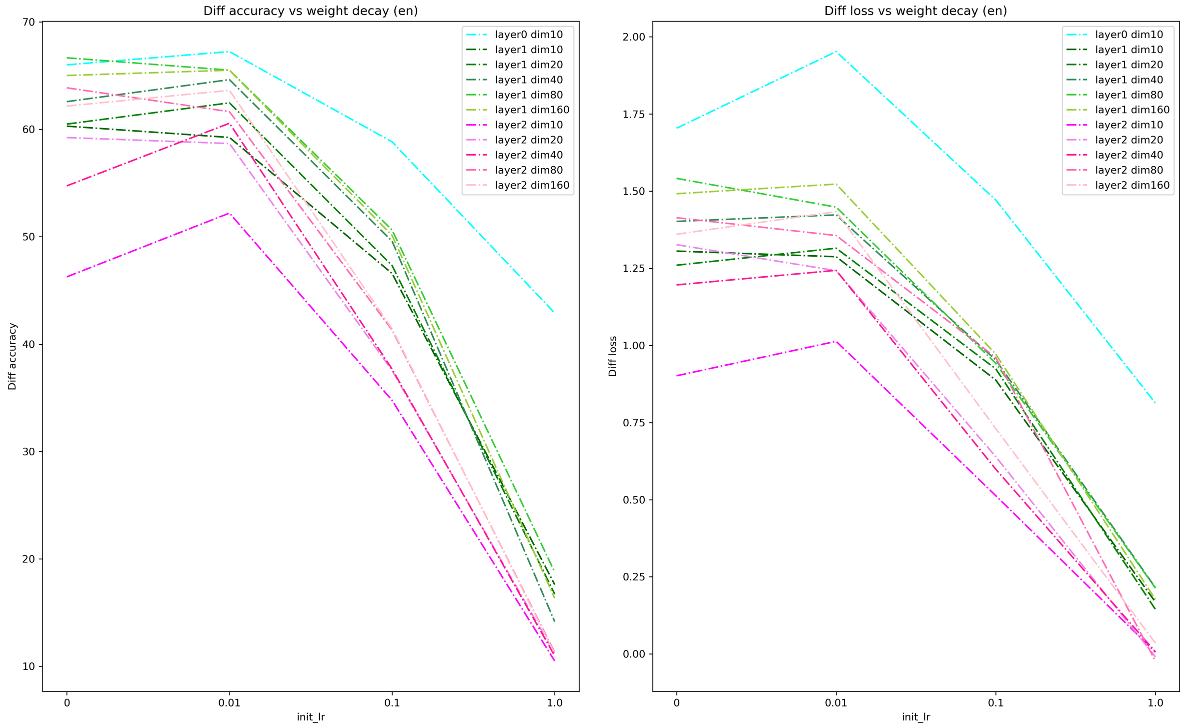

Figure 2: The “difference of accuracy” (Hewitt and Liang, 2019) and the “difference of loss” (Pimentel et al., 2020) criteria against weight decay on model configurations, on UD English. For each configuration, the learning rate leading to the highest accuracy is selected.

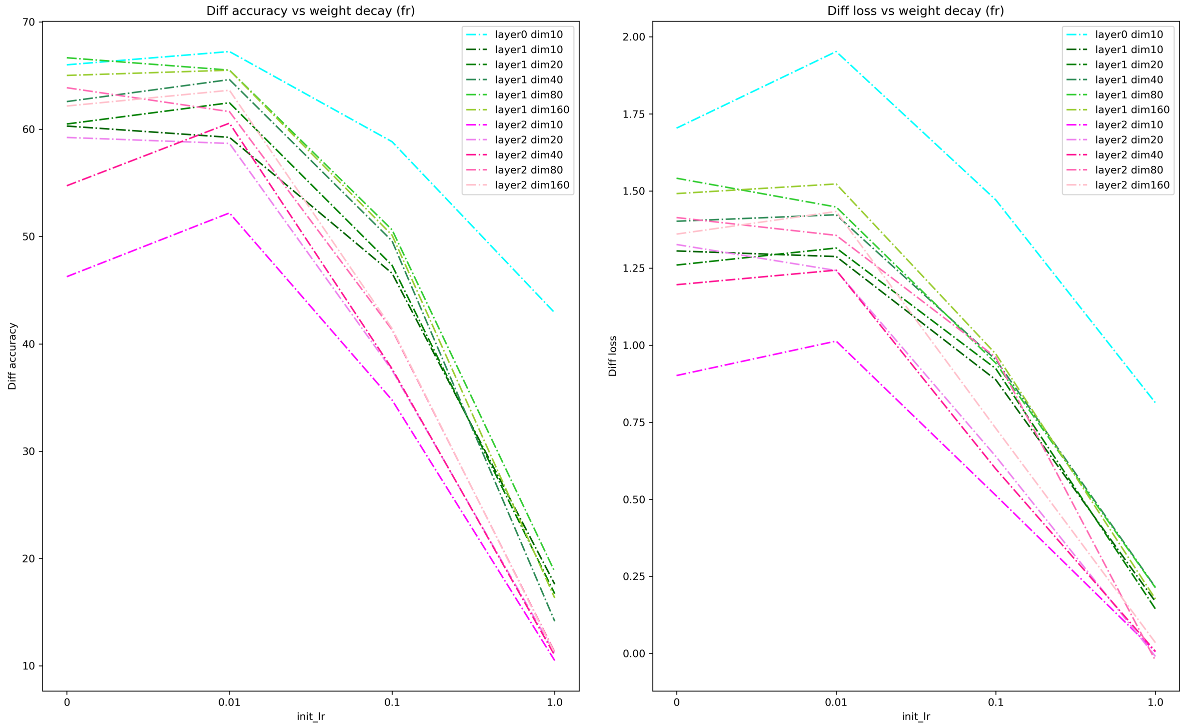

Figure 3: The “difference of accuracy” (Hewitt and Liang, 2019) and the “difference of loss” (Pimentel et al., 2020) criteria against weight decay on model configurations, on UD French. For each configuration, the learning rate leading to the highest accuracy is selected.

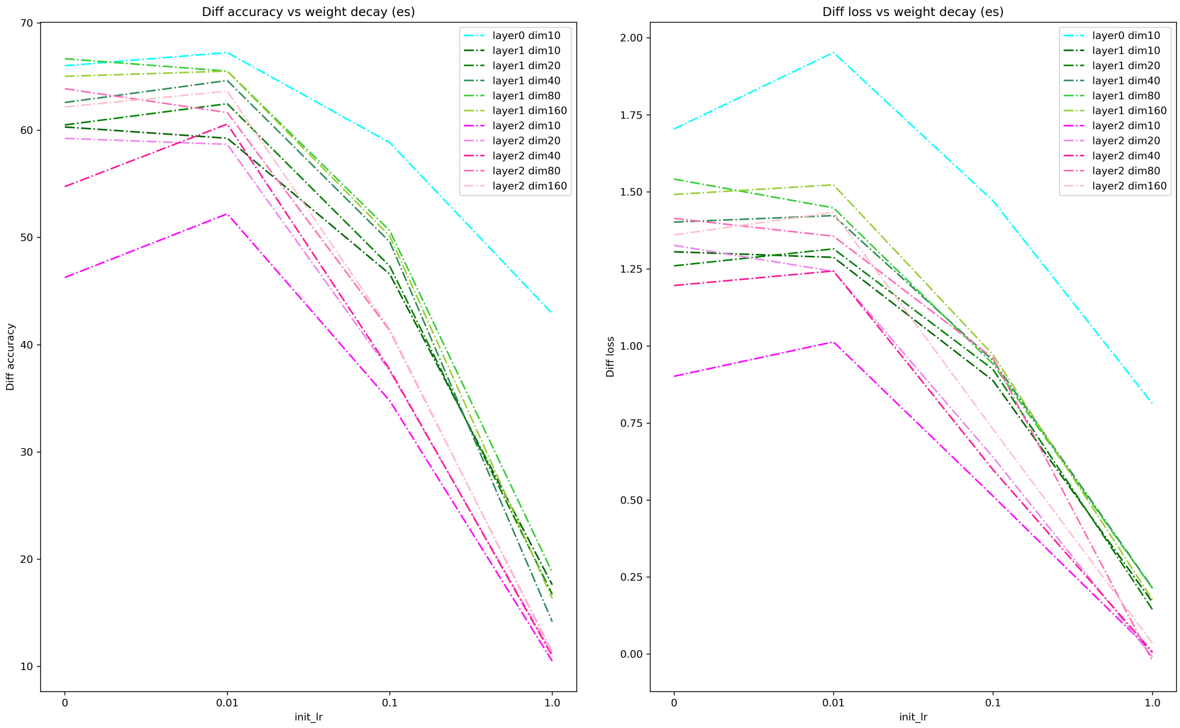

Figure 4: The "difference of accuracy" (Hewitt and Liang, 2019) and the "difference of loss" (Pimentel et al., 2020) criteria against weight decay on model configurations, on UD Spanish. For each configuration, the learning rate leading to the highest accuracy is selected.

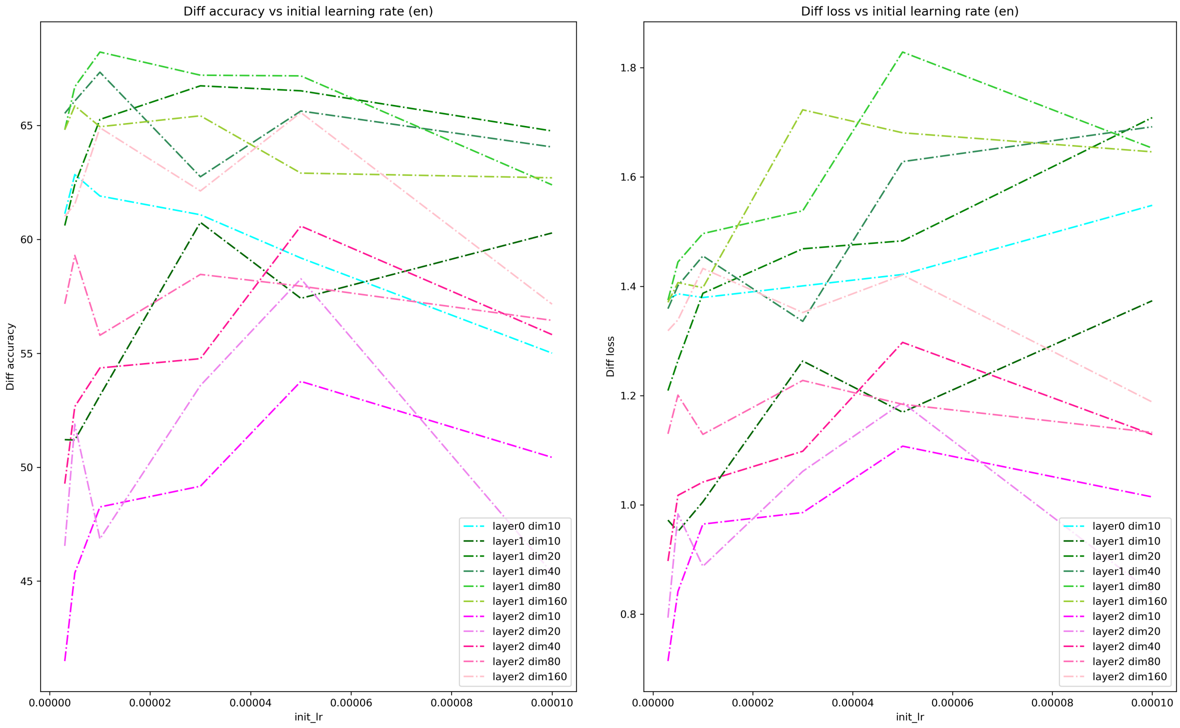

Figure 5: The "difference of accuracy" (Hewitt and Liang, 2019) and the "difference of loss" (Pimentel et al., 2020) criteria with different learning rates on model configurations, on UD English. The weight decay is set to 0.

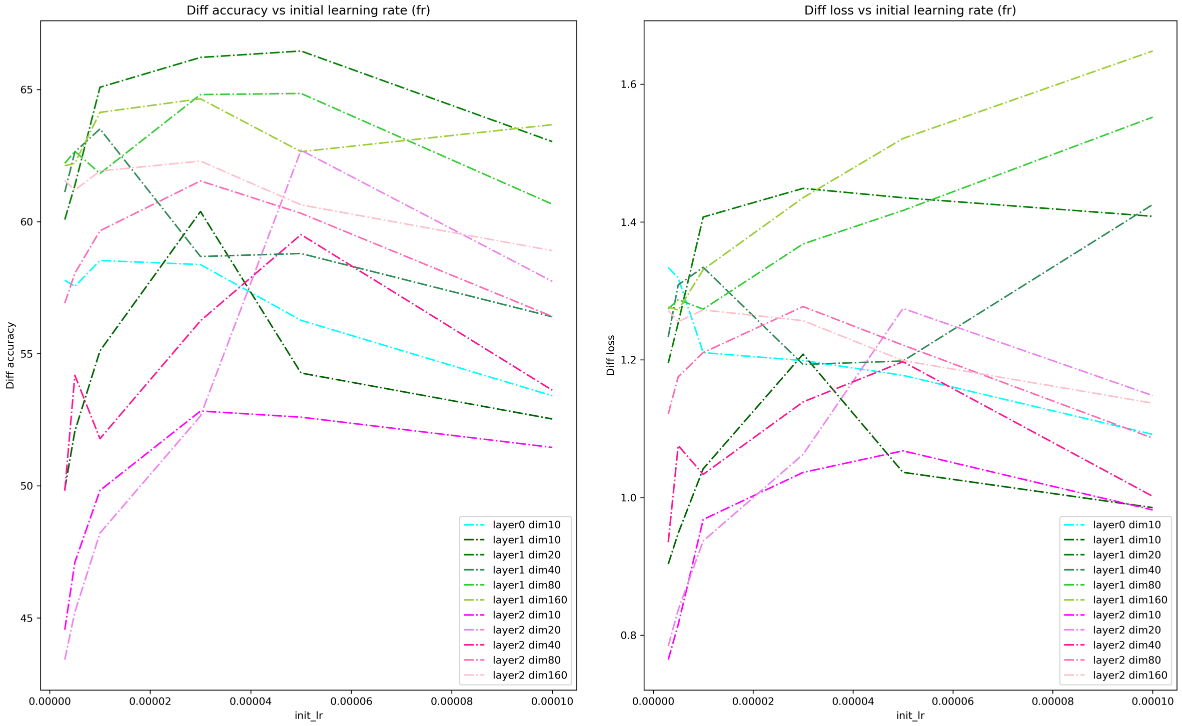

Figure 6: The "difference of accuracy" (Hewitt and Liang, 2019) and the "difference of loss" (Pimentel et al., 2020) criteria with different learning rates on model configurations, on UD French. The weight decay is set to 0.

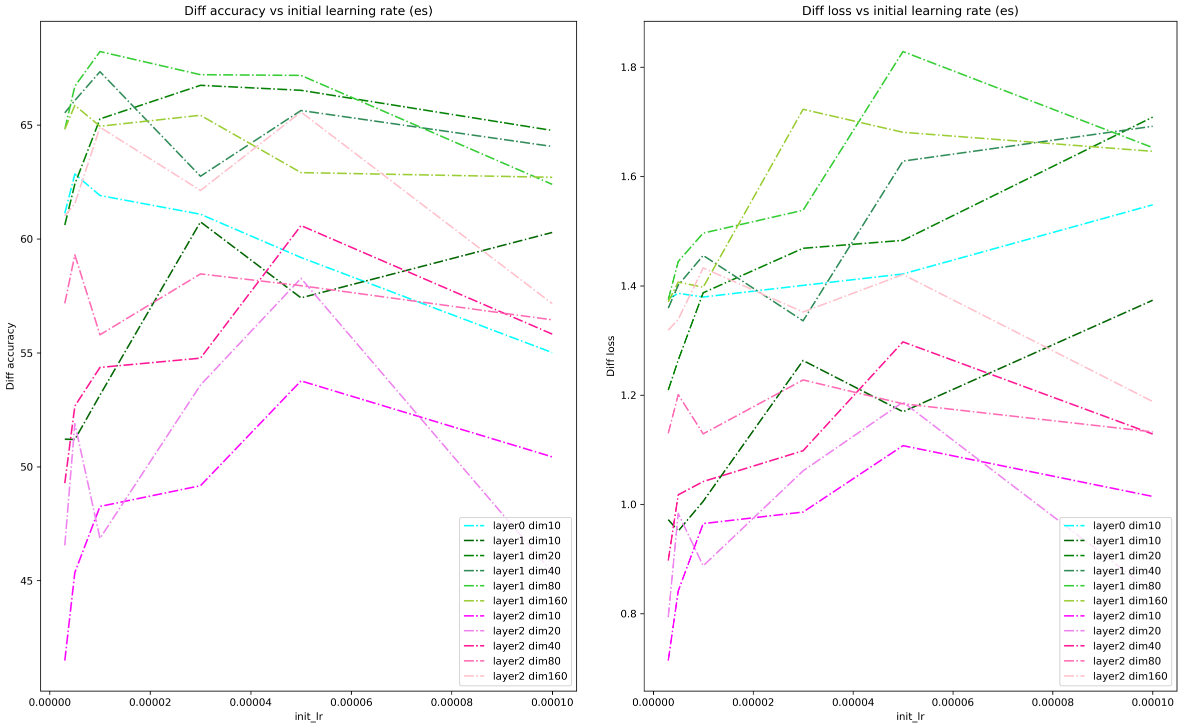

Figure 7: The "difference of accuracy" (Hewitt and Liang, 2019) and the "difference of loss" (Pimentel et al., 2020) criteria with different learning rates on model configurations, on UD Spanish. The weight decay is set to 0.

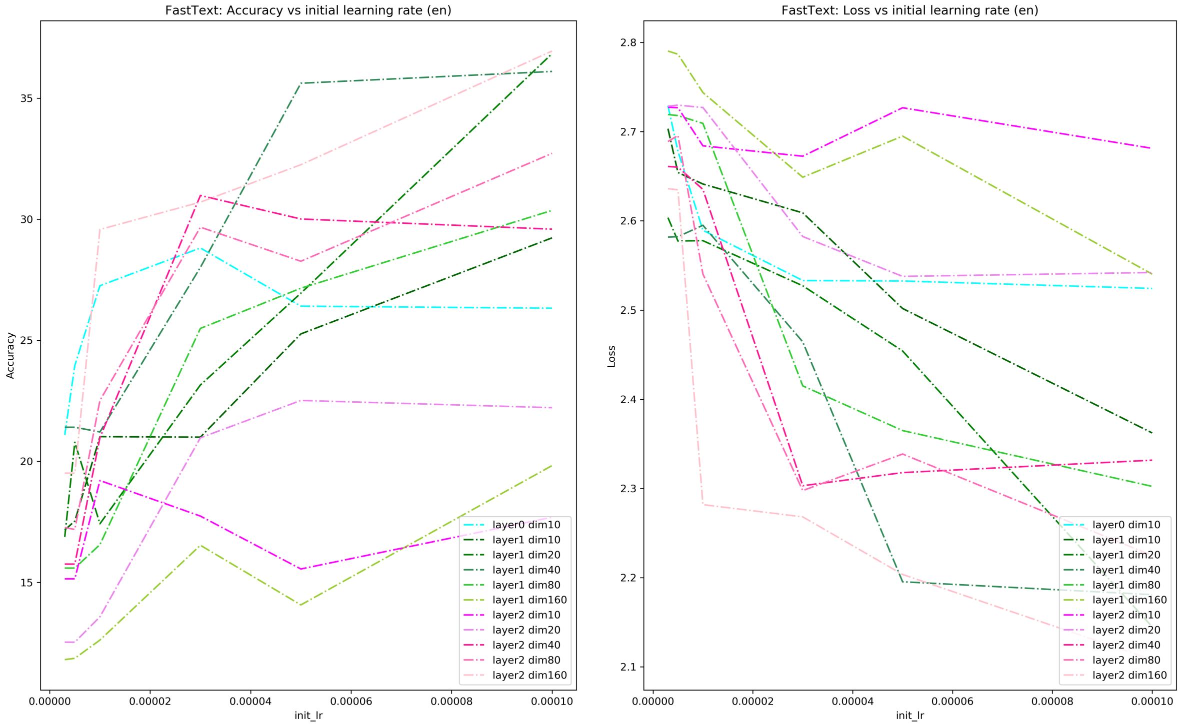

Figure 8: The accuracy and cross entropy loss of probes on FastText. These performances are much worse than those on mBERT, indicating the richness of information encoded in contextuality of mBERT.

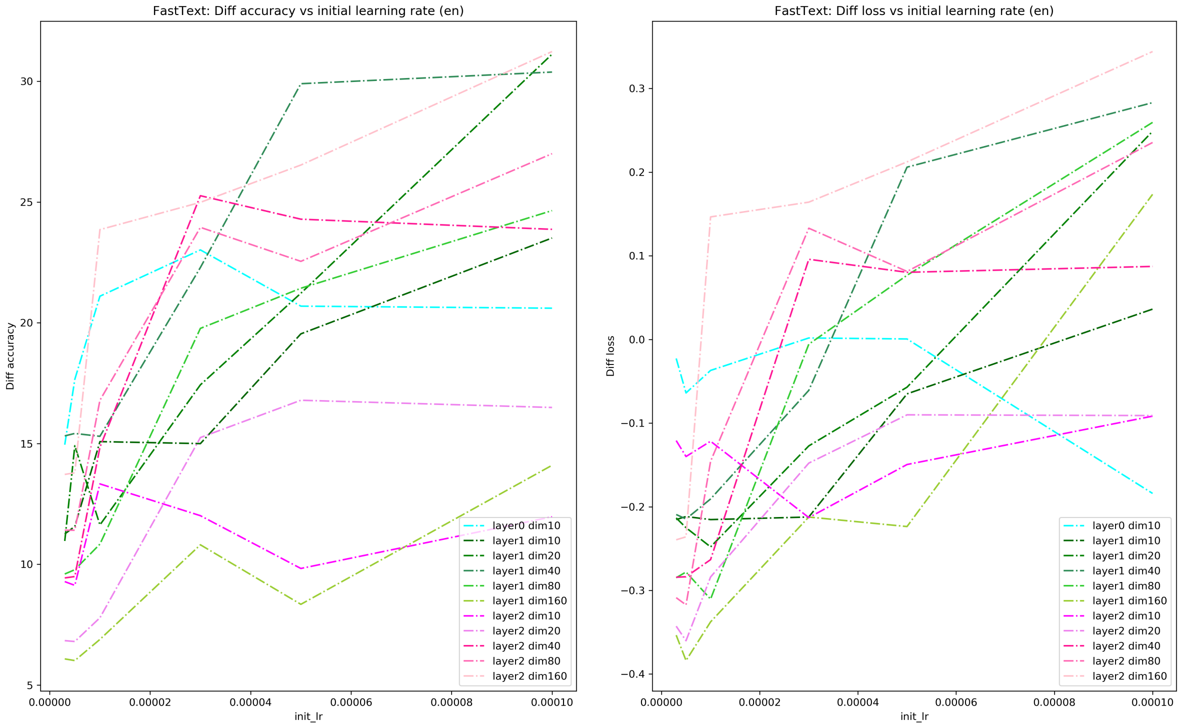

Figure 9: The selectivity (Hewitt and Liang, 2019) and information gain (Pimentel et al., 2020) of probes on FastText. Probes with different capacities are ranked similarly using these two criteria.

With Little Power Comes Great Responsibility

Abstract

Despite its importance to experimental design, statistical power (the probability that, given a real effect, an experiment will reject the null hypothesis) has largely been ignored by the NLP community. Underpowered experiments make it more difficult to discern the difference between statistical noise and meaningful model improvements, and increase the chances of exaggerated findings. By meta-analyzing a set of existing NLP papers and datasets, we characterize typical power for a variety of settings and conclude that underpowered experiments are common in the NLP literature. In particular, for several tasks in the popular GLUE benchmark, small test sets mean that most attempted comparisons to state of the art models will not be adequately powered. Similarly, based on reasonable assumptions, we find that the most typical experimental design for human rating studies will be underpowered to detect small model differences, of the sort that are frequently studied. For machine translation, we find that typical test sets of 2000 sentences have approximately 75% power to detect differences of 1 BLEU point. To improve the situation going forward, we give an overview of best practices for power analysis in NLP and release a series of notebooks to assist with future power analyses.[1]

1 Introduction

Despite its importance to empirical evaluation, relatively little attention has been paid to statistical power in NLP. In particular, *if it is the case that typical experiments in NLP are underpowered*, not only would we expect many meaningful improvements to go undetected, we would also expect many apparently significant differences to be exaggerated (Gelman and Carlin, 2014). In this paper, we build on past work calling for greater rigor in evaluation (McCoy et al., 2019; Azer et al., 2020), including the need for careful hypothesis testing (Koehn, 2004; Berg-Kirkpatrick et al., 2012; Søgaard et al., 2014; Dror et al., 2018), and show why and how power matters to NLP, addressing challenges unique to this domain.

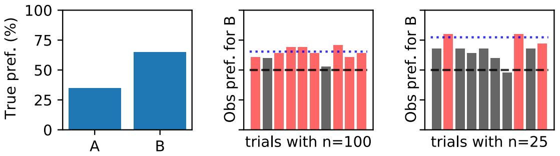

Figure 1: Cartoon example of statistical power in comparing two models: 65% of all people in the population always prefer system B (left). A comparison using a sample of 100 people would be well-powered (middle): over 80% of such samples will show a significant difference (plotted in red) from the null hypothesis that the models are equally good (dashed line). In samples of 25 people (right), far fewer tests will be significant (power $\approx$ 30%). Note that the observed mean of significant findings (dotted line) slightly overestimates the true proportion that prefer system B when $n = 100$ and more severely overestimates it when $n = 25$.

Roughly speaking, power is the probability that a statistical test will successfully detect a *true effect*. As an illustrative example, imagine comparing two dialog systems (see Figure 1). We want to know if people tend to prefer one system over the other. To test this, we will need multiple people to evaluate the systems. But how many? Once we have collected data, a statistical *test* will tell us if we can reject the null hypothesis the systems are equally good. Assuming the systems are not identical, statistical *power* is the probability that the experiment will return a significant result (or equivalently, it is one minus the probability of failing to detect the difference as significant). Although we don't know the magnitude of this difference, *power analysis* helps to estimate how much power an experiment

---

[1] https://github.com/dallascard/NLP-power-analysis

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9263–9274,
November 16–20, 2020.

will have under various assumptions.

Power depends on multiple factors, including the statistical test used, the significance threshold, true effect size, variance, and sample size. All else being equal, experiments with larger samples will have greater power than smaller samples, as shown in Figure 1. Similarly, larger effects and those with less variance are easier to detect, and therefore require fewer samples for equivalent power. Importantly, note that if we *do* find a significant difference, this does *not* imply that the experiment had high power.[2]

Proceeding with a test that is *underpowered* (i.e., too few subjects or items; often taken to mean less than 80% power; Cohen, 1962) means that one is less likely to be able to draw any useful statistical conclusion from the experiment, and has contributed, in part, to the replication crisis in other fields (Button et al., 2013; Szucs and Ioannidis, 2017; Ioannidis et al., 2017). Routinely running experiments with low statistical power undermines the scientific enterprise. Not only will true effects go undetected; when significant effects are found, they are likely to be noisier and have lower positive predictive value (Button et al., 2013).

Moreover, significant findings from underpowered experiments are more likely to exaggerate or reverse the true effect – so-called Type-M (magnitude) and Type-S (sign) errors, respectively (Gelman and Carlin, 2014). This problem can lead to systematic distortions in the literature if only significant findings are published, especially if these results are based on underpowered experiments (Scargle, 1999). The effect of Type-M error can be seen in Figure 1; significant differences are less likely to be found in smaller samples (right), but among those tests that are significant, the observed difference will tend to exaggerate the true difference (left) by more than a larger sample (middle). For further discussion of Type-M and Type-S errors, please refer to Appendix B.

Here, we investigate how these issues affect NLP. Although retrospective analysis of power involves challenges, we present evidence that underpowered experiments are widespread in NLP research. Among human evaluations, we find most experimental designs involve too few items and/or raters to detect small effects (§5). For comparing models in terms of accuracy, we find that some widely used benchmark datasets, including MRPC and SST-2, are now too small to be able to properly measure future progress against top performing models (§3). We also introduce a novel approach to power analysis for machine translation and characterize power in experiments testing for differences in BLEU (§4). Finally, a survey of recent papers reveals a general lack of statistical evaluation and a dearth of detailed reporting (§5.1).

To improve future practice, we suggest broader adoption of power analyses prior to evaluation, provide guidance on running power analyses in NLP, and release a series of notebooks for this purpose.

2 Power Analysis for NLP

Because most NLP tasks do not take the form of standard experiments in other sciences (Kraemer and Blasey, 2015; Westfall et al., 2014), it is nontrivial to run power analyses for many tasks of interest. While we cannot cover every scenario, we present here a generalizable, simulation-based approach to power analysis, along with three sample applications, which can be extended as necessary. Such an approach is modular, reusable, and transparent, and encourages planning of analyses in advance of data collection.

Every power analysis requires assumptions, and there is not likely to be a single correct approach. Rather, the point is to make one's assumptions explicit, and include enough detail so as to account for whatever is likely to be observed. By using reasonable assumptions, one can help to ensure that one's experiment is sufficiently well-powered, In the case of NLP, this means that one recruits enough subjects, collects enough ratings, or uses a large enough test set.

The general procedure we suggest for power analysis is described in detail in Figure 2. At a high level, the idea is to estimate power by running simulations. Recall that power is the probability of detecting a true effect, conditional on the experimental setting (effect size, variance, etc.) and significance threshold. Thus, if one can translate these assumptions into a process for generating simulated data, we can estimate power by generating many simulated datasets using assumed or estimated parameter values, running each sample through a significance test, and reporting the proportion that are found to be significant.

---

[2] Using the observed outcome from a single experiment to compute power falls into the trap of post-hoc power analysis and is not recommended. For additional background on statistical power, power analysis, null-hypothesis significance testing, and post-hoc analysis, please refer to Appendix A.

Define a generative process $G(n, e^*, \mathbf{h})$ parameterized by number of items, n, hypothesized effect e^* for the statistic of interest E, and other relevant parameters $\mathbf{h}$ (e.g., variance). Also choose a statistical test $T(\mathcal{D})$, which returns a p-value p when performed on data $\mathcal{D}$ sampled from $G(n, e^*, \mathbf{h})$. Finally, choose the size of the dataset to be sampled, n, significance threshold, α, and number of repetitions, r.

```
1. For $i$ in range($r$):
    • sample a dataset of size $n$, $\mathcal{D}_i \sim G(n, e^*, \mathbf{h})$
    • compute the effect of interest on this sample, $e_i = E(\mathcal{D}_i)$
    • also compute a p-value according to the test of interest: $p_i = T(D_i)$
2. Power $\approx \frac{1}{r} \sum(\mathbb{I}[p_i \leq \alpha] \cdot \mathbb{I}[\text{sign}(e_i) = \text{sign}(e^*)])$
```

Figure 2: An algorithm for power analysis by simulation. For the example of comparing two systems presented in Figure 1, e^* is the assumed overall proportion of people who prefer system B, relative to the null hypothesis, $p = 0.5$, $G(n, e^*, \mathbf{h})$ is simply Binomial$(n, 0.5 + e^*)$, while e_i is the observed proportion of people who prefer system B in sample i, again relative to 0.5. For extensions to estimate Type-M and Type-S error, see Appendix B.

The key to generalizing this approach is to begin with the end in mind. In particular, if one plans to test for a difference between models, one needs to choose the statistical test that will be used. That test will determine the level of detail required in the generative process for simulating data.

To return to the opening example of evaluating dialog systems, we want to test if people prefer one system over the other (Ai et al., 2007). If we ignore the nuances of human preference for now (but see §5 for a more nuanced approach), and simply assume that each person either prefers system A or system B, the only assumption we need to make for a power analysis in this setting is the proportion of people in the population who prefer system B. We can then simulate samples of n people (each of whom independently has the same probability of preferring system B) as a draw from a binomial distribution, and repeat this thousands of times.[3] For each sample, we then test whether the proportion of people who prefer system B is significantly different from 0.5. The estimated power of this experiment would thus be the proportion of simulated differences that are found to be significant.[4]

The most difficult part of power analyses is estimating the relevant quantities, such as the *true* proportion of people that prefer system B. Note, however, that one can always compute what power would be for a range of possible values, and indeed, this is the recommended procedure. For estimating the relevant parameters within an NLP context, we will primarily rely on data from the literature, measurements on validation data, and estimates from external datasets (see §3.2). However, where appropriate, pilot studies may also be informative.

In the remainder of this paper, we consider three scenarios of interest in depth, and assess the state of power in the NLP literature for each.

3 Comparing Models on Accuracy

It is common in NLP research to look for models which improve over state of the art (SOTA) on various benchmarks. However, an important but rarely asked question is, *can these benchmarks support the kinds of comparisons we want to make?* Many have emphasized the need for proper significance testing to avoid spurious findings, but if an experiment's test set is small, the minimum detectable effect (MDE) size may be large: only large improvements will yield sufficiently powered comparisons (i.e., $\geq 80\%$ power). If an experiment is badly underpowered, it cannot provide useful evidence that one model achieves slightly better performance than another for the underlying data distribution. Reliance on such evidence risks leading to over-confidence about the relative ranking of various models. As we show in §3.3, there is legitimate reason to be concerned about this in the case of certain widely used benchmarks.

3.1 Significance test for comparing classifiers

The standard statistical test for comparing classifiers on paired data is McNemar's test (Dietterich, 1998; Dror et al., 2018), which uses the numbers of items where the models disagree (i.e., the off-diagonal elements in Table 1).[5] McNemar's test assesses whether $\chi^2 = \frac{(p_{10} - p_{01})^2}{p_{10} + p_{01}}$ is significant, and if so, rejects the null hypothesis that the distributions are the same.

---

[3] We don't need to address variance in this scenario, as the variance of a binomial distribution is a function of its mean.

[4] More direct solutions are available for some settings, including this one (see Appendix E.5), but we describe it using the generic approach from Figure 2 for the purpose of illustration. For all cases examined in this paper, simulations take only minutes on a laptop.

[5] Unpaired data (i.e., if two models are evaluated on different data drawn from the same distribution) requires a different approach, such as using a binomial test. See Appendix E.5 for extended discussion.

	M1 correct	M1 incorrect
M2 correct	both correct	only M2 correct
M2 incorrect	only M1 correct	both incorrect

Table 1: A contingency table representing the distribution of possible outcomes for two models (M1 and M2).

Thus, for McNemar's test, the relevant data generating process for simulations can be specified in terms of the expected difference in accuracy between the models, Δ_{acc}, and P_a, the expected proportion of examples for which the models will have the same outcome (i.e., both correct or both incorrect). From these we can compute the expected proportions of examples on which only one model is correct (i.e., the off-diagonals in Table 1), and estimate power via the algorithm in Figure 2. Figure 3 illustrates how power increases with increased sample size, effect size, and agreement rate.[6]

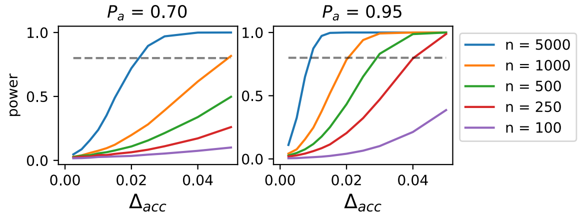

Figure 3: Power for comparing two classifiers on accuracy using paired data depends on the size of the test set (n), the expected agreement (P_a), and the expected difference in accuracy (Δ_{acc}). The dashed line shows 80% power, often taken to be a minimal requirement.

3.2 Estimating parameters

In order to estimate the required parameters (P_a and Δ_{acc}), we consider three options: (1) use results on validation (dev) data; (2) fit a regression based on historical data; (3) use middle-of-the-road assumptions when lacking other information. Using these methods, we can then estimate power or calculate the smallest effect that can be detected with 80% power at $\alpha = 0.05$ (or other thresholds). Both to illustrate this process, and to provide guidance for future work, we demonstrate these approaches below using data from two widely-used datasets for evaluating NLP models: SQuAD 2.0 (Rajpurkar et al., 2016, 2018) and the GLUE benchmark (Wang et al., 2018).

Using validation results: To the extent that we expect performance on test data to match performance on validation data (i.e., in the absence of domain shift), *paired* performance on validation data (i.e., difference in accuracy and agreement rate) provides one method for estimating power when comparing against a baseline model.

To illustrate this, from the authors of SQuAD 2.0, we obtain the pairwise agreement rates between all models submitted to the leaderboard on both validation and test data. We find a very strong correlation between validation and test for both pairwise accuracy differences (Δ_{acc}) and agreement rates (P_a) ($r = 0.99$ for both, as shown in Figure 9 in Appendix D, with results on validation data included in the accompanying online materials), suggesting we can use paired predictions on validation data for power calculations when we have access to the predictions from both models. Note that this approach assumes that the dev and test data have been drawn from the same distribution, and that dev performance has not been artificially inflated (such as by training on validation data directly).

Using historical data: When one does not have access to the baseline model or an informative prior, one can make use of historical trends. That is, we can try to estimate what a typical improvement will look like, given the current state of the art (SOTA). To illustrate this approach, we collect reported results for both SQuAD 2.0 and GLUE, and fit regressions to estimate Δ_{acc} and P_a. Given these parameters, we can assess the likely power and MDE for a typical model improvement against a given baseline accuracy level.

To fit a regression to predict typical improvements to SOTA, we gather data from GLUE papers and manually label 119 accuracy comparisons and 57 claims of improvement (as denoted by bolding of a result and a claim of SOTA in text) across 14 papers (selected as being at or above the BERT score on the GLUE leaderboard with an accompanying paper). In regressing Δ_{acc} on baseline accuracy and task, we achieve an $R^2 = 0.69$, which is not a perfect fit, but still provides a prior on likely effect size. Similarly, we achieve an $R^2 = 0.67$ when fitting a regression to SOTA improvements on the SQuAD 2.0 leaderboard (selected as being a significant improvement in time-ordered submissions). See Appendix E.2.1 for more details.

To assess power for McNemar's test, we must also fit a regression predicting the expected overlap

---

[6] Corresponding plots showing Type-M and Type-S error (Gelman and Carlin, 2014) are in Appendix B. To walk through a numerical example, see Appendix C. For an interactive example, see the accompanying online notebooks.

between the models (P_a). To fit such a regression, from GLUE authors we obtain the model test set predictions on all tasks from a set of 10 high-performing models, which allows us to measure the extent to which their predictions overlap with each other. Using GLUE tasks which measure accuracy, we regress P_a on baseline accuracy and Δ_{acc}, and achieve an R^2 of 0.97.[7] Repeating this for SQuAD 2.0, we get an R^2 of 0.94. See Appendix E.2 for regression coefficients and additional details.

Typical improvements on popular tasks tend to be small (see mean improvements in Table 2). Except for rare transformative work, such as BERT (Devlin et al., 2019), it is generally difficult to do *much* better than a previous SOTA and thus improvements are likely to follow a trend, which is why we are able to use historical data as a guide. In cases where such data is not available or cannot be trusted, other methods are necessary.

No prior: If no informative prior is available and the baseline model or can't be used for comparison on a validation set, then we must fall back on middle of the road assumptions. Lachenbruch (1992) provides a suggested default prior, and we find that MDEs using this method are very similar to those found by using the regression based approach. Appendix E.3 provides more details, and Table 9 in the appendix presents the comparison.

3.3 Assessing power in the literature

Using the regression-based approach of estimating Δ_{acc} and P_a described above, we estimate the MDE for each individual accuracy-based GLUE task in comparison to current SOTA, and report the average effect size of results which claimed improvements. Table 2 summarizes these results, showing for each dataset the size of the test set, the accuracy of the best performing model on each task at the time of writing, the estimated MDE to have 80% power using our regression to predict overlap (P_a), and the average reported difference from their respective baselines.

As can be seen in Table 2, the mean reported effect size ($|\Delta_{acc}|$) is well below the estimated MDE for the three smallest test sets – WNLI, MRPC, and SST-2. Because this mean is based on models comparing to even weaker baselines, we would expect most future improvements to be even smaller. Thus, most future experiments involving these three datasets *will not have adequate power* to test for improvements over the current SOTA in the way that they are routinely used. Moreover, alternative analyses give *even more pessimistic* estimates of likely improvements relative to MDE, as described in Appendix E.4. If an experiment does show significant improvement on a dataset such as MRPC, the potential for Type-M error should make us skeptical that this improvement will generalize to new data from the same domain.

Dataset	**Size**	**SOTA** (%)	**Est. MDE** (%)	$|\Delta_{acc}|$ (%)
WNLI	147	94.5	+5.26	+1.72
MRPC	1,725	92.0	+1.62	+0.63
SST-2	1,821	97.2	+1.02	+0.57
RTE	3,000	91.7	+1.23	+3.89
QNLI	5,463	97.5	+0.55	+1.31
MNLI-m	9,796	91.6	+0.67	+0.97
MNLI-mm	9,847	91.3	+0.68	+1.29
QQP	390,965	91.0	+0.11	+0.36
SQuAD 2.0	8,862	90.7	+0.56	+2.23†

Table 2: Estimated minimum detectable effect (MDE) using a regression-based estimate of likely agreement with leaderboard SOTA as of May 6th, 2020. $|\Delta_{acc}|$ is the average improvement over baseline per task among surveyed papers that claimed SOTA. For future comparisons, unless the expected improvement is larger than the estimated MDE, an experiment is unlikely to be adequately powered, and researchers should instead choose a different (larger) dataset. Note that this likely applies to the vast majority of experiments on WNLI, MRPC, and SST-2, based on recent trends. † indicates that the SQuAD 2.0 average was based on leaderboard improvements, which weren't necessarily reported in a publication. See Appendix E for full table and details.

While the above results are informative about future experiments, we would also ideally like to know about the power of past experiments. Most of the papers from which we collected results did not report a significance test on the test set. Here we estimate the expected power and predicted result of such a test using leave-one-out regressions, where we make a prediction for each reported improvement using all other reported model comparisons. This procedure reveals that **only 46% would have predicted adequate power** (using estimates for expected improvement and agreement), and **approximately 51% would have been significant** (based on estimated agreement and *reported* improvement). Approximately 80% of experiments with at least 80% power would also have been

---

[7] WNLI (Levesque et al., 2012), MRPC (Dolan and Brockett, 2005), SST-2 (Socher et al., 2013), RTE (Dagan et al., 2005; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009), QNLI (Rajpurkar et al., 2016) MNLI (Williams et al., 2018), and QQP (Iyer et al., 2017). For consideration of other metrics, see Appendix F.

found to be significant (37% of all comparisons).

In part because performance on many of these tasks is now so good, a large expected improvement is required in order for a new experiment to have 80% power, suggesting that larger test set sizes may be necessary to continue making well-powered claims of SOTA improvement on individual tasks. For any comparisons which are likely to be underpowered, we should refrain from placing much emphasis on obtaining small improvements over the previously reported best model. In extreme cases, such as MRPC and SST-2, it is worth considering whether it is time to retire these datasets as the basis for model comparison.[8]

4 Machine Translation

To show how our approach to power analysis can be applied to a more difficult setting, we consider automated evaluation of machine translation using BLEU scores (Papineni et al., 2002). As with accuracy, we would like to know what scale of improvements can be detected with reasonable power on typical test sets. This setting is more complicated because (1) BLEU is a corpus-level metric, rather than being averaged across instances, and (2) typical models are trained on vast amounts of parallel data, with little data available that has not been used in training, making it difficult to estimate variation in performance.

Significance testing for BLEU: To test for a significant difference between two MT models we use the randomization test, as recommended in Dror et al. (2018): given the paired output translations from both models, swap the outputs for a random subset of test examples and compute the resulting difference in BLEU. Repeating this thousands of times gives us a null distribution, which can be used to test the observed difference between models.

Generative process for simulations: If large amounts of untouched evaluation data were available, we could approach power analysis by simply evaluating BLEU score on many random subsets of n sentences, and computing the mean and variance of each system. Unfortunately, because MT depends on parallel text (most of which is used in training), evaluation data tends to be scarce. Instead, we introduce a generative process that can produce the necessary inputs for power analysis.

For intuition, note that if we swap the i^{th} pair of model outputs (as is done in the randomization test), leaving rest as they are, we change the difference in BLEU between models by a specific amount, δ_i, which we call the effect of making that swap. While these individual effects are not independent of each other due to the corpus-level nature of the metric, in practice, the sum of individual effects closely approximates the net effect of swapping entire subsets (see Figure 15 in Appendix G).

Based on analyzing several models and datasets, we find the typical distribution of these individual effects can be approximated using a mixture of a Delta distribution at zero, and a Laplace distribution (see Appendix G for details). Concretely, if we assume Δ_B is the expected difference in BLEU between two models on a dataset of n examples, and P_0 is the expected proportion of examples for which $\delta_i = 0$, we can simulate a dataset $\{\delta_i\}_{i=1}^{n}$ of n individual effects using the following process: with probability P_0, $\delta_i = 0$. With probability $1 - P_0$, $\delta_i \sim \text{Laplace}(\mu, b)$, where $\mu = \frac{-2 \cdot \Delta_B}{n(1-P_0)}$, $b = b_0/n$, and b_0 is a user-specified parameter that controls the variance, independent of the sample size. By construction, $\mathbb{E}[\sum_{i=1}^{n} \delta_i] = -2 \cdot \Delta_B$.[9]

Given this generative process, we can then estimate power using the Algorithm in Figure 2. On each iteration, draw a simulated dataset from the generative process, compute the observed difference between models as $\hat{\Delta}_B = -\frac{1}{2}\sum_{i=1}^{n} \delta_i$, and test if this is significantly different from zero using a modified randomization test, in which we assume that the net effect of swapping a subset of instances is simply the sum of the δ_i's in the subset. (Please see online materials for an interactive example).

Empirical estimates: In order to estimate reasonable values for the required parameters, we use several pretrained models from the FAIRSEQ library (Ott et al., 2019) for the WMT English-German translation task. We evaluate these models on the shared task test sets from 2016-2019 and compute BLEU scores using SACREBLEU (Post, 2018). Fitting a Delta-Laplace mixture to the effects of swapping individual output pairs, we estimate values for $\hat{P}_0$ and $\hat{b}_0$, reported in Table 3. (See also Figure 16 in Appendix G; code for computing estimates is provided in the online materials).

---

[8] It is also worth exploring power with respect to claims of improvement on multiple tasks with a single model (Demšar, 2006), rather than each task individually. We leave consideration of this as an interesting direction for future work.

[9] Note that swapping all n examples would reverse the model scores, equivalent to a net effect of $-2 \cdot \Delta_B$.

M1	M2	Test set	n	Δ_B	$\hat{P}_0$	$\hat{b}_0$
TF19*	TF18*	2019	2K	4.3	0.19	23.7
TF18	TF16	2018	3K	4.2	0.09	29.4
TF16	Conv17	2017	3K	1.3	0.12	22.5
TF16	Conv14	2016	3K	7.6	0.10	27.6

Table 3: Relevant parameters from four MT evaluations. TF are Transformer-based (Ott et al., 2018; Edunov et al., 2018; Ng et al., 2019) and Conv are Convolutional models (Gehring et al., 2017) from FAIRSEQ. Test sets are from WMT shared tasks for En-De translation. Δ_B is the reported difference in BLEU, whereas $\hat{P}_0$ and $\hat{b}_0$ are estimated. * indicates ensembles.

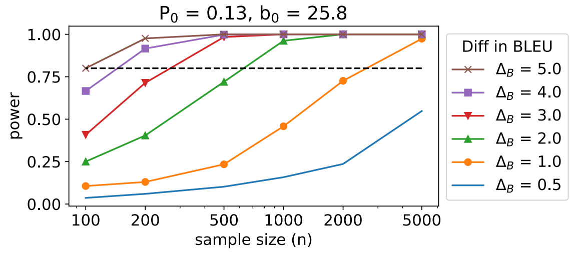

Figure 4: Power analysis for MT, showing how power increases with n and Δ_B, using an average of fitted values for P_0 and b_0. Based on this analysis, we expect that an experiment with a test set of 2000 sentences would have approximately 75% power to detect a difference of 1 BLEU point as significant. For additional plots, refer to Figure 17 in Appendix G.

While far from identical, the four comparisons, each representing different stages of model evolution, all produce similar estimates. Although these estimates are only based on a single language pair, the models and test sets are relatively diverse, and we expect that these estimates will generalize, though better estimates could be obtained by fitting this distribution to a new domain of interest.

Using these estimates, we can now characterize how much power test sets of different test set sizes (n) would have for a range of possible differences in BLEU (Δ_B). Figure 4 shows this for P_0 and b_0 set to the average of the observed values.[10] Based on this estimate, we conclude that for typical MT test sets of around 2,000 examples, an improvement of 1 BLEU point can likely be detected with approximately 75% power. As shown in Figure 4 this power level increases dramatically with sample size and effect size.

This analysis has served, in part, to show how a simulation-based approach to power analysis can be adapted to virtually any task. Additional work is required to test how well these specific parameter estimates will generalize, but the same process can easily be adapted to new language pairs. More generally, there would be great value in the MT community curating larger held-out test sets, both to validate this analysis, and for better powered future comparison.

5 Likert-Scale Human Evaluations

Tasks such as natural language generation are difficult to evaluate using automated methods; as such, human evaluations are central to NLP. Past work has reported great variation in how human evaluations are done (van der Lee et al., 2019). Therefore, we begin with a meta-analysis of a subset of human evaluation experiments from EMNLP 2019, which we then use as the basis for claims about the power of human evaluations in NLP more generally.

5.1 Meta-analysis

To characterize the state of human evaluation in NLP, we identified papers from the main session of EMNLP 2019 that made use of human evaluations (details in Appendix H.2). To generalize across studies, we restrict our analysis to Likert-scale comparisons, which was the most commonly reported type of evaluation. We extracted all cases where a new model was being compared to the best-performing baseline on one more metrics (117 comparisons from 41 papers) and normalized all ratings to be on a 0-1 scale.

One takeaway from this meta-analysis is that the reported effect sizes (that is, difference between the novel model and the best-performing baseline) vary widely (s.d. $= .12$ on a [0, 1] scale). Number of items tested is more consistent: 69% used 100 or fewer, and only 18% used over 200. But, as similarly found by van der Lee et al. (2019), many key details were not reported in this sample of experiments. Most commonly missing was number of ratings per item (34% of all experiments), followed by total number of workers (28%). For 7% of experiments, we could not determine the number of items tested. 57% of experiments collected 3 annotations per item, which was also the modal number of unique annotators. Thus, it is often difficult to ascertain, for any particular experiment, the details of the experimental setting that are necessary to evaluate the validity of the results.

Because the number of items rated was the most

---

[10] For a sensitivity analysis of how power varies under different assumptions for P_0 and b_0, please see Figure 17 in Appendix G.

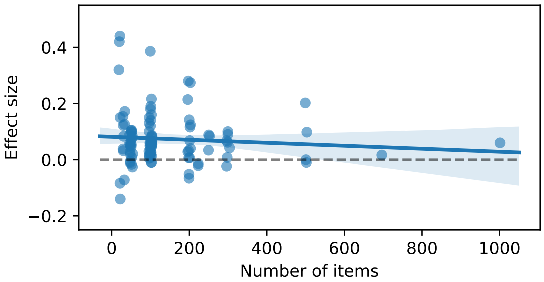

Figure 5: Scaled effect size vs. number of items from our EMNLP 2019 survey, showing higher variance in the smallest samples. There is a slight negative correlation, though it is not significant. As can be seen, most experiments are small ($n \leq 100$).

commonly reported, we use that as our proxy for sample size. Figure 5 shows scaled mean difference between models as a function of number of items. As expected, we see greater variance in effects with smaller samples since, with smaller samples, we expect greater noise. We also observe a slight negative correlation between effect size and sample size. That is, as sample size gets larger (and, thus, as estimates get more precise), the estimated effect size gets smaller. This trend is sometimes used as an indication of publication bias (censoring of null and opposite-direction effects) since, in a sample with no publication bias, the effect size should be independent of the sample size (Begg and Mazumdar, 1994). However, in our case, this correlation is not significant (Kendall's $\tau = -.07$, $p = .32$) and so it is difficult to draw strong conclusions.[11]

5.2 Power analysis for human Likert ratings

What kind of effect sizes can typical human evaluation experimental designs detect? As in previous sections, we can use simulations to explore how many annotators and/or instances should be used to have sufficient power.

Simulating human experiments is conceptually simple (e.g., m raters each rate n generated sentence on overall quality), but for realistic simulations, we need to consider variation in items (some generated sentences are better than others), and variation by rater (some raters use higher ratings and/or respond to different aspects of quality), as well as the overall difference in quality between models. A simulation which treated all workers as identical would fail to capture this variation, and hence might overestimate power (Barr et al., 2013).

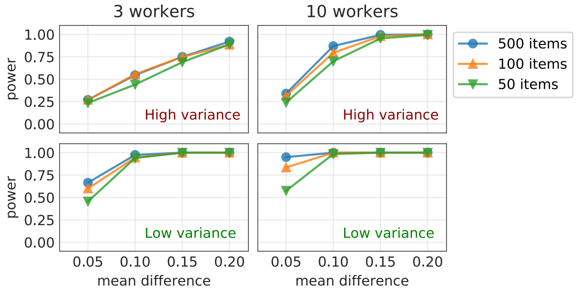

Figure 6: Using parameters estimated with mixed effects models from a high variance setting (top) and a low variance setting (bottom), the left panel shows simulated experiments with 3 workers annotating each item, the right panel shows an unusually high number of annotators per item (10 workers). Under typical assumptions, many common experimental settings (e.g., 3 workers and 100 items) are underpowered.

Unfortunately, details such as worker variance are rarely reported in published papers. To better characterize the typical variation in human evaluations, we rely on a convenience sample of several large datasets to estimate these parameters and use them in our simulations as a proxy for what we might observe in practice. Although focused on different tasks, all use a similar methodology, namely, getting many Likert-scale annotations per instance from many annotators and models (in some cases as many as 20 ratings per item).[12]

In order to extract estimates of these parameters for our simulations, we use hierarchical mixed-effects models, as used in psychology and other behavioral fields (Barr et al., 2013; Gelman and Hill, 2006). Such models incorporate variation in the quality of generated instances, annotator responses, and annotator sensitivity, and are recommended by van der Lee et al. (2019) for analyzing human evaluations. (We provide details in Appendix H.3 and include code for fitting such models as part of the online materials). Using this approach, we obtain an estimate of the relevant parameters from each of the large datasets. From these, we choose sets of parameters to be representative of experiments with high or low variance, with full results in Appendix H.3 (see Table 16 for parameter estimates).

As before, we then use these estimates to simulate data, assess significance on the simulated data (here using mixed effect regression), and compute power as a function of mean difference and sample

---

[11] We exclude from this analysis two large negative effects with $N = 500$ which would exaggerate this correlation.

[12] We use publicly available or author-provided data from Hashimoto et al. (2019); Dathathri et al. (2020); Holtzman et al. (2020), and WMT19 (links in Appendix H.2).

size.[13] The resulting power estimates are shown in Figure 6, plotted in terms of effect size, sample size, and numbers of workers and items, for both the high and low variance scenarios. From this analysis, we highlight a few key takeaways:

- *Many human evaluation studies are likely underpowered:* Using the "high variance" parameters (which are typical of most of the datasets we used), the most common design at EMNLP 2019 (3 workers, 100 items) is underpowered unless the effect size is quite large (0.2 or higher on the [0, 1] scale).
- *Even with low variance, typical designs are underpowered to detect small effects:* Using our estimated parameters for the low variance setting, experiments will be underpowered to detect small effects (0.05 on the [0, 1] scale), unless an unusually large number of ratings per item are collected (10+ for 100 items).
- *Need for improved reporting:* Most human evaluations do not report enough detail to interpret the results. This could be drastically improved through basic power analyses, significance testing using mixed-effects models, and sharing of raw data.

Given our model estimates and simulations, we conclude that, in aggregate, many human evaluations are underpowered and would benefit from larger sample sizes, particularly by using more workers per item. Increased adoption of even approximate power calculations within the NLP community will promote thoughtful consideration of appropriate sample sizes and improve the reliability and replicability of results.

6 Overall Recommendations

- Power analyses should be done prior to evaluation when comparing against a baseline. If a comparison is likely to be underpowered, the pros and cons of running that evaluation should be carefully considered. Underpowered experiments do not provide convincing evidence of progress.
- For new datasets and shared tasks, the number of instances in the test will determine the minimum detectable effect size, and should be chosen accordingly.
- For tasks which no longer have adequate power to detect typical improvements (e.g., MRPC and SST-2), authors should consider expanding the test set or retiring the task.
- To facilitate future power calculation and significance tests, model owners should release final fine-tuned model checkpoints. Alternatively, leaderboard owners may wish to make validation set predictions from all submitted models publicly available.
- For human evaluations, (anonymized) raw data should be shared, along with parameters and code to replicate the analysis, including proper significance testing. Prior to collecting human evaluation data, researchers should create an analysis plan and run power analyses to determine an appropriate sample size (likely requiring more workers and items than is currently typical in NLP).

7 Conclusion

Recent progress in NLP has been extraordinarily rapid, sometimes at the cost of experimental rigor. In this paper, we have presented evidence that underpowered experiments are widespread in NLP. For comparisons based on small samples, there is little reason to think that such an evaluation *could* reliably provide evidence of a significant improvement, and good reason to believe that improvements found to be significant will exaggerate or reverse the true effect. Going forward, a combination of larger test sets, simple power analyses, and wider sharing of code, data, and experimental details will help to build the foundation for a higher standard of experimental methodology in NLP.

Acknowledgments

Toyota Research Institute ("TRI") provided funds to assist the authors with their research but this article solely reflects the opinions and conclusions of its authors and not TRI or any other Toyota entity. Thanks to Sam Bowman, Amanpreet Singh, Kevin Clark, Naman Goyal, and Colin Raffel for providing data from submissions to the GLUE leaderboard, as well as Taylor Berg-Kirkpatrick, Sumanth Dathathri, Ari Holtzman, Hannah Rashkin, and Nikita Srivatsan for providing raw human evaluation data, not all of which made it into the paper.

---

[13] These simulations require estimates for 7 parameters: the baseline, the effect size, variance by worker, variance by worker as a function of model, variance by item, variance by item as a function of model, and residual variance.

Abstract

Large datasets have become commonplace in NLP research. However, the increased emphasis on data quantity has made it challenging to assess the quality of data. We introduce *Data Maps*—a model-based tool to characterize and diagnose datasets. We leverage a largely ignored source of information: the behavior of the model on individual instances during training (*training dynamics*) for building data maps. This yields two intuitive measures for each example—the model's confidence in the *true* class, and the variability of this confidence across epochs—obtained in a single run of training. Experiments across four datasets show that these model-dependent measures reveal three distinct regions in the data map, each with pronounced characteristics. First, our data maps show the presence of *ambiguous* regions with respect to the model, which contribute the most towards out-of-distribution generalization. Second, the most populous regions in the data are *easy to learn* for the model, and play an important role in model optimization. Finally, data maps uncover a region with instances that the model finds *hard to learn*; these often correspond to labeling errors. Our results indicate that a shift in focus from quantity to quality of data could lead to robust models and improved out-of-distribution generalization.

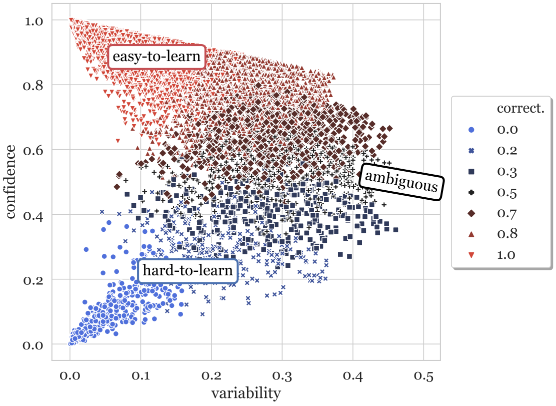

Figure 1: Data map for *SNLI* train set, based on a RoBERTa-large classifier. The x-axis shows **variability** and y-axis, the **confidence**; the colors/shapes indicate **correctness**. The top-left corner of the data map (low **variability**, high **confidence**) corresponds to ***easy-to-learn*** examples, the bottom-left corner (low **variability**, low **confidence**) corresponds to ***hard-to-learn*** examples, and examples on the right (with high **variability**) are ***ambiguous***; all definitions are with respect to the RoBERTa-large model. The modal group in the data is formed by the *easy-to-learn* regions. For clarity we only plot 25K random samples from the *SNLI* train set. Fig. 8b in App. §C shows the same map in greater relief.

1 Introduction

The creation of large labeled datasets has fueled the advance of AI (Russakovsky et al., 2015; Antol et al., 2015) and NLP in particular (Bowman et al., 2015; Rajpurkar et al., 2016). The common belief is that the more abundant the labeled data, the higher the likelihood of learning diverse phenomena, which in turn leads to models that generalize well. In practice, however, out-of-distribution (OOD) generalization remains a challenge (Yogatama et al., 2019; Linzen, 2020); and, while recent large pretrained language models help, they fail to close this gap (Hendrycks et al., 2020). This urges a closer look at datasets, where not all examples might contribute equally towards learning (Vodrahalli et al., 2018). However, the scale of data can make this assessment challenging. How can we *automatically* characterize data instances with respect to their role in achieving good performance in- and out-of- distribution? Answering this question may take us a step closer to bridging the gap between dataset collection and broader task

objectives.

Drawing analogies from cartography, we propose to find coordinates for instances within the broader trends of a dataset. We introduce *data maps*: a model-based tool for contextualizing examples in a dataset. We construct coordinates for data maps by leveraging *training dynamics*—the behavior of a model as training progresses. We consider the mean and standard deviation of the *gold label* probabilities, predicted for each example across training epochs; these are referred to as **confidence** and **variability**, respectively (§2).

Fig. 1 shows the data map for the *SNLI* dataset (Bowman et al., 2015) constructed using the RoBERTa-large model (Liu et al., 2019). The map reveals three distinct regions in the dataset: a region with instances whose true class probabilities fluctuate frequently during training (high **variability**), and are hence *ambiguous* for the model; a region with *easy-to-learn* instances that the model predicts correctly and consistently (high **confidence**, low **variability**); and a region with *hard-to-learn* instances with low **confidence**, low **variability**, many of which we find are *mis*labeled during annotation .[1] Similar regions are observed across three other datasets: *MultiNLI* (Williams et al., 2018), *WinoGrande* (Sakaguchi et al., 2020) and *SQuAD* (Rajpurkar et al., 2016), with respect to respective RoBERTa-large classifiers.

We further investigate the above regions by training models exclusively on examples from each region (§3). Training on *ambiguous* instances promotes generalization to OOD test sets, with little or no effect on in-distribution (ID) performance.[2] Our data maps also reveal that datasets contain a majority of *easy-to-learn* instances, which are not as critical for ID or OOD performance, but without any such instances, training could fail to converge (§4). In §5, we show that *hard-to-learn* instances frequently correspond to labeling errors. Lastly, we discuss connections between our measures and uncertainty measures (§6).

Our findings indicate that data maps could serve as effective tools to diagnose large datasets, at the reasonable cost of training a model on them. Locating different regions within the data might pave the way for constructing higher quality datasets., and ultimately models that generalize better. Our code and higher resolution visualizations are publicly available.[3]

2 Mapping Datasets with Training Dynamics

Our goal is to construct *Data Maps* for datasets to help visualize a dataset with respect to a model, as well as understand the contributions of different groups of instances towards that model's learning. Intuitively, instances that a model always predicts correctly are different from those it almost never does, or those on which it vacillates. For building such maps, each instance in the dataset must be contextualized in the larger set. We consider one contextualization approach, based on statistics arising from the behavior of the training procedure across time, or the "training dynamics". We formally define our notations (§2.1) and describe our data maps (§2.2).

2.1 Training Dynamics

Consider a training dataset of size N, $\mathcal{D} = \{(\boldsymbol{x}, y^*)_i\}_{i=1}^N$ where the ith instance consists of the observation, $\boldsymbol{x}_i$ and its true label under the task, y_i^*. Our method assumes a particular model (family) whose parameters are selected to minimize empirical risk using a particular algorithm.[4] We assume the model defines a probability distribution over labels given an observation. We assume a stochastic gradient-based optimization procedure is used, with training instances randomly ordered at each epoch, across E epochs.

The training dynamics of instance i are defined as statistics calculated across the E epochs. The values of these measures then serve as coordinates in our map. The first measure aims to capture how confidently the learner assigns the *true label* to the observation, based on its probability distribution. We define **confidence** as the mean model probability of the true label (y_i^*) across epochs:

$$\hat{\mu}_i = \frac{1}{E} \sum_{e=1}^{E} p_{\boldsymbol{\theta}^{(e)}}(y_i^* \mid \boldsymbol{x}_i)$$

where $p_{\boldsymbol{\theta}^{(e)}}$ denotes the model's probability with parameters $\boldsymbol{\theta}^{(e)}$ at the end of the e^{th} epoch.[5] In

---

[1] All terms are defined with respect to the model.

[2] We define out-of-distribution (OOD) test sets as those which are collected independently of the original dataset, and ID test sets as those which are sampled from it.

[3] `https://github.com/allenai/cartography`

[4] In this paper, the model is RoBERTa (Liu et al., 2019), currently established as a strong performer across many tasks.

[5] Note that $\hat{\mu}_i$ is with respect to the true label y_i^*, not the probability assigned to the model's highest-scoring label (as used in active learning, for example).

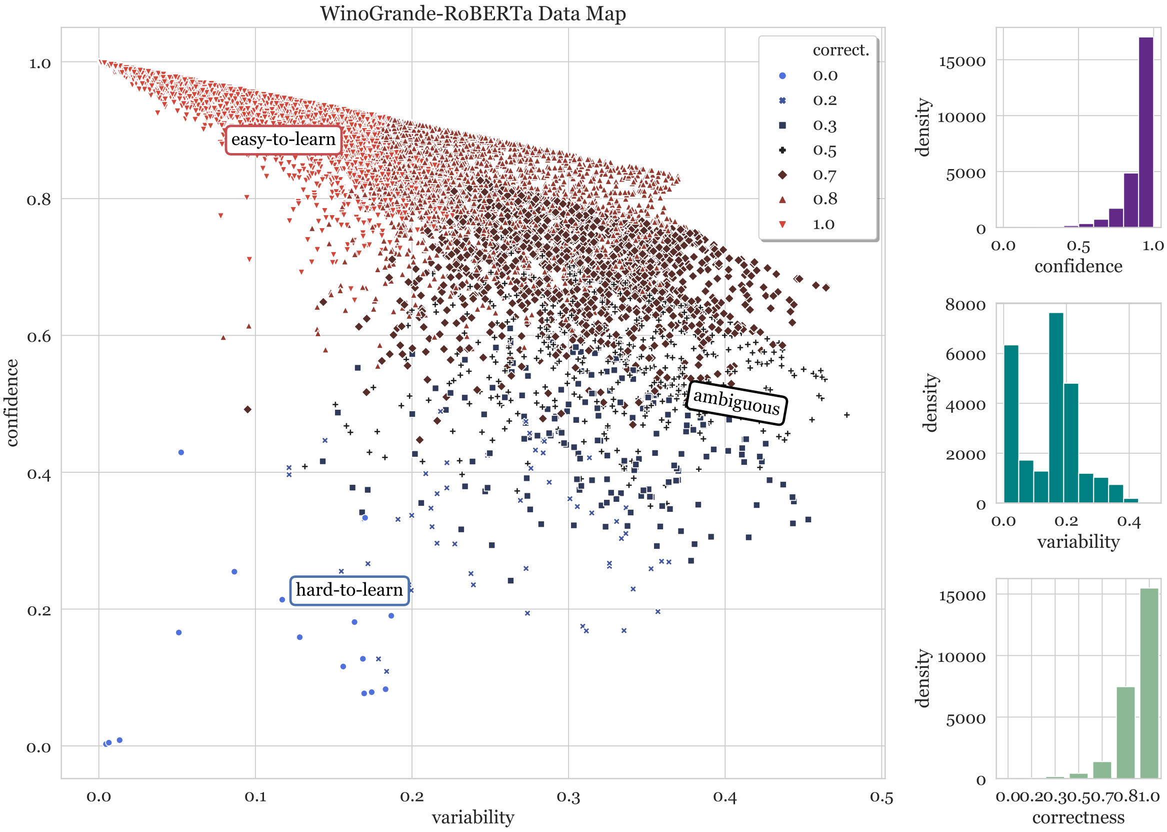

Figure 2: Data map for the *WinoGrande* (Sakaguchi et al., 2020) train set, based on a RoBERTa-large classifier, with the same axes as Fig. 1. Density plots for the three different measures based on training dynamics are shown towards the right. *Hard-to-learn* regions have lower density in *WinoGrande*, compared to *SNLI*, perhaps as a result of a rigorous validation of collected annotations. However, manual errors remain, which we showcase in Tab. 1 as well as in Section §5. The plot shows only 25K train examples for clarity, and is best viewed enlarged.

some cases we also consider a coarser, and perhaps more intuitive statistic, the fraction of times the model correctly labels $\boldsymbol{x}_i$ across epochs, named **correctness**; this score only has $1 + E$ possible values. Intuitively, a high-**confidence** instance is "easier" for the given learner.

Lastly, we also consider **variability**, which measures the spread of $p_{\boldsymbol{\theta}^{(e)}}(y_i^* \mid \boldsymbol{x}_i)$ across epochs, using the standard deviation:

$$\hat{\sigma}_i = \sqrt{\frac{\sum_{e=1}^{E} \left(p_{\boldsymbol{\theta}^{(e)}}(y_i^* \mid \boldsymbol{x}_i) - \hat{\mu}_i\right)^2}{E}}$$

Note that **variability** also depends on the gold label, y_i^*. A given instance to which the model assigns the same label consistently (whether accurately or not) will have low **variability**; one which the model is indecisive about across training, will have high **variability**.

Finally, we observe that **confidence** and **variability** are fairly stable across different parameter initializations.[6] Training dynamics can be computed at different granularities, such as steps vs. epochs; see App. A.1.

2.2 Data Maps

We construct data maps for four large datasets: *WinoGrande* (Sakaguchi et al., 2020)—a cloze-style task for commonsense reasoning, two NLI datasets (*SNLI*; Bowman et al., 2015; and *MultiNLI*; Williams et al., 2018), and *QNLI*, which is a sentence-level question answering task derived from *SQuAD* (Rajpurkar et al., 2016). All data maps are built with models based on RoBERTa-large architectures. Details on the model and datasets can be found in App. §A.2 and §A.3.

Fig. 1 presents the data map for the *SNLI* dataset. As is evident, the data follows a bell-shaped curve with respect to **confidence** and **variability**;

---

[6] The average Pearson correlation coefficient between five random seeds' resulting training runs is 0.75 or higher (for both measures, on *WinoGrande*).

	Instance	**Option1**	**Option2**
easy-to-learn	The man chose to buy the roses instead of the carnations because the __ were more beautiful.	roses*	carnations
	We enjoyed the meeting tonight but not the play as the __ was rather dull.	meeting	play*
hard-to-learn	Jason got into a deep financial hole, unlike Joel, because __ managed their fortune poorly.	Jason^{+}	Joel*
	In the mornings, Aaron can hit the snooze button a lot, and Samuel can't. __ has to be at work at 10 am.	Aaron*	Samuel^{-}
	Amy's handwriting was meticulous, while Cynthia's handwriting was often sloppy, because __ was careless about their work.	Amy*	Cynthia^{+}
ambiguous	The dog ran up to Leslie and away from Lawrence because __ had soap for the dog to take a bath.	Leslie^{-}	Lawrence*
	Kayla dated many more people at once than Betty, because __ was in an exclusive relationship.	Kayla*	Betty^{+}

Table 1: Examples from the *WinoGrande* train set from different regions in the data map, with gold standard* labels. Our best assessment of the correct^{+} and equally plausible^{-} labels are highlighted.

correctness further determines discrete regions therein. The vast majority of instances belong to the high **confidence** and low **variability** region of the map (Fig. 1, top-left). The model *consistently* predicts such instances correctly with *high* confidence; thus, we refer to them as ***easy-to-learn*** (for the model). A second, smaller group is formed by instances with low **variability** and low **confidence** (Fig. 1, bottom-left corner). Since such instances are seldom predicted correctly during training, we refer to them as ***hard-to-learn*** (for the model). The third notable group contains *ambiguous* examples, or those with high **variability** (Fig. 1, right-hand side); the model tends to be indecisive about these instances, such that they may or may not correspond to high **confidence** or **correctness**. We refer to such instances as ***ambiguous*** (to the model).

Fig. 2 shows the data map for *WinoGrande*, which exhibits high structural similarity to the *SNLI* data map (Fig. 1). The most remarkable difference between the maps is in the density of the *hard-to-learn* region, which is much lower for *WinoGrande*, as is evident from the histograms below. One explanation for this might be that *WinoGrande* labels were rigorously validated post annotation. App. §C includes data maps for all four datasets, with respect to RoBERTa-large, in greater relief.

Different model architectures trained on a given dataset could be effectively compared using data maps, as an alternative to standard quantitative evaluation methods. App. §C includes data maps for *WinoGrande* (Fig. 9b) and *SNLI* (Fig. 10 and Fig. 11) based on other (somewhat weaker) architectures. While data maps based on similar architectures have similar appearance, the regions to which a given instance belongs might vary. Data maps for weaker architectures still display similar regions, but the regions are not as distinct as those in RoBERTa based data maps.

Tab. 1 shows examples from *WinoGrande* belonging to the different regions defined above. *easy-to-learn* examples are straightforward for the model, as well as for humans. In contrast, most *hard-to-learn* and some *ambiguous* examples could be challenging for humans (see green highlights in Tab. 1), which might explain why the model shows lower **confidence** on them. These categories could be harder for models either because of labeling errors (blue highlights) or simply because the model is indecisive about the correct label. See App. §A.4 for similar examples from *SNLI*.

The next four sections include a diagnosis of the different data regions defined above. The effect of training models on each region on both in- and out-of-distribution performance is studied in §3. The effect of selecting decreasing amounts of data is discussed in §4. We investigate the presence of mislabeled instances in the *hard-to-learn* regions of the data maps in §5. Lastly, we demonstrate connections between training dynamics measures and measures of uncertainty in §6.

3 Data Selection using Data Maps

Data maps reveal distinct regions in datasets; it is natural to wonder what roles do instances from different regions play in learning and generalization. We answer this empirically by training models *exclusively* on instances selected from distinct regions, followed by standard in-distribution (ID), as well as out-of-distribution (OOD) evaluation.

Our strategy is straightforward—we train the model from scratch on a subset of the training data selected by ranking instances based on the different training dynamics measures.[7] We hypothesize that *ambiguous* and *hard-to-learn* regions could

---

[7] Hyperparameters are also tuned from scratch (App. §A.3).

		WinoG. Val. (ID)	*WSC* (OOD)
	100% train	$79.7_{0.2}$	$86.0_{0.1}$
33% train	random	$73.3_{1.3}$	$85.6_{0.4}$
	high-**correctness**	$70.8_{0.6}$	$84.1_{0.4}$
	high-**confidence**	$69.4_{0.5}$	$83.9_{0.5}$
	low-**variability**	$70.1_{1.0}$	$83.7_{1.4}$
	forgetting	$75.5_{1.3}$	$84.8_{0.7}$
	AL-uncertainty	$75.7_{0.8}$	$85.7_{0.8}$
	AL-greedyK	$74.2_{0.4}$	$86.5_{0.5}$
	AFLite	$76.8_{0.8}$	$86.6_{0.6}$
	low-**correctness**	$78.2_{0.6}$	$86.3_{0.6}$
	hard-to-learn	$77.9_{1.3}$	$87.2_{0.7}$
	ambiguous	$\mathbf{78.7}_{0.4}$	$\mathbf{87.6}_{0.6}$

Table 2: ID and OOD accuracies for RoBERTa-large models trained on different selections of *WinoGrande*. Reported values are averaged over 3 random seeds, with s.d. reported as a subscript. Selection of 33% training instances with highest **variability** (*ambiguous*) achieves the best OOD performance, outperforming all other baselines from this work, as well as prior work.

be the most informative for learning, since these examples are the most challenging for the model (Shrivastava et al., 2016). We compare these two settings to RoBERTa-large models trained on data subsets, selected using several other methods. All subsets considered contain 33% of the training data (to control for the effect of train data size on performance).

Baselines The two most natural baselines are those where all data is used (**100% train**), and where a 33% random sample is used (**random**). Our second set of baselines considers subsets which are the most *easy-to-learn* for the model (**high-confidence**), and those that the model is most decisive about (**low-variability**), which comprises a mixture of *easy-to-learn* and *hard-to-learn* examples. We also consider baselines based on **high-** and **low-correctness**. Finally, we also compare with our implementation of the following methods for data selection from prior work (discussed in §7): **forgetting** (Toneva et al., 2018), **AFLite** (LeBras et al., 2020), **AL-uncertainty** (Joshi et al., 2009), and **AL-greedyK** (Sener and Savarese, 2018).

Results We test our selections on the same datasets from the previous section—*WinoGrande*, *SNLI*, *MultiNLI* and *QNLI*. We report ID validation performance, and OOD performance on test sets either created independently of the dataset (*NLI Diagnostics* (Wang et al., 2019) for *SNLI* and *MultiNLI*, and *WSC* (Levesque et al., 2011) for *WinoGrande*), or specifically to be adversarial to the dataset (*Adversarial SQuAD* (Jia and Liang, 2017) for *QNLI*); see App. §A.2 for details.

Tab. 2 shows our results on *WinoGrande*.[8] Training on the most *ambiguous* data results in the best OOD performance, exceeding that of 100% train, even with just a third of the data. A similar effect is seen with *hard-to-learn*, as well as its coarse-grained counterpart, low-**correctness**. In each of the three cases, ID performance is also higher than all other 33% baselines, though we observe some degradation compared to the full training set; this is expected as with larger amounts of data models tend to fit the dataset distribution rather than the task (Torralba and Efros, 2011). The only selection methods that underperform the random baseline are **forgetting**, and the ones where we select data the model is highly confident and decisive about (high-**confidence**, high-**correctness**, and low-**variability**). The latter pattern, as well as our overall results, highlight the important role played by examples which are challenging for the model, i.e., *ambiguous* and *hard-to-learn* examples.

Given that our selection methods outperform baselines from prior work, we only report random and 100% train selection baselines on the remaining datasets, where we see similar trends. Tab. 3 shows results for *SNLI* and *MultiNLI*, where the random selection baseline is already within 1% of the **100% train** baseline.[9] Selecting 33% of the most *ambiguous* examples achieves even better ID performance, within 0.2% of the 100% train baseline, while exceeding OOD performance substantially on each of the linguistic categories in the *NLI Diagnostics* test set.[10] While *hard-to-learn* does not perform as well as *ambiguous* on most cases, it still matches or outperforms the 100% train baseline on OOD test sets. Tab. 4 shows a similar trend for *QNLI*, where we gain over 2% performance on the OOD *Adversarial SQuAD* test set, with minimal loss in ID accuracy.

Overall, regions revealed by data maps provide ways to substantially improve OOD performance

---

[8] The official test set for *WinoGrande* has been filtered with AFLite, making ID evaluation more challenging than OOD. However, we apply all our selection methods (including the AFLite selection) on *WinoGrande*'s unfiltered training data.

[9] The ID performance of all models exceeds human accuracy (88%) for *SNLI*. However, the difference in ID and OOD performance in SNLI is quite high, showing that there is still room for improvement in the NLI task.

[10] While *MultiNLI*-mismatched is technically out-of-domain, performance is close to matched (ID).

		SNLI						*MultiNLI*						
		ID	*NLI Diagnostics* (OOD)					ID (Val.)		*NLI Diagnostics* (OOD)				
		Test	Lex.	PAS	LS	Kno.	All	Mat.	MisM.	Lex.	PAS	LS	Kno.	All
	100% train	92.0	54.6	67.9	62.7	52.1	61.8	**90.2**	**90.1**	59.9	68.4	67.3	57.8	65.0
33% train	*random*	91.3	53.0	66.8	59.7	50.7	60.4	89.8	89.2	59.3	69.6	66.5	56.3	64.6
	hard-to-learn	91.8	55.2	**69.1**	63.2	51.7	62.0	89.5	89.7	59.3	68.9	**69.5**	58.8	65.3

Table 3: ID and OOD accuracies for RoBERTa-large models trained on different selections of *SNLI* and *MultiNLI*; we report the best performance over 3 random seeds (see Appendix §B for *SNLI* validation results). *ambiguous* and *hard-to-learn* subsets of data promote OOD generalization, at minimal degradation of ID performance. OOD performance improves across all fine-grained linguistic categories in the *NLI Diagnostics* set.

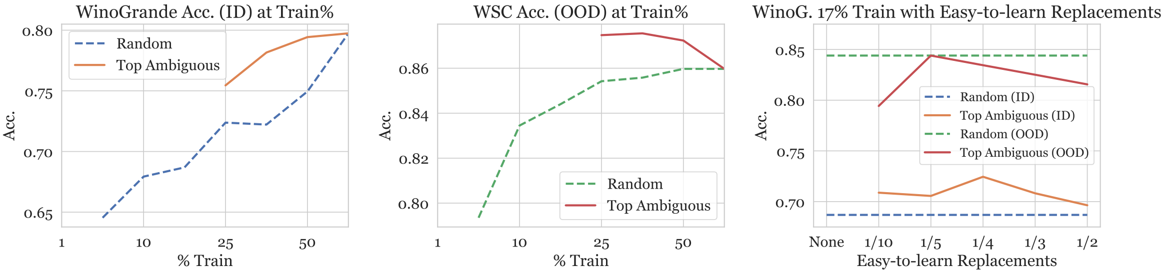

Figure 3: ID (left) and OOD (centre) *WinoGrande* performance with increasing % of *ambiguous* (and randomly-sampled) training data. RoBERTa-large optimization fails when trained on small amounts ($< 25\%$) of the most *ambiguous* data (results correspond to majority baseline performance and are not shown here, for better visibility). (Right) Replacing small amounts of *ambiguous* examples from the 17% subset with *easy-to-learn* examples results in successful optimization and ID improvements, at the cost of decreased OOD accuracy. All reported performances are averaged over 3 random seeds.

		In-dist.	Out-of-dist.
		QNLI Val.	*Adversarial SQuAD*
	100% train	$93.7_{0.3}$	$81.7_{0.6}$
33% train	*random*	$92.7_{0.3}$	$78.3_{0.4}$
	hard-to-learn	$93.3_{0.2}$	$83.3_{0.6}$
	ambiguous	$93.8_{0.3}$	$\mathbf{83.9}_{0.2}$

Table 4: QNLI performance on ID validation and OOD test sets, showing substantial improvements in the latter with a third of the original data. Reported values are averaged over 3 random seeds, with s.d. as subscripts.

across datasets. Regional selections of data not only improve model generalization, but also do so using substantially less data, providing a method to potentially speed up training. We note, however, that discovering such examples requires computing training dynamics, which involves training a model on the full dataset. Future directions involve building more efficient data maps, to better fulfill the training speedup potential.

4 Role of *Easy-to-Learn* Instances

Data maps uncover *ambiguous* regions, small subsets from which lead to improved OOD performance, with minimal degradation of ID performance (§3). We next investigate how performance is affected as we vary the size of the *ambiguous* subsets. We retrain our model with subsets containing the top 50%, 33%, 25%, 17%, 10%, 5% and 1% *ambiguous* instances of *WinoGrande* (Fig. 3, left and center). Large *ambiguous* subsets (25% or more) result in high ID and OOD performance. Surprisingly however, for smaller *ambiguous* subsets (17% or less), the model performs at chance level, despite random restarts.[11] In contrast, a baseline that randomly selects subsets of similar sizes is able to learn (while naturally performing worse as data decreases, eventually failing at 1%). This indicates that *ambiguous* instances alone might be insufficient for learning.

Given that the model barely struggles with *easy-*

---

[11] This is common for large models trained on small datasets (Devlin et al., 2019; Phang et al., 2018; Dodge et al., 2020).

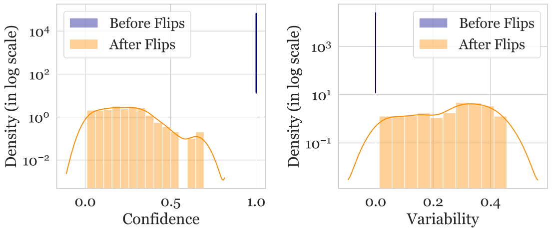

Figure 4: Retraining *WinoGrande* with 1% noised (label-flipped) data changes the training dynamics of the noisy examples. After retraining, there is a noticeable distributional shift towards lower **confidence**, with some shift towards higher **variability** as well.

to-learn instances (by definition), we next replace some *ambiguous* examples with *easy-to-learn* examples in the 17% most *ambiguous* subset. Interestingly, replacing just a tenth of the *ambiguous* data with *easy-to-learn* instances, the model not only successfully learns, but also outperforms the random selection baseline's ID performance (Fig. 3 right). This indicates that for successful optimization, it is important to include *easier*-to-learn instances. However, with too many replacements, performance starts decreasing again; this trend was seen in the previous section with the high-**confidence** baseline (Tab. 2). OOD performance shows a similar trend, but matches or is worse than the baseline. Selection of the optimal balance of *easy-to-learn* and *ambiguous* examples in low data regimes is an open problem; we defer this exploration to future work.

5 Detecting Mislabeled Examples

Crowdsourced datasets are often subject to noise attributed to incorrect labeled annotations (Sheng et al., 2008; Krishna et al., 2016; Ekambaram et al., 2017), which may lead to training models that are not representative of the task at hand. Recent studies have shown that over-parameterized neural networks can fit the incorrect labels blindly (Zhang et al., 2017), which might hurt their generalization ability (Hu et al., 2020). For large datasets, identifying mislabeled examples can be prohibitively expensive. Our data maps provide a semi-automated method to identify such mislabeled instances, without significantly more effort than simply training a model on the data. We hypothesize that *hard-to-learn* examples—those with low **confidence**—might be mislabeled, as has also been suggested in prior work (Manning, 2011; Toneva et al., 2018).

To verify this hypothesis, we design an experimental setting where we artificially inject noise in the training data, by flipping the labels of 1% of the training data for *WinoGrande*. Motivated by our qualitative analysis (Tab 1), we select the candidates for flipping from the *easy-to-learn* region—this minimizes the risk of selecting already mislabeled examples. We retrain RoBERTa with the partly noised data, and recompute **confidence** and **variability** of all instances. Fig. 4 shows the training dynamics measures, before and after re-training. Flipped instances move to the lower **confidence** regions after retraining, with some movement towards higher **variability**. This indicates that perhaps the *hard-to-learn* region (low **confidence**) of the map contains other mislabeled instances. We next explore a simple method to automatically detect such instances.

Automatic Noise Detection We train a linear model to classify examples as mislabeled (noise) or not, using a single feature: the **confidence** score from the retrained RoBERTa model on *WinoGrande*. This model is trained using a balanced training set for this task by sampling equal numbers of noisy (label-flipped) and clean examples from the original train set. This simple classifier is quite effective—a sanity check evaluation on a similarly constructed test set yields 100% F1.[12]

Next, we run the trained noise classifier on the entire original training set, with features extracted from the original training dynamics measures (computed without added noise). We first observe that despite training on a balanced dataset, our classifier predicts only a few examples as mislabeled—only 31 *WinoGrande* instances (out a total of 40K). A similar experiment on *SNLI* results in 15K noisy examples (out of 500K). These results are encouraging and follow our intuitions that most instances in data are indeed labeled "correctly". Indeed, *WinoGrande* contains a lower portion of noisy examples, as indicated by our data maps (Fig. 2).

We further investigated these trends via a human evaluation on the output of the classifier. We created an evaluation set by randomly selecting 50 instances from each predicted class as per our classifier. Two of the authors re-annotated these 100 instances (without access to the original or predicted labels); some instances were annotated as too ambiguous for the authors. After discussions

---

[12] A similar experiment with only **variability** scores as features resulted in a much poorer classifier—70% F1.

to resolve their differences, both annotators agreed on 96% of the instances in each dataset. Using our annotations as a new gold standard, we found that for *WinoGrande*, 67% of the instances predicted as noisy by the linear classifier are indeed either mislabeled or ambiguous, compared to only 13% of the ones predicted as correctly labeled. Similar patterns are observed for *SNLI* (76% vs. 4%).

Our results demonstrate the potential of using data maps as a tool to "clean-up" datasets, by identifying mislabeled or ambiguous instances.[13] Notably, our results were obtained using a simple method; this encourages exploration of methods that might lead to more accurate noise-detectors.

6 Training Dynamics as Uncertainty Measures

We introduced data maps, and used training dynamics measures as coordinates for data points in §2. We now take a closer look at these measures, and find intuitive connections with measures of *uncertainty*. When a model fails to predict the correct label, the error may come from ambiguity inherent to the example (*intrinsic uncertainty*), but it may also come from the model's limitations (often referred to as *model uncertainty*).[14] To understand how examples contribute to a dataset, it is important to separate these two sources of error.

We start by studying the relationship between intrinsic uncertainty and our training dynamics measures. Human agreement can serve as a proxy for intrinsic uncertainty. We estimate human agreement using the multiple human annotations available in *SNLI*'s development set.[15] For each annotator, we compute whether they agree with the majority label from the other four, breaking ties randomly and then averaging over annotators.[16,17]

Fig. 5 visualizes the relation between our training dynamics measures (**confidence** and **variability**) and human agreement, averaged over the examples. We observe a strong relationship between human agreement and **confidence**: high **confidence** indicates high agreement between annotators, while low **confidence** often indicates disagreement on the example. In contrast, once **confidence** is known, **variability** does not provide much information about the agreement.

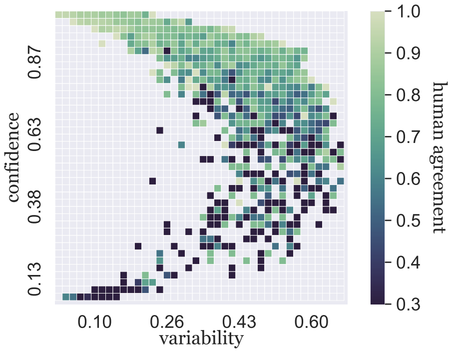

Figure 5: Visualizing human agreement on the *SNLI* (dev. set only) data map reveals its strong relationship to **confidence**. Each cell in the heatmap bins examples based on **confidence** and **variability**, then colors the cell by the mean human agreement.

The connection between our second measure, **variability**, and *model uncertainty* is more straightforward: **variability**, by definition, captures exactly the uncertainty of the model. See App. B.1 for an additional discussion (with empirical justifications) on connections between training dynamics measures and dropout-based (Srivastava et al., 2014), first-principles uncertainty estimates.

These relations are further supported by previous work, which showed that deep ensembles provide well-calibrated uncertainty estimates (Lakshminarayanan et al., 2017; Gustafsson et al., 2019; Snoek et al., 2019). Generally, such approaches ensemble models trained from scratch; while ensembles of training checkpoints lose some diversity (Fort et al., 2019), they offer a cheaper alternative capturing some of the benefits (Chen et al., 2017a). Future work will involve investigation of such alternatives for building data maps.

7 Related Work

Our work builds data maps using training dynamics measures for scoring data instances. Loss landscapes (Xing et al., 2018) are similar to training dynamics, but also consider variables from the stochastic optimization algorithm. Toneva et al. (2018) also use training dynamics to find train examples which are frequently "forgotten", i.e., mis-

---

[13] In preliminary experiments, retraining *WinoGrande* after removal of noise did not yield a large difference in performance, given the relatively small amount of noise.

[14] These are also sometimes called the *aleatoric* and *epistemic* uncertainty, respectively (Gal, 2016).

[15] Only *SNLI* dev. and test set have multiple annotations on all instances. We obtain training dynamics with RoBERTa-large run on train and dev. combined.

[16] Normally, this provides the minimum-variance unbiased estimate, though *SNLI*'s development set throws away examples without a majority, which introduces some bias.

[17] Note that the model only has seen the majority vote, while we take into account all annotator labels to quantify agreement.

classified during a later epoch of training, despite being classified correctly earlier; our **correctness** metric provides similar discrete scores, and results in models with better performance. Variants of such approaches address catastrophic forgetting, and are useful for analyzing data instances (Pan et al., 2020; Krymolowski, 2002).

Prior work has proposed other criteria to score instances. AFLite (LeBras et al., 2020) is an adversarial filtering algorithm which ranks instances based on their "predictability", i.e. the ability of simple linear classifiers to predict them correctly. While AFLite, among others (Li and Vasconcelos, 2019; Gururangan et al., 2018), advocate removing "easy" instances from the dataset, our work shows that *easy-to-learn* instances can be useful. Similar intuitions have guided other work such as curriculum learning (Bengio et al., 2009) and self-paced learning (Kumar et al., 2010; Lee and Grauman, 2011) where all examples are prioritized based on their "difficulty".

Other approaches have used training loss (Han et al., 2018; Arazo et al., 2019; Shen and Sanghavi, 2019), confidence (Hovy et al., 2013), and meta-learning (Ren et al., 2018), to differentiate instances within datasets. Perhaps our measures are the closest to those from Chang et al. (2017); they propose prediction variance and threshold closeness—which correspond to **variability** and **confidence**, respectively.[18] However, they use these measures to reweight all instances, similar to sampling effective batches in online learning (Loshchilov and Hutter, 2016). Our work, instead, does a hard selection for the purpose of studying different groups within data.

Our methods are also reminiscent of active learning methods (Settles, 2009; Peris and Casacuberta, 2018; P.V.S and Meyer, 2019), such as uncertainty sampling (Lewis and Gale, 1994) which selects (unlabeled) data points, which a model trained on a small labeled subset, has least confidence in, or predicts as farthest (in vector space, based on cosine similarity) (Sener and Savarese, 2018; Wolf, 2011). Our approach uses labeled data for selection, similar to core-set selection approaches (Wei et al., 2013). Active learning approaches could be used in conjunction with data maps to create better datasets, similar to approaches proposed in Mishra et al. (2020). For instance, creating datasets with more *ambiguous* examples (with respect to a given model) could make it beneficial for OOD generalization.

Data error detection also involves instance scoring. Influence functions (Koh and Liang, 2017), forgetting events (Toneva et al., 2018), cross validation (Chen et al., 2019), Shapely values (Ghorbani and Zou, 2019), and the area-under-margin metric (Pleiss et al., 2020) have all been used to identify mislabeled examples. Some approaches avoid hard examples altogether (Bottou et al., 2005; Northcutt et al., 2017) to reduce fit to noisy data. Our use of training dynamics to locate mislabeled examples involves minimal additional effort beyond training a model on the dataset.

8 Conclusion

We presented *data maps*: an automatic method to visualize and diagnose large datasets using training dynamics. Our data maps for four different datasets reveal similar terrains in each dataset: groups of *ambiguous* instances useful for high performance, *easy-to-learn* instances which aid optimization, and *hard-to-learn* instances which often correspond to data errors. While our maps are based on RoBERTa-large, the methods to build them are model-agnostic (App. §C.1). Our work shows the effectiveness of simple training dynamics measures based on mean and standard deviation; exploration of more sophisticated measures to build data maps is an exciting future direction. Data maps not only help diagnose and make better use of existing datasets, but also hold potential for guiding the construction of new datasets. Moreover, data maps could facilitate comparison of different model architectures trained on a given dataset, resulting in alternative evaluation methodologies. Our implementation is publicly available to facilitate such efforts.[19]

A Supplemental Material

A.1 Training Dynamics Computation

Both **confidence** and **variability** are computed across epochs, but could alternatively be computed over other granularities, e.g. over every few steps of optimization. This might enable more efficient computation of the same. However, care must be taken to ignore the first few steps till optimization stabilizes. In our experiments, we considered all epochs including the first to compute the training dynamics, since the first epoch contains multiple steps of optimization for large training sets.

Moreover, it is possible to stop training early, or before the training converges for computing training dynamics. This early *burn-out* scheme results in **confidence** and **variability** measures which correlate well with **confidence** and **variability** (see Fig. 6). For our experiments, we use later burn-outs corresponding to model convergence.

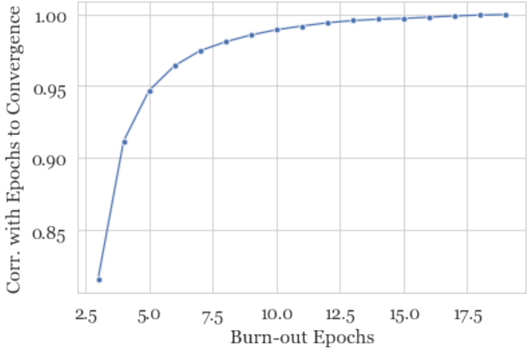

Figure 6: Pearson correlation coefficient of instance **variability** on *WinoGrande* between training dynamics when model is trained to convergence and when model is stopped early. The high correlation indicates that training till convergence is not required to compute a good approximation of the training dynamics.

A.2 Datasets

This appendix provides further details on datasets. We perform our experimental evaluation on four large datasets, each with at least 10K instances. Sizes of the different datasets are reported in Tab. 5. Instances in each of the original datasets are labeled by crowdworkers, whereas the OOD test sets are either manually or semi-automatically created. The performance in each case is reported as accuracy.

WinoGrande This dataset contains a large scale crowd-sourced collection of Winograd schema challenge (*WSC* Levesque et al., 2011) style questions. Commonsense reasoning is required to select an entity from a pair of entities to complete a sentence. Following Sakaguchi et al. (2020), we use the multiple choice architecture based on RoBERTa (Liu et al., 2019). For OOD evaluation, we use the validation set from the original *WSC* as provided under the SuperGLUE benchmark (Wang et al., 2019). We used a rule-based method to convert *WSC* validation and training data to the cloze-style format followed in *WinoGrande*, removing all the repetitions included in the training data. Figure 2 shows the data map for *WinoGrande*.

SNLI* and *MultiNLI The task of natural language inference involves prediction of the relationship between a premise and hypothesis sentence pair. The label determines whether the hypothesis entails, contradicts or is neutral to the premise. We experiment with the Stanford natural language inference (*SNLI*) dataset (Bowman et al., 2015) and its multi-genre counterpart, *MultiNLI* (Williams et al., 2018).[20] Several challenge sets have been proposed to evaluate models OOD. As an OOD test set, we consider NLI diagnostics (Wang et al., 2018) which contains a set of hand-crafted examples designed to demonstrate NLI model performance on several fine-grained semantic categories, such as lexical semantics, logical reasoning, predicate argument structure and commonsense knowledge. In addition, we also report performance on the OOD mismatched *MultiNLI* validation set. Figure 8a shows the data map for *MultiNLI*.

QNLI Rajpurkar et al. (2016) proposed the *SQuAD* dataset containing question and document pairs, where the answer to the question is a span in the document. The *QNLI* dataset, provided as part of the GLUE benchmark (Wang et al., 2018) reformulates this as a sentence-level binary classification task. Here, the goal is to determine if a candidate sentence from the document contains the answer to the given question. As an OOD test set, we consider the *Adversarial SQuAD* challenge set (Jia and Liang, 2017) where distractor sentences are added to the document to confound the model. We automatically convert this to the *QNLI* format. Figure 9a shows the data map for *QNLI*.

---

[20] For MultiNLI, we use the version released under the GLUE benchmark (Wang et al., 2018).

	In-dist.			Out-of-dist.
	Train	Val.	Test	Test
WinoGrande	40399	1268	-	424
SNLI	549368	9843	9825	1105
MultiNLI	392703	9816	9833	1105
QNLI	104744	5464	-	5324

Table 5: Dataset sizes. ID test set in *MultiNLI* is the mismatched validation set, which we did not use for validation, but as test. We did not use the provided test sets in *WinoGrande* and *QNLI*, rather report OOD performance for both cases.

A.3 Experimental Settings

For each of our classifiers, we minimize cross entropy with the Adam optimizer (Kingma and Ba, 2014) following the AdamW learning rate schedule from `PyTorch`[21]. Each experiment is run with 3 random seeds and a learning rate[22] chosen using the `AllenTune` package (Dodge et al., 2019). Initializations greatly affect performance, as noted in Dodge et al. (2020). *WinoGrande* and *SNLI* RoBERTa-large models are trained for 6 epochs, and *MultiNLI* and *QNLI* are trained for 5 epochs each. Each experiment is performed on a single Quadro RTX 8000 GPU. Based on the available GPU memory, our experiments on all datasets use a batch size of 96, except for *WinoGrande*, where a batch size of 64 is used. Our implementation uses the `Huggingface Transformers` library (Wolf et al., 2019). For the active learning baselines, we train a acquisition model using RoBERTa-large on a randomly sampled 1% subset of the full training set.

A.4 *SNLI* Qualitative Analysis

Qualitative samples from different regions of the *SNLI* data map are provided in Tab. 6.

B Additional Results

Results on the *SNLI* validation set are provided in Tab. 7.

B.1 Training Dynamics vs. Dropout

To empirically test the hypothesis that **confidence** and **variability** from the training dynamics respectively quantify intrinsic and model uncertainty, we compare **confidence** and **variability** against an established method of capturing intrinsic and model uncertainty from the literature based on dropout (Srivastava et al., 2014). Dropout can be seen as variational Bayesian inference (Gal and Ghahramani, 2016), with predictions from different dropout masks corresponding to predictions sampled from the posterior. Thus, **confidence** and **variability** computed from sampled dropout predictions measure the average and standard deviation of the gold label's probability under the posterior—quantifying the intrinsic and model uncertainty in a principled way.

We computed **confidence** and **variability** from both training dynamics and dropout on *WinoGrande*'s development set.[23] Figure 7 visualizes a regression analysis of the relationship between **confidence** and **variability** from training dynamics and dropout. **confidence** from training dynamics and dropout correlate between 0.450 and 0.452 for Pearson's r at 95% confidence. Likewise, **variability** from training dynamics and dropout share a Pearson's r from 0.390 to 0.393 at 95% confidence. Thus, the training dynamics empirically demonstrate a positive, predictive relationship with these first-principles estimates of the intrinsic and model uncertainty. Compared to dropout, however, training dynamics have the pragmatic advantage that all information required to calculate them is already available from training, without additional work or computation.

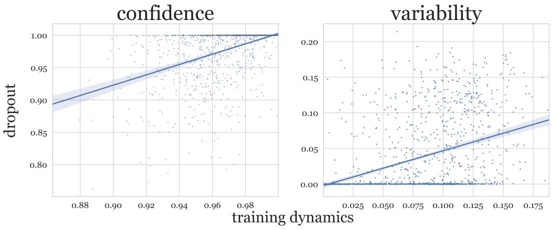

Figure 7: The **confidence** (left) and **variability** (right) from sampled dropout predictions correlate positively with those from the training dynamics on *WinoGrande* (dev. set). Shaded regions are bootstrapped 95% confidence intervals for the regression line.

C Additional Data Maps

All the data maps have been provided in Fig. 8 and Fig. 9.

---

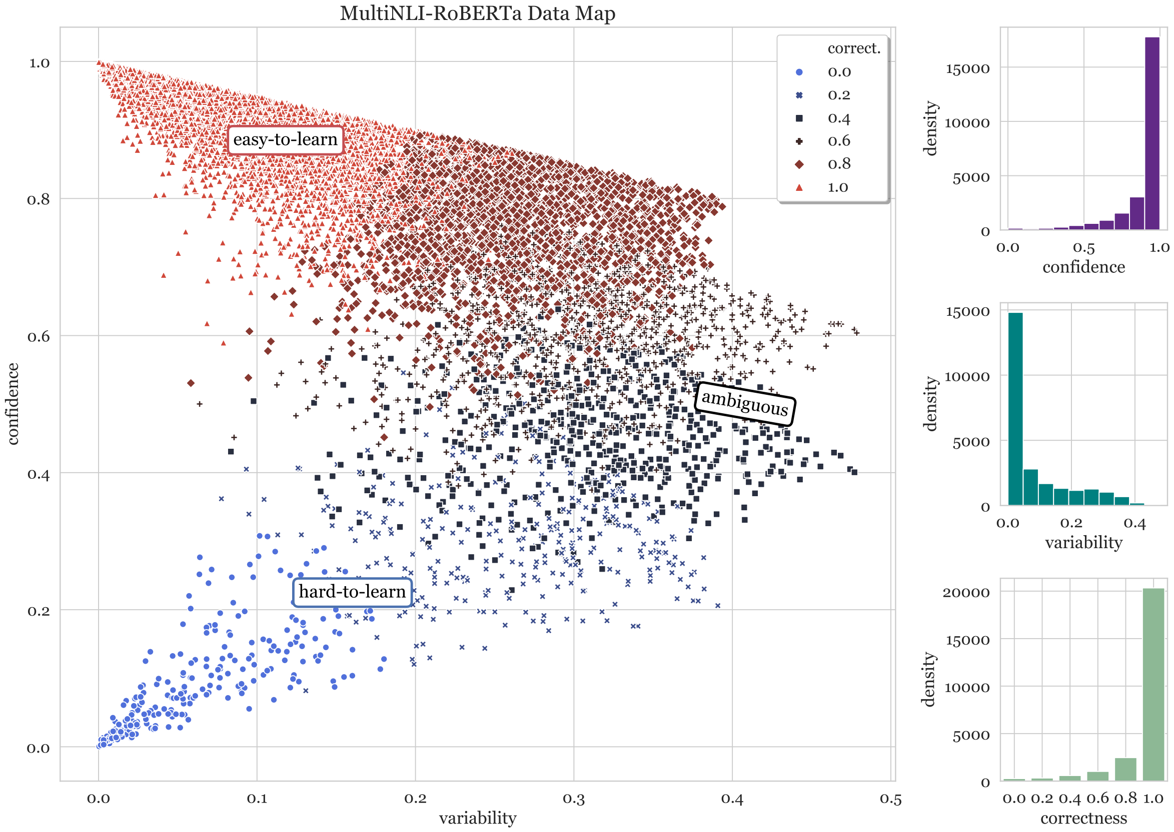
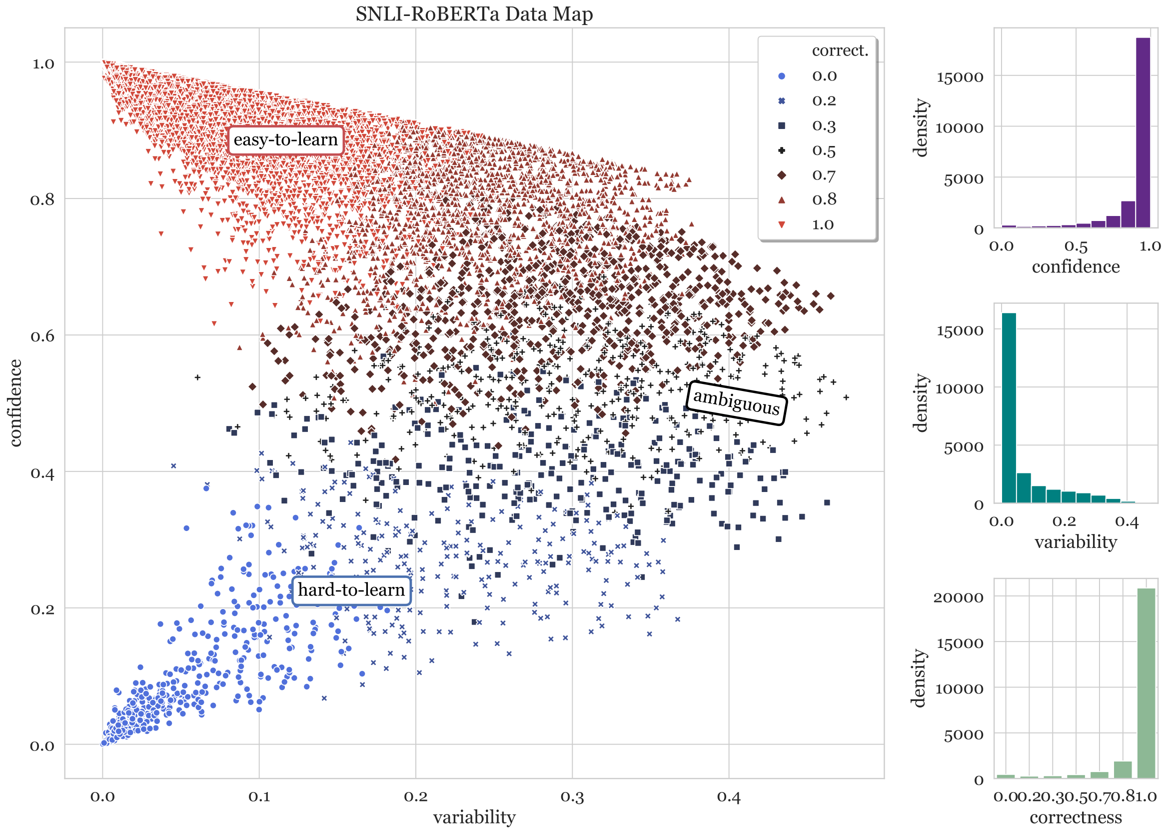
C.1 Effect of Encoder in building Data Maps

While training dynamics are inherently model dependent, data maps can be built for any model, and might reveal similar structures. Since models can be of varying capacities with respect to a task or dataset, instances might receive different co-ordinates on data maps built based on different models. For instance, BERT is known to be worse at reasoning than RoBERTa (Sakaguchi et al., 2020; Talmor et al., 2019), and RoBERTa being a larger model is likely very sample efficient (Kaplan et al., 2020). However, the overall structure of data maps based on different models remains the same; Fig. 9b shows the data map built for *WinoGrande* using a BERT-large classifier.

Four different architectures for the SNLI dataset are compared in Fig. 10 and Fig. 11.

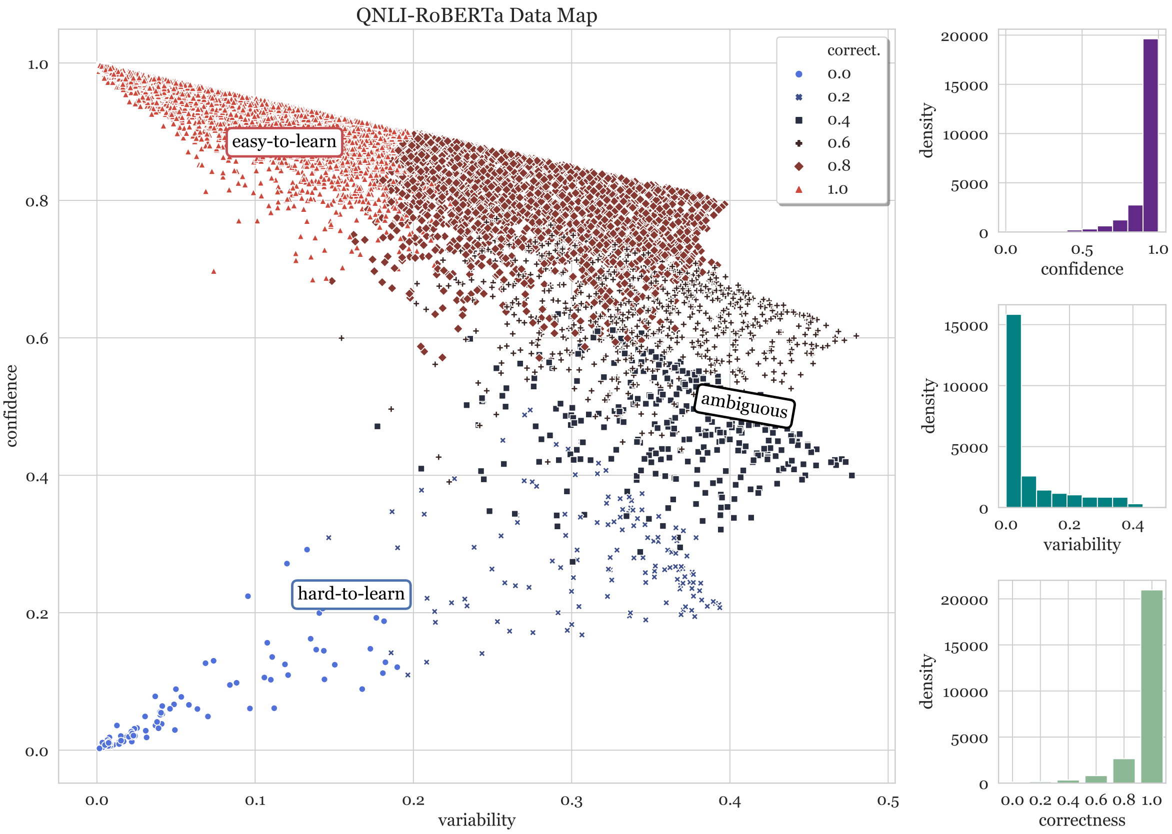


(a) Data Map for *MultiNLI* (Williams et al., 2018) and density plots for different measures based on training dynamics (below). For clarity we only use 50K random samples from *MultiNLI* in the scatter plot. Trends are very similar to *SNLI*, even though *MultiNLI* contains samples from diverse genres.

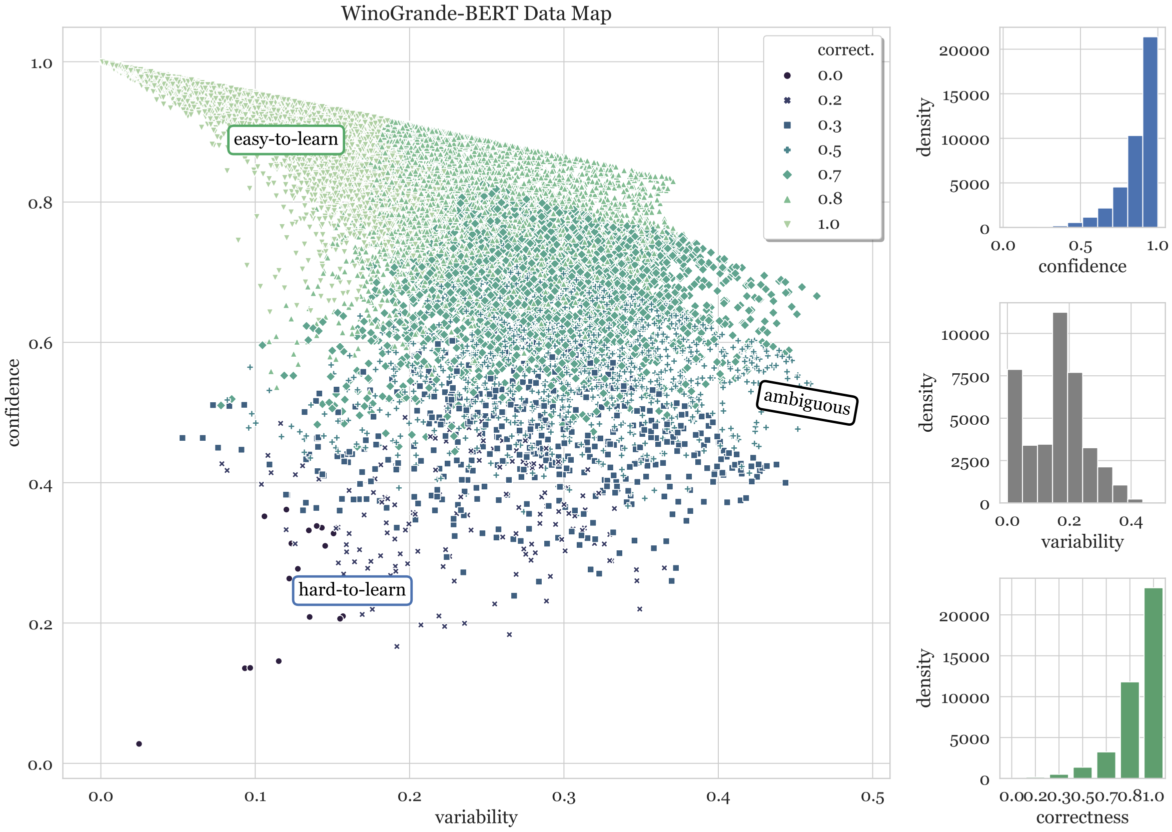


(b) (Left) Data Map for *SNLI*, same as Fig. 1, provided here in greater relief again for comparison with other datasets. *SNLI* is larger than all other datasets, and thus has a higher density of *easy-to-learn* examples. (Right) Densities of the above statistics across the entire dataset; examples which are *easy-to-learn* (for RoBERTa) form the vast majority of *SNLI*.

Figure 8: Data maps for *NLI datasets; each data map plots 25K instances, for clarity.



(a) Data map for the sentence-level *SQuAD* dataset, *QNLI* (left) and density plots for different measures based on training dynamics (right). Unlike other datasets, *QNLI* has fewer instances with low **variability** and **confidence** close to 0.5.



(b) Data map for *WinoGrande* built based on a **BERT**-large (Devlin et al., 2019) model. While similar regions can be seen as a *WinoGrande*-RoBERTa data map (Fig. 2), the densities of different regions can be different. Moreover the same instances might be mapped to different regions across maps.

Figure 9: Additional data maps, each plotting 25K instances, for clarity.

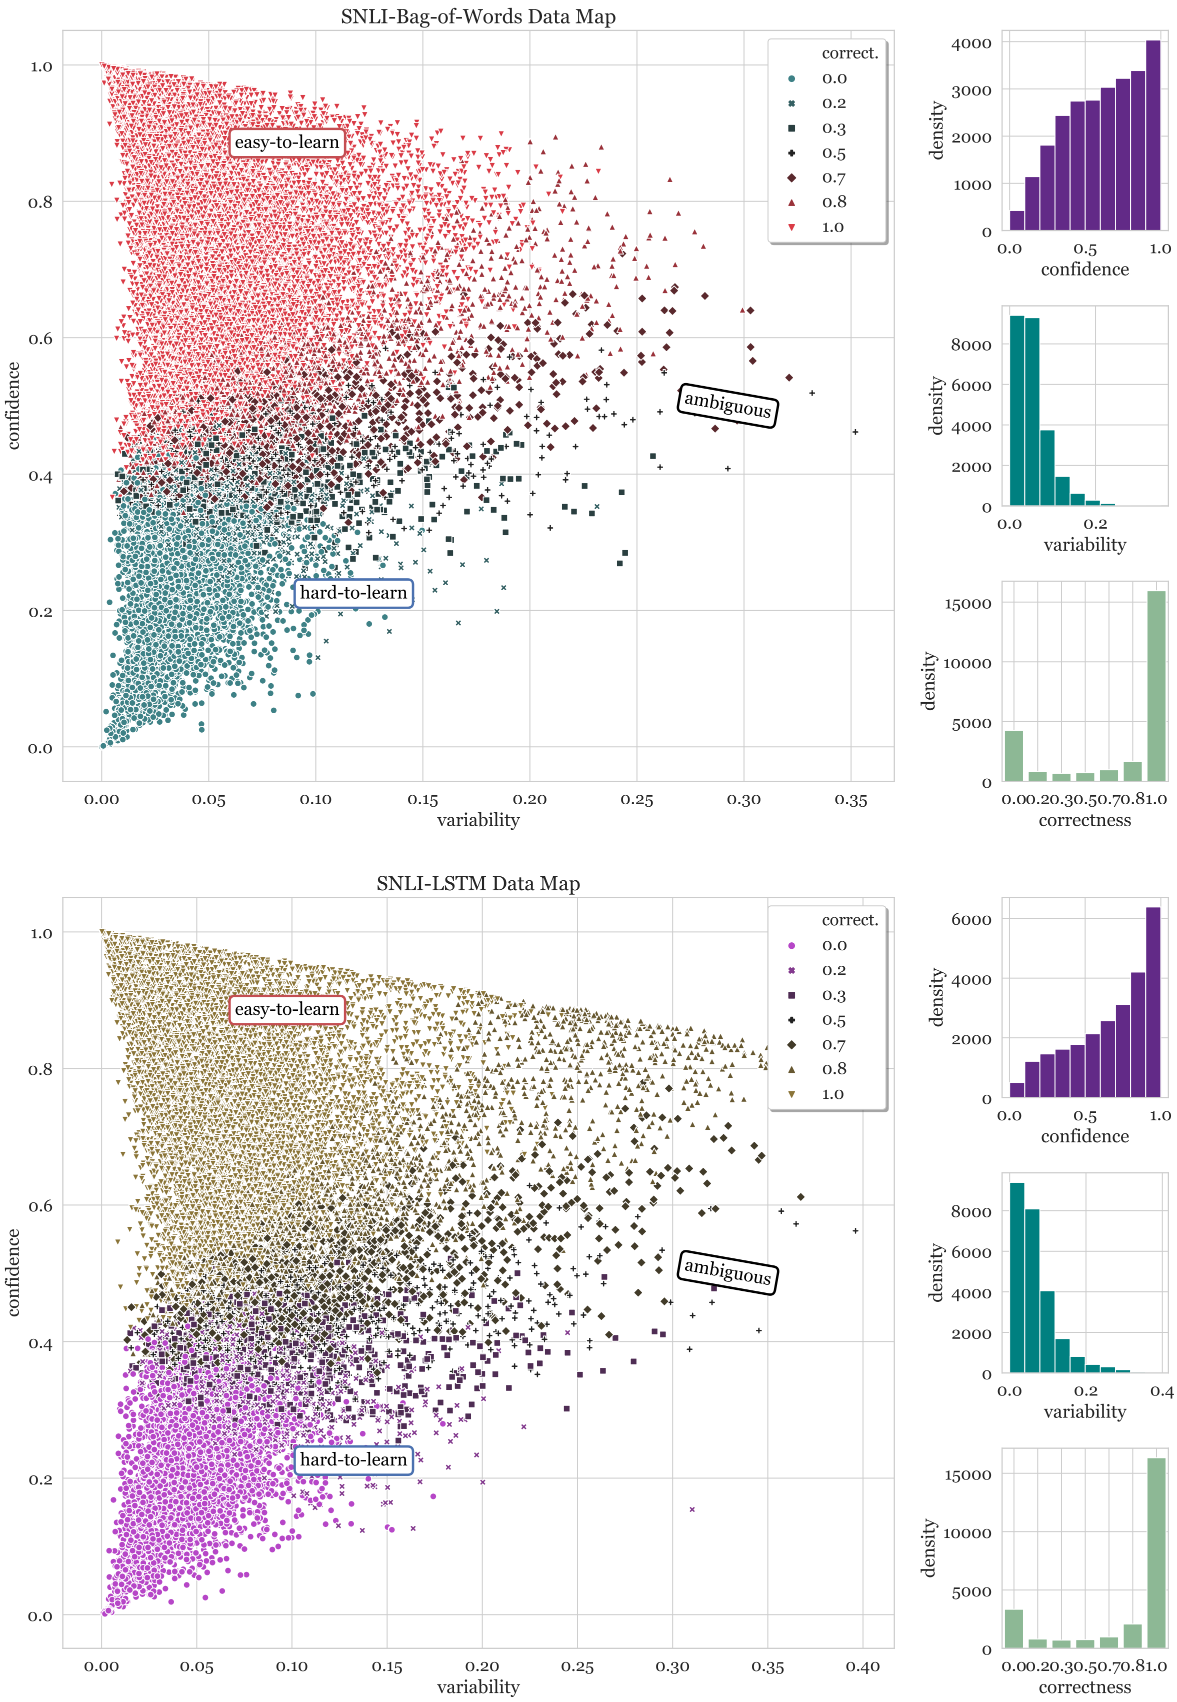


Figure 10: Data maps for SNLI based on non-RoBERTa (and weaker) architectures—bag of words (BoW; Top) and LSTMs (Bottom). Although these maps exhibit bell-shaped curves, similar to the RoBERTa data map for SNLI in 8b, the curvature is somewhat smaller. The spread of the data is larger across the regions, which are not as distinct as in the RoBERTa data map. These shapes could be attributed to these architectures being weaker (and hence unable to overfit to data) than those involving representations from large, pretrained language models. Each data map plots 25K instances, for clarity, and are best viewed enlarged.

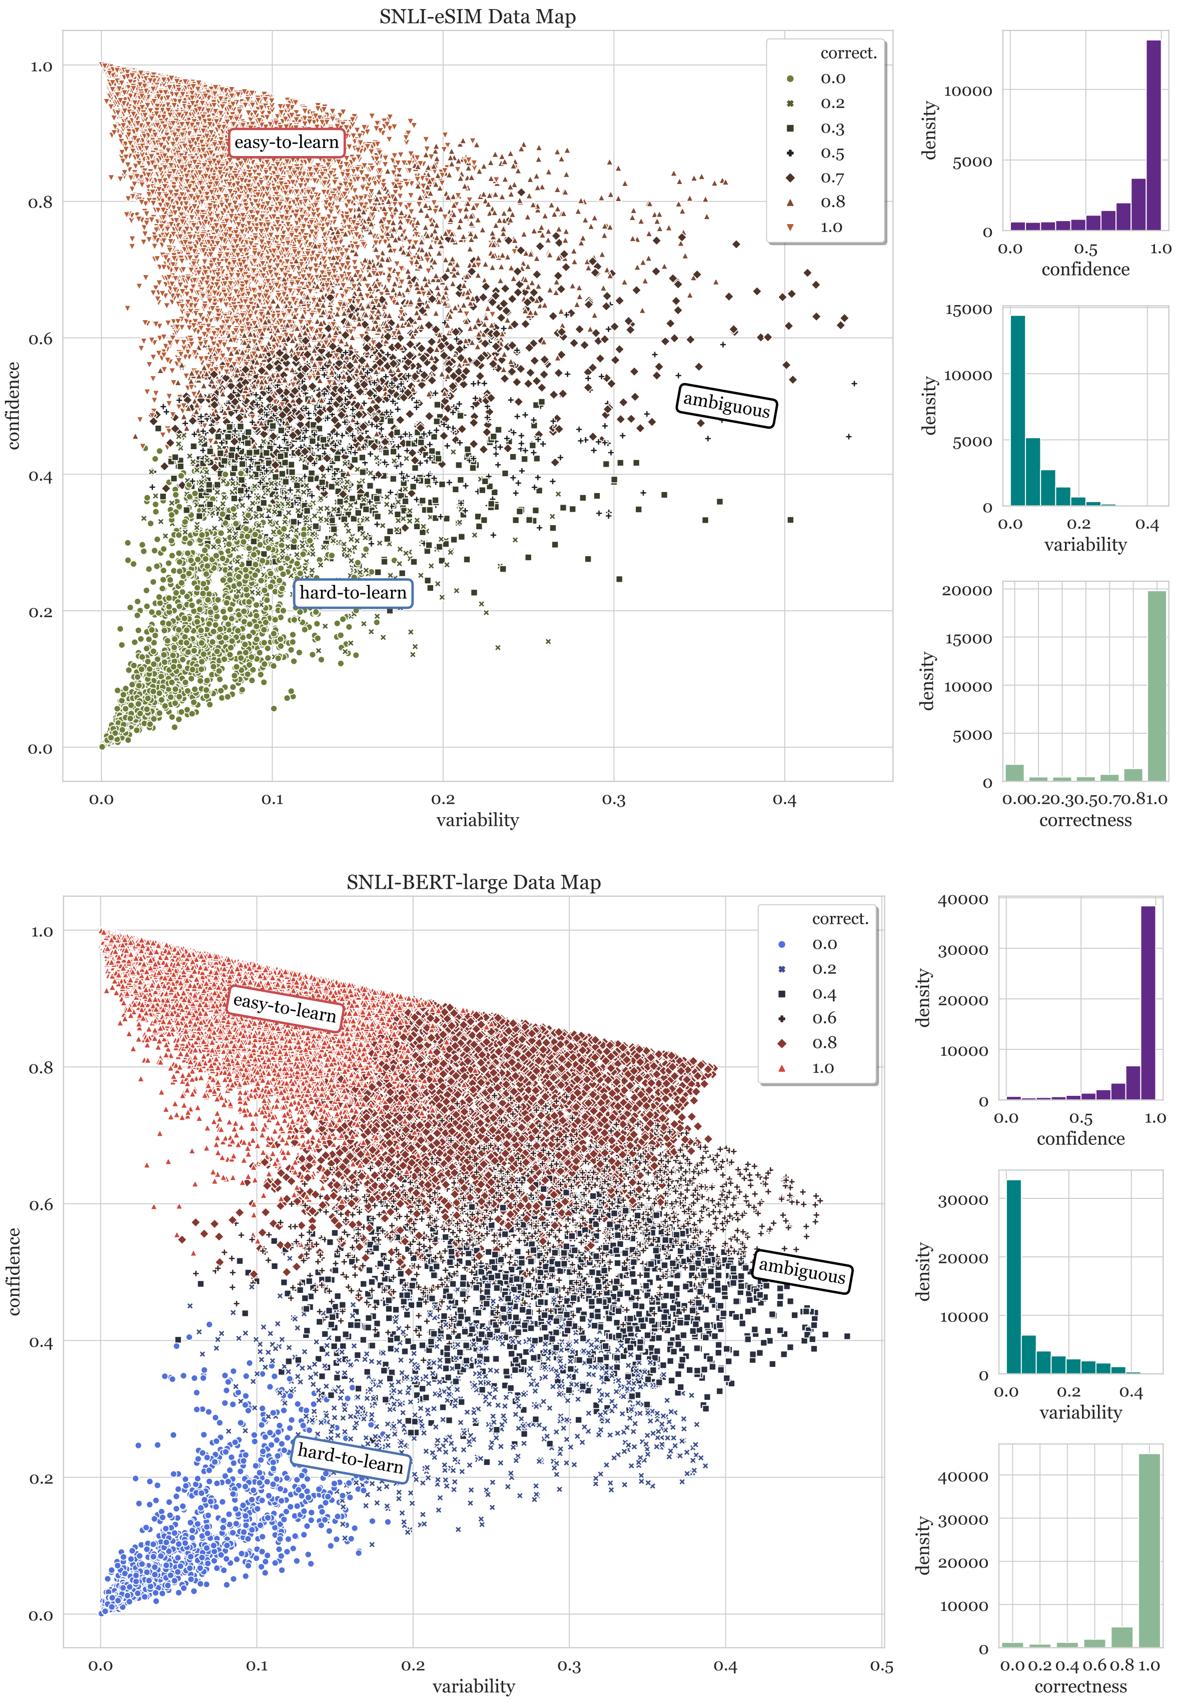

Figure 11: Data maps for SNLI based on other (weaker) architectures—bag of words eSim (Chen et al., 2017b) (Top) and BERT-large (Bottom). Although these maps exhibit bell-shaped curves, similar to the RoBERTa data map for SNLI in 8b, the curvature is somewhat smaller for eSIM. The spread of the data is larger across the regions, which are not as distinct as in the RoBERTa data map. Each data map plots 25K instances, for clarity, and are best viewed enlarged.

Evaluating and Characterizing Human Rationales

Samuel Carton[*], **Anirudh Rathore**[*], **Chenhao Tan**
University of Colorado Boulder
{samuel.carton,anirudh.rathore,chenhao.tan}@colorado.edu

Abstract

Two main approaches for evaluating the quality of machine-generated rationales are: 1) using human rationales as a gold standard; and 2) automated metrics based on how rationales affect model behavior. An open question, however, is how human rationales fare with these automatic metrics. Analyzing a variety of datasets and models, we find that human rationales do not necessarily perform well on these metrics. To unpack this finding, we propose improved metrics to account for model-dependent baseline performance. We then propose two methods to further characterize rationale quality, one based on model retraining and one on using "fidelity curves" to reveal properties such as irrelevance and redundancy. Our work leads to actionable suggestions for evaluating and characterizing rationales.

1 Introduction

Explanations in NLP often take the form of *rationales*, subsets of input tokens that are considered important to the model's decision (DeYoung et al., 2020). As interest in explainable AI has increased, so has interest in evaluating the quality of explanatory rationales. However, this is a challenging task because it can be difficult to pin down exactly what constitutes "good" rationales for model predictions (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Serrano and Smith, 2019).

Two main strategies that have been proposed in recent work are: 1) to view human-generated rationales as a gold standard and evaluate model-generated rationales in comparison to them; and 2) to assess the "fidelity" of a rationale to a prediction using automatic metrics.

The human-gold-standard approach views rationales as an additional form of label that can be collected alongside document-level labels. Because NLP tasks tend to involve human-generated labels, it makes intuitive sense that human-generated rationales might be considered authoritative.

When human rationales are not available, evaluations of machine rationales turn to automatic metrics. These metrics divorce rationale evaluation from an external standard, seeking instead to judge whether rationales are coherent relative to model behavior. Popular recent metrics are *sufficiency* and *comprehensiveness* (i.e., necessity), which assess whether a rationale is sufficient/necessary for a model prediction by comparing the model's behavior on the full input to its behavior on input masked according to the rationale or its complement. We use the term *fidelity* to refer jointly to sufficiency and comprehensiveness.

To the best of our knowledge, no existing work has systematically examined human rationales using these automatic metrics. However, this is an important step towards evaluating rationales because it helps characterize the disparities between the two types of approach. Are human rationales sufficient to allow models to predict human labels? Are they comprehensive? And what other insights can we gain about human rationales and fidelity metrics by performing this assessment?

In practice, both human rationales and automatic metrics can fail to work as intended (Table 1). For instance, human rationales may be insufficient because they fail to include needed information (e.g., the album title in Table 1.1), or non-comprehensive because they miss redundant-yet-relevant information (e.g., the second personal attack in Table 1.2).

By contrast, a truly sufficient rationale can be deemed insufficient due to a model not learning expected classification rules (e.g., "sits" $\sim$ "laying" in Table 1.3). While this type of failure is inevitable in machine learning, more avoidable are cases where model bias causes rationales to be evaluated incorrectly or inconsistently. For instance,

Table 1: Example rationales drawn from various datasets. Underlined tokens are rationales provided by humans. Human annotators can fail to produce faithful rationales (row 1 and 2), and fidelity metrics themselves can be misleading (row 3 and 4).

in Table 1.4, the model has learned a heavy bias toward the no-attack class (i.e., the model predicts no-attack for the empty input), so an empty rationale for a no-attack prediction is deemed perfectly sufficient yet entirely noncomprehensive.

To investigate the empirical properties of human rationales and automatic metrics, we analyze the fidelity of human rationales across six datasets. We show that human rationales do not necessarily have high sufficiency or comprehensiveness based on automatic metrics, and their fidelity varies greatly from model to model and class to class.

We propose extensions to existing fidelity metrics and develop novel methods to further characterize the quality of human rationales. First, we note that fidelity is highly model-dependent, and that model behavior can result in misleading fidelity results. We propose a normalization procedure to allow for fair comparison of these metrics across models, classes, and datasets. We show that this normalization helps contextualize fidelity results by accounting for baseline model behavior.

Second, we evaluate model accuracy on full vs. rationale-only data, linking typical output-sufficiency to performance outcomes (i.e., *accuracy-sufficiency*). We examine the effect of allowing models to adapt to rationale-only data during training, drawing a distinction between a rationale's "incidental" fidelity and its "potential" fidelity to a model. We analyze the effect of these two interventions and discuss their implications for evaluation of (and learning from) human rationales.

Finally, we introduce the idea of "fidelity curves", which examine how sufficiency and comprehensiveness degrade as tokens are randomly occluded from a rationale. We discuss how the shapes of these curves can be used to infer fine-grained attributes about rationales, such as the extent to which they contain redundant or highly interdependent tokens. We find that rationales in our datasets vary greatly in their level of irrelevancy, redundancy, and mutual dependence. We find that our three classification tasks exhibit less dependence and more redundancy in their rationales than our three document/query-style tasks.

Evaluating rationales is a significant challenge. We argue that in order to be confident in either human rationales or automatic fidelity metrics, we have to understand how these two evaluation approaches interact with one another, and what caveats they can reveal about each other. Our analyses lead to the following actionable implications:

- Fidelity metrics are highly model-dependent and should be normalized to assist interpretation.
- Models trained on rationale-only data can provide accuracy-based metrics to complement the "incidental" metrics.
- "Fidelity curves" provide a novel way to infer fine-grained qualities about rationales, such as irrelevance and redundancy.

2 Datasets

The goal of this paper is to evaluate and characterize human rationales. We analyze six datasets, four drawn from the ERASER collection (DeYoung et al., 2020), and two from other sources. They consist of three single-text classification tasks and three document/query-style tasks where it is important to understand the relations between texts.

For each dataset, the human rationales have a qualitative *expected comprehensiveness* based on whether, by construction or design, they are intended to contain all pertinent information for their respective prediction task. Four of our six datasets are expected to have comprehensive rationales.

- **WikiAttack** (Carton et al., 2018). A classification dataset of 115,859 Wikipedia revision com-

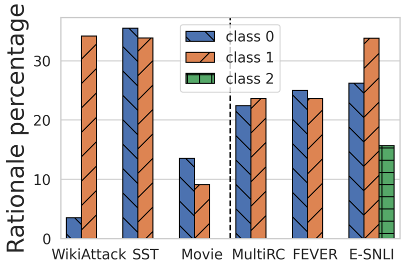
Dataset	Text length	Task type	Rationale				
			Length	Ratio	Comprehensive	Granularity	Class asymmetry
WikiAttack	51.8	classification	6.5	19.1%	✓	Token	✓
SST	19.3	classification	6.5	34.6%	✓	Token	✗
Movie	774.3	classification	82.4	11.3%	✗	Token	✗
MultiRC	321.7	document/query-style	69.8	22.9%	✓	Sentence	✗
FEVER	320.7	document/query-style	53.6	24.0%	✗	Sentence	✗
E-SNLI	21.3	document/query-style	5.0	25.2%	✓	Token	✓

Table 2: Basic statistics. Dataset rationales exhibit a range of average rationale-to-text ratios, expected comprehensivenesses, granularities, and class asymmetries.

ments labeled for presence of personal attacks by Wulczyn et al. (2017) and augmented with 1,049 human rationales by Carton et al. (2018). The rationales in this dataset are expected to be comprehensive, as labelers were asked to identify all personal attacks in each text.

- **Stanford Sentiment Treebank (SST)** (Socher et al., 2013). A classification dataset of 9,620 movie review snippets annotated for positive/negative sentiment at every syntactic tree node. We flatten these into rationales using a heuristic algorithm (see the appendix). The rationales are expected to be comprehensive, as they contain all high-sentiment phrases.
- **Movie** (Zaidan and Eisner, 2008). A classification dataset of 2,000 movie reviews labeled with rationales. The rationales are not necessarily comprehensive, as annotators were not instructed to identify all evidence.
- **MultiRC** (Khashabi et al., 2018) A reading comprehension dataset of 32,091 document-question-answer triplets that are true or false. Rationales are expected to be comprehensive as they each consist of 2-4 sentences from a document that are required to answer the given question.
- **FEVER** (Thorne et al., 2018) A fact verification dataset of 76,051 snippets of Wikipedia articles paired with claims that they support or refute. Rationales consist of a single contiguous sub-snippet (and the claim itself), and are not expected to be comprehensive as they may not cover all pertinent information.
- **E-SNLI** (Camburu et al., 2018) A textual entailment dataset of 568,939 short snippets and claims for which each snippet either refutes, supports, or is neutral toward. Explanations for this dataset are expected to be comprehensive as the texts are short and labelers were instructed to identify all relevant tokens.

Table 2 shows the basic statistics of each dataset. Significant variation exists between datasets in rationale length and rationale percentage. For example, rationales only cover 11.3% of the words in Movie, consistent with our expectation of non-comprehensiveness. We also report rationale granularity, whether annotations were provided at the token or sentence level, and class asymmetry, whether rationale lengths vary significantly between classes. For the purpose of this analysis, tokenization is provided by the individual dataset sources, so we simply split texts by whitespace.



WikiAttack	0: no-attack, 1: personal-attack
SST	0: negative, 1: positive
Movie	0: negative, 1: positive
MultiRC	0: false, 1: true
FEVER	0: refutes, 1: supports
E-SNLI	0: contradiction, 1: entailment, 2: neutral

Figure 1: Percentage of rationales by class. Significant variations exist in WikiAttack and E-SNLI.

Fig. 1 shows class asymmetry in rationale percentages. For WikiAttack, labelers were asked to highlight personal attacks, and thus evidence for the no-attack class comes in the form of no highlighted tokens. This results in a situation where rationales for no-attack examples constitute less than 5% on average, while they constitute 35% of personal-attack examples. Significant variation between classes also exists in E-SNLI: entailment contains close to 40% of tokens as rationales, but neutral merely consists of 16% — another case of evidence through absence (negative evidence).

3 Evaluating Human Rationales

Popular automatic metrics for evaluating machine-generated rationales are *sufficiency* and *comprehensiveness*, articulated by Yu et al. (2019) and employed in the ERASER benchmark (DeYoung et al., 2020). *Sufficiency* measures how well rationales can provide the same prediction as using full information, while *comprehensiveness* measures how well rationales include all relevant information.

It remains an open question whether human-generated rationales have good sufficiency and comprehensiveness. We find that this is in fact not necessarily the case. This result reveals a contradiction in the evaluation of machine-generated rationales: human-generated rationales are used as a gold standard, but being similar to human-generated rationales may not lead to high sufficiency and comprehensiveness. Another important observation from our experiments is that there exists significant variation between datasets and classes within the same dataset.

3.1 Formal Definitions & Experiment Setup

A rationale is *sufficient* if it contains enough information to allow the model to make a prediction close to what it would make with full information. Formally, we represent rationales as a binary mask $\boldsymbol{\alpha}$ over the input $\boldsymbol{x}$ that indicates whether each token belongs to the rationale or not (1 to include, 0 to exclude). The sufficiency of rationales for a given prediction $\hat{y}$ is based on the difference in class probability between using full information and using only the rationale:

$$\mathrm{Suff}(\boldsymbol{x}, \hat{y}, \boldsymbol{\alpha}) = 1 - \max(0, p(\hat{y}|\boldsymbol{x}) - p(\hat{y}|\boldsymbol{x}, \boldsymbol{\alpha})), \quad (1)$$

where $\hat{y} = \arg\max_y p(y|\boldsymbol{x})$. Note that we use the reverse of the difference so that higher sufficiency indicates faithful rationales. We also enforce the difference in class probability to be above 0, which differs from DeYoung et al. (2020).[1] This operation bounds sufficiency to between 0 and 1.

Comprehensiveness (i.e., necessity) captures the extent to which a rationale is needed for a prediction, by assessing the model's prediction on the complement of the rationale ($\mathbf{1} - \boldsymbol{\alpha}$). For a highly comprehensive explanation, the model's prediction on its complement should differ greatly from its prediction on the full information. As above, we enforce this value to be bounded between 0 and 1:

$$\mathrm{Comp}(\boldsymbol{x}, \hat{y}, \boldsymbol{\alpha}) = \max(0, p(\hat{y}|\boldsymbol{x}) - p(\hat{y}|\boldsymbol{x}, \mathbf{1} - \boldsymbol{\alpha})). \quad (2)$$

Our definitions entail that a faithful rationale should have both high sufficiency and comprehensiveness.

Implicit in the definition of sufficiency and comprehensiveness is a dependence on the properties of the underlying model. To study the relationship between model property and human rationale fidelity, we experiment with a range of models: logistic regression, random forests, LSTM (Hochreiter and Schmidhuber, 1997) and RoBERTa (Liu et al., 2019). We use the same train/dev/test splits as in the original datasets. We report the resulting model with the best validation accuracy in the main paper. To apply rationale masking, we simply remove the tokens which correspond with 0s in the rationale mask. See the supplementary material for implementation details. Our code is available at `https://github.com/BoulderDS/evaluating-human-rationales`.

3.2 Overall Results

Fig. 2a shows the accuracy of our models on each dataset. As expected, RoBERTa shows the best performance followed generally by LSTM, then random forest and logistic regression. The only exception is Movie, where LSTM models struggle with the long texts (774 tokens on average) due to the limited dataset size and vanishing gradients.

We find that **human rationales do not necessarily have high sufficiency and comprehensiveness**. Moreover, human-generated rationales obtain weaker sufficiency in highly accurate models (Fig. 2b). In fact, human rationales have lower sufficiency in RoBERTa than logistic regression or random forest in five of six datasets. This finding demonstrates that the sufficiency of an explanation can be inversely correlated with model performance, which is a problem for comparing explanation methods across different models.

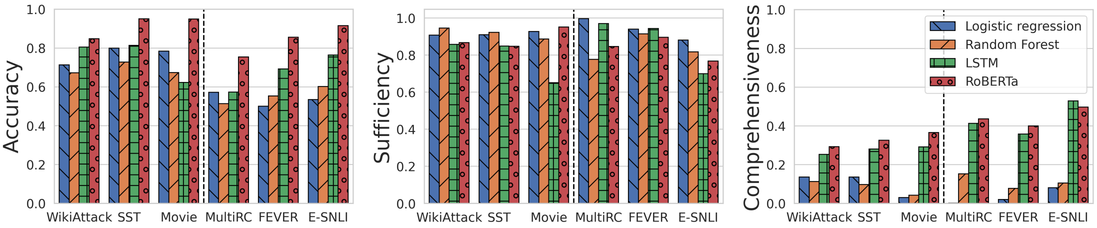
By contrast, strong models show better comprehensiveness scores for human rationales (Fig. 2c), with values ranging from 0.3 to 0.5 for RoBERTa. E-SNLI demonstrates the highest comprehensiveness in this model while Movie and MultiRC, both expected to be non-comprehensive, respectively achieve the 2nd and 4th highest comprehensiveness, in defiance of our expectations.

Moving forward, we focus on RoBERTa as it is the most accurate and represents the industry standard for general NLP.

Classes matter. Breaking down fidelity by class reveals further nuances. Fig. 3b shows that sufficiency is mostly even between classes, though significant differences exist for E-SNLI. Surpris-

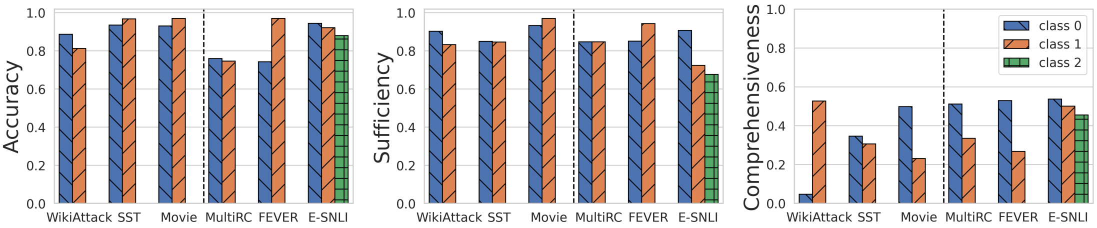
---

[1] Arguably, the sufficiency metric should not go above 1 no matter how good the rationales are. That said, our results demonstrate similar qualitative trends from the definitions without the max operation. See the appendix.



(a) Accuracy (b) Sufficiency (c) Comprehensiveness

Figure 2: Accuracy, sufficiency, and comprehensiveness of human rationales with different models. While RoBERTa performs significantly better in all datasets in accuracy, it is rarely the best in sufficiency. In comparison, human rationales tend to have abysmal comprehensiveness with classic models.



(a) Accuracy by class (b) Sufficiency by class (c) Comprehensiveness by class

Figure 3: Accuracy, sufficiency, and comprehensiveness of human rationales grouped by class for RoBERTa. While sufficiency is relatively stable across classes, we observe dramatic differences between classes in comprehensiveness (e.g., WikiAttack and Movie).

ingly, in WikiAttack, sufficiency is higher in the no-attack class where there are a small number of tokens in human rationales.

The evenness in sufficiency is not mirrored in comprehensiveness (Fig. 3c), which differs wildly from class to class for different datasets. The most extreme case is WikiAttack, where by design the "rationale" for a no-attack comment is for nothing to be highlighted. The comprehensiveness of these empty rationales is correspondingly low. Interestingly, E-SNLI demonstrates a relatively even spread of comprehensiveness across classes despite its class-asymmetric rationale lengths.

Movie, MultiRC, and FEVER all show large class discrepancies in comprehensiveness despite having similar-length rationales across classes. In FEVER, for example, this means that removing the identified evidence for a "refutes" outcome tends to have a higher impact on the model prediction than for "support" outcomes. This could be due to task semantics (e.g., that refuting evidence is generally more unique than supporting evidence), or model bias (e.g., that the model tends to predict "supports" by default and therefore is less affected by removing the rationales for this outcome).

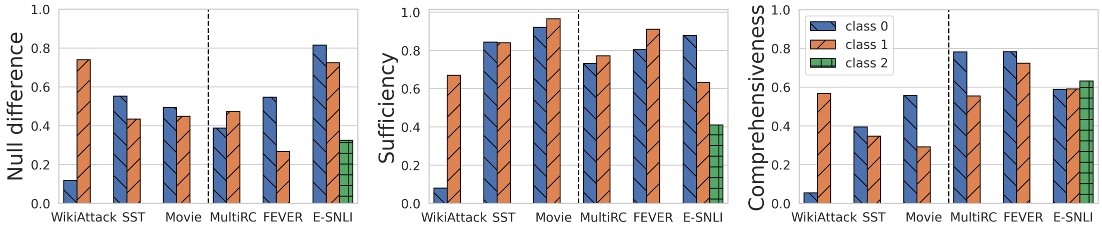
4 Normalizing Sufficiency and Comprehensiveness

Human rationales do not necessarily have high fidelity, suggesting that either human rationales or evaluation metrics may be problematic. We start by rethinking the fidelity metrics in this section and will propose novel methods to characterize human rationales in §5.

A salient observation in Fig. 2 is that sufficiency and comprehensiveness are in completely separate value ranges, although they are both theoretically bounded between 0 and 1. To properly interpret these numbers, we need to establish a baseline for them. We do so by defining a "*null difference*", the difference in output between the model operating on full information vs. no information (i.e., the empty input). This value is equivalent to (the complement of) the sufficiency of an all-zero (empty) rationale mask, or the comprehensiveness of an all-one mask.

Null difference is an intrinsic value for a given model and dataset, and depends on the class balance of the dataset, the bias term(s) learned by the model, and the calibration of output probability. It serves as a baseline value in the sense that no rationale should be much less sufficient than an all-zero rationale or much more comprehensive than an all-one rationales. By normalizing sufficiency and comprehensiveness scores against this value, we can estimate how faithful rationales are relative to the baseline fidelity of the model.

We use min-max normalization to normalize sufficiency and comprehensiveness with this null dif-



(a) Null difference.

(b) Normalized sufficiency.

(c) Normalized comprehensiveness.

Figure 4: Normalization is critical for interpreting sufficiency and comprehensiveness. Here we show evaluations of human-generated rationales based on RoBERTa.

ference. Formally, we define the metrics as follows:

$$\mathrm{NullDiff}(\boldsymbol{x}, \hat{y}) = \max(0, p(\hat{y}|\boldsymbol{x}) - p(\hat{y}|\boldsymbol{x}, \boldsymbol{0})) \quad (3)$$

$$\mathrm{NormSuff}(\boldsymbol{x}, \hat{y}, \boldsymbol{\alpha}) = \frac{\mathrm{Suff}(\boldsymbol{x},\hat{y},\boldsymbol{\alpha}) - \mathrm{Suff}(\boldsymbol{x},\hat{y},\boldsymbol{0})}{1 - \mathrm{Suff}(\boldsymbol{x},\hat{y},\boldsymbol{0})} \quad (4)$$

$$\mathrm{NormComp}(\boldsymbol{x}, \hat{y}, \boldsymbol{\alpha}) = \frac{\mathrm{Comp}(\boldsymbol{x},\hat{y},\boldsymbol{\alpha})}{\mathrm{Comp}(\boldsymbol{x},\hat{y},\boldsymbol{1})} \quad (5)$$

where $\hat{y} = \arg\max_y p(y|\boldsymbol{x})$. Note that $\mathrm{NullDiff}(\boldsymbol{x}, \hat{y}) = 1 - \mathrm{Suff}(\boldsymbol{x}, \hat{y}, \boldsymbol{0}) = \mathrm{Comp}(\boldsymbol{x}, \hat{y}, \boldsymbol{1})$. We clip $\mathrm{NormSuff}$ and $\mathrm{NormComp}$ between 0 and 1.

Fig. 4a shows the null difference for RoBERTa across all datasets by class. Significant variation exists between classes, especially for WikiAttack, FEVER, and E-SNLI, an observation that helps contextualize some of the results in Fig. 3, as reflected by the normalized fidelity metrics.

Fig. 4b shows that normalized sufficiency is much lower in the no-attack class in WikiAttack, meaning that no-attack rationales are barely more informative than an empty rationale. This resolves the puzzle that the short/empty rationales in the no-attack class have high sufficiency in Fig. 3b. It is also more consistent with the low comprehensiveness measured for these rationales.

Fig. 4c shows us that the comprehensiveness scores even out for FEVER under this normalization, suggesting that the previous result was simply a product of model bias. By contrast, the asymmetric scores for Movie and MultiRC shown in Fig. 3c cannot be explained by model bias, indicating that the interaction between task semantics and model learning may cause rationales to be more comprehensive in the negative class than in the positive class for these datasets.

Another outcome of normalization is to map sufficiency and comprehensiveness to the same scale. Comprehensiveness in single-text classification tasks are generally lower than that in document/query-style tasks.

These results suggest that sufficiency and comprehensiveness metrics are highly model-dependent and should not be compared across models without care.

Fidelity and model training. Examining how human rationale fidelity changes from epoch to epoch as models train (Fig. 5) further demonstrates the model-dependence of these measures. Random noise causes the models to have nonzero (but low) fidelity scores at epoch 0. However, we observe that even after accuracy stabilizes, sufficiency and comprehensiveness may continue to fluctuate significantly, e.g., FEVER sufficiency.[2] Further, the maximum fidelity may not co-occur with the maximum accuracy (e.g., MultiRC comprehensiveness). While most of the fluctuation isn't drastic, these differences could prove decisive in a head-to-head comparison of fidelity scores across different models or rationalization techniques. These observations suggest that we need to be cautious before claiming definitive fidelity for a given model using these automatic metrics.

5 Characterizing Human Rationales beyond Sufficiency/Comprehensiveness

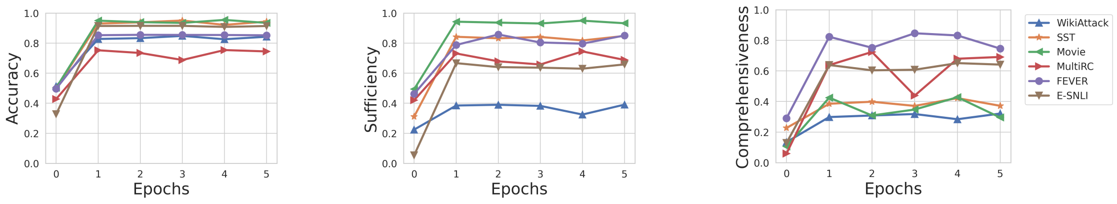
Sufficiency and comprehensiveness offer a limited perspective on the qualities of rationales. For example, does the 0.77 E-SNLI sufficiency reported in Fig. 2b correspond with a similar drop in accuracy, or do the rationales render the model less confident but equally accurate? And how can we distinguish between a highly concise rationale and one bloated with unnecessary information? We propose extensions of the basic fidelity framework to address these more nuanced questions.

5.1 Accuracy Evaluation with Rationales

Existing fidelity metrics measure differences in output probability rather than model performance, prompting the question of what is the practical effect of rationale fidelity. Moreover, they generally involve a model trained on complete texts but then evaluated on reduced texts based on rationales, ren-

---

[2] We observe similar issues with logistic regression, random forest, and LSTM. See the appendix.



(a) Accuracy (b) Normalized sufficiency (c) Normalized comprehensiveness

Figure 5: Accuracy, normalized sufficiency, and normalized comprehensiveness vs. #epochs in RoBERTa. While accuracy stabilizes after 1 epoch, sufficiency and comprehensiveness demonstrate significant fluctuation.

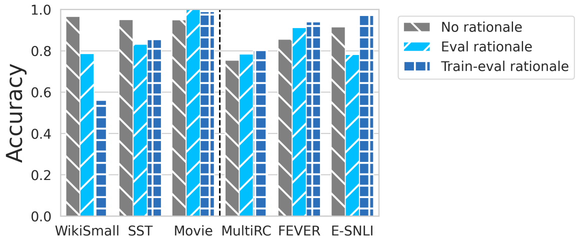


Figure 6: RoBERTa accuracy depending on whether we adapt models to rationale-only data. Human rationales are effective in improving accuracy in Movie and E-SNLI, but not in WikiAttack and SST.

	Training	Testing
No-rationale	No	No
Eval-rationale	No	Yes
Train-eval-rationale	Yes	Yes

Table 3: Use of rationales in different accuracy evaluations. The full-text model uses *no* rationale in training.

dering it unclear what outcome differences we can attribute to the missing information, and what to domain transfer between full and reduced text.

To answer these questions, we compare the accuracy of three variant training/evaluation regimes: 1) trained and evaluated on full text (*No rationale*); 2) trained on full text and evaluated on rationale-only text (*Eval rationale*); and 3) trained and evaluated on rationale-only text (*Train-eval rationale*).

The first variant is standard RoBERTa model training and evaluation. The second variant is the typical rationale evaluation setting: trained on full data and evaluated on reduced data. The third variant seeks to assess what performance gains can arise from model adaptation to the reduced data distribution. Table 3 summarizes the variants.[3]

Comparing the performance of these three models pits the benefits of data completeness (training on full information) against those of in-domain training (training on the same distribution as the evaluation data). If the former proves more valuable we would expect *Eval rationale* to outperform *Train-eval rationale*, and vice versa. In either case, we expect *No rationale* to have the best performance as it benefits from both qualities.

Fig. 6 shows some surprising divergences from these expectations. In four out of six cases, either *Train-eval rationale* accuracy or *Eval rationale* accuracy outperforms *No rationale* accuracy.

The effect of rationales in evaluation gives yet another perspective on the basic fidelity results presented in Fig. 2b. While the 0.77 sufficiency for E-SNLI corresponds with a significant accuracy drop between *No rationale* and *Eval rationale*, the 0.85 sufficiency for MultiRC corresponds with an *increase* in accuracy across these variants. The almost identical sufficiency of SST corresponds with a drop. "Insufficient" explanations can improve model performance, which suggests caution in using fidelity based on output probability as the sole arbiter of explanation quality.

The effect of model adaptation has interesting implications as well. We observe an improvement in performance from *Eval rationale* to *Train-eval rationale* in 4 out of 6 datasets, significant in the case of E-SNLI. In 3 out of 4 of these cases, the performance of *Train-eval rationale* also exceeds that of the *No rationale* setting.

This result is a hopeful sign for the topic area of *learning-from-explanation*, which seeks to use explanations as additional training supervision for models (Hancock et al., 2018; Zaidan and Eisner, 2008). It tells us that for a majority of our datasets, a perfectly human-mimicking rationale layer could boost the accuracy of a model's predictions. It is even possible that a version of this analysis could be used as a preliminary assessment of the usefulness of a rationale dataset as accuracy-boosting signal, though we leave this for future work.

In summary, from a model accuracy perspective, the quality of human rationales is strong for FEVER, MultiRC, and Movie, mixed for E-SNLI, and poor for SST and WikiAttack. This provides a somewhat different view from Fig. 4b. For exam-

---

[3] We only have human rationales on 1,049 instances in WikiAttack, so we use a different train/dev/test split from §3.

	Sufficiency	Comprehensiveness
brevity	fast drop	fast drop
redundancy	slow drop	fast drop
irrelevance	slow drop	slow drop
dependency	fast drop	slow drop

Table 4: Implications of irrelevance and redundancy on sufficiency and comprehensiveness.

ple, human rationales in MultiRC has lower (normalized) sufficiency based on output probability than SST but provide better accuracy sufficiency.

5.2 Fidelity Curves

Sufficiency and comprehensiveness struggle to convey more fine-grained qualities of human rationales. One problem that is not revealed by these measures is irrelevance. A rationale can be crammed with tokens that are not pertinent to prediction and still have high sufficiency and comprehensiveness, the most extreme example being a rationale that comprises the entire text.

We propose to assess rationale irrelevancy by looking at how sufficiency and comprehensiveness degrade as tokens are removed from the rationale. A rationale bloated with many irrelevant tokens should demonstrate a slow dropoff in sufficiency as tokens are removed, since many of these tokens will not be contributory. A rationale with more informational brevity should show a faster drop, as tokens are removed which were needed for prediction. We assess this by creating a "sufficiency curve" which traces this degradation at higher and higher occlusion rates.

In general, we suggest that a slow drop in sufficiency can be attributed to irrelevant or redundant tokens, while a fast drop in sufficiency can be due to dropping tokens that are either individually predictive or pieces of dependencies where multiple tokens are required to make a prediction. We can tell the difference by looking at the comprehensiveness curve — if individually predictive tokens are leaked into the rationale complement, the comprehensiveness should fall quickly, while if pieces of dependencies are, it should fall slowly. Table 4 summarizes our expectations.

We construct these fidelity curves as follows: For a given rationale $\boldsymbol{\alpha}$ and each of a series of replacement rates $R = 0, 0.05, 0.1, ..., 1.0$, we generate a reduced mask $\boldsymbol{\alpha}_r$ by randomly setting r fraction of tokens to 0 from the rationale. By calculating the mean normalized sufficiency and comprehensiveness over several trials for each replacement rate, we can draw a "sufficiency curve" (Fig. 7a) and a "comprehensiveness curve" (Fig. 7b).

Movie, WikiAttack, and SST exhibit slow drops in their sufficiency curves, showing that rationales in these datasets contain relatively many irrelevant or redundant tokens, and therefore remain sufficient even as some of their tokens are removed. Their comprehensiveness curves complete the story. The curves for all three datasets show relatively fast drops, implying redundancy rather than irrelevancy.

In comparison, E-SNLI, FEVER, and MultiRC all display relatively fast drops in sufficiency, implying fewer irrelevant or redundant tokens. They demonstrate generally higher comprehensiveness but somewhat different shapes (E-SNLI and MultiRC mostly show a slow drop, indicating dependence, while FEVER shows a fast drop, indicating irrelevance). The difference here between FEVER and MultiRC is interesting as they are similar in task, text, and rationale properties (Table 2). A possible explanation is that rationales in MultiRC are designed to consist of multiple mutually-dependent sentences whereas those of FEVER are single contiguous snippets of the text. This greater level of dependency is thus reflected in the slow-dropping comprehensiveness curve of MultiRC.

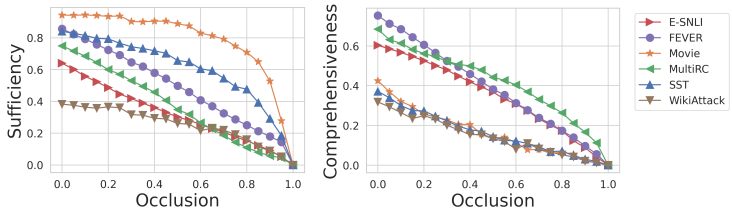
Hence, we find that human rationales for the three classification tasks are characterized by redundancy in human rationales, particularly Movie. The three document/query-style datasets, by contrast, are characterized by a relatively high degree of token dependency, explaining their relatively high comprehensiveness in Fig. 4c. While this observation is intuitive given the semantics of these tasks, it demonstrates the effectiveness of the proposed fidelity curves.

6 Related Work

We summarize additional related work in the following three areas.

Feature attribution. Feature attribution seeks to explain model behavior by attributing model predictions to specific inputs. Popular techniques include LIME (Ribeiro et al., 2016), integrated gradients (Sundararajan et al., 2017), SHAP (Lundberg and Lee, 2017), and attention mechanisms (Lei et al., 2016; Paranjape et al., 2020).

Human rationales. Many recent datasets in NLP have been released with rationales accompanying the document-level labels. ERASER (DeYoung et al., 2020) includes three additional datasets: CoS-



(a) Sufficiency (b) Comprehensiveness

	Sufficiency	Comprehensiveness
WikiAttack	slow drop	fast drop
SST	slow drop	fast drop
Movie	slow drop	fast drop
MultiRC	fast drop	fast→slow drop
FEVER	fast drop	fast drop
E-SNLI	fast drop	slow drop

(c) Summary by dataset.

Figure 7: Fidelity curves for all datasets (normalized sufficiency and comprehensiveness). Human rationales tend to be redundant in the single-text classification datasets, and dependent in the document/query-style datasets.

E (Rajani et al., 2019), BoolQ (Clark et al., 2019), and Evidence Inference (Lehman et al., 2019). Other rationale datasets include that of Kaushik et al. (2019) and Sen et al. (2020).

Attribution evaluation. A growing amount of work seeks to evaluate the quality of feature attribution. Beyond collecting human rationales as a gold-standard, a common human-based method is to test the utility of attribution masks in task-based human subject experiments (Carton et al., 2020; Lai and Tan, 2019; Poursabzi-Sangdeh et al., 2018; Lage et al., 2018; Lai et al., 2020).

Automatic model-based metrics beyond sufficiency and comprehensiveness include local model fidelity (Ribeiro et al., 2016), switching point (Nguyen, 2018), and area-over-the-perturbation-curve (Samek et al., 2016).

7 Concluding Discussion

Human explanations contain a lot of promise. The explainable AI community hopes to use them as a guide for evaluating model explanations and, possibly, for teaching models to make robust and well-reasoned decisions. In this work, we contribute to that effort by analyzing human rationales through the lens of automatic rationale evaluation methods, namely, sufficiency and comprehensiveness. We find that human rationales do not necessarily have high sufficiency or comprehensiveness.

Interpreting fidelity variance. Furthermore, there exists significant variance across datasets and classes. In §5.2, we speculate that some of these differences (e.g., dependency) can be explained by the semantic differences between classification and document/query-style tasks.

However, with such a small sample size of datasets ($n = 6$), it is difficult to determine whether these differences are due solely to task type or to other factors such as annotation instructions or individual dataset semantics. WikiAttack and E-SNLI, for example, display class asymmetry in their rationales, which likely contribute to their outlier status in Fig. 4 and 6 respectively. As we note in Fig. 2, modeling outcomes also have a heavy impact on explanation fidelity. While E-SNLI comprises an even class balance, our model learns a strong bias in favor of the neutral class, which contributes to a class imbalance in fidelity for that dataset (Fig. 4).

As more human-rationale datasets are released, it will become increasingly possible to categorize them by rationale properties. Our goal is to highlight the variance in these properties and call for more widespread empirical evaluations thereof.

Actionable implications. When human rationales are found to be unfaithful, this can mean that either they fail to capture relevant signal, or that the model improperly utilizes that signal, perhaps as a result of learning spurious associations. In either case, analysis can expose inconsistencies between human and model understanding of the task.

We propose three ways to extend fidelity metrics: normalization, model adaptation, and random ablation. Each addresses one shortcoming of the basic metric: normalization addresses the differences in class biases across models, adaptation the problem of domain inconsistency between full and rationale-only data, and ablation the inability of existing metrics to capture qualities like redundancy. While not all of these issues are salient for every application involving rationale fidelity, we offer them as potential solutions where necessary.

Overall, our results suggest that the idea of one-size-fits-all fidelity benchmarks might be problematic: human rationales may not be simply treated as gold standard. We need to design careful procedures to collect human rationales, understand properties of the resulting human rationales, and cautiously interpret the evaluation metrics.

A Derivation of Rationales for SST

The Stanford Sentiment Treebank (SST) consists of 9,620 short movie review snippets formatted as syntactic trees with a sentiment label in [-2,2] for each node, ranging from the single-token leaf nodes to the top-level node corresponding to the whole snippet.

We use a heuristic algorithm for flattening this representation into a 1-dimensional rationale for each document: beginning with the top node and traversing the tree in a breadth-first manner, we consider a node to be part of the rationale if the magnitude of its sentiment is greater than that of any of its descendants. That is, if the sentiment of a node cannot be explained by any of its syntactic constituents, then we consider it to be explanatory and include it in the top-level rationale.

Practically speaking, this results in a rationale dataset that is comprehensive by design, including all high-sentiment words and phrases that could explain the overall sentiment of each snippet. Table 5 shows a few examples of the resultant rationales.

B Model Implementation Details

We consider the following models:

- Logistic regression. We use the scikit-Learn implementation of logistic regression (Pedregosa et al., 2011), scanning across regularization constant ($C = \{0.001, 0.01, 0.1, 1, 10, 100, 1000\}$).
- Random forest. We use the scikit-Learn implementation of random forests, scanning across number of estimators ($\{16, 32, 64, 128, 256, 512\}$).
- LSTM (Hochreiter and Schmidhuber, 1997). We use the Pytorch (Paszke et al., 2017) implementation of a 1-layer BiLSTM, tuning across hidden layer size ($\{100, 200, 300\}$) and learning rate ($\{5e^{-4}, 1e^{-3}, 2e^{-3}\}$).
- RoBERTA (Liu et al., 2019). We use the HuggingFace (Wolf et al., 2020) pretrained distribution of this model with roughly 117m parameters. We tune the learning rate across values $\{5e^{-6}, 1e^{-5}, 2e^{-5}\}$, with 50 linear warmup steps.

We train all LSTM models for 10 epochs and RoBERTa models for 5 epochs, tuning on development set accuracy. All neural network training was done on two 24G Nvidia Titan RTX GPUs. Training time varied from dataset to dataset, from minutes for SST to roughly 6 hours per model for E-SNLI.

To apply masking, we simply remove the tokens corresponding with 0s in the rationale mask. We always keep special tokens such as [CLS] and [SEP].

Following DeYoung et al. (2020), we flatten the three document/query-style datasets to single documents by simply appending the query to the document with a "[SEP]" token.

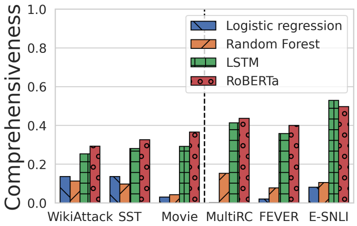
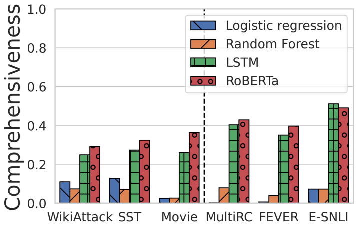
(b) ERASER sufficiency

Figure 8: Clipped sufficiency vs. ERASER sufficiency.



(a) Clipped comprehensiveness



(b) ERASER comprehensiveness

Figure 9: Clipped comprehensiveness vs. ERASER comprehensiveness.

C Eraser Sufficiency/Comprehensiveness vs. Our Definitions

Our definition of sufficiency and comprehensiveness diverge from that of DeYoung et al. (2020) in clipping the absolute difference between the full and rationalized class probability. This choice erases negative probability differences, cases where the rationalization makes the predicted class more probable than it already was. We do this as a way to bound fidelity metrics between 0 and 1. It also serves to simplify the mathematics of normalization, but practically speaking we find that it makes little difference (Fig. 8 and Fig. 9).

D The Effect of Normalization

We discuss the effect of normalization by class in §4. Fig. 10 compares the non-normalized against the normalized fidelity at the dataset level. This view makes clear the comprehensiveness gap between the classification datasets and the document/query-style datasets, and shows a wider range of sufficiency scores among the six datasets, when accounting for model bias.

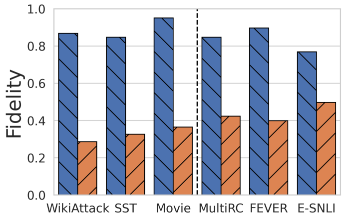
Fig. 11 shows the effect of normalization on fidelity scores for all models. We can see that it corrects the trend of weaker models showing better sufficiency that we observe in Fig. 2b, though logistic regression shows very high sufficiency and comprehensiveness for SST. Upon investigation, we find that this is because this model tends to have low confidence, often producing class probabilities between 0.5 and 0.7. This situation leads to relatively small null differences (Fig. 11a), which leads to the high observed comprehensiveness. In comparison, the null difference is substantially greater in deep models.

E The Effect of Hyperparameters and Training

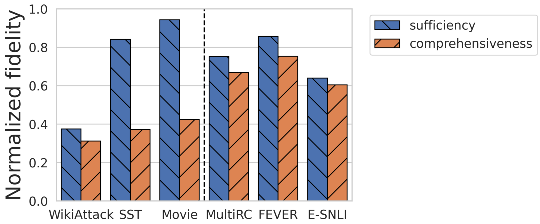
We largely focus on RoBERTa in this study because it is close the current state-of-the-art for NLP. However, we do some additional analysis on the other three models.

Fig. 12 shows how accuracy and rationale fidelity change with the value of the C regularization hyperparameter for the logistic regression model. Both the normalized sufficiency and comprehensiveness rise with model accuracy. The outlier is MultiRC, which is unable to achieve nontrivial accuracy, but which nevertheless experiences a rise in rationale fidelity.

The trends are less clear in Fig. 13, which tracks accuracy and fidelity over a range of numbers of



(a) Non-normalized fidelity



(b) Normalized fidelity

Figure 10: Non-normalized versus normalized fidelity.

estimators for the model. This may be because the accuracy of these models does not improve much with the increase in estimators.

Finally, Fig. 14 shows the change in accuracy and fidelity over training epochs for the LSTM model. We again see that fidelity metrics have a tendency to fluctuate when accuracy has seemingly stabilized, such as FEVER.

F Distribution of Fidelity Scores

Fig. 15 shows box plots of normalized fidelity scores for the six datasets. We see a wide range of variances. WikiAttack and E-SNLI, the two datasets with assymmetric rationales, display the highest variance in sufficiency, while WikiAttack, Movie, and MultiRC who relatively high variance in their comprehensiveness scores.

Abstract

We present a method to produce abstractive summaries of long documents that exceed several thousand words via neural abstractive summarization. We perform a simple extractive step before generating a summary, which is then used to condition the transformer language model on relevant information before being tasked with generating a summary. We also show that this approach produces more abstractive summaries compared to prior work that employs a copy mechanism while still achieving higher ROUGE scores. We provide extensive comparisons with strong baseline methods, prior state of the art work as well as multiple variants of our approach including those using only transformers, only extractive techniques and combinations of the two. We examine these models using four different summarization tasks and datasets: arXiv papers, PubMed papers, the Newsroom and BigPatent datasets. We find that transformer based methods produce summaries with fewer n-gram copies, leading to n-gram copying statistics that are more similar to human generated abstracts. We include a human evaluation, finding that transformers are ranked highly for coherence and fluency, but purely extractive methods score higher for informativeness and relevance. We hope that these architectures and experiments may serve as strong points of comparison for future work.[1]

1 Introduction

Automatic text summarization is the process of compressing a document while preserving key information content and meaning. This process is often achieved through extractive or abstractive techniques. Extractive summarization is the strategy of selecting a subset of words, phrases or sentences from the input document to form a summary. Abstractive summarization consists of creating sentences summarizing content and capturing key ideas and elements of the source text, usually involving significant changes and paraphrases of text from the original source sentences. While extractive summarization is able to preserve saliency, the broader flow or coherency of the multiple sentences forming the summary can be less natural compared to a human generated summary. On the other hand, abstractive methods should produce coherent summaries without copying sentences verbatim while remaining faithful to statements asserted in the input document.

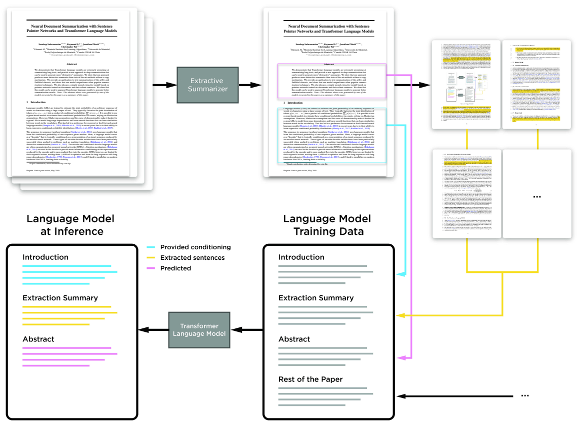

Figure 1: Our approach for abstractive summarization of a scientific article. An older version of this paper is shown as the reference document. First, a sentence pointer network extracts important sentences from the paper. Next, these sentences are provided along with the whole scientific article to be arranged in the following order: Introduction, extracted Sentences, abstract & the rest of the paper. A transformer language model is trained on articles organized in this format. During inference, the introduction and the extracted sentences are given to the language model as context to generate a summary. In domains like news and patent documents, the introduction can be replaced by the entire document.

Recent work by (Radford et al., 2019) (GPT-2) has demonstrated that Transformer Language

Models (TLMs) trained on web text can inadvertently learn to perform abstractive summarization, since a large crawl of web documents may contain some documents which have a "tl;dr" token followed by a summary. We are interested here in explicitly configuring autoregressive transformer models to generate summaries in an intentional and focused manner. Since summaries or abstracts typically appear at the beginning of a document, a model trained from such web-crawl data does not enforce strong conditioning on the text to be summarized. Our tests using models naively trained on web-crawl data yielded summarization quality far below baseline methods. However, in this paper we explore what can be achieved through simply ordering the passages of an input text, correctly structuring the task definition and training procedure. We also examine the impact of combining this approach with simple but high quality extractive techniques.

While pure language models can be applied to short input documents, memory considerations make it difficult to scale to long documents. Further, as high quality extractive summarization methods illustrate, much of the content of a long document is not needed to create a summary. For these reasons we also explore a hybrid approach which combines an extractive and abstractive approach. We achieve this by stepping away from the classical end-to-end sequence-to-sequence paradigm, using an initial extractive step that reduces the amount of context for a subsequent abstractive step (see figure 1). Such an approach could be thought of as a form of hard attention. Moreover, we show that such a paradigm works even for datasets where the entire input can fit in memory, i.e. see Table 4 and 5. We take an approach whereby we restructure the input to a TLM by reordering the document and inserting standardized delimiters to identify the introduction, our extracted sentences, the abstract or summary and the rest-of-the-article. With our method, the resulting TLM can focus its attention on the relevant content and its model complexity on the summarization task.

In general, as we shall detail in our experiments below, we find that TLMs are surprisingly effective at summarizing *long documents*, outperforming typical seq2seq approaches, even without using copying/pointing mechanisms, an encoder or additional losses. Our contribution consists of an extensive set of large scale experiments comparing our hybrid extractive and abstractive approach to long document summarization with different variants of our model, strong and simple baselines as well as with state-of-the-art summarization models (see section 3.2 for a complete description of comparisons). We examine these models through ROUGE scores, through a study of the amount of n-gram copying performed by different models, as well as through a human evaluation using a standard protocol. We find that our hybrid approach yields results that surpass current state-of-the-art results on several metrics of these evaluations.

We see our extensive experimentation and the wide variety of evaluation protocols provided here as being a key part of the contribution provided by this work and we hope that the analysis, insights and models here will serve as strong yet simple baselines for future comparison and research.

2 Related Work

The earliest attempts at automatic summarization focused on extractive techniques, which find words or sentences in a document that capture its most salient content. Recently, with advances in distributed representations of words, phrases and sentences, researchers have proposed to use these to compute similarity scores. Such techniques were further refined by Nallapati et al. (2016b); Cheng and Lapata (2016); Chen and Bansal (2018) with encoder-decoder architectures - the representations learned by the encoder are used to choose the most salient sentences. Cheng and Lapata (2016) and Nallapati et al. (2016b) trained encoder-decoder neural networks as a binary classifier to determine if each sentence in a document should belong to the extractive summary or not. Chen and Bansal (2018) use a pointer network (Vinyals et al., 2015) to sequentially pick sentences from the document that comprise its extractive summary. Such techniques however heavily rely on the span of words from the input document.

Human summarizers have four common characteristics. They are able to (1) interpret a source document, (2) prioritize the most important parts of the input text, (3) paraphrase key concepts into coherent paragraphs and (4) generate diverse output summaries. While extractive methods are arguably well suited for identifying the most relevant information, such techniques may lack the fluency and coherency of human generated summaries. Abstractive summarization has shown the most promise towards addressing points (3) and (4) above. Abstractive generation may produce sentences not seen in the original input document. Motivated by neural network success in machine translation experiments, the attention-based encoder decoder paradigm has recently been widely studied in abstractive summarization (Rush et al., 2015; Nallapati et al., 2016a; Chopra et al., 2016). The advantages of extractive, abstractive and attention-based models were first combined in (Gu et al., 2016; Gulcehre et al., 2016) with a copy mechanism for out-of-vocabulary words present in the source document. Similarly, (See et al., 2017) used the attention scores to calculate the probability of generating vs copying a word.

The most similar approach to our hybrid extractive and abstractive technique is that of Chen and Bansal (2018); Gehrmann et al. (2018); Hsu et al. (2018); Liu et al. (2018). In such set-ups, an *extractor* first selects salient sentences from the input. Then, an abstractive summarizer rewrites extracted sentences into a final summary. Our framework has a few advantages over previous methods. 1), we explore high capacity transformer LMs akin to Radford et al. (2019) as our abstractive summarizer, which results in grammatical and fluent generations 2), our language modeling formulation of the problem allows us to easily "recycle" the input document and use it additional in-domain data for LM training. 3) We improve over previous approaches without the use of a copy mechanism, which results in fewer n-gram copies from the input document. Liu et al. (2018) generate Wikipedia articles given references to source material and extracted sentences. They rank the importance of paragraphs found in the reference material based on techniques such as TextRank (Mihalcea and Tarau, 2004), a graph based ranking technique. In contrast, the extractive methods we use here are trained discriminatively using an extractive abstract as the target that is generated using an oracle. Wikipedia article synthesis also necessarily combines potentially redundant information from multiple documents that is relatively specific and less abstractive compared to the task of writing the abstract of a scientific paper. As seen in Figure 2, human generated (ground-truth) abstractive summaries in our datasets actually have very little word overlap with the source document.

3 Framework

Our model comprises two distinct trainable components: 1) an extractive model, comprising a hierarchical encoder that outputs sentence representations, used to either point to or classify sentences in the input, and 2) a transformer language model, conditioned on the extracted sentences as well as a part of or the entire input document.

3.1 Extractive Models

We describe the two neural extractive models used in this section. We used different types of extraction techniques to demonstrate the TLM model sensitivity to the extracted sentences. For instance, the Sentence Pointer performs much better on the arxiv dataset (see table 2) but the classifier is stronger on the Pubmed dataset (see table 3).

Hierarchical Seq2seq Sentence Pointer Our extractive model is similar to the sentence pointer architecture developed by (Chen and Bansal, 2018) with the main difference being the choice of encoder. We use a hierarchical bidirectional LSTM encoder with word and sentence level LSTMs while (Chen and Bansal, 2018) use a convolutional word level encoder for faster training and inference. The decoder is in both cases is an LSTM.

The procedure to determine ground-truth extraction targets is similar to previous work (Nallapati et al., 2017): the ground truth is determined by computing the average ROUGE$_{1,2,L}$ score of each document sentence against each summary sentence. Considering the input document as a list of N sentences $D = (S_1, \ldots, S_N)$ and the target summary as a list of M sentences $T = (S'_1, \ldots, S'_M)$, our heuristic provides $N \times M$ scores, such that: $\text{SCORES}_{\text{extraction}} = \{\frac{1}{3}\sum_{r \in 1,2,L} \text{ROUGE}_r(S_i, S'_j) | S_i \in D; S'_j \in T\}$.

Since single sentence extraction may not always contain the same information content as a target summary, we extended the number ground-truth extraction sentences per output summary sentence to two. This is done by choosing the top 2 sentences in D that have the highest $\text{SCORES}_{\text{extraction}}$ with respect to a given sentence in T. The resulting $2M$ ordered sentences are used as context in the TLM. The TLM benefits from a more structured and larger context from the extractive summarization model during training.

First, the "sentence-encoder" or token-level RNN is a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) encoding each sentence. The last hidden state of the last layer from the two directions produces sentence embeddings: $(\mathbf{s}_1, \ldots, \mathbf{s}_N)$, where N is the number of sentences in the document. The sentence-level LSTM or the "document encoder", another bi-directional LSTM, encodes this sequence of sentence embeddings to produce document representations: $(\mathbf{d}_1, \ldots, \mathbf{d}_N)$.

The decoder is an autoregressive pointer LSTM taking the sentence-level LSTM hidden state of the previously extracted sentence as input and predicting the next extracted sentence. Let i_t the index of the previous extracted sentence at time step t. The input to the decoder is $\mathbf{s}_{i_t}$.The decoder's output is computed by an attention mechanism from the decoder's hidden state $\mathbf{h}_t$ over the document representations $(\mathbf{d}_1, \ldots, \mathbf{d}_N)$. We used the dot product attention method from (Luong et al., 2015). The attention weights $\mathbf{a}_t$ produce a context vector $\mathbf{c}_t$, which is then used to compute an attention aware hidden state $\tilde{\mathbf{h}}_t$.

The attention weights $\mathbf{a}_t$ are used as output probability distribution over the document sentences, of the choice for the next extracted sentence. The model is trained to minimize the cross-entropy of picking the correct sentence at each decoder time step. At inference, we use beam-search to generate the extracted summary.

Sentence Classifier As with the pointer network, we use a hierarchical LSTM to encode the document and produce a sequence of sentence representations $\mathbf{d}_1, ..., \mathbf{d}_N$ where N is the number of sentences in the document. We compute a final document representation as follows:

$$\mathbf{d} = \tanh\left(\mathbf{b}_d + \mathbf{W}_d \frac{1}{N} \sum_{i=1}^{N} \mathbf{d}_i\right) \tag{1}$$

where $\mathbf{b}_d$ and $\mathbf{W}_d$ are learnable parameters. Finally, the probability of each sentence belonging to the extractive summary is given by:

$$o_i = \sigma\left(\mathbf{W}_o \begin{bmatrix} \mathbf{d}_i \\ \mathbf{d} \end{bmatrix} + \mathbf{b}_o\right) \tag{2}$$

where σ is the sigmoid activation function. The model is trained to minimize the binary cross-entropy loss with respect to the sentences in the gold-extracted summary.

Model details and training parameters are included in the appendix.

3.2 Transformer Language Models (TLM)

Instead of formulating abstractive summarization as a seq2seq problem using an encoder-decoder architecture, we only use a single transformer language model that is trained *from scratch*, with appropriately "formatted" data (see figure 1, we also describe the formatting later in this section).

We use a transformer (Vaswani et al., 2017) language model (TLM) architecture identical to Radford et al. (2019). Our model has 220M parameters with 20 layers, 768 dimensional embeddings, 3072 dimensional position-wise MLPs and 12 attention heads. The only difference in our architectures (to our knowledge) is that we do not scale weights at initialization. We trained the language model for 5 days on 16 V100 GPUs on a single Nvidia DGX-2 box. We used a linear ramp-up learning rate schedule for the first $40,000$ updates, to maximum learning rate of $2.5 \times e^{-4}$ followed by a cosine annealing schedule to 0 over the next $200,000$ steps with the Adam optimizer. We used mixed-precision training (Micikevicius et al., 2017) with a batch size of 256 sequences of 1024 tokens each.

In order to get an unconditional language model to do abstractive summarization, we can use the fact that LMs are trained by factorizing the joint distribution over words autoregressively. In other words, they typically factorize the joint distribution of tokens $p(x_1, x_2 \ldots x_n)$ into a product of conditional probabilities $\prod_i^n p(x_i|x_{<i})$. We therefore organize the training data for our models such that the ground-truth summary *follows* the information used by the model to generate a summary. As such, we can model the joint distribution of the document and the summary during training, and sample from the conditional distribution of the summary given document when we wish to perform inference.

When dealing with extremely long documents that may not fit into a single window of tokens seen by a transformer language model, such as an entire scientific article, we use its introduction as a proxy for having enough information to generate an abstract (summary) and use the remainder of the paper as in domain language model training data (Fig 1). In such cases, we organize the arXiv and PubMed datasets as follows: 1) the paper introduction, 2) extracted sentences from the sentence pointer model, 3) the abstract, and 4) the rest of the paper. This ensures that at inference time, we can provide the language model the paper introduction and the extracted sentences as conditioning to generate its abstract. We found that using the ground truth extracted sentences during training and the model extracted sentences at inference performed better than using the model extracted sentences everywhere. On other datasets, the paper introduction would be the entire document. In such case, the rest of the paper does not exist and is therefore not included.

We use a special token to indicate the start of the summary and use it at test time to signal to the model to start generating the summary. The rest of the article is provided as additional in-domain training data for the LM. The entire dataset is segmented into non-overlapping examples of $1,024$ tokens each. We use "topk" sampling at inference (Fan et al., 2018; Radford et al., 2019), with $k = 30$ and a softmax temperature of 0.7 to generate summaries.

4 Results and Analysis

Datasets We experiment with four different large-scale and long document summarization datasets - arXiv, PubMed (Cohan et al., 2018), bigPatent (Sharma et al., 2019) and Newsroom (Grusky et al., 2018a). Statistics are reported in Table 1.

Dataset	#Documents	Comp Ratio	Sum Len	Doc Len
arXiv	215,913	39.8	292.8	6,913.8
PubMed	133,215	16.2	214.4	3,224.4
Newsroom	1,212,726	43.0	30.4	750.9
BigPatent	1,341,362	36.4	116.5	3,572.8

Table 1: Statistics from Sharma et al. (2019) for the datasets used in this work - The number of document/summary pairs, the ratio of the number of words in the document to the abstract and the number of words in the summary and document.

Data preprocessing Both our extractive and abstractive models use sub-word units computed using *byte pair encoding* (Sennrich et al., 2015) with $40,000$ replacements. To address memory issues in the sentence pointer network, we only keep 300 sentences per article, and 35 tokens per sentence.

Evaluation We evaluate our method using full-length F-1 ROUGE scores (Lin, 2004) and re-used the code from (Cohan et al., 2018) for this purpose. All ROUGE numbers reported in this work have a 95% confidence interval of at most 0.24.

Comparison We compare our results to several previously proposed extractive, abstractive and mixed summarization models on ROUGE scores. ROUGE scores tend to measure lexical overlap (Ng and Abrecht, 2015) which favors extractive methods of summarization. Since ROUGE scores do not capture system summary fluency and readability (which typically does not favor abstractive summarization), we also include a human evaluation. For this reason, Tables 2, 3, 4, 5 have a "Type" column to inform the reader on the type model evaluated (Ext=extractive, Mix=mixed and Abs=abstractive). All prior results reported on the arXiv and Pubmed benchmark are obtained from Cohan et al. (2018), except for the *Bottom-up* model[2] (Gehrmann et al., 2018). Similarly, prior results for the BigPatent dataset are obtained from (Sharma et al., 2019) and Newsroom from (Grusky et al., 2018a) and (Mendes et al., 2019). These methods include *LexRank* (Erkan and Radev, 2004), *SumBasic* (Vanderwende et al., 2007), *LSA* (Steinberger and Jezek, 2004), *Attention-Seq2Seq* (Nallapati et al., 2016a; Chopra et al., 2016), *Pointer-Generator Seq2Seq* (See et al., 2017), *Discourse-aware*, which is a hierarchical extension to the pointer generator model, (Cohan et al., 2018), *Sent-rewriting* (Chen and Bansal, 2018), *RNN-Ext* (Chen and Bansal, 2018), *Exconsumm* (Mendes et al., 2019).

We present our main results on summarizing arXiv and PubMed papers in tables 2, 3. TLM+I+E (G,M) sets a new state-of-the-art on Arxiv, Pubmed and bigPatent datasets on abstractive summarization ROUGE scores. Our extractive models are able to outperform previous extractive baselines on both the arXiv and Pubmed datasets. Our extractive techniques also score higher than our abstractive techniques on arXiv and Pubmed. Again, ROUGE does not capture all aspects of a summary's quality such as fluency and coherence. For instance, previous work that have used RL to maximize ROUGE scores have concluded that "RL has the highest ROUGE-1 and ROUGE-L scores, it produces the least readable summaries" (Paulus et al., 2017). Our TLM conditioned on the extractive summary produced by our best extractive model (TLM-I+E (G,M)) outperforms prior abstractive/mixed results on the arXiv, Pubmed and bigPatent datasets, except on ROUGE-L.

On Newsroom, our TLM model performs close to 7 times better than the other purely abstractive model (Seq2Seq with attention). We achieve better performance than the pointer generator even on the

abstractive and mixed which their model should be better suited for since it has a copy mechanism. The Exconsumm model (Mendes et al., 2019) however, which is primarily an extractive model does better on this dataset. We suspect the poor ROUGE-L result is due to the absence of a copy mechanism that makes it hard to get *exact* large n-gram matches. Figure 2 further supports this hypothesis, it is evident that a model with a copy mechanism is often able to copy even upto 25-grams from the article. Further, Graham (2015) finds that ROUGE-L is poorly correlated with human judgements when compared to ROUGE-1,2,3. In table 8 and table 9, we present qualitative results of abstracts of notable papers in our field and of our TLM conditioned on the introductions and extracted summaries of a random example from the arXiv test set. Table 7 shows similar qualitative examples on the Newsroom dataset. Tables 2, 3 and 4 also provide different train / test settings for our TLM conditioned on extracted sentences. We show a performance upper bound conditioning the Transformer LM on oracle / ground-truth extracted sentences at both train and test time (TLM-I+E (G,G)). We also experiment with using either the ground-truth extracted sentences (TLM-I+E (G,M)) or the model extracted sentences (TLM-I+E (M,M)) during training and find that latter slightly impairs performance. It is important to note that, across datasets, introducing extracted sentences with TLM+I+E or TLM+E has consistently performed better over TLM+I or TLM. For bigPatent in table 4 and newsroom in table 5 TLM and TLM+E models have access to the same text since the whole article can fit in the transformer window size. This is particularly interesting since our results show that explicitly delimiting the extracted sentences has large positive affects on summary performance. As anticipated, introducing extracted sentences allows the TLM model to focus less on information retrieval and more on language generation.

Table 5: Summarization results on the Newsroom dataset. Previous work results from Grusky et al. (2018a) and Mendes et al. (2019). Note that extractive/mixed/abstractive columns denote the type of ground-truth summary. The Newsroom dataset has targets that are extracted from the input (extractive), that are created with heuristics (mixed) and that are created by humans (abstractive). Also note that the "Type" column refers to the model type for each row.

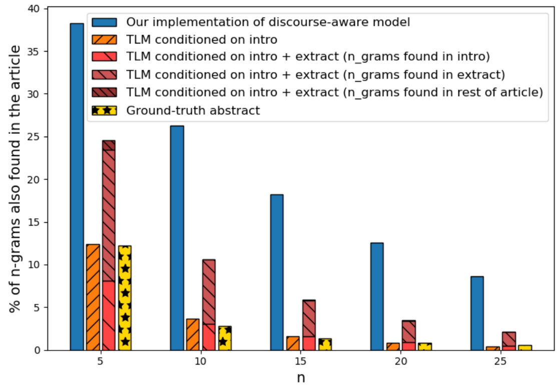

Figure 2: n-gram overlaps between the abstracts generated by different models and the input article on the arXiv dataset. We show in detail which part of the input was copied for our TLM conditioned on intro + extract.

stractive summarization systems that use a copy mechanism effectively generate the summary by copying over large chunks from the article, essentially doing "extractive" summarization. Following this work, we measure how much a model copies from the article by counting the proportion of n-grams from the generated abstract that are also found in the article. These statistics measured on the arXiv dataset are presented in figure 2. First, the original abstract and our TLM conditioned on the intro have small and very similar overlap fractions with the original article. A model using a pointing mechanism (we used our own implementation of the model developed by Cohan et al. (2018))[3] copies more than our transformer model, especially for higher n-grams. In particular, more than 10% of the 20-grams from the abstracts generated by the pointing model are also found in the article, showing that it tends to copy long sequences of words. On the other hand, our proposed model produces more "abstractive" summaries, demonstrating its ability to paraphrase. Our model tends to copy longer sequences when conditioned on the introduction and the sentences from the extractor. We hypothesize that providing extracted sentences from the article that already contain a lot of words present in the reference abstract, makes the transformer's task easier, by allowing it to copy words and phrases from the extracted sentences. We find empirical evidence of this in figure 2, showing that the majority of n-gram copies come from the extracted sentences. For 5-grams, close to 2/3rd of the words copied are from the extracted sentences. As the number of grams increases to 25-grams, 4/5th of the words copied are from the extracted sentences.

4.2 Human Evaluation

We performed a human evaluation using the same experimental setup as in (Grusky et al., 2018a) in Table 6. For the same 60 Newsroom test articles, we obtain the summaries for 5 different models (ground truth, sentence classifier, sentence pointer, TLM conditioned on article, TLM conditioned on article + pointer extracts).

Sentence classifier	Ext	3.62	3.79	**3.47**	**3.89**

Table 6: Human evaluation on Newsroom abstractive summarization test data. Each pair of (article, summary) is presented to three unique crowd workers, who are asked to judge the summaries along four criteria: Coherence (COH: does the summary make sense as a whole), Fluency (FLU: is it well written), Informativeness (INF: does the summary catch the most important points of the article), and Relevance (REL: are the facts in the summary consistent with the article).

As expected, Transformers are quite good making coherent and fluent summaries but not necessarily on informativeness and relevance. Transformers have a logarithmic or constant path length (as opposed to linear in RNNs) between a networks output and any of its inputs, making gradient flow much easier. This is a clear advantage over RNNs that tend to repeat sentences. Transformers are also known to hallucinate (Lee et al., 2019) but we notice that including extracted sentences, TLM

---

[3] This model achieved the following ROUGE-1, 2, 3 and L on the arXiv dataset: 41.33, 14.73, 6.80, 36.34

+ Intro + Extract, improve relevance by 3% over TLM + Intro, bringing relevance closer to extractive methods. Interestingly, on Coherence, both our TLM variants also score better than the ground truth. Over the four categories, TLM + Intro + Extract performs best on average over TLM + Intro, despite the former having higher ROUGE scores on the abstractive test set in table 5. Somewhat counter-intuitively we observe that human written summaries are often rated lower than model summaries. However, other work has also found that human written ground truth summaries consistently receive lower scores when compared to model written summaries when evaluated by turkers (see for example Table 3 in the PEGASUS paper of (Zhang et al., 2020)). We believe that this could be because Newsroom summaries are sometimes noisy, ungrammatical and incoherent.

Document — A new plan from the government of the Philippines would offer free wireless internet to people across the country while also likely eating into the annual revenue of the nations telecoms. Bloomberg reports that the Philippines government plans to roll-out its free Wi-Fi services to roughly half of the countrys municipalities over the next few months and the country has its sights set on nationwide coverage by the end of 2016. The free wireless internet service will be made available in public areas such as schools, hospitals, airports and parks, and is expected to cost the government roughly $32 million per year. [...]
Abstractive — : The government is reportedly considering a nationwide service plan to give free Wi-Fi access to rural areas.
Mixed — The government of the Philippines is considering a new plan to provide free wireless internet to the nation's largest cities and towns.
Extractive — The new plan will include free wireless internet to residents across the country while also probably eating into the annual revenue of the country's telecoms.
Document — (CBS) - Controversy over a new Microsoft patent has people questioning whether or not the intention has racist undertones. CNET reported that Microsoft has been granted a U.S. patent that will steer pedestrians away from areas that are high in crime. [...]
Absractive Summary — The new Microsoft patent claims a device could provide pedestrian navigation directions from a smartphone.
Mixed Summary Microsoft won a U.S. patent for a new way to steer pedestrians out of areas that are high in crime

Table 7: Qualitative Results - News articles and our model generated summaries on the NewsRoom dataset

4.3 Qualitative Results

Here we provide some qualitative results. Running our algorithm on a close to final version of this paper (excluding this section) and selecting the best sample from a set of 10-20 runs we found the following abstract: "we present a hybrid extractive and abstractive approach for generating summaries from long documents. we use an initial extractive step that reduces the amount of context for a subsequent abstractive step (see figure [fig: model]). we show that this approach can produce a good summarization quality on both short and long documents, even without using copying and pointing mechanisms. further, by considering the context in both the text and the discourse, we find that the hybrid approach is effective at capturing the underlying context. we examine these models through rouge scores, through a study of the amount of n-gram copying performed by different models, as well as through a human evaluation using a standard protocol. our results show that our hybrid approach yields results that outperform current state-of-the-art results on several metrics of these evaluations."

5 Conclusion

We have demonstrated that Transformer language models can generate high-quality summaries of long sequences of text via an extractive step followed by an abstractive step. We quantitatively measure the positive impact of the extractive step, by comparing it to a abstractive model variant that only sees the input text itself. Our approach outperforms previous extractive and abstractive summarization methods on the arXiv, PubMed and bigPatent datasets and is less prone to copying entire phrases or sentences from the input text. As with other problem domains, we have observed that abstractive summaries generated by transformers can generate imaginary content. We advise that such evaluations should probe multiple aspects of the summarization results including both factual correctness and coherency. We also note that for evaluating the correctness of the summaries of scientific articles and patents one must have highly trained evaluators who are willing to invest significant amounts of time to read the underlying papers and patents. Such studies could therefore require significant investments of resources. While we believe that this work is a step forward towards generating more abstractive summaries, it remains an open challenge to develop abstactive models that respect the underlying facts of the content being summarized while matching the creative ability of humans to coherently and concisely synthesize summaries. However, the TLMs we use here are of moderate size compared to what is now possible. It would be very interesting to see what kind of performance larger models could achieve.

Acknowledgments

We would like to thank Nicolas Chapados and Harm de Vries for their helpful feedback and Minh Dao for helping with the figures. We would also like to thank Guillaume Lample for discussions about TLM training.

Generated abstract for "the attention model paper" (Bahdanau et al., 2014) - In this paper, we propose a neural machine translation model, which learns to align and translate a source sentence without encoding it into a fixed length vector. The proposed model allows the neural network to align and translate jointly, and in addition, predicts a target word based on the context vectors associated with these source positions. We show that the proposed model achieves significantly improved translation performance than the conventional encoder decoder neural network approach, when the sentences in the training corpus are long . Quantitative analysis reveals that the proposed model finds a linguistically plausible soft alignment between a source sentence and the target sentence. Finally, we compare the performance of the proposed model with the state-of-the-art standard neural network translation models and show that the proposed approach outperforms the conventional approach in terms of both translation performance and the quality of the translations.	**Original abstract** - Neural machine translation is a recently proposed approach to machine translation. Unlike the traditional statistical machine translation, the neural machine translation aims at building a single neural network that can be jointly tuned to maximize the translation performance. The models proposed recently for neural machine translation often belong to a family of encoder-decoders and consists of an encoder that encodes a source sentence into a fixed-length vector from which a decoder generates a translation. In this paper, we conjecture that the use of a fixed-length vector is a bottleneck in improving the performance of this basic encoder-decoder architecture, and propose to extend this by allowing a model to automatically (soft-)search for parts of a source sentence that are relevant to predicting a target word, without having to form these parts as a hard segment explicitly. With this new approach, we achieve a translation performance comparable to the existing state-of-the-art phrase-based system on the task of English-to-French translation. Furthermore, qualitative analysis reveals that the (soft-)alignments found by the model agree well with our intuition.
Generated abstract for "the GPT-2 paper" (Radford et al., 2019) - Language models have been successful in creating rich representations of complex systems, including tasks such as sentiment analysis. In this paper we demonstrate their ability to generalize well across domains and tasks. We demonstrate the utility of language models by demonstrating that a variety of tasks can be modeled using language models. We demonstrate the potential of language models in downstream tasks by highlighting the ability of these models to perform a wide range of tasks in a zero shot setting.	**Original abstract** - Natural language processing tasks, such as question answering, machine translation, reading comprehension, and summarization, are typically approached with supervised learning on task-specific datasets. We demonstrate that language models begin to learn these tasks without any explicit supervision when trained on a new dataset of millions of webpages called WebText. When conditioned on a document plus questions, the answers generated by the language model reach 55 F1 on the CoQA dataset - matching or exceeding the performance of 3 out of 4 baseline systems without using the 127,000+ training examples. The capacity of the language model is essential to the success of zero-shot task transfer and increasing it improves performance in a log-linear fashion across tasks. Our largest model, GPT-2, is a 1.5B parameter Transformer that achieves state of the art results on 7 out of 8 tested language modeling datasets in a zero-shot setting but still underfits WebText. Samples from the model reflect these improvements and contain coherent paragraphs of text. These findings suggest a promising path towards building language processing systems which learn to perform tasks from their naturally occurring demonstrations.
Generated abstract for "the BERT paper" (Devlin et al., 2018) - We develop an architecture for deep bidirectional language models that allows the representation to fuse the left and the right context of a given token. Our framework uses bidirectional transformer encoder representations that enable the model to fuse the context representations of a token. We show that our architecture achieves state-of-the-art performance on a large suite of tasks, outperforming many systems with task-specific architectures. Our results are based on a set of eleven task specific tasks that are benchmarks for a large suite of nlp tasks.	**Original abstract** - We introduce a new language representation model called BERT, which stands for Bidirectional Encoder Representations from Transformers. Unlike recent language representation models, BERT is designed to pre-train deep bidirectional representations from unlabeled text by jointly conditioning on both left and right context in all layers. As a result, the pre-trained BERT model can be fine-tuned with just one additional output layer to create state-of-the-art models for a wide range of tasks, such as question answering and language inference, without substantial task-specific architecture modifications. BERT is conceptually simple and empirically powerful. It obtains new state-of-the-art results on eleven natural language processing tasks, including pushing the GLUE score to 80.5% (7.7% point absolute improvement), MultiNLI accuracy to 86.7% (4.6% absolute improvement), SQuAD v1.1 question answering Test F1 to 93.2 (1.5 point absolute improvement) and SQuAD v2.0 Test F1 to 83.1 (5.1 point absolute improvement).
Generated abstract for "the seq2seq paper" (Sutskever et al., 2014) - We present a novel approach to sequence to sequence learning using deep recurrent neural networks (LSTMs). First , we transform a sequence to a vector representation that contains all the long short term memory (LSTM) features, and then we use the LSTM to generate elements of the output sequence using a simple left to right beam-search decoder. The advantage of this approach is that it learns to map all the words in the input sequence to a fixed dimensional vector representation, while the LSTM does not require any special training to learn the sentence representation. We demonstrate the LSTMs ability to train on the WMT14 English to French translation task using a simple left to right beam-search decoder. The model was found to be highly invariant to the active and passive voice.	**Original abstract** - Deep Neural Networks (DNNs) are powerful models that have achieved excellent performance on difficult learning tasks. Although DNNs work well whenever large labeled training sets are available, they cannot be used to map sequences to sequences. In this paper, we present a general end-to-end approach to sequence learning that makes minimal assumptions on the sequence structure. Our method uses a multilayered Long Short-Term Memory (LSTM) to map the input sequence to a vector of a fixed dimensionality, and then another deep LSTM to decode the target sequence from the vector. Our main result is that on an English to French translation task from the WMT'14 dataset, the translations produced by the LSTM achieve a BLEU score of 34.8 on the entire test set, where the LSTM's BLEU score was penalized on out-of-vocabulary words. Additionally, the LSTM did not have difficulty on long sentences. For comparison, a phrase-based SMT system achieves a BLEU score of 33.3 on the same dataset. When we used the LSTM to rerank the 1000 hypotheses produced by the aforementioned SMT system, its BLEU score increases to 36.5, which is close to the previous best result on this task. The LSTM also learned sensible phrase and sentence representations that are sensitive to word order and are relatively invariant to the active and the passive voice. Finally, we found that reversing the order of the words in all source sentences (but not target sentences) improved the LSTM's performance markedly, because doing so introduced many short term dependencies between the source and the target sentence which made the optimization problem easier.
Generated abstract for "the GAN paper" (Goodfellow et al., 2014) - Adversarial nets are a class of deep generative networks that utilize the advantages of piecewise linear units. Here, we explore a novel model estimation procedure that combines several methods, such as backpropagation and dropout, to learn generative models. The proposed adversarial net framework can be thought of as analog to a team of counterfeiters, who try to produce fake currency and use it without being detected, while the discriminative model is analogous to the police, trying to detect the counterfeit currency. We refer to this special case as adversarial nets. We explore the special case when the generative model generates samples by passing random noise through a multilayer perceptron, and the discriminative model is also a multilayer perceptron.	**Original abstract** - We propose a new framework for estimating generative models via an adversarial process, in which we simultaneously train two models: a generative model G that captures the data distribution, and a discriminative model D that estimates the probability that a sample came from the training data rather than G. The training procedure for G is to maximize the probability of D making a mistake. This framework corresponds to a minimax two-player game. In the space of arbitrary functions G and D, a unique solution exists, with G recovering the training data distribution and D equal to 1/2 everywhere. In the case where G and D are defined by multilayer perceptrons, the entire system can be trained with backpropagation. There is no need for any Markov chains or unrolled approximate inference networks during either training or generation of samples. Experiments demonstrate the potential of the framework through qualitative and quantitative evaluation of the generated samples.

Samples from the arXiv test set

Samples from the TLM-I and TLM-I+E (G,M) models on a random example from the arXiv test set.

Table 9: Qualitative Results - Generated abstracts from our models on a random example from the test set of (Cohan et al., 2018)

TLM conditioned on intro — deep convolutional neural networks (cnns) have created new benchmarks in the object recognition challenge . most of these benchmark datasets contain thousands of images of interest . in addition to these datasets , several standard data - sets , such as pascal voc 2012 and the ms coco , have been used in conjunction with the same network in order to improve the object detection task . in this paper , we present a method for object localization using the deep convolutional neural networks trained for the simpler task of image - level classification . we propose localization candidates (or bounding boxes) which maximize classification scores for a class of interest . we explore the beam search strategy where the number of candidate bounding boxes are restricted as we traverse from the root node towards the leaf nodes . we then gradually explore smaller and smaller regions of interest till a point is reached where the classifier is not able to discriminate among the classes of interest . the detection candidates are organized in a search tree , the root node being represented by the entire test image . we then gradually explore smaller and smaller regions of interest till a point is reached where the classifier is not able to distinguish among the classes of interest .
TLM conditioned on intro + pointer network extracted sentences — deep convolutional neural networks (cnns) are widely used in image recognition applications . however , they face a number of challenges . first , cnn models are computationally expensive to train and to perform . second , they are not easy to implement and can not exploit global features . to alleviate these issues , we present a method that leverages the correlation between semantic information present in feature maps and localization of an object of interest . the method leverages feature map activations for object localization . we demonstrate that this method is significantly faster than state - of - the - art in localization accuracy by a significant margin of up to 8 map on two standard data - sets with complex scenes , pascal voc 2012 and the much larger ms coco .
Ground truth abstract — object localization is an important computer vision problem with a variety of applications . the lack of large scale object - level annotations and the relative abundance of image - level labels makes a compelling case for weak supervision in the object localization task . deep convolutional neural networks are a class of state-of-the-art methods for the related problem of object recognition . in this paper , we describe a novel object localization algorithm which uses classification networks trained on only image labels . this weakly supervised method leverages local spatial and semantic patterns captured in the convolutional layers of classification networks . we propose an efficient beam search based approach to detect and localize multiple objects in images . the proposed method significantly outperforms the state-of-the-art in standard object localization data - sets with a 8 point increase in map scores .

T-SNE of learned word embeddings

We visualize the word embeddings learned by our TLM model using t-sne. We find that words that are often associated with computer science are clustered in a different part of space when compared to words associated with physics. We use the arXiv REST API to find the submission category of each paper in the training set and then find the ~300 most representative words for each category, using TF-IDF scores and plot them.

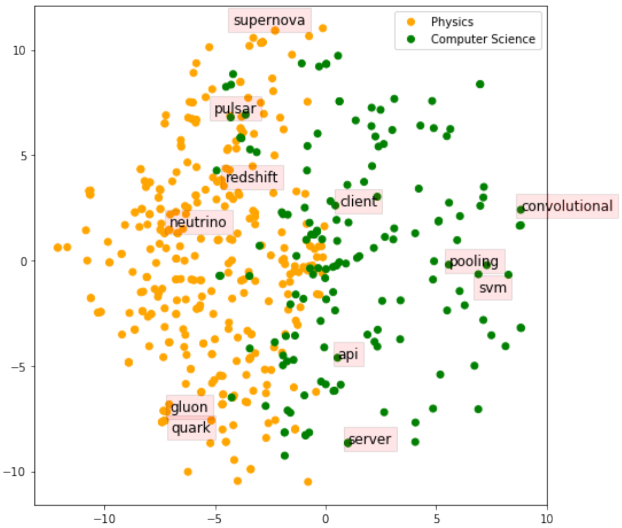

Figure 3: t-sne visualization of the TLM-learned word embeddings. The model appears to partition the space based on the broad paper categoty in which it frequently occurs.

Extractive Model Details

The model uses word embeddings of size 300. The token-level LSTM (sentence encoder), sentence-level LSTM (document encoder) and decoder each have 2 layers of 512 units and a dropout of 0.5 is applied at the output of each intermediate layer. We trained it with Adam, a learning rate 0.001, a weight decay of 10^{-5}, and using batch sizes of 32. We evaluate the model every 200 updates, using a patience of 50. At inference, we decode using beam search with a beam size of 4 for the pointer model and pick the k most likely sentences from the sentence classifier, where k is the average number of sentences in the summary across the training dataset.

Multi-Fact Correction in Abstractive Text Summarization

Abstract

Pre-trained neural abstractive summarization systems have dominated extractive strategies on news summarization performance, at least in terms of ROUGE. However, system-generated abstractive summaries often face the pitfall of factual inconsistency: generating incorrect facts with respect to the source text. To address this challenge, we propose *Span-Fact*, a suite of two factual correction models that leverages knowledge learned from question answering models to make corrections in system-generated summaries via *span selection*. Our models employ single or multi-masking strategies to either iteratively or auto-regressively replace entities in order to ensure semantic consistency w.r.t. the source text, while retaining the syntactic structure of summaries generated by abstractive summarization models. Experiments show that our models significantly boost the factual consistency of system-generated summaries without sacrificing summary quality in terms of both automatic metrics and human evaluation.

1 Introduction

Informative text summarization aims to shorten a long piece of text while preserving its main message. Existing systems can be divided into two main types: extractive and abstractive. Extractive strategies directly copy text snippets from the source to form summaries, while abstractive strategies generate summaries containing novel sentences not found in the source. Despite the fact that extractive strategies are simpler and less expensive, and can generate summaries that are more grammatically and semantically correct, abstractive strategies are becoming increasingly popular thanks to its flexibility, coherency and vocabulary diversity (Zhang et al., 2020a).

CNNDM Source	(CNN) About a quarter of a million Australian homes and businesses have no power after a "once in a decade" storm battered Sydney and nearby areas. About 4,500 people have been isolated by flood waters as "the roads are cut off and we won't be able to reach them for a few days,"...

Recently, with the advent of Transformer-based models (Vaswani et al., 2017) pre-trained using self-supervised objectives on large text corpora (Devlin et al., 2019; Radford et al., 2018; Lewis et al., 2020; Raffel et al., 2020), abstractive summarization models are surpassing extractive ones on automatic evaluation metrics such as ROUGE (Lin, 2004). However, several studies (Falke

et al., 2019; Goodrich et al., 2019; Kryściński et al., 2019; Wang et al., 2020; Durmus et al., 2020; Maynez et al., 2020) observe that despite high ROUGE scores, system-generated abstractive summaries are often factually inconsistent with respect to the source text. Factual inconsistency is a well-known problem for conditional text generation, which requires models to generate readable text that is faithful to the input document. Consequently, sequence-to-sequence generation models need to learn to balance signals between the source for faithfulness and the learned language modeling prior for fluency (Kryściński et al., 2019). The dual objectives render abstractive summarization models highly prone to hallucinating content that is factually inconsistent with the source documents (Maynez et al., 2020).

Prior work has pushed the frontier of guaranteeing factual consistency in abstractive summarization systems. Most focus on proposing evaluation metrics that are specific to factual consistency, as multiple human evaluations have shown that ROUGE or BERTScore (Zhang et al., 2020b) correlates poorly with faithfulness (Kryściński et al., 2019; Maynez et al., 2020). These evaluation models range from using fact triples (Goodrich et al., 2019), textual entailment predictions (Falke et al., 2019), adversarially pre-trained classifiers (Kryściński et al., 2019), to question answering (QA) systems (Wang et al., 2020; Durmus et al., 2020). It is worth noting that QA-based evaluation metrics show surprisingly high correlations with human judgment on factuality (Wang et al., 2020), indicating that QA models are robust in capturing facts that can benefit summarization tasks.

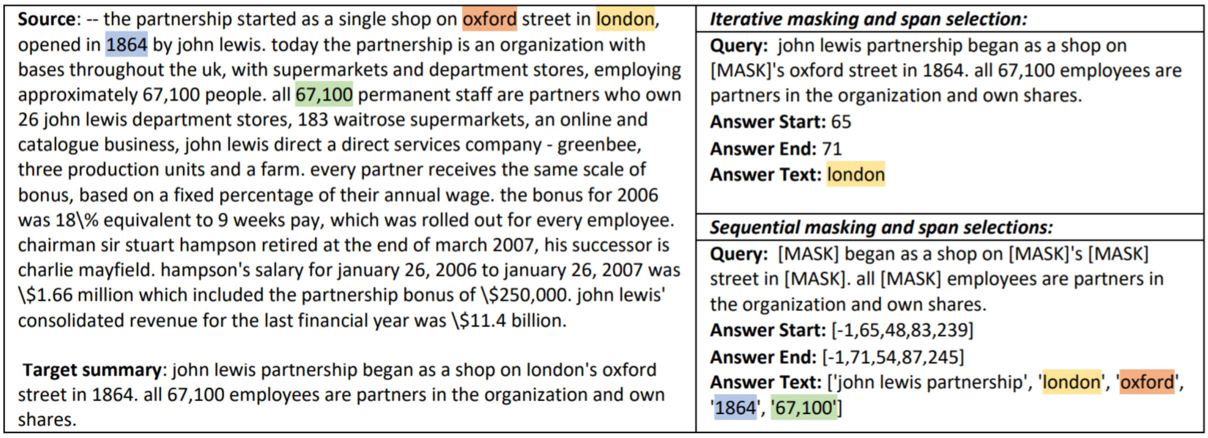
On the other hand, some work focuses on model design to incorporate factual triples (Cao et al., 2018; Zhu et al., 2020) or textual entailment (Li et al., 2018; Falke et al., 2019) to boost factual consistency in generated summaries. Such models are efficient in boosting factual scores, but often at the expense of significantly lowering ROUGE scores of the generated summaries. This happens because the models struggle between generating pivotal content while retaining true facts, often with an eventual propensity to sacrificing informativeness for the sake of correctness of the summary. In addition, these models inherit the backbone of generative models that suffer from hallucination despite the regularization from complex knowledge graphs or text entailment signals.

In this work, we propose SpanFact, a suite of two neural-based factual correctors that improve summary factual correctness without sacrificing informativeness. To ensure the retention of semantic meaning in the original documents while keeping the syntactic structures generated by advanced summarization models, we focus on factual edits on entities only, a major source of hallucinated errors in abstractive summarization systems in practice (Kryściński et al., 2019; Maynez et al., 2020). The proposed model is inspired by the observation that fact-checking QA model is a reliable medium in assessing whether an entity should be included in a summary as a fact (Wang et al., 2020; Durmus et al., 2020). To our knowledge, we are the first to adapt QA knowledge to enhance abstractive summarization. Compared to sequential generation models that incorporate complex knowledge graph and NLI mechanisms to boost factuality, our approach is lightweight and can be readily applied to any system-generated summaries without retraining the model. Empirical results on multiple summarization datasets show that the proposed approach significantly improves summarization quality over multiple factuality measures without sacrificing ROUGE scores.

Our contributions are summarized as follows. (i) We propose SpanFact, a new factual correction framework that focuses on correcting erroneous facts in generated summaries, generalizable to any summarization system. (ii) We propose two methods to solve multi-fact correction problem with single or multi-span selection in an iterative or auto-regressive manner, respectively. (iii) Experimental results on multiple summarization benchmarks demonstrate that our approach can significantly improve multiple factuality measurements without a huge drop on ROUGE scores.

2 Related Work

The general neural-based encoder-decoder structure for abstractive summarization is first proposed by Rush et al. (2015). Later work improves this structure with better encoders, such as LSTMs (Chopra et al., 2016) and GRUs (Nallapati et al., 2016), that are able to capture long-range dependencies, as well as with reinforcement learning methods that directly optimize summarization evaluation scores (Paulus et al., 2018). One drawback of the earlier neural-based summarization models is the inability to produce out-of-



Source: -- the partnership started as a single shop on oxford street in london, opened in 1864 by john lewis. today the partnership is an organization with bases throughout the uk, with supermarkets and department stores, employing approximately 67,100 people. all 67,100 permanent staff are partners who own 26 john lewis department stores, 183 waitrose supermarkets, an online and catalogue business, john lewis direct a direct services company - greenbee, three production units and a farm. every partner receives the same scale of bonus, based on a fixed percentage of their annual wage. the bonus for 2006 was 18\% equivalent to 9 weeks pay, which was rolled out for every employee. chairman sir stuart hampson retired at the end of march 2007, his successor is charlie mayfield. hampson's salary for january 26, 2006 to january 26, 2007 was \$1.66 million which included the partnership bonus of \$250,000. john lewis' consolidated revenue for the last financial year was \$11.4 billion.

Target summary: john lewis partnership began as a shop on london's oxford street in 1864. all 67,100 employees are partners in the organization and own shares.

Iterative masking and span selection:

Query: john lewis partnership began as a shop on [MASK]'s oxford street in 1864. all 67,100 employees are partners in the organization and own shares.

Answer Start: 65

Answer End: 71

Answer Text: london

Sequential masking and span selections:

Answer Start: [-1,65,48,83,239]

Answer End: [-1,71,54,87,245]

Answer Text: ['john lewis partnership', 'london', 'oxford', '1864', '67,100']

Figure 1: Training example created for the QA-span prediction model (upper right) and the auto-regressive fact correction model (bottom right).

vocabulary words, as the model can only generate whole words based on a fixed vocabulary. See et al. (2017) proposes a pointer-generator framework that can copy words directly from the source through a pointer network (Vinyals et al., 2015), in addition to the traditional sequence-to-sequence generation model.

Abstractive summarization starts to shine with the advent of self-supervised algorithms, which allow deeper and more complicated neural networks such as Transformers (Vaswani et al., 2017) to learn diverse language priors from large-scale corpora. Models such as BERT (Devlin et al., 2019), GPT (Radford et al., 2018) and BART (Lewis et al., 2020) have achieved new state-of-the-art performances on abstractive summarization (Liu and Lapata, 2019; Lewis et al., 2020; Zhang et al., 2020a; Shi et al., 2019; Fabbri et al., 2019). These models often finetune pre-trained Transformers with supervised summarization datasets that contain pairs of source and summary.

However, encoder-decoder architectures widely used in abstractive summarization systems are inherently difficult to control and prone to hallucination (Vinyals and Le, 2015; Koehn and Knowles, 2017; Lee et al., 2018), and often leads to factual inconsistency: the system-generated summary is fluent but unfaithful to the source (Cao et al., 2018). Studies have shown that 8% to 30% system-generated abstractive summaries have factual errors (Falke et al., 2019; Kryściński et al., 2019) that cannot be discovered by ROUGE scores. Recent studies have proposed new methods to ensure factual consistency in summarization. Cao et al. (2018); Zhu et al. (2020) propose RNN-based and Transformer-based decoders that attend to both source and extracted knowledge triples, respectively. Li et al. (2018) propose an entailment-reward augmented maximum-likelihood training objective, and Falke et al. (2019) proposes to rerank beam results based on entailment scores to the source.

Our fact correction models are inherently different from these models, as we focus on post-correcting summaries generated by any model. Our models are trained with the objective of predicting masked entities identified for fact correction (Figure 1), and learn to fill in the entity masks of any system-generated summaries with single or multi-span selection mechanism (Figure 2). The most similar work to ours is proposed concurrently by Meng et al. (2020), where they fine-tune a BART (Lewis et al., 2020) model on distant supervision examples and use it as a post-editing model for factual error correction.

3 Multi-Fact Correction Models

In this section, we describe two models proposed for factual error correction: (i) QA-span Fact Correction model, and (ii) Auto-regressive Fact Correction model. As both methods rely on span selection with different masking and prediction strategies, we call them SpanFact collectively.

3.1 Problem Formulation

Let (x, y) be a document-summary pair, where $x = (x_1, \dots, x_M)$ is the source sequence with M tokens, and $y = (y_1, \dots, y_N)$ is the target sequence with N tokens. An abstractive summarization model aims to model the conditional

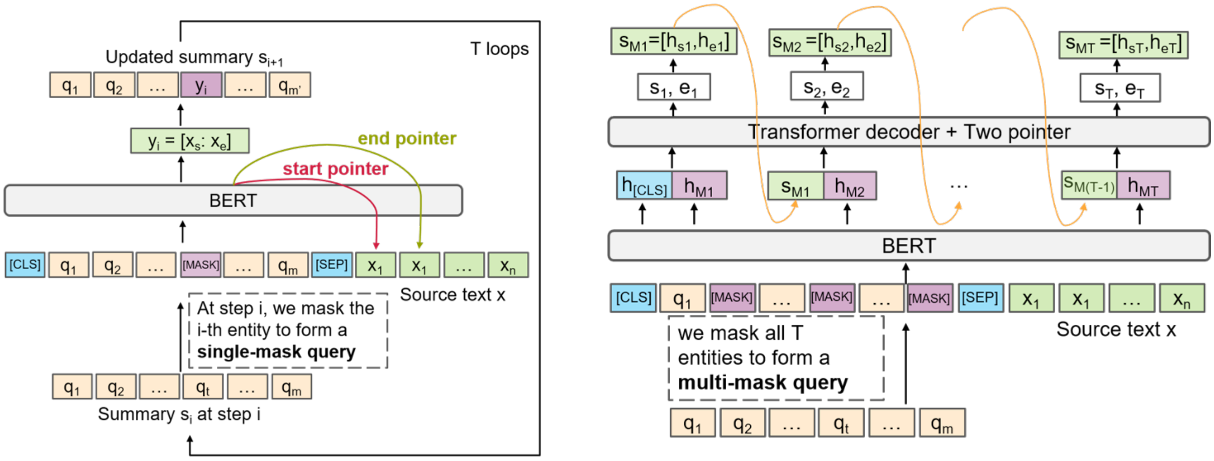

Figure 2: Model architecture (Left: QA-span fact correction model. Right: Auto-regressive fact correction model).

likelihood $p(y|x)$, which can be factorized into a product $p(y|x) = \prod_{t=1}^{T} p(y_t|y_{1,...,t-1}, x)$, where $y_{1,...,t-1}$ denote the preceding tokens before position t. The conditional maximum-likelihood objective ideally requires summarization models to not only optimize for informativeness but also correctness. However, in reality this often fails as the models have a high propensity for leaning towards informativeness than correctness (Li et al., 2018).

Suppose a summarization system generates a sequence of tokens $y' = (y'_1, \dots, y'_N)$ to form a summary. Our factual correction models aim to edit an informative-yet-incorrect summary into $y'' = (y''_1, \dots, y''_K)$ such that

$$f(x, y'') > f(x, y') \,, \tag{1}$$

where f is a metric measuring factual consistency between the source and system summary.

3.2 Span Selection Dataset

Our fact correction models are inspired by the *span selection* task, which is often used in reading comprehension tasks such as question answering. Figure 1 shows examples of the *span selection* datasets we created for training our QA-span and auto-regressive fact correction models, respectively. The *query* is a reference summary masked with one or all entities,[1] and the passage is the corresponding source document to be summarized. If an entity appears multiple times in the source document, we rank them based on the fuzzy string-matching scores (a variation of Levenshtein distance) between the query sentence and the source sentence containing the entity. Our models explicitly learn to predict the span of the masked entity rather than pointing to a specific token as in Pointer Network (Vinyals et al., 2015), because the original tokens and replaced tokens often have different lengths.

Our QA-span fact correction model iteratively mask and replace one entity at a time, while the auto-regressive model masks all the entities simultaneously, and replace them in an auto-regressive fashion from left to right. Figure 2 shows an overview of our models. Comparing the two models, the QA-span fact correction model works better when only a few errors exist in the draft summary, as the prediction of each mask is relatively independent of each other. On the other hand, the auto-regressive fact correction model starts with a skeleton summary that has all the entities masked, which is often more robust when summaries contain many factual errors.

3.3 QA-Span Fact Correction Model

In the iterative setting, our model aims to conduct entity correction by answering a query that contains only one mask at a time. Suppose a system summary has T entities. At time step i, we mask the i-th entity and use this masked sequence as the query to our QA-span model. The prediction is placed into the masked slot in the query to generate an updated system summary to be used in the next step.

Given the source text x and a masked query $q = (y'_1, \dots, \texttt{[MASK]}, \dots y'_m)$, our iterative correction model aims to predict the answer span via modeling $p(i = \text{start})$ and $p(i = \text{end})$. For span

---

[1] In this work, we use SpaCy NER tagger (Honnibal and Montani, 2017) to identify entities for data construction.

selection, we use the BertForQuestionAnswering[2] model, which adds two separate non-linear layers on top of Transformers as pointers to the start and end token position for the answer. We initialize the fact-correction model from a pre-trained BERT model (Devlin et al., 2019), and perform finetuning with the span selection datasets we created from the summarization datasets (Figure 1).

The input to the BERT model is a concatenation of two segments: the masked query q and the source x, separated by special delimiter markers as (`[CLS]`, q, `[SEP]`, x). Each token in the sequence is assigned with three embeddings: token embedding, position embedding, and segmentation embedding.[3] These embeddings are summed into a single vector and fed to the multi-layer Transformer model:

$$\tilde{\boldsymbol{h}}^{l} = \text{LN}(\boldsymbol{h}^{l-1} + \text{MHAtt}(\boldsymbol{h}^{l-1}))\,, \tag{2}$$

$$\boldsymbol{h}^{l} = \text{LN}(\tilde{\boldsymbol{h}}^{l} + \text{FFN}(\tilde{\boldsymbol{h}}^{l}))\,, \tag{3}$$

where $\boldsymbol{h}^0$ are the input vectors, and l represents the depth of stacked layers. LN and MHAtt are layer normalization and multi-head attention operations (Vaswani et al., 2017). The top layer provides the hidden states for the input tokens with rich contextual information. The start (s) and end (e) of the answer span are predicted as:

$$a_i^{start} = p(i = s) = \frac{\exp(q_i^s)}{\sum_{j=0}^{H-1} \exp(q_j^s)}\,, \tag{4}$$

$$a_i^{end} = p(i = e) = \frac{\exp(q_i^e)}{\sum_{j=0}^{H-1} \exp(q_j^e)}\,, \tag{5}$$

$$q_i^s = \text{ReLU}(\boldsymbol{w}_s^\top \boldsymbol{h}_i + b_s)\,, \tag{6}$$

$$q_i^e = \text{ReLU}(\boldsymbol{w}_e^\top \boldsymbol{h}_i + b_e)\,, \tag{7}$$

where H is the number of encoder's hidden states, $\boldsymbol{w}_s, \boldsymbol{w}_e \in \mathbb{R}^d$ and $b_s, b_e \in \mathbb{R}$ are trainable parameters. The final span is selected based on the argmax of Eqn. (4) and (5) with the constraint of $p_{start} < p_{end}$ and $p_{end} - p_{start} < k$.

3.4 Auto-regressive Fact Correction Model

One disadvantage of the QA-style span-prediction strategy is that if the sequence contains too many factual errors, masking out one entity at a time may lead to highly erroneous skeleton summary to start with. The model might be making predictions on top of wrong entities from later in the sequence. Masking one entity at a time is essentially a greedy local method that is prone to error accumulation. To alleviate this issue, we propose a new sequential fact correction model to handle errors in a more global manner with beam search. Specifically, we mask out all the entities simultaneously, and use a novel *auto-regressive* span-selection decoder to predict fillers for the multiple masks sequentially. By doing this, we assume dependency between the masks: the earlier predicted entities will be used as corrected context for better predictions in the later steps.

Given a source text $x = (x_1, \ldots, x_n)$ and a draft summary $(y'_1, \ldots y'_m)$. Our model first masks out all the entities (with T masks), and leaves a skeleton summary as the query $q = (y'_1, \ldots, \texttt{[MASK]}_1, \ldots, \texttt{[MASK]}_T \ldots y'_m)$. Then, we concatenate the query q with the source x (similar to Section 3.3) as inputs to the encoder. The inputs are fed into BERT to obtain contextual hidden representations.

We then *select* the encoder's hidden states for the T masks $\boldsymbol{h}_{y'_{mask_1}}, \ldots, \boldsymbol{h}_{y'_{mask_T}}$ as partial input to an auto-regressive Transformer-based decoder. Unlike generation tasks that require an `[EOS]` token to indicate the end of decoding, our decoder runs T steps to predict the answer spans for these T masks. At step t, we first fuse the hidden representation $\boldsymbol{h}_{\texttt{[MASK]}_t} \in \mathbb{R}^d$ of the t-th `[MASK]` token and previously predicted entity representation $\boldsymbol{s}_{t-1}^{ent} \in \mathbb{R}^d$:

$$\boldsymbol{z}_t = \mathbf{W}[\boldsymbol{h}_{\texttt{[MASK]}_t}; \boldsymbol{s}_{t-1}^{ent}]\,, \tag{8}$$

where $\mathbf{W} \in \mathbb{R}^{2d \times d}$, $\boldsymbol{s}_0^{ent} = \boldsymbol{h}_{\texttt{[CLS]}}$ (the representation of `[CLS]` token), and $[;]$ denotes vector concatenation.

The input $\boldsymbol{z}_t$ is then fed to the Transformer decoder (as in Eqn. (2) and (3)) to generate the decoder's hidden state $\boldsymbol{h}'_t$ at time step t. Based on $\boldsymbol{h}'_t$, we use a two-pointer network to predict the start and end positions of the answer entity in the source (encoder's hidden states). This is achieved with cross-attention of $\boldsymbol{h}'_t$ w.r.t. the encoder's hidden states, similar to Eqn (4) and (5). This operation results in two distributions over the encoder's hidden states for the start and end span positions. The final prediction of the start and end positions for mask t is obtained by taking the argmax[4] over

---

[2] https://github.com/huggingface/transformers

[3] The segmentation embedding is used to distinguish the query (with two special tokens `[CLS]` and `[SEP]`) and the source in our models.

[4] The argmax is used for selecting the start and end indexes

the pointer position distributions:

$$p_{start} = \arg\max(a_1^{start}, ..., a_M^{start}) \,, \qquad (9)$$

$$p_{end} = \arg\max(a_1^{end}, ..., a_M^{end}) \,, \qquad (10)$$

under the constraint that $p_{start} < p_{end}$ and $p_{end} - p_{start} < k$.

Based on the start and end positions for the predicted entity, we can obtain the predicted entity representation at time step t as the mean over the in-span encoder's hidden states:

$$\boldsymbol{s}_t^{ent} = \text{Mean-Pool}(\{\boldsymbol{h}_{p_{start}}, \boldsymbol{h}_{p_{end}}\}) \,, \qquad (11)$$

which is used as the input for the next step of decoding. It is worth noting that although the argmax operations in Eqn. (9) and (10) are non-differentiable, the model is trained based on the start and end positions of the ground-truth answer w.r.t. the start and end logits in Eqn. (4) and (5), which makes the gradient back-propagates to the encoder. Meanwhile, the encoder's hidden states used to compose $\boldsymbol{s}_i^{ent}$ in Eqn. (11) also carry the gradients. During inference, beam search is used to find the best sequence of predicted spans in the source to replace the masks.

Compared to the conventional Pointer Network (Vinyals et al., 2015; See et al., 2017) that only points to one token at a time, our sequential span selection decoder has the flexibility to replace a mask by any number of entity tokens, which is often required in summary factual correction.

4 Experiment

In this section, we present our results on using SpanFact for multiple summarization datasets.

4.1 Experimental Setup

Training data for our fact correction models are generated as described in Section 3.2 on CNN/DailyMail (Hermann et al., 2015), XSum (Narayan et al., 2018) and Gigaword (Graff et al., 2003; Rush et al., 2015). The statistics of these three dataset are provided in Table 2. During training, if an entity does not have a corresponding span in the source, we point the answer span to the `[CLS]` token. During inference, if the answer span predicted is the `[CLS]` token, we replace back the original masked entity.

Datasets	# docs (train/val/test)	doc len.	summ. len.	# mask
CNN	90,266/1,220/1093	760.50	45.70	4.40

XSum	204,045/11,332/11,334	431.07	23.26	2.28
Gigaword	3,803,957/189,651/1,951	31.3	8.3	1.97

Table 2: Comparison of summarization datasets on train/validation/test set splits, average document and summary length (numbers of words). We also report the average number of entity masks on the reference summary for each dataset.

Our fact correction models are implemented via the Huggingface Transformers library (Wolf et al., 2019) in PyTorch (Paszke et al., 2017). We initialize all encoder models with the checkpoint of an uncased, large BERT model pretrained on English data and SQuAD for all experiments. Both source and target texts were tokenized with BERT's sub-words tokenizer. The max sequence length is set to 512 for the encoder. We use a shallow Transformer decoder (L=2) for the auto-regressive span selection decoder, as the pre-trained BERT-large encoder is already robust for selecting right spans in the single-span selection task with only two pointers (Section 3.3). The Transformer decoder has 1024 hidden units and the feed-forward intermediate size for all layers is 4,096.

All models were finetuned on our span prediction data for 2 epochs with batch size 12. AdamW optimizer (Loshchilov and Hutter, 2017) with ϵ =1e-8 and an initial learning rate 3e-5 is used for training. Our learning rate schedule follows a linear decay scheduler with warmup=10,000. During inference, we use beam search with $b = 5$ and $k = 10$ (constraint for the distance between the start and end pointer). The best model checkpoints are chosen based on performance on the validation set. Experiments are conducted using 4 Quadro RTX 8000 GPUs with 48GB of memory.

4.2 Evaluation Metrics

We use three automatic evaluation metrics to evaluate our models. The first is ROUGE (Lin, 2004), the standard summarization quality metric, which has high correlation with summary informativeness in the news domain (Kryściński et al., 2019).

Since ROUGE has been criticized for its poor correlation with factual consistency (Kryściński et al., 2019; Wang et al., 2020), we use two additional automatic metrics that specifically focus on factual consistency: FactCC (Kryściński et al.,

---

for the answer span, and the softmax is used for computing the loss for back-propagation.

2019) and QAGS (Wang et al., 2020). FactCC is a pre-trained binary classifier that evaluates the factuality of a system-generated summary by predicting whether it is consistent or inconsistent w.r.t. the source. This classifier was trained on adversarial examples obtained by heuristically injecting noise into reference summaries.

In addition, very recent work proposed QA-based models for factuality evaluation (Wang et al., 2020; Durmus et al., 2020; Maynez et al., 2020), and Wang et al. (2020) showed that their evaluation models have higher correlation with human judgements on factuality when compared with FactCC (Kryściński et al., 2019). We thus include our re-implementation of a question generation and question answering model (QGQA) following Wang et al. (2020) as an evaluation metric for factuality.[5] This model generates a set of questions based on the system-generated summary, and then answers these questions using either the source or the summary to obtain two sets of answers. The answers are compared against each other using an answer-similarity metric (token-level F1), and the averaged similarity metric over all questions is used as the QGQA score. Answers generated from a highly faithful system summary should be similar to those generated from the source.

4.3 Baselines

We compare against the following abstractive summarization baselines. On CNNDM and XSum, we use BertSumAbs, BertSumExtAbs and TransformerAbs (Liu and Lapata, 2019). In addition, we also compare with Bottom-up (Gehrmann et al., 2018). On Gigaword, we use the pointer-generator (See et al., 2017), base and full GenParse models (Song et al., 2020) for comparison. For the factual correction baseline, we compare with the Two-encoder Pointer Generator[6] (Split Encoder) (Shah et al., 2020), which employs a similar setting to ours for masking entities w.r.t. the source, and uses dual encoders to copy and generate from both the source and the masked query for fact update. Compared to our span selection models that can fill in the mask with any number of tokens, their models aim to regenerate the mask query based on the source. In other words, their decoder regenerates the whole sequence token by token with a pointer-generator, which inherits the backbone of generative models that suffer from hallucination.

4.4 Experimental Results

Tables 3, 4, and 5 summarize the results on the CNN/DailyMail, XSum and Gigaword datasets, respectively. Each block in the tables compares the original summarization model's output with

---

[5] We were not able to obtain any of the QA evaluation model or code from Wang et al. (2020); Durmus et al. (2020); Maynez et al. (2020) as the authors are still in the stage of making the code public. We used pre-trained UniLM model for question generation (QG) and BertForQuestionAnswering model for question answering (QA). The QG model is fine-tuned on NewsQA (Trischler et al., 2017) with entity-answer conditional task (Wang et al., 2020), and the QA model is pre-trained on SQuAD 2.0 (Rajpurkar et al., 2018).

Split Encoders	59.46	48.32	33.11	15.63	30.67
QA-Span	58.25	45.62	33.30	15.70	30.95
Auto-regressive	**60.66**	**49.82**	32.86	15.22	30.51

Table 5: Factual correctness scores and ROUGE scores on Gigaword test set.

BertAbs	Better	Worse	Same
QA-Span vs. original	**28.6%**	18.7%	52.7%
Auto-regressive vs. original	**31.3%**	16.7%	52%
QA-Span vs. Auto-regressive	26%	27.3%	46.7%
TransformerAbs	Better	Worse	Same
QA-Span vs. original	**38%**	11.3%	40.7%
Auto-regressive vs. original	**36%**	19.3%	44.7%
QA-Span vs. Auto-regressive	32.7%	28%	39.3%
Bottom-up	Better	Worse	Same
QA-Span vs. original	**34%**	12%	54%
Auto-regressive vs. original	**31.4%**	13.3%	55.3%
QA-Span vs. Auto-regressive	41.3%	32%	26.7%

Table 6: Human evaluation results on pairwise comparison of factual correctness on 450 (9×50) randomly sampled articles.

the corrected outputs obtained by our baseline and proposed models.

On CNN/DailyMail (Table 3), our correction models significantly boost factual consistency measures (QGQA and FactCC) by large margins, with only small drops on ROUGE. This shows our models have the ability to improve the correctness of system-generated summaries without sacrificing informativeness. When comparing our two proposed models, we observe that the QA-span model performs better than the auto-regressive model. This is expected as CNN/DailyMail's reference summaries tend to be more extractive (See et al., 2017), and summarization models tend to make few errors per summary (Narayan et al., 2018). Thus, the iterative procedure of the QA-span model is more robust with high precision as it has more correct context from the query, with only minimum negative influence from other concurrent errors. This is also reflected in the high scores of QGQA and FactCC across all the models we tested. Since QGQA and FactCC are based on comparing system-generated summary w.r.t. the source text, high score means high semantic similarity between system summary to the source.

On XSum (Table 4) and Gigaword (Table 5), both of our correction models boost factual consistency measures by large margins with a slight drop in ROUGE (-0.5 to -1.5) on average. This is still encouraging, as abstractive summarization models that use complex factual controlling components for generation often have drops of 5-10 ROUGE points (Zhu et al., 2020).

We also notice that the QGQA and FactCC scores of all summarization models are lower than that on CNN/DailyMail. The scores are especially low on XSum. This is likely due to the data construction protocol of XSum, where the first sentence of a source document is used as the summary and the remainder of the article is used as the source. As a result, many entities that appear in the reference summary never appear in the source, which may cause abstractive summarization models to hallucinate severely with many factual errors (Maynez et al., 2020). As the system summaries often contain many errors, our QA-span model that relies on answering a single-mask query often has the wrong context to condition on at each step, which negatively affects the performance of this model. In contrast, the strategy of masking all the entities would provide the auto-regressive model a better query for entity replacement. We can observe in Table 4 that the auto-regressive model performs better than the QA-span model on XSum.

4.5 Human Evaluation

To provide qualitative analysis of the proposed models, we conduct human evaluation on pairwise comparison of CNN/DailyMail summaries enhanced by different correction strategies. We select three state-of-the-art abstractive summarization models as the backbones, and collect three sets of pairwise summaries for each setting: (i) Original vs. QA-Span corrected; (ii) Original vs. Auto-regressive corrected; (iii) QA-Span corrected vs. Auto-regressive corrected. Nine sets of 50 randomly selected samples (total 450 samples) are labeled by AMT tuckers. For each pair (in anonymized order), three annotators from Amazon Mechanical Turk (AMT) are asked to judge which is more factually correct based on the

FactCC Dataset	FactCC Score	QAQG	Human Eval
Before Corr.	84.89	88.65	87.79
QA-span	**86.08**	**91.07**	**90.74**
Auto-regressive	85.96	90.51	90.35

Table 7: Test results on the human annotated dataset provided by FactCC (Kryściński et al., 2019). We show the performance comparisons of the original summaries and the summaries corrected by SpanFact.

source document. As shown in Table 6, summaries from our two models are chosen more frequently as the factually correct one compared to the original. Between the two correction models, the preferences are comparable.

In addition, we also test our fact correction models on the FactCC test set provided by Kryściński et al. (2019) and manually checked the outputs. Table 7 shows the results of the original summaries and the summaries corrected by our models in terms of automatic fact evaluation and our manual evaluation. Among 508 system-generated summary sentences, 62 were incorrect. The QA-span model was able to correct 18 out of 62 right, and the auto-regressive model was able to correct 16 out of 62. Among the 446 sentences that are labeled as correct by the annotators in Kryściński et al. (2019), our two models made 3 and 4 wrong changes in the entities, respectively,[7] while keeping most of the entities unchanged or changed with equivalent entities.

5 Conclusion

We present SpanFact, a suite of two factual correction models that use span selection mechanisms to replace one or multiple entity masks at a time. SpanFact can be used for fact correction on any abstractive summaries. Empirical results show that our models improve the factuality of summaries generated by state-of-the-art abstractive summarization systems without a huge drop on ROUGE scores. For future work, we plan to apply our method for other type of spans, such as noun phrases, verbs, and clauses.

Evaluating the Factual Consistency of Abstractive Text Summarization

Abstract

The most common metrics for assessing summarization algorithms do not account for whether summaries are factually consistent with source documents. We propose a weakly-supervised, model-based approach for verifying factual consistency and identifying conflicts between source documents and generated summaries. Training data is generated by applying a series of rule-based transformations to the sentences of source documents. The factual consistency model is then trained jointly for three tasks: 1) predict whether each summary sentence is factually consistent or not, 2) in either case, extract a span in the source document to support this consistency prediction, 3) for each summary sentence that is deemed inconsistent, extract the inconsistent span from it. Transferring this model to summaries generated by several neural models reveals that this highly scalable approach outperforms previous models, including those trained with strong supervision using datasets from related domains, such as natural language inference and fact checking. Additionally, human evaluation shows that the auxiliary span extraction tasks provide useful assistance in the process of verifying factual consistency. We also release a manually annotated dataset for factual consistency verification, code for training data generation, and trained model weights at `https://github.com/salesforce/factCC`.

1 Introduction

The goal of text summarization is to transduce long documents into a shorter form that retains the most important aspects from the source document. Common approaches to summarization are *extractive* (Dorr et al., 2003; Nallapati et al., 2017) where models directly copy salient parts of the source document into the summary, *abstractive* (Rush et al., 2015; Paulus et al., 2017) where the important parts are paraphrased to form novel sentences, and *hybrid* (Gehrmann et al., 2018), combining the two methods by employing specialized extractive and abstractive components.

Advancements in neural architectures (Cho et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017), transfer learning (McCann et al., 2017; Devlin et al., 2018), and availability of large-scale supervised datasets (Nallapati et al., 2016; Grusky et al., 2018) allowed deep learning-based approaches to dominate the field. State-of-the-art solutions utilize self-attentive Transformer blocks (Liu, 2019; Liu and Lapata, 2019), attention and copying mechanisms (See et al., 2017; Cohan et al., 2018), and multi-objective training strategies (Guo et al., 2018; Pasunuru and Bansal, 2018), including reinforcement learning techniques (Kryściński et al., 2018; Dong et al., 2018; Wu and Hu, 2018).

Despite significant efforts made by the research community, there are still many challenges limiting progress in summarization: insufficient evaluation protocols that omit important dimensions, such as factual consistency, noisy datasets that leave the task underconstrained, and strong, domain-specific layout biases in the data that dominate training signal (Kryściński et al., 2019).

We address the problem of verifying factual consistency between source documents and generated summaries: a factually consistent summary contains only statements that are entailed by the source document. Recent studies show that up to 30% of summaries generated by abstractive models contain factual inconsistencies (Cao et al., 2018; Goodrich et al., 2019; Falke et al., 2019; Kryściński et al., 2019). Such high levels of factual inconsistency render automatically generated summaries virtually useless in practice.

The problem of factual consistency is closely related to natural language inference (NLI) and fact

checking. Current NLI datasets (Bowman et al., 2015; Williams et al., 2018) focus on classifying logical entailment between short, single sentence pairs, but verifying factual consistency requires the entire source document. Fact checking focuses on verifying facts against the whole of available knowledge, whereas factual consistency checking focuses on adherence of facts to information provided by a source document without guarantee that the information is true.

We propose a novel, weakly-supervised BERT-based (Devlin et al., 2018) model for verifying factual consistency, and we add specialized modules that explain which portions of both the source document and generated summary are pertinent to the model’s decision. Training data is generated from source documents by applying a series of rule-based transformations that were inspired by error-analysis of neural summarization model outputs. Through human evaluation we show that the explanatory modules that augment our factual consistency model provide useful assistance to humans as they verify the factual consistency between a source document and generated summaries. Together with this manuscript we release a manually annotated dataset for factual consistency verification, code for training data generation, and trained model weights at `https://github.com/salesforce/factCC`.

2 Related Work

This work builds on prior research in factual consistency in text summarization and natural language generation. Goodrich et al. (2019) proposed an automatic, model-dependent metric for evaluating the factual accuracy of generated text. Facts are represented as *subject-relation-object* triplets and factual accuracy is defined as the precision between facts extracted from the summary and source document. Despite positive results, the authors highlighted remaining challenges, such as its inability to adapt to negated relations or relation names expressed by synonyms.

A parallel line of research focused on improving factual consistency of summarization models by exploring different architectural choices and strategies for both training and inference. In Falke et al. (2019), the authors proposed re-ranking potential summaries based on factual correctness during beam search. The solution used textual entailment (NLI) models to score summaries by means of the entailment probability between all source document-summary sentence pairs. The summary with the highest aggregate entailment score was used as the final output of the summarization model. The authors concluded that out-of-the-box NLI models do not transfer well to the task of factual correctness. In Cao et al. (2018), the authors proposed a novel, dual-encoder architecture that in parallel encodes the source documents and all the facts contained in them. During generation, the decoder attends to both the encoded source and facts which, according to the authors, forces the output to be conditioned on the both inputs. Human evaluation showed that the proposed technique substantially lowered the number of errors in generated single-sentence summaries.

The synthetic data generation process proposed as part of our approach is based on prior work done in the domains of data augmentation and weakly-supervised learning. Wei and Zou (2019) proposed an augmentation framework aimed at boosting performance of text classification models. The authors used 4 text transformations to synthesize data: synonym replacement, random insertion, random swap, random deletion, and showed increased performance of classifiers on 5 downstream tasks, both for convolutional and recurrent neural models. In (Sennrich et al., 2015; Edunov et al., 2018) the authors introduced and analyzed the effects of using backtranslation based data augmentation on the performance of machine translation models, while Iyyer et al. (2018) used the mentioned transformation to synthesize training data for a paraphrase generation network. Meng et al. (2018) investigated a two step approach for training text classification models on weakly-supervised data, which includes pretraining models on fully synthetic data.

3 Methods

A careful study of the outputs of state-of-the-art summarization models provided us with valuable insights about the specifics of factual errors made during generation and possible means of detecting them. Primarily, checking factual consistency on a *sentence-sentence* level, where each sentence of the summary is verified against each sentence from the source document, is insufficient. Some cases might require a longer, multi-sentence context from the source document due to ambiguities present in either of the compared sentences. Summary sentences might paraphrase multiple fragments of the source document, while source document sentences might use certain linguistic constructs, such as coreference, which bind different parts of the document together. In addition, errors made by summarization models are most often related to the use of incorrect entity names, numbers, and pronouns. Other errors such as negations and common sense error occur less often. Taking these insights into account, we propose and test a *document-sentence* approach for factual consistency checking, where each sentence of the summary is verified against the entire body of the source document.

3.1 Training data

Currently, there are no training datasets for factual consistency checking. Creating a large-scale, high-quality dataset with supervision collected from human annotators is expensive and time consuming. We consider an alternative approach to acquiring training data that is highly scalable.

Considering the state of summarization, in which the level of abstraction of generated summaries is low and models mostly paraphrase single sentences and short spans from the source (Kryściński et al., 2018; Zhang et al., 2018), we propose using a synthetic, weakly-supervised dataset for the task at hand. Our data creation method requires an unannotated collection of source documents in the same domain as the summarization models that are to be checked. Examples are created by first sampling single sentences, later referred to as *claims*, from the source documents. Claims then pass through a set of textual transformations that output novel sentences with both *positive* and *negative* labels. Though transformations are applied to single sentences, we found that, in keeping with our aforementioned observations of model-generated summaries, the process of verifying their consistency often requires referring to the entire document. A detailed description of the data generation function is presented in Figure 1. The benefit of using a synthetic dataset is that it allows for creation of large volumes of data at a marginal cost. The data generation process also allows to collect additional metadata that can be used in the training process. In our case, the metadata contains information about the original location of the extracted claim in the source document and the locations in the claim where text transformations were applied.

Our data generation process draws inspiration from data augmentation and adversarial example generation techniques in NLP (Iyyer et al., 2018; Wu et al., 2019; Zhang et al., 2019; Wei and Zou, 2019). The proposed process incorporates both semantically invariant ($\mathcal{T}^+$), and variant ($\mathcal{T}^-$) text transformations to generate novel claims with `CORRECT` and `INCORRECT` labels accordingly. This work uses the following transformations:

Paraphrasing A paraphrasing transformation covers cases where source document sentences are rephrased by the summarization model. Paraphrases were produced by backtranslation using Neural Machine Translation systems (Iyyer et al., 2018). The claim sentence was translated to an intermediate language and translated back to English yielding a semantically-equivalent sentence with minor syntactic and lexical changes. *French*, *German*, *Chinese*, *Spanish*, and *Russian* were used as intermediate languages. These languages were chosen based on the performance of recent NMT systems with the expectation that well-performing languages could ensure better translation quality.

Transformation	Original sentence	Transformed sentence
Paraphrasing	Sheriff Lee Baca has now decided to recall some 200 badges his department has handed out to local politicians just two weeks after the picture was released by the U.S. attorney's office in support of bribery charges against three city officials.	Two weeks after the US Attorney's Office issued photos to support bribery allegations against three municipal officials, Lee Baca has now decided to recall about 200 badges issued by his department to local politicians.
Sentence negation	Snow was predicted later in the weekend for Atlanta and areas even further south.	Snow wasn't predicted later in the weekend for Atlanta and areas even further south.
Pronoun swap	It comes after his estranged wife Mona Dotcom filed a $20 million legal claim for cash and assets.	It comes after your estranged wife Mona Dotcom filed a $20 million legal claim for cash and assets.
Entity swap	Charlton coach Guy Luzon had said on Monday: 'Alou Diarra is training with us.'	Charlton coach Bordeaux had said on Monday: 'Alou Diarra is training with us.'
Number swap	He says he wants to pay off the $12.6million lien so he can sell the house and be done with it.	He says he wants to pay off the $3.45million lien so he can sell the house and be done done with it.
Noise injection	Snow was predicted later in the weekend for Atlanta and areas even further south.	Snow was was predicted later in the weekend for Atlanta and areas ~~even~~ further south.

Table 2: Examples of text transformations used to generate training data. Green and red text highlight the changes made by the transformation. Paraphrasing is a semantically invariant transformation, Sentence negation, entity, pronoun, and number swaps are semantically variant transformation.

We used the Google Cloud Translation API [1] for translations.

Entity and Number swapping To learn how to identify examples where the summarization model used incorrect numbers or entities during generation we used the Entity and Number swapping transformation. An NER system was applied to both the claim and source document to extract all entities. To generate a novel, semantically changed claim, an entity in the claim sentence was replaced with an entity from the document. Both of the swapped entities were chosen at random while ensuring that they were unique. Extracted entities were divided into two groups, *named entities*, covering person, location and institution names, and *numbers*, such as dates and all other numeric values. Entities were swapped within their respective groups. We used the SpaCy NER tagger (Honnibal and Montani, 2017).

Pronoun swapping To learn how to find incorrect pronoun use in claims we used a pronoun swapping transformation. First, all gender-specific pronouns were first extracted from the claim. Next, a randomly chosen pronoun was swapped with a different one from the same pronoun group to ensure syntactic correctness, i.e. a possessive pronoun could only be replaced with another possessive pronoun. New sentences were considered semantically variant.

Sentence negation To give the consistency checking model the ability to handle negated sentences we used a sentence negation transformation. First, a claim was scanned in search of auxiliary verbs. To switch the meaning, a randomly chosen auxiliary verb was replaced with its negation. Positive sentences would be negated by adding *not* or *n't* after the verb, negative sentences would be switched by removing the negation.

Noise injection Given that verified summaries are generated by neural networks, they should be expected to contain certain types of noise. In order to make the factual consistency model robust to such generation errors, training examples were injected with noise. For each token in a claim the decision was made whether noise should be added at the given position with a preset probability. If noise should be injected, the token was randomly duplicated or removed from the sequence. Examples of all transformations are shown in Table 2.

3.2 Development and test data

Apart from the synthetic training set, separate, manually annotated, validation and test sets were created. Both of the annotated sets used summaries output by state-of-the-art summarization models. Each summary was split into sentences and all *(document, sentence)* pairs were annotated by the authors of this work. Since the focus was to collect data for verifying the factual consistency of summarization models, any unreadable sentences

caused by poor generation were not labeled. The validation set consists of 931 examples, the test set contains 503 examples. The model outputs used for annotation were provided by the authors of papers: Hsu et al. (2018); Gehrmann et al. (2018); Jiang and Bansal (2018); Chen and Bansal (2018); See et al. (2017); Kryściński et al. (2018); Li et al. (2018); Pasunuru and Bansal (2018); Zhang et al. (2018); Guo et al. (2018).

Effort was made to collect a larger set of annotations through crowdsourcing platforms, however the inter-annotator agreement and general quality of annotations was too low to be considered reliable. This aligns with the conclusions of (Falke et al., 2019), where the authors showed that for the task of factual consistency the inter-annotator agreement coefficient κ reached 0.75 only when 12 annotations were collected for each example. This in turn yields high annotations costs that our approach aims to circumvent.

Model	CNN/DailyMail Accuracy *(weighted)*	CNN/DailyMail F1-score	XSum Accuracy *(weighted)*	XSum F1-score
BERT+MNLI	51.39	0.86	**59.92**	0.58
BERT+FEVER	52.07	**0.88**	55.23	0.26

FactCCX (ours)	**72.88**	0.87	53.05	0.60

Table 3: Performance of models evaluated by means of weighted (class-balanced) accuracy and F1 score on the manually annotated test set of CNN/DailyMail (this work) and XSum (Maynez et al., 2020).

3.3 Models

Considering the significant improvements in natural language understanding (NLU) tasks (including NLI) coming from using pre-trained Transformer-based models [2], we decided to use BERT (Devlin et al., 2018) as the base model for our work. An *uncased*, *base* (110M params) BERT architecture was used as the starting checkpoint and fine-tuned on the generated training data. The source document and claim sentence were fed as input to the model and two-way classification (`CONSISTENT`/`INCONSISTENT`) was done using a single-layer classifier based on the `[CLS]` token. We refer to this model as the factual consistency checking model (**FactCC**).

We also trained a version of FactCC with additional span selection heads using supervision of start and end indices for selection and transformation spans in the source and claim. Span selection heads allow the model not only to classify the consistency of the claim, but also highlight spans in the source document that contain the support for the claim and spans in the claim where a possible mistake was made. We refer to this model as the factual consistency checking model with explanations (**FactCCX**).

4 Experiments

4.1 Experimental Setup

Training data was generated as described in Section 3.1 using news articles from the CNN/DailyMail (Nallapati et al., 2016) dataset as source documents. 1,003,355 training examples were created, out of which 50.2% were labeled as negative (`INCONSISTENT`) and the remaining 49.8% were labeled as positive (`CONSISTENT`). Models were evaluated in two settings: 1) with summaries from models trained on the CNN/DailyMail (Nallapati et al., 2016) dataset, which contains longer and more extractive reference summaries, and 2) with summaries from models trained on the XSum (Narayan et al.,

2018) dataset, which contains single-sentence, highly abstractive reference summaries. The CNN/DailyMail validation and test sets were manually annotated, as described in Section 3.2, while the XSum test data was collected by Maynez et al. (2020)

Models were implemented using the Transformers library (Wolf et al., 2019) written in PyTorch (Paszke et al., 2017). Models were trained for 10 epochs using batch size of 12 examples and learning rate of `2e-5`. Experiments were conducted on 8 Nvidia V100 GPUs, training took 23 hours on average. Best model checkpoints were chosen based on the performance on the validation set, final model performance was evaluated on the test set.

4.2 Results

To understand whether datasets for related tasks transfer to the task of verifying factual consistency of summarization models, we trained factual consistency checking models on the MNLI entailment data (Williams et al., 2018) and FEVER fact-checking data (Thorne et al., 2018). For fair comparison, before training, we removed examples assigned to the neutral class from both of the datasets. Table 3 shows the performance of trained models evaluated by means of class-balanced accuracy and F1 score. Both FactCC and FactCCX models substantially outperform classifiers trained on the MNLI and FEVER datasets when evaluated on the CNN/DailyMail test set. However, on the more abstractive XSum data, results show a reverse trend with the MNLI model achieving highest performance. Considering that both MNLI and FEVER datasets contain abstractive, human-written claims, while our data generation pipeline lacks multi-sentence paraphrasing transformations, such outcome was expected. In the case of more extractive outputs, the results suggests priority of weak-supervision in-domain over strong-supervision in adjacent domains for factual consistency checking.

To compare our models with other NLI models for factual consistency checking, we conducted the sentence ranking experiment described by Falke et al. (2019) using the test data provided by the authors. In this experiment an article sentence is paired with two claim sentences, *positive* and *negative*. The goal is to see how often a model assigns a higher probability of being correct to the positive rather than the negative claim. Results are presented in Table 5. Despite being trained in a *(document, sentence)* setting, our model transfers well to the *(sentence-sentence* setting and outperforms all other NLI models, including BERT fine-tuned on the MNLI dataset. We were unable to replicate the summary re-ranking experiment because the experimental test setup does not rely on data that can be reused.

Considering that strongly supervised data is not available for factual consistency verification, proxy datasets must be used to train automatic verification models. Empirical results presented in this section suggest that when verifying less abstractive domains, it is more beneficial to train on weakly-supervised, but in-domain data, rather than to rely on the models ability to transfer knowledge from strongly supervised datasets in related domains. The experiments also highlight the necessity of extending the data generation pipeline with more abstractive, multi-sentence paraphrasing transformations as part of future work.

In addition to improved performance, using synthetic data allows to train models with explainable components, such as FactCCX. Examples of span selections generated by the model are show in Table 4. The test set consists of model-generated summaries that do not have annotations for quantifying the quality of spans returned by FactCCX. Instead, span quality is measured through human evaluation and discussed in Section 5.

5 Analysis

To further understand performance of our proposed models, we conducted human-based experiments and manually inspected model outputs.

5.1 Human Studies

Experiments using human annotators demonstrated that the span highlights returned by FactCCX are useful tools for researchers and crowdsource workers manually assessing the factual consistency of summaries. For each experiment, examples were annotated by 3 human judges selected from English-speaking countries. These experiments used 100 examples sampled from the manually annotated CNN/DM test set. Data points were sampled to ensure an equal split between `CONSISTENT` and `INCONSISTENT` examples.

To establish whether model-generated highlighted spans in the article and claim are helpful for the task of factual consistency checking, we hired human annotators to complete the mentioned task. Each of the verified *document-sentence* pairs was augmented with the highlighted spans output by FactCCX. Judges were asked to evaluate the correctness of the claim and instructed to use the provided segment highlights as suggestions. After the annotation task, judges were asked whether the highlighted spans were helpful for solving the task. The helpfulness of *article* and *claim* highlights were evaluated separately. The left part of Table 6 presents the results of the survey. A combined number of 91.75% annotators found the article highlights at least somewhat helpful, 81.33% of annotators found the claim highlights at least somewhat helpful. To ensure that low-quality judges do not bias the scores, we applied different data filters to the annotations: *Raw Data* considered all submitted annotations, *Golden Aligned* only considered annotations where the annotator-assigned label aligned with the author-assigned label for the example, *Majority Aligned* only considered examples where the annotator-assigned aligned with the majority-vote label assigned for the example by all judges. As shown in Table 6, filtering the annotations does not yield substantial changes in the helpfulness assessment.

Despite instructing the annotators to consider the provided highlights only as a suggestion when solving the underlying task, the annotators perception of the task could have been biased by the model-highlighted spans. To check how well the model-generated span highlights align with an unbiased human judgement, we repeated the previous experiment with only one change: model-generated highlights were not displayed to the annotators. The annotators were asked to solve the underlying task and highlight the spans of the source and claim that they found adequate. Using the annotations provided by the judges, we computed the overlap between the model-generated spans and unbiased human spans. Results are shown in the right part of Table 6. The overlap between spans was evaluated using two metrics. *Accuracy* is based on a binary score of whether the entire model-generated span was contained within the human-selected span. *F1* score is computed between the tokens of the model-generated span and the tokens of the human-selected span. Results show 65.33% and 65.66% *accuracy* and 0.6207 and 0.6650 *F1* for the *article* and *claim* highlights, respectively. We again applied different data filters to understand how the quality of annotations affects the score. We found that in this case, *accuracy* and *F1* score were higher in the *Majority Aligned* than in the case of using *Raw Data*, and performance increases dramatically in the *Majority Aligned*. This suggests that when model-generated highlights are not provided, the task is less constrained and requires more careful preci-

	Model Highlight Helpfulness			Model-Annotator Highlight Overlap	
Annotation subset	Helpful	Somewhat Helpful	Not Helpful	Accuracy	F1 score
Article Highlights					
Raw Data	79.21%	12.54%	8.25%	65.33%	0.6207
Golden Aligned	77.73%	12.66%	9.61%	74.87%	0.7161
Majority Aligned	81.11%	11.48%	7.41%	69.88%	0.6679
Claim Highlights					
Raw Data	64.44%	16.89%	18.67%	65.66%	0.6650
Golden Aligned	67.28%	16.05%	16.67%	80.54%	0.8190
Majority Aligned	67.17%	16.67%	16.16%	69.48%	0.6992

Table 6: Quality of spans highlighted in the *article* and *claim* by the FactCCX model evaluated by human annotators. The left side shows whether the highlights were considered helpful for the task of factual consistency annotations. The right side shows the overlap between model generated and human annotated highlights. Different rows show how the scores change depending on how the collected annotations are filtered.

sion on the part of judges.

To further understand the affects of providing model-generated highlights to annotators, we ran two factual consistency annotation tasks designed to test annotation efficiency. In the first, highlights were provided to the annotators. In the second, annotators did not receive highlights. In both, we measured the average time spent by an annotator on the task and the inter-annotator agreement of annotations. Results are shown in Table 7. When completing the task with highlights, annotators were 21% faster, and the inter-annotator agreement, measured with Fleiss' κ, increased by 38%.

Crowdsourcing experiments support the hypothesis that model-generated highlights from FactCCX can play a valuable role in supporting human-based factual consistency checking.

5.2 Qualitative Study

To better understand the limitations of our proposed approach, we manually inspected examples that were misclassified by our models. The majority of errors were related to commonsense mistakes made by summarization models. Humans can easily spot such errors, but they are difficult to capture with transformations necessary to generate data for weak supervision.

Our analysis also showed that the proposed models fail to correctly classify examples where the verified claim is highly abstractive. This is especially true when the claim finds support in multiple spans distant from each other in the source document, as mostly found in the XSum dataset. Additionally, the current set of transformations do not adequately capture temporal inconsistencies or incorrect coreference. Nonetheless, the current transformations yield models already useful to humans by their own judgment; this analysis points toward key areas for future work. Correct and incorrect model predictions are presented in Appendix A.

	Task without model highlights	Task with model highlights
Average work time (sec)	224.89	178.34
Inter-annotator agreement (κ)	0.1571	0.2526

Table 7: Annotation speed and inter-annotator agreement measured for factual consistency checking with and without assisting, model generated highlights.

6 Conclusions

We introduced a novel approach for factual consistency checking of summaries generated by abstractive neural models. In our approach, models are trained to perform factual consistency checking on the *document-sentence* level, which allows them to handle a broader range of errors in comparison to previously proposed *sentence-sentence* approaches. Models are trained using artificially generated, weakly-supervised data created based on insights coming from the analysis of errors made by state-of-the-art summarization models. Quantitative studies showed that on less abstractive domains, such as CNN/DailyMail news articles, our proposed approach outperforms other models trained on existing textual entailment and fact-checking data, motivating our use of weak-supervision over transfer learning from related domains. Experiments with human annotators showed that our proposed approach, including an explainable factual consistency checking model, can be a valuable tool for assisting humans in factual consistency checking. Shortcomings of our approach explained in Section 5.2 can serve as guidelines for future work. We hope that this work will encourage continued research into factual consistency checking of abstractive summarization models.

Article (CNN/DM)

(cnn) james best, best known for his portrayal of bumbling sheriff rosco p. coltrane on tv's "the dukes of hazzard," died monday after a brief illness. he was 88. best died in hospice in hickory, north carolina, of complications from pneumonia, said steve latshaw, a longtime friend and hollywood colleague. although he'd been a busy actor for decades in theater and in hollywood, best didn't become famous until 1979, when "the dukes of hazzard's" cornpone charms began beaming into millions of american homes almost every friday night. for seven seasons, best's rosco p. coltrane chased the moonshine-running duke boys back and forth across the back roads of fictitious hazzard county, georgia, although his "hot pursuit" usually ended with him crashing his patrol car. although rosco was slow-witted and corrupt, best gave him a childlike enthusiasm that got laughs and made him endearing. his character became known for his distinctive "kew-kew-kew" chuckle and for goofy catchphrases such as "cuff 'em and stuff 'em!" upon making an arrest. among the most popular shows on tv in the early '80s, "the dukes of hazzard" ran until 1985 and spawned tv movies, an animated series and video games. several of best's "hazzard" co-stars paid tribute to the late actor on social media. (...)

Claim

"hazzard" ran from 1979 to 1985 and was among the most popular shows on tv.

Article (CNN/DM)

(cnn) the attorney for a suburban new york cardiologist charged in what authorities say was a failed scheme to have another physician hurt or killed is calling the allegations against his client "completely unsubstantiated." appearing Saturday morning on cnn's "new day," randy zelin defended his client, dr. anthony moschetto, who faces criminal solicitation, conspiracy, burglary, arson, criminal prescription sale and weapons charges in connection to what prosecutors called a plot to take out a rival doctor on long island. "none of anything in this case has any evidentiary value," zelin told cnn's christi paul. "it doesn't matter what anyone says, he is presumed to be innocent." moschetto, 54, pleaded not guilty to all charges wednesday. he was released after posting $2 million bond and surrendering his passport. zelin said that his next move is to get dr. moshetto back to work. "he's got patients to see. This man, while he was in a detention cell, the only thing that he cared about were his patients. and amazingly, his patients were flooding the office with calls, making sure that he was ok," zelin said. (...)

Claim

a lawyer for dr. anthony moschetto says the charges against him are baseless.

Article (CNN/DM)

(cnn) north korea accused mexico of illegally holding one of its cargo ships wednesday and demanded the release of the vessel and crew. the ship, the mu du bong, was detained after it ran aground off the coast of mexico in july. mexico defended the move wednesday, saying it followed proper protocol because the company that owns the ship, north korea's ocean maritime management company, has skirted united nations sanctions. "because the company has avoided the sanctions imposed by the u.n. security council, the mexican government is acting on the basis of its international obligations as a responsible u.n. member state," the permanent mission of mexico to the united nations said. the security council blacklisted ocean maritime management in july, saying it "played a key role in arranging the shipment of concealed arms and related materiel" on another ship, the chong chon gang, which was detained by panama in 2013. but an myong hun, north korea's deputy ambassador to the united nations, said there was no reason to hold the mu du bong and accused mexico of violating the crew members' human rights by keeping them from their families.

Claim

north korea accused mexico of using one of its cargo ships.

More than 5,300 bottles of alcohol were seized by the investigators in the southern city of Liuzhou. They also found packets of a white powder called Sildenafil, better known as the anti-impotence drug Viagra. Police in the Guangxi region are now investigating the two distillers. The Liuzhou Food and Drug Administration said (in Chinese) that the powder was added to three different types of 'baijiu' - a strong, clear spirit that is the most popular drink in China. They said the haul was worth up to 700,000 yuan. Doctors recommend that adults requiring prescription should take only one dose of Viagra a day, with a lower dose for those over the age of 65. China continues to face widespread food safety problems. In June, police in cities across China seized more than 100,000 tonnes of smuggled meat, some of which was more than 40 years old. The 2008 tainted milk scandal outraged the nation. Some 300,000 people were affected and at least six babies died after consuming milk adulterated with melamine.

Claim

police in southern china have seized more than 1,000 alcohol bottles and seized more than 1,200 bottles of contaminated milk, local media report.

Article (XSUM)

A review for the Commission on Local Tax Reform said there was no ”magic bullet” to cure defects in the system. It said the council tax had built-in problems ”from day one” but a failure to modify it had stored up more difficulties for policy makers. The commission, set up by the Scottish government and council body Cosla, will report back later this year. Prof Kenneth Gibb, from the University of Glasgow, was asked to review different systems of local taxation across the world. He found that a tax on property was used by almost all OECD countries and was seen by academics as a ”good tax” because it was stable, difficult to avoid and could have a desirable impact on housing markets. But it also generated confusion with taxpayers unclear whether it was a tax on wealth or a charge for services such as refuse collection. Some felt it was unfair because it was not linked to current income. Prof Gibb noted that a local income tax, used by many countries, was generally perceived as fairer. But he found such a system created difficulties for local authorities because it meant their income fluctuated. There was also little opportunity to vary tax rates to reflect local priorities. He said: ”It is clear there is no magic bullet. ”Past experience from the UK and across the world shows that reform is always going to be difficult and will inevitably be bound up with the previous experiences and traumas of past reform. ”So whilst the current council tax has many deficiencies, change and reform is a major undertaking.” The commission now intends to hold a public consultation across Scotland before publishing its report in the autumn. A Scottish government spokesman said ministers consider the current council tax system ”as a whole to be unfair”. He added: ”That is why, along with our local government partners, we have established the cross-party Commission on Local Tax Reform to examine fairer alternatives. ”The Scottish government awaits the commission’s report, which is due in the Autumn.

Claim

the scottish government has been accused of ”unfairly unfair” by a watchdog after a report found that a council tax system was not stored

Article (XSUM)

The Australian, 21, beat world number 29 Querrey 6-4 6-4 in 53 minutes to progress to the second round. Kyrgios, ranked a career-high 12th in the world, won the Japan Open on Sunday and is closing in on the top 10. ”I was just a bit bored at times,” said Kyrgios, when asked why he was not his usual vocal self against Querrey. ”I was feeling very tired. It was just tough. I’m just tired so maybe I just wanted to get the job done.” Kyrgios said his success in Japan, and the travelling involved in playing at the Qi Zhong Stadium, an hour from Shanghai city centre, had taken its toll. ”I didn’t have the greatest sleep last night and obviously got in late the day before,” he said. ”The ride to the courts isn’t great either.” It was at the Shanghai Masters last year that Kyrgios was fined $1,500 for a foul-mouthed outburst, describing the tournament a ”circus”.

Claim

australia’s nick kyrgios said he was ”not afraid to sleep” after reaching the second round of the shanghai masters.

Re-evaluating Evaluation in Text Summarization

Manik Bhandari, Pranav Gour, Atabak Ashfaq, Pengfei Liu, Graham Neubig
Carnegie Mellon University
`{mbhandar,pgour,aashfaq,pliu3,gneubig}@cs.cmu.edu`

Abstract

Automated evaluation metrics as a stand-in for manual evaluation are an essential part of the development of text-generation tasks such as text summarization. However, while the field has progressed, our standard metrics have not – for nearly 20 years ROUGE has been the standard evaluation in most summarization papers. In this paper, we make an attempt to *re-evaluate the evaluation method* for text summarization: assessing the reliability of automatic metrics using *top-scoring system outputs*, both abstractive and extractive, on *recently popular datasets* for both system-level and summary-level evaluation settings. We find that conclusions about evaluation metrics on older datasets do not necessarily hold on modern datasets and systems. We release a dataset of human judgments that are collected from 25 top-scoring neural summarization systems (14 abstractive and 11 extractive): `https://github.com/neulab/REALSumm`

1 Introduction

In text summarization, *manual evaluation*, as exemplified by the Pyramid method (Nenkova and Passonneau, 2004), is the gold-standard in evaluation. However, due to time required and relatively high cost of annotation, the great majority of research papers on summarization use exclusively automatic evaluation metrics, such as ROUGE (Lin, 2004) , JS-2 (Louis and Nenkova, 2013), S3 (Peyrard et al., 2017), BERTScore (Zhang et al., 2020), MoverScore (Zhao et al., 2019) etc. Among these metrics, ROUGE is by far the most popular, and there is relatively little discussion of how ROUGE may deviate from human judgment and the potential for this deviation to change conclusions drawn regarding relative merit of baseline and proposed methods. To characterize the relative goodness of evaluation metrics, it is necessary to perform *meta-evaluation* (Graham, 2015; Lin and Och, 2004), where a dataset annotated with human judgments (e.g. TAC[1] 2008 (Dang and Owczarzak, 2008)) is used to test the degree to which automatic metrics correlate therewith.

However, the classic TAC meta-evaluation datasets are now 6-12 years old[2] and it is not clear whether conclusions found there will hold with modern systems and summarization tasks. Two earlier works exemplify this disconnect: (1) Peyrard (2019) observed that the human-annotated summaries in the TAC dataset are mostly of lower quality than those produced by modern systems and that various automated evaluation metrics strongly disagree in the higher-scoring range in which current systems now operate. (2) Rankel et al. (2013) observed that the correlation between ROUGE and human judgments in the TAC dataset decreases when looking at the best systems only, even for systems from eight years ago, which are far from today's state-of-the-art.

Constrained by few existing human judgment datasets, it remains unknown how existing metrics behave on current top-scoring summarization systems. In this paper, we ask the question: does the rapid progress of model development in summarization models require us to *re-evaluate* the evaluation process used for text summarization? To this end, we create and release a large benchmark for meta-evaluating summarization metrics including:

- **Outputs** from 25 top-scoring extractive and abstractive summarization systems on the `CNN/DailyMail` dataset.
- **Automatic evaluations** from several evaluation metrics including traditional metrics (e.g. ROUGE) and modern semantic matching metrics (e.g. BERTScore, MoverScore).

---

[1] https://tac.nist.gov/

[2] In TAC, summarization was in 2008, 2009, 2010, 2011, 2014. In 2014, the task was biomedical summarization.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9347–9359,
November 16–20, 2020.

Ability of metrics to	Observations on existing human judgments (`TAC`)	Observations on new human judgments (`CNNDM`)
Exp-I: evaluate all systems? (Sec. 4.1)	MoverScore and JS-2 outperform all other metrics.	ROUGE-2 outperforms all other metrics. MoverScore and JS-2 performs worse both in extractive (only achieved nearly 0.1 *Pearson* correlation) and abstractive summaries.
Exp-II: evaluate top-k systems? (Sec. 4.2)	As k becomes smaller, ROUGE-2 de-correlates with humans.	For extractive and abstractive systems, ROUGE-2 highly correlates with humans. For evaluating a mix of extractive and abstractive systems, all metrics de-correlate.
Exp-III: compare 2 systems? (Sec. 4.3)	MoverScore and JS-2 outperform all other metrics.	ROUGE-2 is the most reliable for abstractive systems while ROUGE-1 is most reliable for extractive systems.
Exp-IV: evaluate summaries? (Sec. 4.4)	(1) MoverScore and JS-2 outperform all other metrics. (2) Metrics have much lower correlations when evaluating summaries than systems.	(1) ROUGE metrics outperform all other metrics. (2) For extractive summaries, most metrics are better at evaluating summaries than systems. For abstractive summaries, some metrics are better at summary level, others are better at system level.

Table 1: Summary of our experiments, observations on existing human judgments on the `TAC`, and contrasting observations on newly obtained human judgments on the `CNNDM` dataset. Please refer to Sec. 4 for more details.

- **Manual evaluations** using the lightweight pyramids method (Shapira et al., 2019), which we use as a gold-standard to evaluate summarization systems as well as automated metrics.

Using this benchmark, we perform an extensive analysis, which indicates the need to re-examine our assumptions about the evaluation of automatic summarization systems. Specifically, we conduct four experiments analyzing the correspondence between various metrics and human evaluation. Somewhat surprisingly, we find that many of the previously attested properties of metrics found on the `TAC` dataset demonstrate different trends on our newly collected `CNNDM` dataset, as shown in Tab. 1. For example, MoverScore is the best performing metric for evaluating summaries on dataset `TAC`, but it is significantly worse than ROUGE-2 on our collected `CNNDM` set. Additionally, many previous works (Novikova et al., 2017; Peyrard et al., 2017; Chaganty et al., 2018) show that metrics have much lower correlations at comparing summaries than systems. For extractive summaries on `CNNDM`, however, most metrics are better at comparing summaries than systems.

Calls for Future Research These observations demonstrate the limitations of our current best-performing metrics, highlighting (1) the need for future meta-evaluation to (i) be across multiple datasets and (ii) evaluate metrics on different application scenarios, e.g. summary level vs. system level (2) the need for more systematic meta-evaluation of summarization metrics that updates with our ever-evolving systems and datasets, and (3) the potential benefit to the summarization community of a shared task similar to the WMT[3] Metrics Task in Machine Translation, where systems and metrics co-evolve.

2 Preliminaries

In this section we describe the datasets, systems, metrics, and meta evaluation methods used below.

2.1 Datasets

TAC-2008, 2009 (Dang and Owczarzak, 2008, 2009) are multi-document, multi-reference summarization datasets. Human judgments are available on for the system summaries submitted during the TAC-2008, TAC-2009 shared tasks.

CNN/DailyMail (CNNDM) (Hermann et al., 2015; Nallapati et al., 2016) is a commonly used summarization dataset that contains news articles and associated highlights as summaries. We use the version without entities anonymized.

2.2 Representative Systems

We use the following representative top-scoring systems that either achieve state-of-the-art (SOTA) results or competitive performance, for which we could gather the outputs on the `CNNDM` dataset.

Extractive summarization systems. We use CNN-LSTM-BiClassifier (CLSTM-SL; Kedzie et al. (2018)), Latent (Zhang et al., 2018), BanditSum (Dong et al., 2018), REFRESH (Narayan et al., 2018), NeuSum (Zhou et al., 2018), HIBERT (Zhang et al., 2019b), Bert-Sum-Ext (Liu and Lapata, 2019a), CNN-Transformer-BiClassifier (CTrans-SL; Zhong et al. (2019)), CNN-Transformer-Pointer (CTrans-PN; Zhong et al. (2019)), HeterGraph (Wang et al., 2020) and MatchSum (Zhong et al., 2020) as representatives of extractive systems, totaling 11 extractive system outputs for each document in the `CNNDM` test set.

Abstractive summarization systems. We use pointer-generator+coverage (See et al., 2017), fastAbsRL (Chen and Bansal, 2018), fastAbsRL-rank (Chen and Bansal, 2018), Bottom-up (Gehrmann et al., 2018), T5 (Raffel et al., 2019),

---

[3] http://www.statmt.org/wmt20/

Unilm-v1 (Dong et al., 2019), Unilm-v2 (Dong et al., 2019), twoStageRL (Zhang et al., 2019a), preSummAbs (Liu and Lapata, 2019b), preSummAbs-ext (Liu and Lapata, 2019b) BART (Lewis et al., 2019) and Semsim (Yoon et al., 2020) as abstractive systems. In total, we use 14 abstractive system outputs for each document in the `CNNDM` test set.

2.3 Evaluation Metrics

We examine eight metrics that measure the agreement between two texts, in our case, between the system summary and reference summary.
BERTScore (BScore) measures soft overlap between contextual BERT embeddings of tokens between the two texts[4] (Zhang et al., 2020).
MoverScore (MScore) applies a distance measure to contextualized BERT and ELMo word embeddings[5] (Zhao et al., 2019).
Sentence Mover Similarity (SMS) applies minimum distance matching between text based on sentence embeddings (Clark et al., 2019).
Word Mover Similarity (WMS) measures similarity using minimum distance matching between texts which are represented as a bag of word embeddings[6] (Kusner et al., 2015).
JS divergence (JS-2) measures Jensen-Shannon divergence between the two text's bigram distributions[7] (Lin et al., 2006).
ROUGE-1 and ROUGE-2 measure overlap of unigrams and bigrams respectively[8] (Lin, 2004).
ROUGE-L measures overlap of the longest common subsequence between two texts (Lin, 2004).
We use the recall variant of all metrics (since the Pyramid method of human evaluations is inherently recall based) except MScore which has no specific recall variant.

2.4 Correlation Measures

***Pearson* Correlation** is a measure of linear correlation between two variables and is popular in meta-evaluating metrics at the system level (Lee Rodgers, 1988). We use the implementation given by Virtanen et al. (2020).
William's Significance Test is a means of calculating the statistical significance of differences in correlations for dependent variables (Williams, 1959; Graham and Baldwin, 2014). This is useful for us since metrics evaluated on the same dataset are not independent of each other.

2.5 Meta Evaluation Strategies

There are two broad meta-evaluation strategies: summary-level and system-level.
Setup: For each document $d_i, i \in \{1 \dots n\}$ in a dataset $\mathcal{D}$, we have J system outputs, where the outputs can come from (1) extractive systems (Ext), (2) abstractive systems (Abs) or (3) a union of both (Mix). Let $s_{ij}, j \in \{1 \dots J\}$ be the j^{th} summary of the i^{th} document, m_i be a specific metric and K be a correlation measure.

2.5.1 Summary Level

Summary-level correlation is calculated as follows:

$$K^{sum}_{m_1 m_2} = \frac{1}{n}\sum_{i=1}^{n}\Big(K\big([m_1(s_{i1})\dots m_1(s_{iJ})], [m_2(s_{i1})\dots m_2(s_{iJ})]\big)\Big). \tag{1}$$

Here, correlation is calculated for each document, among the different system outputs of that document, and the mean value is reported.

2.5.2 System Level

System-level correlation is calculated as follows:

$$K^{sys}_{m_1 m_2} = K\Big(\Big[\frac{1}{n}\sum_{i=1}^{n} m_1(s_{i1})\dots\frac{1}{n}\sum_{i=1}^{n} m_1(s_{iJ})\Big], \Big[\frac{1}{n}\sum_{i=1}^{n} m_2(s_{i1})\dots\frac{1}{n}\sum_{i=1}^{n} m_2(s_{iJ})\Big]\Big). \tag{2}$$

Additionally, the "quality" of a system sys_j is defined as the mean human score received by it i.e.

$$\text{HScore}^{sys_j}_{mean} = \frac{1}{n}\sum_{i=1}^{n}\text{humanScore}(s_{ij}). \tag{3}$$

3 Collection of Human Judgments

We follow a 3-step process to collect human judgments: (1) we *collect* system-generated summaries on the most-commonly used summarization dataset, `CNNDM`; (2) we *select* representative test samples from `CNNDM` and (3) we manually *evaluate* system-generated summaries of the above-selected test samples.

[7] JS-2 is calculated using the function defined in github.com/UKPLab/coling2016-genetic-swarm-MDS

[8] For ROUGE-1,2, and L, we used the python wrapper: https://github.com/sebastianGehrmann/rouge-baselines

3.1 System-Generated Summary Collection

We collect the system-generated summaries from 25 top-scoring systems,[9] covering 11 extractive and 14 abstractive systems (Sec. 2.2) on the `CNNDM` dataset. We organize our collected generated summaries into three groups based on system type:

- `CNNDM Abs` denotes collected output summaries from abstractive systems.
- `CNNDM Ext` denotes collected output summaries from extractive systems.
- `CNNDM Mix` is the union of the two.

3.2 Representative Sample Selection

Since collecting human annotations is costly, we sample 100 documents from `CNNDM` test set (11,490 samples) and evaluate system generated summaries of these 100 documents. We aim to include documents of varying difficulties in the representative sample. As a proxy to the difficulty of summarizing a document, we use the mean score received by the system generated summaries for the document. Based on this, we partition the `CNNDM` test set into 5 equal sized bins and sample 4 documents from each bin. We repeat this process for 5 metrics (BERTScore, MoverScore, R-1, R-2, R-L) obtaining a sample of 100 documents. This methodology is detailed in Alg. 1 in Sec. A.1.

3.3 Human Evaluation

In text summarization, a “good” summary should represent as much relevant content from the input document as possible, within the acceptable length limits. Many human evaluation methods have been proposed to capture this desideratum (Nenkova and Passonneau, 2004; Chaganty et al., 2018; Fan et al., 2018; Shapira et al., 2019). Among these, *Pyramid* (Nenkova and Passonneau, 2004) is a reliable and widely used method, that evaluates content selection by (1) exhaustively obtaining Semantic Content Units (SCUs) from reference summaries, (2) weighting them based on the number of times they are mentioned and (3) scoring a system summary based on which SCUs can be inferred.

Recently, Shapira et al. (2019) extended Pyramid to a lightweight, crowdsourcable method - LitePyramids, which uses Amazon Mechanical Turk[10] (AMT) for gathering human annotations. LitePyramids simplifies Pyramid by (1) allowing crowd workers to extract a subset of all possible SCUs and (2) eliminating the difficult task of merging duplicate SCUs from different reference summaries, instead using SCU sampling to simulate frequency-based weighting.

Both Pyramid and LitePyramid rely on the presence of multiple references per document to assign importance weights to SCUs. However in the `CNNDM` dataset there is only one reference summary per document. We therefore adapt the LitePyramid method for the single-reference setting as follows.

SCU Extraction The LitePyramids annotation instructions define a Semantic Content Unit (SCU) as a *sentence containing a single fact written as briefly and clearly as possible*. Instead, we focus on shorter, more fine-grained SCUs that contain at most 2-3 entities. This allows for partial content overlap between a generated and reference summary, and also makes the task easy for workers. Tab. 2 gives an example. We exhaustively extract (up to 16) SCUs[11] from each reference summary. Requiring the set of SCUs to be exhaustive increases the complexity of the SCU generation task, and hence instead of relying on crowd-workers, we create SCUs from reference summaries ourselves. In the end, we obtained nearly 10.5 SCUs on average from each reference summary.

System Evaluation During system evaluation the full set of SCUs is presented to crowd workers. Workers are paid similar to Shapira et al. (2019), scaling the rates for fewer SCUs and shorter summary texts. For abstractive systems, we pay \$0.20 per summary and for extractive systems, we pay \$0.15 per summary since extractive summaries are more readable and might precisely overlap with SCUs. We post-process system output summaries before presenting them to annotators by true-casing the text using Stanford CoreNLP (Manning et al., 2014) and replacing “unknown” tokens with a special symbol “□” (Chaganty et al., 2018).

Tab. 2 depicts an example reference summary, system summary, SCUs extracted from the reference summary, and annotations obtained in evaluating the system summary.

Annotation Scoring For robustness (Shapira et al., 2019), each system summary is evaluated by 4 crowd workers. Each worker annotates up to 16 SCUs by marking an SCU “present” if it can be

---

[9] We contacted the authors of these systems to gather the corresponding outputs, including variants of the systems.

[10] https://www.mturk.com/

[11] In our representative sample we found no document having more than 16 SCUs.

(a) Reference Summary: Bayern Munich beat Porto 6 - 1 in the Champions League on Tuesday. Pep Guardiola's side progressed 7 - 4 on aggregate to reach semi-finals. Thomas Muller scored 27th Champions League goal to pass Mario Gomez. Muller is now the leading German scorer in the competition. After game Muller led the celebrations with supporters using a megaphone.

(b) System Summary (BART, Lewis et al. (2019)): Bayern Munich beat Porto 6 - 1 at the Allianz Arena on Tuesday night. Thomas Muller scored his 27th Champions League goal. The 25 - year - old became the highest - scoring German since the tournament took its current shape in 1992. Bayern players remained on the pitch for some time as they celebrated with supporters.

(c) SCUs with corresponding evaluations:

- Bayern Munich beat Porto. ✓
- Bayern Munich won 6 - 1. ✓
- Bayern Munich won in Champions League. ✓
- Bayern Munich won on Tuesday. ✓
- Bayern Munich is managed by Pep Guardiola. ×
- Bayern Munich progressed in the competition. ✓
- Bayern Munich reached semi-finals. ×
- Bayern Munich progressed 7 - 4 on aggregate. ×
- Thomas Muller scored 27th Champions League goal. ✓
- Thomas Muller passed Mario Gomez in goals. ×
- Thomas Muller is now the leading German scorer in the competition. ✓
- After the game Thomas Muller led the celebrations. ×
- Thomas Muller led the celebrations using a megaphone. ×

Table 2: Example of a summary and corresponding annotation. (a) shows a reference summary from the representative sample of the `CNNDM` test set. (b) shows the corresponding system summary generated by BART, one of the abstractive systems used in the study. (c) shows the SCUs (Semantic Content Units) extracted from (a) and the "*Present*(✓)"/"*Not Present*(×)" marked by crowd workers when evaluating (b).

inferred from the system summary or "not present" otherwise. We obtain a total of 10,000 human annotations (100 documents × 25 systems × 4 workers). For each document, we identify a "noisy" worker as one who disagrees with the majority (i.e. marks an SCU as "present" when majority thinks "not present" or vice-versa), on the largest number of SCUs. We remove the annotations of noisy workers and retain 7,742 annotations of the 10,000. After this filtering, we obtain an average inter-annotator agreement (Krippendorff's alpha (Krippendorff, 2011)) of 0.66.[12] Finally, we use the majority vote to mark the presence of an SCU in a system summary, breaking ties by the class, "not present".

4 Experiments

Motivated by the central research question: "does the rapid progress of model development in summarization models require us to *re-evaluate* the evaluation process used for text summarization?" We use the collected human judgments to meta-evaluate current metrics from four diverse viewpoints, measuring the ability of metrics to: (1) evaluate *all* systems; (2) evaluate top-k strongest systems; (3) compare *two* systems; (4) evaluate individual summaries. We find that many previously attested properties of metrics observed on `TAC` exhibit different trends on the new `CNNDM` dataset.

4.1 Exp-I: Evaluating *All* Systems

Automatic metrics are widely used to determine where a new system may rank against existing state-of-the-art systems. Thus, in meta-evaluation studies, calculating correlation of automatic metrics with human judgments at the system level is a commonly-used setting (Novikova et al., 2017; Bojar et al., 2016; Graham, 2015). We follow this setting and specifically, ask two questions: **Can metrics reliably compare different systems?** To answer this we observe the *Pearson* correlation between different metrics and human judgments in Fig. 2, finding that:

(1) MoverScore and JS-2, which were the best performing metrics on `TAC`, have poor correlations with humans in comparing `CNNDM Ext` systems.

(2) Most metrics have high correlations on the `TAC-2008` dataset but many suffer on `TAC-2009`, especially ROUGE based metrics. However, ROUGE metrics consistently perform well on the collected `CNNDM` datasets.

Are some metrics significantly better than others in comparing systems? Since automated metrics calculated on the same data are not independent, we must perform the William's test (Williams, 1959) to establish if the difference in correlations between metrics is statistically significant (Graham and Baldwin, 2014). In Fig. 1 we report the p-values of William's test. We find that

---

[12] The agreement was 0.57 and 0.72 for extractive and abstractive systems respectively.

[13] Dark cells with p-value = 0.05 have been rounded up.

Figure 1: p-value of William's Significance Test for the hypothesis "Is the system on left (y-axis) significantly better than system on top (x-axis)". 'BScore' refers to BERTScore and 'MScore' refers to MoverScore. A dark green value in cell (i, j) denotes metric m_i has a significantly higher *Pearson* correlation with human scores compared to metric m_j (p-value < 0.05).[13] '-' in cell (i, j) refers to the case when *Pearson* correlation of m_i with human scores is less that of m_j (Sec. 4.1).

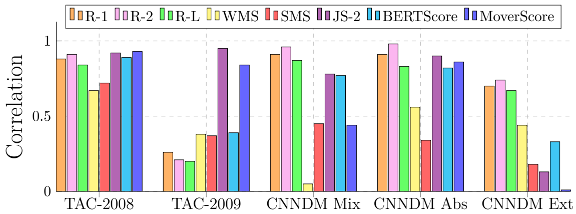

Figure 2: System-level *Pearson* correlation between metrics and human scores (Sec. 4.1).

(1) MoverScore and JS-2 are significantly better than other metrics in correlating with human judgments on the `TAC` datasets.
(2) However, on `CNNDM Abs` and `CNNDM Mix`, R-2 significantly outperforms all others whereas on `CNNDM Ext` none of the metrics show significant improvements over others.
Takeaway: These results suggest that metrics run the risk of overfitting to some datasets, highlighting the need to meta-evaluate metrics for modern datasets and systems. Additionally, there is no one-size-fits-all metric that can outperform others on all datasets. This suggests the utility of using different metrics for different datasets to evaluate systems e.g. MoverScore on `TAC-2008`, JS-2 on `TAC-2009` and R-2 on `CNNDM` datasets.

4.2 Exp-II: Evaluating *Top-k* Systems

Most papers that propose a new state-of-the-art system often use automatic metrics as a proxy to human judgments to compare their proposed method against other top scoring systems. However, *can metrics reliably quantify the improvements that one high quality system makes over other competitive systems?* To answer this, instead of focusing on all of the collected systems, we evaluate the correlation between automatic metrics and human judgments in comparing the *top-k* systems, where *top-k* are chosen based on a system's mean human score (Eqn. 3).[14] Our observations are presented in Fig. 3. We find that:
(1) As k becomes smaller, metrics de-correlate with humans on the `TAC-2008` and `CNNDM Mix` datasets, even getting negative correlations for small values of k (Fig. 8a, 8c). Interestingly, SMS, R-1, R-2 and R-L *improve* in performance as k becomes smaller on `CNNDM Ext`.
(2) R-2 had negative correlations with human judgments on `TAC-2009` for $k < 50$, however it remains highly correlated with human judgments on `CNNDM Abs` for all values of k.
Takeaway: Metrics cannot reliably quantify the improvements made by one system over others, especially for the top few systems across all datasets. Some metrics, however, are well suited for specific datasets, e.g. JS-2 and R-2 are reliable indicators of improvements on `TAC-2009` and `CNNDM Abs` respectively.

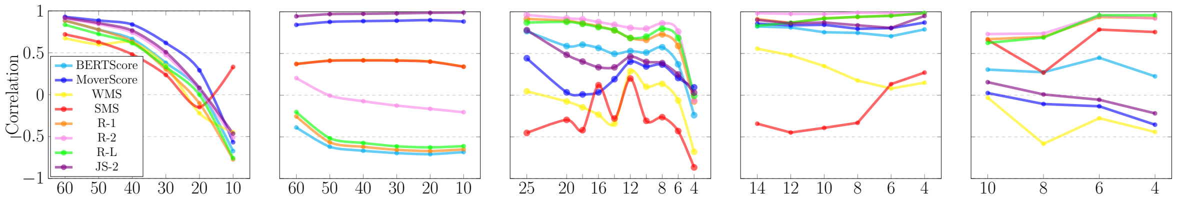
4.3 Exp-III: Comparing Two-Systems

Instead of comparing many systems (Sec. 4.1, 4.2) ranking *two* systems aims to test the discriminative power of a metric, i.e., the degree to which the metric can capture statistically significant differences between two summarization systems.

We analyze the reliability of metrics along a useful dimension: *can metrics reliably say if one system is significantly better than another*? Since we only have 100 annotated summaries to compare any two systems, sys_1 and sys_2, we use paired bootstrap resampling, to test with statistical sig-

---

[14] As a caveat, we *do not* perform significance testing for this experiment, due to the small number of data points.



(a) TAC-2008 (b) TAC-2009 (c) CNNDM Mix (d) CNNDM Abs (e) CNNDM Ext

Figure 3: System-level *Pearson* correlation with humans on top-k systems (Sec. 4.2).

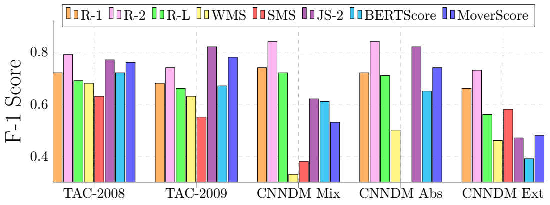


Figure 4: F1-Scores with bootstrapping (Sec. 4.3).

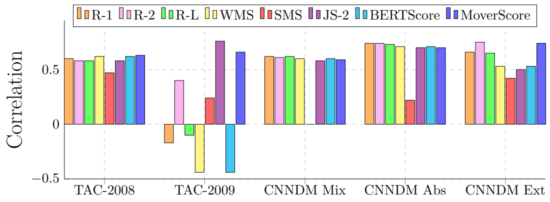
nificance if sys_1 is better than sys_2 according to metric m (Koehn, 2004; Dror et al., 2018). We take all $\binom{J}{2}$ pairs of systems and compare their mean human score (Eqn. 3) using paired bootstrap resampling. We assign a label $y_{true} = 1$ if sys_1 is better than sys_2 with 95% confidence, $y_{true} = 2$ for vice-versa and $y_{true} = 0$ if the confidence is below 95%. We treat this as the ground truth label of the pair (sys_1, sys_2). This process is then repeated for all metrics, to get a "prediction", y^m_{pred} from each metric m for the same $\binom{J}{2}$ pairs. If m is a good proxy for human judgments, the F1 score (Goutte and Gaussier, 2005) between y^m_{pred} and y_{true} should be high. We calculate the weighted macro F1 score for all metrics and view them in Fig. 4.

We find that ROUGE based metrics perform moderately well in this task. R-2 performs the best on `CNNDM` datasets. While on the `TAC 2009` dataset, JS-2 achieves the highest F1 score, its performance is low on `CNNDM Ext`.

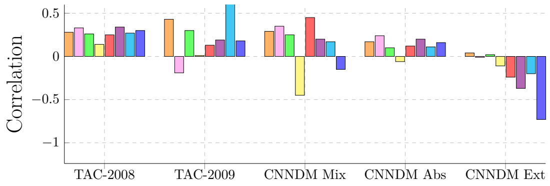
Takeaway: Different metrics are better suited for different datasets. For example, on the `CNNDM` datasets, we recommend using R-2 while, on the TAC datasets, we recommend using JS-2.

4.4 Exp-IV: Evaluating Summaries

In addition to comparing systems, real-world application scenarios also require metrics to reliably compare multiple summaries of a document. For example, top-scoring reinforcement learning based summarization systems (Böhm et al., 2019) and the current state-of-the-art extractive system (Zhong et al., 2020) heavily rely on summary-level reward scores to guide the optimization process.



(a) Summary-level *Pearson* correlation with human scores.



(b) Difference between system-level and summary-level *Pearson* correlation.

Figure 5: *Pearson* correlation between metrics and human judgments across different datasets (Sec. 4.4).

In this experiment, we ask the question: *how well do different metrics perform at the summary level, i.e. in comparing system summaries generated from the same document?* We use Eq. 1 to calculate *Pearson* correlation between different metrics and human judgments for different datasets and collected system outputs. Our observations are summarized in Fig. 5. We find that:

(1) As compared to semantic matching metrics, R-1, R-2 and R-L have lower correlations on the `TAC` datasets but are strong indicators of good summaries especially for extractive summaries on the `CNNDM` dataset.

(2) Notably, BERTScore, WMS, R-1 and R-L have *negative* correlations on `TAC-2009` but perform moderately well on other datasets including `CNNDM`.

(3) Previous meta-evaluation studies (Novikova et al., 2017; Peyrard et al., 2017; Chaganty et al., 2018) conclude that automatic metrics tend to correlate well with humans at the system level but have poor correlations at the instance (here summary) level. We find this observation only holds on

`TAC-2008`. Some metrics' summary-level correlations can outperform system-level on the `CNNDM` dataset as shown in Fig. 7b (bins below $y = 0$). Notably, MoverScore has a correlation of only 0.05 on `CNNDM Ext` at the system level but 0.74 at the summary level.

Takeaway: Meta-evaluations of metrics on the old `TAC` datasets show significantly different trends than meta-evaluation on modern systems and datasets. Even though some metrics might be good at comparing summaries, they may point in the wrong direction when comparing systems. Moreover, some metrics show poor generalization ability to different datasets (e.g. BERTScore on `TAC-2009` vs other datasets). This highlights the need for empirically testing the efficacy of different automatic metrics in evaluating summaries on multiple datasets.

5 Related Work

This work is connected to the following threads of topics in text summarization.

Human Judgment Collection Despite many approaches to the acquisition of human judgment (Chaganty et al., 2018; Nenkova and Passonneau, 2004; Shapira et al., 2019; Fan et al., 2018), *Pyramid* (Nenkova and Passonneau, 2004) has been a mainstream method to meta-evaluate various automatic metrics. Specifically, Pyramid provides a robust technique for evaluating content selection by exhaustively obtaining a set of Semantic Content Units (SCUs) from a set of references, and then scoring system summaries on how many SCUs can be inferred from them. Recently, Shapira et al. (2019) proposed a lightweight and crowdsourceable version of the original Pyramid, and demonstrated it on the DUC 2005 (Dang, 2005) and 2006 (Dang, 2006) multi-document summarization datasets. In this paper, our human evaluation methodology is based on the Pyramid (Nenkova and Passonneau, 2004) and LitePyramids (Shapira et al., 2019) techniques. Chaganty et al. (2018) also obtain human evaluations on system summaries on the CNNDM dataset, but with a focus on language quality of summaries. In comparison, our work is focused on evaluating content selection. Our work also covers more systems than their study (11 extractive + 14 abstractive vs. 4 abstractive).

Meta-evaluation with Human Judgment The effectiveness of different automatic metrics - ROUGE-2 (Lin, 2004), ROUGE-L (Lin, 2004), ROUGE-WE (Ng and Abrecht, 2015), JS-2 (Louis and Nenkova, 2013) and S3 (Peyrard et al., 2017) is commonly evaluated based on their correlation with human judgments (e.g., on the TAC-2008 (Dang and Owczarzak, 2008) and TAC-2009 (Dang and Owczarzak, 2009) datasets). As an important supplementary technique to meta-evaluation, Graham (2015) advocate for the use of a significance test, William's test (Williams, 1959), to measure the improved correlations of a metric with human scores and show that the popular variant of ROUGE (mean ROUGE-2 score) is sub-optimal. Unlike these works, instead of proposing a new metric, in this paper, we upgrade the meta-evaluation environment by introducing a sizeable human judgment dataset evaluating current top-scoring systems and mainstream datasets. And then, we re-evaluate diverse metrics at both system-level and summary-level settings. (Novikova et al., 2017) also analyzes existing metrics, but they only focus on dialog generation.

6 Implications and Future Directions

Our work not only diagnoses the limitations of current metrics but also highlights the importance of upgrading the existing meta-evaluation testbed, keeping it up-to-date with the rapid development of systems and datasets. In closing, we highlight some potential future directions: (1) The choice of metrics depends not only on different tasks (e.g, summarization, translation) but also on different datasets (e.g., `TAC`, `CNNDM`) and application scenarios (e.g, system-level, summary-level). Future works on meta-evaluation should investigate the effect of these settings on the performance of metrics. (2) Metrics easily overfit on limited datasets. Multi-dataset meta-evaluation can help us better understand each metric's peculiarity, therefore achieving a better choice of metrics under diverse scenarios. (3) Our collected human judgments can be used as supervision to instantiate the most recently-proposed *pretrain-then-finetune* framework (originally for machine translation) (Sellam et al., 2020), learning a robust metric for text summarization.

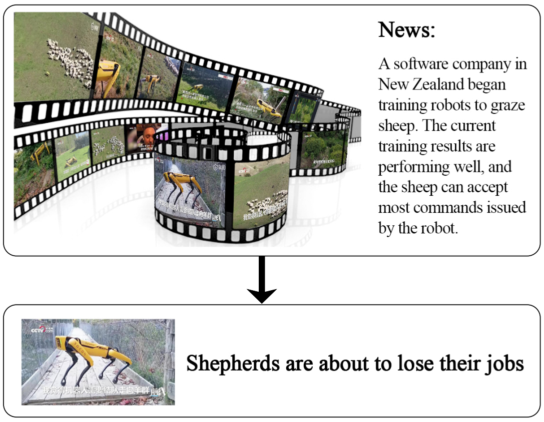
Abstract

A popular multimedia news format nowadays is providing users with a lively video and a corresponding news article, which is employed by influential news media including CNN, BBC, and social media including Twitter and Weibo. In such a case, automatically choosing a proper cover frame of the video and generating an appropriate textual summary of the article can help editors save time, and readers make the decision more effectively. Hence, in this paper, we propose the task of Video-based Multimodal Summarization with Multimodal Output (VMSMO) to tackle such a problem. The main challenge in this task is to jointly model the temporal dependency of video with semantic meaning of article. To this end, we propose a Dual-Interaction-based Multimodal Summarizer (DIMS), consisting of a dual interaction module and multimodal generator. In the dual interaction module, we propose a conditional self-attention mechanism that captures local semantic information within video and a global-attention mechanism that handles the semantic relationship between news text and video from a high level. Extensive experiments conducted on a large-scale real-world VMSMO dataset[1] show that DIMS achieves the state-of-the-art performance in terms of both automatic metrics and human evaluations.

1 Introduction

Existing experiments (Li et al., 2017) have proven that multimodal news can significantly improve users' sense of satisfaction for informativeness. As one of these multimedia data forms, introducing news events with video and textual descriptions is becoming increasingly popular, and has been employed as the main form of news reporting by news media including BBC, Weibo, CNN, and Daily Mail. An illustration is shown in Figure 1, where the news contains a video with a cover picture and a full news article with a short textual summary. In such a case, automatically generating multimodal summaries, *i.e.,* choosing a proper cover frame of the video and generating an appropriate textual summary of the article can help editors save time and readers make decisions more effectively.



A software company in New Zealand began training robots to graze sheep. The current training results are performing well, and the sheep can accept most commands issued by the robot.

Shepherds are about to lose their jobs

Figure 1: An example of video-based multimodal summarization with multimodal output.

There are several works focusing on multimodal summarization. The most related work to ours is (Zhu et al., 2018), where they propose the task of generating textual summary and picking the most representative picture from 6 input candidates. However, in real-world applications, the input is usually a video consisting of hundreds of frames. Consequently, the temporal dependency in a video cannot be simply modeled by static encoding methods. Hence, in this work, we propose a novel task, Video-based Multimodal Summarization with Multimodal Output (VMSMO), which selects cover frame from news video and generates textual summary of the news article in the meantime.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 9360–9369,
November 16–20, 2020.

The cover image of the video should be the salient point of the whole video, while the textual summary should also extract the important information from source articles. Since the video and the article focus on the same event with the same report content, these two information formats complement each other in the summarizing process. However, how to fully explore the relationship between temporal dependency of frames in video and semantic meaning of article still remains a problem, since the video and the article come from two different space.

Hence, in this paper, we propose a model named *Dual-Interaction-based Multimodal Summarizer (DIMS)*, which learns to summarize article and video simultaneously by conducting a dual interaction strategy in the process. Specifically, we first employ Recurrent Neural Networks (RNN) to encode text and video. Note that by the encoding RNN, the spatial and temporal dependencies between images in the video are captured. Next, we design a dual interaction module to let the video and text fully interact with each other. Specifically, we propose a conditional self-attention mechanism which learns local video representation under the guidance of article, and a global-attention mechanism to learn high-level representation of video-aware article and article-aware video. Last, the multimodal generator generates the textual summary and extracts the cover image based on the fusion representation from the last step. To evaluate the performance of our model, we collect the first large-scale news article-summary dataset associated with video-cover from social media websites. Extensive experiments on this dataset show that DIMS significantly outperforms the state-of-the-art baseline methods in commonly-used metrics by a large margin.

To summarize, our contributions are threefold:

- We propose a novel Video-based Multimodal Summarization with Multimodal Output (VMSMO) task which chooses a proper cover frame for the video and generates an appropriate textual summary of the article.
- We propose a Dual-Interaction-based Multimodal Summarizer (DIMS) model, which jointly models the temporal dependency of video with semantic meaning of article, and generates textual summary with video cover simultaneously.
- We construct a large-scale dataset for VMSMO, and experimental results demonstrate that our model outperforms other baselines in terms of both automatic and human evaluations.

2 Related Work

Our research builds on previous works in three fields: text summarization, multimodal summarization, and visual question answering.

Text Summarization. Our proposed task bases on text summarization, the methods of which can be divided into extractive and abstractive methods (Gao et al., 2020b). Extractive models (Zhang et al., 2018; Narayan et al., 2018; Chen et al., 2018; Luo et al., 2019; Xiao and Carenini, 2019) directly pick sentences from article and regard the aggregate of them as the summary. In contrast, abstractive models (Sutskever et al., 2014; See et al., 2017; Wenbo et al., 2019; Gui et al., 2019; Gao et al., 2019a; Chen et al., 2019a; Gao et al., 2019b) generate a summary from scratch and the abstractive summaries are typically less redundant.

Multimodal Summarization. A series of works (Li et al., 2017, 2018; Palaskar et al., 2019; Chan et al., 2019; Chen et al., 2019b; Gao et al., 2020a) focused on generating better textual summaries with the help of multimodal input. Multimodal summarization with multimodal output is relatively less explored. Zhu et al. (2018) proposed to jointly generate textual summary and select the most relevant image from 6 candidates. Following their work, Zhu et al. (2020) added a multimodal objective function to use the loss from the textual summary generation and the image selection. However, in the real-world application, we usually need to choose the cover figure for a continuous video consisting of hundreds of frames. Consequently, the temporal dependency between frames in a video cannot be simply modeled by several static encoding methods.

Visual Question Answering. Visual Question Answering (VQA) task is similar to our task in taking images and a corresponding text as input. Most works consider VQA task as a classification problem and the understanding of image subregions or image recognition becomes particularly important (Goyal et al., 2017; Malinowski et al., 2015; Wu et al., 2016; Xiong et al., 2016). As for the interaction models, one of the state-of-the-art VQA models (Li et al., 2019) proposed a positional self-attention with a co-attention mechanism, which is faster than the recurrent neural network (RNN). Guo et al. (2019) devised an image-

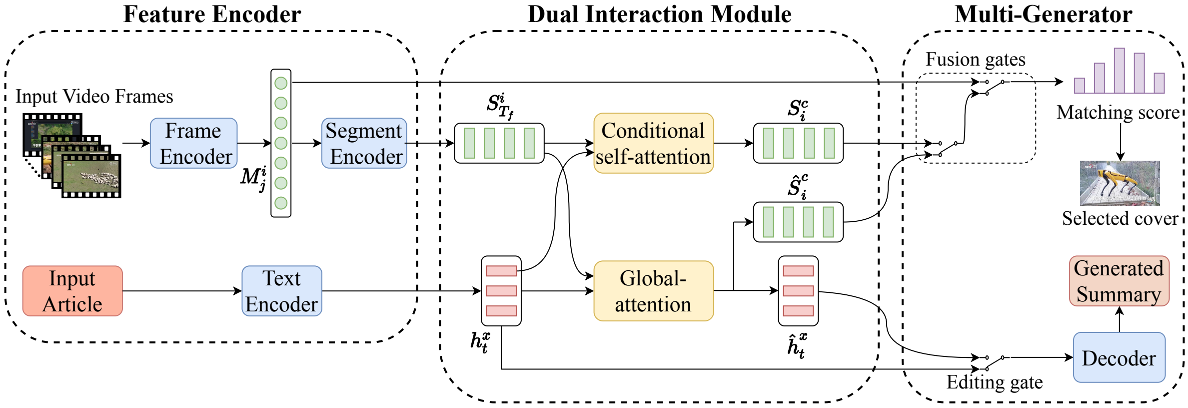

Figure 2: Overview of DIMS. We divide our model into three parts: (1) *Feature Encoder* encodes the input article and video separately; (2) *Dual Interaction Module* learns fused representation of video and article from different level; (3) *Multi-Generator* generates the textual summary and chooses the video cover simultaneously.

question-answer synergistic network, where candidate answers are coarsely scored according to their relevance to the image and question pair and answers with a high probability of being correct are re-ranked by synergizing with image and question.

3 Problem Formulation

Before presenting our approach for the VMSMO, we first introduce the notations and key concepts. For an input news article $X = \{x_1, x_2, \dots, x_{T_d}\}$ which has T_d words, we assume there is a ground truth textual summary $Y = \{y_1, y_2, \dots, y_{T_y}\}$ which has T_y words. Meanwhile, there is a news video V corresponding to the article, and we assume there is a ground truth cover picture C that extracts the most important frame from the video content. For a given article X and the corresponding video V, our model emphasizes salient parts of both inputs by conducting deep interaction. The goal is to generate a textual summary $Y^{'}$ that successfully grasp the main points of the article and choose a frame picture $C^{'}$ that covers the gist of the video.

4 Model

4.1 Overview

In this section, we propose our Dual Interaction-based Multimodal Summarizer (DIMS), which can be divided into three parts in Figure 2:

- *Feature Encoder* is composed of a text encoder and a video encoder which encodes the input article and video separately.
- *Dual Interaction Module* conducts deep interaction, including conditional self-attention and global-attention mechanism between video segment and article to learn different levels of representation of the two inputs.
- *Multi-Generator* generates the textual summary and chooses the video cover by incorporating the fused information.

4.2 Feature Encoder

4.2.1 Text encoder

To model the semantic meaning of the input news text $X = \{x_1, x_2, \dots, x_{T_d}\}$, we first use a word embedding matrix e to map a one-hot representation of each word x_i into to a high-dimensional vector space. Then, in order to encode contextual information from these embedding representation, we use bi-directional recurrent neural networks (Bi-RNN) (Hochreiter and Schmidhuber, 1997) to model the temporal interactions between words:

$$h_t^x = \text{Bi-RNN}_X(e(x_t), h_{t-1}^x), \tag{1}$$

where h_t^x denotes the hidden state of t-th step in Bi-RNN for X. Following (See et al., 2017; Ma et al., 2018), we choose the long short-term memory (LSTM) as the Bi-RNN cell.

4.2.2 Video Encoder

A news video usually lasts several minutes and consists of hundreds of frames. Intuitively, a video can be divided into several segments, each of which corresponds to different content. Hence, we choose to encode video hierarchically. More specifically, we equally divide frames in the video into several segments and employ a low-level frame encoder and a high-level segment encoder to learn hierarchical representation.

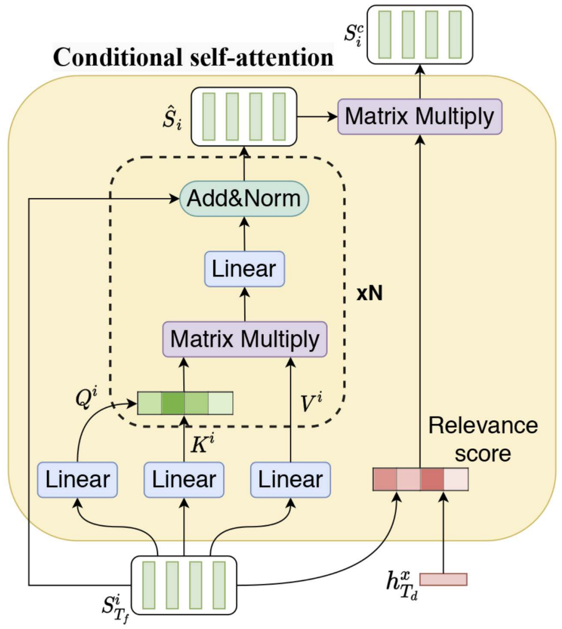

Figure 3: Conditional self-attention module, which captures local semantic information within video segments under the guidance of article representation.

Frame encoder. We utilize the Resnet-v1 model (He et al., 2016) to encode frames to alleviate gradient vanishing (He et al., 2016) and reduce computational costs:

$$O_j^i = \text{Resnet-v1}(m_j^i), \tag{2}$$
$$M_j^i = \text{relu}\left(F_v(O_j^i)\right), \tag{3}$$

where m_j^i is the j-th frame in i-th segment and $F_v(\cdot)$ is a linear transformation function.

Segment encoder. As mentioned before, it is important to model the continuity of images in video, which cannot be captured by a static encoding strategy. We employ RNN network as segment encoder due to its superiority in exploiting the temporal dependency among frames Zhao et al. (2017):

$$S_j^i = \text{Bi-RNN}_\text{S}(M_j^i, S_{j-1}^i). \tag{4}$$

S_j^i denotes the hidden state of j-th step in Bi-RNN for segment s_i, and the final hidden state $S_{T_f}^i$ denotes the overall representation of the segment s_i, where T_f is the number of frames in a segment.

4.3 Dual Interaction Module

The cover image of the video should contain the key point of the whole video, while the textural summary should also cover extract the important information from source articles. Hence, these two information formats complement each other in the summarizing process. In this section, we conduct a deep interaction between the video and article to jointly model the temporal dependency of video and semantic meaning of text. The module consists of a conditional self-attention mechanism that captures local semantic information within video segments and a global-attention mechanism that handles the semantic relationship between news text and video from a high level.

Conditional self-attention mechanism. Traditional self-attention can be used to obtain contextual video representation due to its flexibility in relating two elements in a distance-agnostic manner. However, as illustrated in Xie et al. (2020), the semantic understanding often relies on more complicated dependencies than the pairwise one, especially conditional dependency upon a given premise. Hence, in the VMSMO task, we capture the local semantic information of video conditioned on the input text information.

Our conditional self-attention module shown in Figure 3 is composed of a stack of N identical layers and a conditional layer. The identical layer learns to encode local video segments while the conditional layer learns to assign high weights to the video segments conditioned on their relationship to the article. We first use a fully-connected layer to project each segment representation $S_{T_f}^i$ into the query Q^i, key K^i, and value V^i. Then, the scaled dot-product self-attention is defined as:

$$\alpha_{i,j} = \frac{\exp\left(Q^i K^j\right)}{\sum_{n=1}^{T_s} \exp\left(Q^i K^n\right)}, \tag{5}$$
$$\hat{S}_i = \sum_{j=1}^{T_s} \frac{\alpha_{i,j} V^j}{\sqrt{d}}, \tag{6}$$

where d stands for hidden dimension and T_s is the segment number in a video. $\hat{S}_i$ is then fed into the feed-forward sub-layer including a residual connection (He et al., 2016) and layer normalization (Ba et al., 2016).

Next, we highlight the salient part of the video under the guidance of article. Taking the article information $h_{T_d}^x$ as condition, the attention score on each original segment representation $S_{T_f}^i$ is calculated as:

$$\beta_i = \sigma\left(F_s(S_{T_f}^i h_{T_d}^x)\right). \tag{7}$$

The final conditional segment representation S_i^c is denoted as $\beta_i \hat{S}_i$.

Global-attention mechanism. The global-attention module grounds the article representation on the video segments and fuses the information of the article into the video, which results in an article-aware video representation and a video-aware article representation. Formally, we utilize a two-way attention mechanism to obtain the co-attention between the encoded text representation h^x_t and the encoded segment representation $S^i_{T_f}$:

$$E^t_i = F_h(h^x_t)\left(F_t(S^i_{T_f})\right)^T. \tag{8}$$

We use E^t_i to denote the attention weight on the t-th word by the i-th video segment. To learn the alignments between text and segment information, the global representations of video-aware article $\hat{h}^x_t$ and article-aware video $\hat{S}^c_i$ are computed as:

$$\hat{h}^x_t = \sum\nolimits_{i=1}^{T_d} E^t_i S^i_{T_f}, \tag{9}$$

$$\hat{S}^c_i = \sum\nolimits_{t=1}^{T_s} \left(E^t_i\right)^T h^x_t. \tag{10}$$

4.4 Multi-Generator

In the VMSMO task, the multi-generator module not only needs to generate the textual summary but also needs to choose the video cover.

Textual summary generation. For the first task, we use the final state of the input text representation $h^x_{T_d}$ as the initial state d_0 of the RNN decoder, and the t-th generation procedure is:

$$d_t = \text{LSTM}_{\text{dec}}(d_{t-1}, [e(y_{t-1}); h^c_{t-1}]), \tag{11}$$

where d_t is the hidden state of the t-th decoding step and h^c_{t-1} is the context vector calculated by the standard attention mechanism (Bahdanau et al., 2014), and is introduced below.

To take advantage of the article representation h^x_t and the video-aware article representation $\hat{h}^x_t$, we apply an "editing gate" γ_e to decide how much information of each side should be focused on:

$$\gamma_e = \sigma\left(F_d(d_t)\right), \tag{12}$$

$$g_i = \gamma_e h^x_i + (1-\gamma_e)\hat{h}^x_i. \tag{13}$$

Then the context vector h^c_{t-1} is calculated as:

$$\delta_{it} = \frac{\exp(F_a(g_i, d_t))}{\sum_j \exp(F_a(g_j, d_t))}. \tag{14}$$

$$h^c_t = \sum\nolimits_i \delta_{it} g_i, \tag{15}$$

Finally, the context vector h^c_t is concatenated with the decoder state d_t and fed into a linear layer to obtain the generated word distribution P_v:

$$d^o_t = \sigma\left(F_p([d_t; h^c_t])\right), \tag{16}$$

$$P_v = \text{softmax}\left(F_o(d^o_t)\right). \tag{17}$$

Following See et al. (2017), we also equip our model with pointer network to handle the out-of-vocabulary problem. The loss of textual summary generation is the negative log likelihood of the target word y_t:

$$\mathcal{L}_{seq} = -\sum\nolimits_{t=1}^{T_y} \log P_v(y_t). \tag{18}$$

Cover frame selector. The cover frame is chosen based on hierarchical video representations, *i.e.*, the original frame representation M^i_j and the conditional segment representation S^c_i with the article-aware segment representation $\hat{S}^c_i$:

$$p^i_j = \gamma^1_f S^c_i + \gamma^2_f \hat{S}^c_i + (1-\gamma^1_f-\gamma^2_f)M^i_j, \tag{19}$$

$$y^c_{i,j} = \sigma\left(F_c(p^i_j)\right), \tag{20}$$

where $y^c_{i,j}$ is the matching score of the candidate frames. The fusion gates γ^1_f and γ^2_f here are determined by the last text encoder hidden state $h^x_{T_d}$:

$$\gamma^1_f = \sigma\left(F_m(h^x_{T_d})\right), \tag{21}$$

$$\gamma^2_f = \sigma\left(F_n(h^x_{T_d})\right). \tag{22}$$

We use pairwise hinge loss to measure the selection accuracy:

$$\mathcal{L}_{pic} = \sum^{N} \max\left(0, y^c_{\text{negative}} - y^c_{\text{positive}} + \text{margin}\right), \tag{23}$$

where $y^c_{negative}$ and $y^c_{positive}$ corresponds to the matching score of the negative samples and the ground truth frame, respectively. The margin in the $\mathcal{L}_{pic}$ is the rescale margin in hinge loss.

The overall loss for the model is:

$$\mathcal{L} = \mathcal{L}_{seq} + \mathcal{L}_{pic}. \tag{24}$$

5 Experimental Setup

5.1 Dataset

To our best knowledge, there is no existing large-scale dataset for VMSMO task. Hence, we collect the first large-scale dataset for VMSMO task from Weibo, the largest social network website in China. Most of China's mainstream media have Weibo accounts, and they publish the latest news in their accounts with lively videos and articles. Correspondingly, each sample of our data contains an article with a textual summary and a video with a cover picture. The average video duration is one minute and the frame rate of video is 25 fps. For the text part, the average length of article is 96.84 words and the average length of textual summary is 11.19 words. Overall, there are 184,920 samples in the dataset, which is split into a training set of 180,000 samples, a validation set of 2,460 samples, and a test set of 2,460 samples.

5.2 Comparisons

We compare our proposed method against summarization baselines and VQA baselines.

Traditional Textual Summarization baselines:

Lead: selects the first sentence of article as the textual summary (Nallapati et al., 2017).

TexkRank: a graph-based extractive summarizer which adds sentences as nodes and uses edges to weight similarity (Mihalcea and Tarau, 2004).

PG: a sequence-to-sequence framework combined with attention mechanism and pointer network (See et al., 2017).

Unified: a model which combines the strength of extractive and abstractive summarization (Hsu et al., 2018).

GPG: Shen et al. (2019) proposed to generate textual summary by "editing" pointed tokens instead of hard copying.

Multimodal baselines:

How2: a model proposed to generate textual summary with video information (Palaskar et al., 2019).

Synergistic: a image-question-answer synergistic network to value the role of the answer for precise visual dialog(Guo et al., 2019).

PSAC: a model adding the positional self-attention with co-attention on VQA task (Li et al., 2019).

MSMO: the first model on multi-output task, which paid attention to text and images during generating textual summary and used coverage to help select picture (Zhu et al., 2018).

MOF: the model based on MSMO which added consideration of image accuracy as another loss (Zhu et al., 2020).

5.3 Evaluation Metrics

The quality of generated textual summary is evaluated by standard full-length Rouge F1 (Lin, 2004) following previous works (See et al., 2017; Chen et al., 2018). R-1, R-2, and R-L refer to unigram, bigrams, and the longest common subsequence respectively. The quality of chosen cover frame is evaluated by mean average precision (MAP) (Zhou et al., 2018) and recall at position ($R_n@k$) (Tao et al., 2019). $R_n@k$ measures if the positive sample is ranked in the top k positions of n candidates.

	R-1	R-2	R-L
extractive summarization			
Lead	16.2	5.3	13.9
TextRank	13.7	4.0	12.5
abstractive summarization			
PG (See et al., 2017)	19.4	6.8	17.4
Unified (Hsu et al., 2018)	23.0	6.0	20.9
GPG (Shen et al., 2019)	20.1	4.5	17.3
our models			
DIMS	**25.1**	**9.6**	**23.2**

Table 1: Rouge scores comparison with traditional textual summarization baselines.

5.4 Implementation Details

We implement our experiments in Tensorflow (Abadi et al., 2016) on an NVIDIA GTX 1080 Ti GPU. The code for our model is available online[2]. For all models, we set the word embedding dimension and the hidden dimension to 128. The encoding step is set to 100, while the minimum decoding step is 10 and the maximum step is 30. For video preprocessing, we extract one of every 120 frames to obtain 10 frames as cover candidates. All candidates are resized to 128x64. We regard the frame that has the maximum cosine similarity with the ground truth cover as the positive sample, and others as negative samples. Note that the average cosine similarity of positive samples is 0.90, which is a high score, demonstrating the high quality of the constructed candidates. In the conditional self-attention mechanism, the stacked layer number is set to 2. For hierarchical encoding, each segment contains 5 frames. Experiments are performed with a batch size of 16. All the parameters in our model are initialized by Gaussian distribution. During training, we use Adagrad optimizer as our optimizing algorithm and we also apply gradient clipping with a range of $[-2, 2]$. The vocabulary size is limited to 50k. For testing, we use beam search with beam size 4 and we decode until an end-of-sequence token is reached. We select the 5 best checkpoints based on performance on the validation set and report averaged results on the test set.

6 Experimental Result

6.1 Overall Performance

We first examine *whether our DIMS outperforms other baselines* as listed in Table 1 and Table 2. Firstly, abstractive models outperform all extractive methods, demonstrating that our proposed dataset is suitable for abstractive summarization. Secondly, the video-enhanced models outperform traditional textural summarization models, indicating that video information helps generate summary. Finally, our model outperforms `MOF` by 17.8%, 68.4%, 29.6%, in terms of Rouge-1, Rouge-2, Rouge-L, and 6.3%, 15.2% in MAP and $R@1$ respectively, which proves the superiority of our model. All our Rouge scores have a 95% confidence interval of at most ±0.55 as reported by the official Rouge script.

In addition to automatic evaluation, system performance was also evaluated on the generated textual summary by human judgments on 70 randomly selected cases similar to Liu and Lapata (2019). Our first evaluation study quantified the degree to which summarization models retain key information from the articles following a question-answering (QA) paradigm (Narayan et al., 2018). A set of questions was created based on the gold summary. Then we examined whether participants were able to answer these questions by reading system summaries alone. We created 183 questions in total varying from two to three questions per gold summary. Correct answers were marked with 1 and 0 otherwise. The average of all question scores is set to the system score.

	QA(%)	Rating
How2	46.2	-0.24
MOF	51.3	-0.14
Unified	53.8	0.00
DIMS	**66.7**	**0.38**

Table 3: System scores based on questions answered by human and summary quality rating.

Our second evaluation estimated the overall quality of the textual summaries by asking participants to rank them according to its *Informativeness* (does the summary convey important contents about the topic in question?), *Coherence* (is the summary fluent and grammatical?), and *Succinctness* (does the summary avoid repetition?). Participants were presented with the gold summary and summaries generated from several systems better on autometrics and were asked to decide which was the best and the worst. The rating of each system was calculated as the percentage of times it was chosen as best minus the times it was selected as worst, ranging from -1 (worst) to 1 (best).

Both evaluations were conducted by three highly educated native-speaker annotators. Participants evaluated summaries produced by `Unified`, `How2`, `MOF` and our `DIMS`, all of which achieved high perfromance in automatic evaluations. As shown in Table 3, on both evaluations, participants overwhelmingly prefer our model. All pairwise comparisons among systems are statistically significant using the paired student t-test for significance at $\alpha = 0.01$.

Figure 4: Visualizations of global-attention matrix between the news article and two frames in the same video.

6.2 Ablation Study

Next, we conduct ablation tests to assess the importance of the conditional self-attention mechanism (-S), as well as the global-attention (-G) in Table 2. All ablation models perform worse than `DIMS` in terms of all metrics, which demonstrates the preeminence of `DIMS`. Specifically, the global-attention module contributes mostly to the textual summary generation, while the conditional self-attention module is more important for choosing cover frame.

6.3 Analysis of Multi-task learning

Our model aims to generate textural summary and choose cover frame at the same time, which can be regarded as a multi-task. Hence, in this section, we examine whether these two tasks can complement each other. We separate our model into two single-task architecture, named as `DIMS-textual summary` and `DIMS-cover frame`, which generates textural summary and chooses video cover frame, respectively. The result is shown in Table 2. It can be seen that the multi-task `DIMS` outperforms single-task `DIMS-textual summary` and `DIMS-cover frame`, improving the performance of summarization by 20.8% in terms of ROUGE-L score, and increasing the accuracy of cover selection by 7.0% on MAP.

6.4 Visualization of dual interaction module

To study the multimodal interaction module, we visualize the global-attention matrix E_i^t in Equation 8 on one randomly sampled case, as shown in Figure 4. In this case, we show the attention on article words of two representative images in the video. The darker the color is, the higher the attention weight is. It can be seen that for the left figure, the word *hand in hand* has a higher weight than *picture*, while for the right figure, the word *Book Fair* has the highest weight. This corresponds to the fact that the main body of the left frame is two old men, and the right frame is about reading books.

Article: On August 26, in Shanxi Ankang, a 12-year-old junior girl Yu Taoxin goose-stepped like parade during the military training in the new semester, and won thousands of praises. Yu Taoxin said that her father was a veteran, and she worked hard in military training because of the influence of her father. Her father told her that military training should be strict as in the army. 8月26日，陕西安康，12岁的初一女生余陶鑫，在新学期军训期间，她踢出阅兵式般的标准步伐，获千万点赞。余陶鑫说，爸爸是名退伍军人，军训刻苦是因为受到爸爸影响，爸爸曾告诉她，军训时就应和在部队里一样，严格要求自己。
Reference summary: A 12-year-old girl goose-stepped like parade during the military training, “My father is a veteran.” 12岁女孩军训走出阅兵式步伐， “爸爸是退伍军人”
QA: *What happened on the 12-year-old girl?* [*She goose-stepped like parade.*] 这个12岁女孩做了什么？[她走出阅兵式步伐。] *Why did she do this?* [*She was influenced by her father*] 她为什么这样做？[她受到爸爸的影响。]
Unfied: 12-year-old gril Yu Taoxin goose-stepped during military training. 12岁女生余陶鑫军训期间阅兵式般的标准步伐
How2: 12-year-old girls were organized military training, and veteran mother parade. 12岁女生组团军训，退伍军人妈妈阅兵式
MOF: A 12-year-old junior citizen [unk]: father gave a kicked like. 1名12岁初一市民[unk]：爸爸踢式点赞
DIMS: A 12-year-old junior girl goose-stepped like parade: My father is a veteran, and military training should be strict as in the army. 12岁初一女生踢出阅兵式：爸爸是名退伍军人，军训时就应和在部队一样

Table 4: Examples of the generated summary by baselines and DIMS.

We show a case study in Table 4, which includes the input article and the generated summary by different models. We also show the question-answering pair in human evaluation and the chosen cover. The result shows that the summary generated by our model is both fluent and accurate, and the cover frame chosen is also similar to the ground truth frame.

7 Conclusion

In this paper, we propose the task of Video-based Multimodal Summarization with Multimodal Output (VMSMO) which chooses a proper video cover and generates an appropriate textual summary for a video-attached article. We propose a model named Dual-Interaction-based Multimodal Summarizer (DIMS) including a local conditional self-attention mechanism and a global-attention mechanism to jointly model and summarize multimodal input. Our model achieves state-of-the-art results in terms of autometrics and outperforms human evaluations by a large margin. In near future, we aim to incorporate the video script information in the multimodal summarization process.
